## Message from the 28th USENIX Security Symposium Program Co-Chairs

Welcome to the USENIX Security Symposium in Santa Clara, CA! We hope you enjoy the outstanding technical program and invited talks. Now in its 28th year, the symposium brings together researchers and practitioners from across the field. We encourage you to engage with the community through our events, hallway track, and questions for speakers.

This was an exciting year for the USENIX Security Symposium as we transitioned to a new paper reviewing model with multiple submission deadlines. We want to use this opportunity to detail the model we instituted this year, as well as the process we used to develop it.

The USENIX board asked us in June of 2018 if we would be willing to move to multiple submission deadlines for the 2019 Symposium, and tasked us with developing a plan to do so. We studied the processes and choices made by conferences that had previously transitioned to multiple submission deadlines, including the IEEE Symposium on Security and Privacy, the Privacy-Enhancing Technologies Symposium, the ACM International Conference on Mobile Computing and Networking, and the Conference on Cryptographic Hardware and Embedded Systems, and consulted with former and current chairs of these conferences. We then developed a preliminary plan that we presented to the USENIX Security Steering Committee for feedback. After incorporating their suggested changes and receiving approval, we presented the plan to the USENIX Security community at USENIX Security 2018 in August 2018 in a community meeting to gather feedback before publishing the official Call for Papers.

We made the following choices in designing the new submission model:

- There would be four evenly-spaced submission deadlines throughout the year. We felt that this was a “sweet spot” that would allow for the two-and-a-half-month review cycle that the community was used to, while still giving authors multiple opportunities to submit their work when they felt it was ready. Since 2019 was a transitional year, we had two submission deadlines. The first deadline in the fall was November 15, 2018, and the second deadline in the winter was February 15, 2019.
- Like other conferences that have transitioned to multiple deadlines, we instituted a paper revision and resubmission process, which we describe in more detail below.
- To try to make the reviewing and revision process as constructive as possible, we introduced “journal-style” reviewing outcomes. That is, instead of rating papers “Accept”, “Weak Accept”, “Weak Reject”, or similar, we specified that reviewers could give outcomes of “Accept”, “Minor Revision”, “Major Revision”, “Reject and Resubmit”, and “Reject”.

“Accept” has the same meaning as before. “Minor Revision” replaces “Accept with Shepherding”. Papers with this outcome were assigned a shepherd who articulated a specific list of textual changes, such as adding additional citations or clarifying details of experiments, that the authors were requested to make, with the specific guidance that papers in this category were not accepted until the changes were made to the reviewers’ satisfaction.

“Major Revision” was the most significant change to the process. Papers receiving this outcome were returned to the authors with a list of specific changes requested by the reviewers. These included performing additional experiments, adding additional case studies or analyses, or requests for rewriting that were considered beyond the scope of what a shepherd could reasonably guide. Authors of “Major Revision” papers were invited to resubmit to either of the next two submission deadlines, with the promise that we would attempt to assign the same set of reviewers to review the resubmission, and that the resubmission would be evaluated according to the reviews and the specific changes requested by the reviewers. Papers receiving this outcome were considered to still be under submission for the next two deadlines, and we asked authors to explicitly withdraw their papers from consideration if they wished to submit the same work to another conference.

Finally, papers that were rejected could receive two possible outcomes. A “Reject and Resubmit” outcome was intended to signal to the authors that the reviewers thought the work could likely be revised to be accepted, but that the scope of the changes reviewers felt was required for acceptance was beyond what the reviewers could articulate in a specific list of “Major Revision” requests, or would likely take longer than the four months that authors would have to revise their work for a “Major Revision”. Papers receiving this outcome could not submit to either of the next two submission deadlines. Papers receiving a “Reject” outcome were not allowed to resubmit for a full year after the submission date.

- There would be two in-person program committee meetings a year. While program committee meetings are expensive and time-consuming, we received feedback from many community members that they serve an important role for calibration and discussion. In the 2019 transitional year, we held only one in-person meeting associated with the winter submission deadline.
- As in previous years, for each submission deadline, we used a double-blind review process with two rounds of reviews.

We expected the total number of submissions to increase this year, in line with the experience of other conferences that have transitioned to multiple submission deadlines. Accordingly, we gathered the largest program committee ever, with 100 members and two chairs. We endeavored to assemble a diverse program committee in terms of area of expertise, seniority level, geography, gender, race, and institution type. Members of the resulting program committee were 19% from industry, government, or nonprofit, 25% female, and 27% based outside the US. The 2018 USENIX Security chairs invited members of the community to volunteer themselves and others to serve on the 2019 program committee using a web form; we found this to be an incredibly valuable resource when assembling our program committee.

A major goal of our changes to the reviewing system was to focus on returning helpful, constructive reviews to authors, and to provide as much guidance as possible in moving submitted papers towards publication. Following last year, we also assembled a Review Task Force (RTF) of five experienced program committee members to help ensure review quality and encourage positive discussion. RTF members provided feedback on reviews, helped manage online discussion, and acted as proxies for program committee members not in attendance in the in-person program committee meeting, in exchange for a reduced reviewing workload. We found significant value in the RTF, and expanded their roles this year, particularly in facilitating online discussion and helping reviewers calibrate the new review outcomes across papers.

We received 260 submissions in the fall November 15, 2018 deadline. We administratively rejected four papers for violating the call for papers, and two papers were withdrawn, leaving 254 submissions to be considered in Fall Round 1. Each paper was assigned two reviews in the first round. Following three weeks of review and a week of online discussion, 93 papers were early rejected on December 14. Of these, 41 were Rejected and 45 received a Reject and Resubmit outcome. A paper was rejected if it received only scores of Reject or Reject and Resubmit, and neither reviewer saw value in additional reviews. The outcome was agreed upon by the reviewers. Authors of rejected papers were not given the opportunity to appeal. We believed that this early rejection step was critical, because it meant that the authors could immediately begin making changes to their submission and have it evaluated by other reviewers at another venue. The authors of the remaining 161 papers were given the opportunity to respond to the reviews and specific questions from the reviewers. Each fall Round 2 paper received two or more additional reviews. After three more weeks of reviewing and 1.5 weeks of online discussion, we notified authors of the Round 2 decisions on January 18, 2019. Of these papers, 11 were Rejected, 77 received a Reject and Resubmit Outcome, 48 received a Major Revision outcome, 20 received a Minor Revision outcome, and 5 were Accepted. All 20 Minor Revision papers from the fall submission deadline were accepted by February 18, 2019.

We received 481 submissions in the winter February 15, 2019 deadline. 38 of these were resubmissions of papers that received a Major Revision decision from the fall deadline. Additionally, the authors of two Major Revision papers explicitly wrote to withdraw their paper from the USENIX Security review process. We administratively rejected 20 papers for violating the call for papers, and four were withdrawn by the authors, leaving 457 papers to be considered in the winter Round 1. We assigned the same reviewers as in the previous round to the resubmitted Major Revision papers, except in cases where additional conflicts of interest arose or were discovered between the two deadlines, and assigned two reviewers to all other papers. 211 papers were early rejected on March 21, 2019: 122 Rejected and 89 Reject and Resubmit. We also asked the reviewers on Major Revision resubmissions to make decisions in Round 1: six papers were Accepted, 24 papers received a Minor Revision, one paper received a Reject and Resubmit, and seven papers were Rejected. We chose to disallow multiple Major Revision decisions in order to make sure that paper outcomes were decided in a reasonable time frame for authors. This left 216 papers in Round 2.

The in-person PC meeting was held on April 29 and 30 at the University of Florida in Gainesville, Florida. We invited all program committee members to attend the meeting but made attendance optional; 49 program committee members attended. We were able to discuss 91 papers during the meeting, and all other decisions were made in online discussion. Among the papers in Round 2, 11 papers were Accepted, 48 received Minor Revisions, 33 received Major Revisions, 108 received a Reject and Resubmit outcome, and 16 were Rejected. Further, one Minor Revision paper was ultimately rejected by the reviewers; all the others were accepted by the camera-ready deadline of June 1.

In total, we accepted 113 of the 697 distinct, non-withdrawn submissions that we received this year, for a 16% acceptance rate overall. The acceptance rate for the resubmitted Major Revision papers was 76%. Both the number of papers accepted and the number of papers submitted are new records for the symposium, which was exceptionally competitive this year. We congratulate the authors on their excellent work and achievements!

It was an honor to be part of the large community effort that brings together the USENIX Security Symposium. The demands placed on the program committee this year were exceptionally high, both in terms of reviewing load and in calibrating a new reviewing system. Each member submitted about 22 reviews, for a total of 822 reviews in the fall and 1450 reviews in winter, or 2272 reviews total, and more than 8600 comments were left in the discussions. It is our sincere hope that the new process not only assisted in creating the strongest possible program, but also that it helped to improve the quality of reviews and mentorship provided to the community.

We would especially like to thank our Review Task Force: Kevin Butler, Srdjan Capkun, Rachel Greenstadt, Jon McCune, and Franzi Roesner. Yoshi Kohno was our steering committee liaison and was a great help. Michael Bailey also provided valuable feedback from the board. We also thank the many external reviewers who provided additional expertise. We would like to thank the invited talks committee (Devdatta Akhawe, Alex Gantmann, Giancarlo Pellegrino, Elissa Redmiles), the Test of Time award committee (Matt Blaze, Dan Boneh, Kevin Fu, Fabian Monrose), the poster session chair Brad Reaves, and the lightning talks chair Christina Garman. We are extremely grateful to the staff at USENIX who run everything behind the scenes, particularly Casey Henderson, Jasmine Murcia, and Michele Nelson. Finally, we thank all of the authors of the 703 submitted papers for participating in the 28th USENIX Security Symposium.

## Abstract

Bluetooth Low Energy (BLE) is a fast-growing wireless technology with a large number of potential use cases, particularly in the IoT domain. Increasingly, these use cases require the storage of sensitive user data or critical device controls on the BLE device, as well as the access of this data by an augmentative mobile application. Uncontrolled access to such data could violate user privacy, cause a device to malfunction, or even endanger lives. The BLE standard provides security mechanisms such as pairing and bonding to protect sensitive data such that only authenticated devices can access it. In this paper we show how unauthorized co-located Android applications can access pairing-protected BLE data, without the user's knowledge. We discuss mitigation strategies in terms of the various stakeholders involved in this ecosystem, and argue that at present, the only possible option for securing BLE data is for BLE developers to implement remedial measures in the form of application-layer security between the BLE device and the Android application. We introduce BLECryptcracer, a tool for identifying the presence of such application-layer security, and present the results of a large-scale static analysis over 18,900+ BLE-enabled Android applications. Our findings indicate that over 45% of these applications do not implement measures to protect BLE data, and that cryptography is sometimes applied incorrectly in those that do. This implies that a potentially large number of corresponding BLE peripheral devices are vulnerable to unauthorized data access.

## 1 Introduction

Bluetooth is a well-known technology standard for wireless data transfer, currently deployed in billions of devices worldwide [37]. A more recent addition to the Bluetooth standard is Bluetooth Low Energy (BLE), which differs from Classic Bluetooth in that it incorporates a simplified version of the Bluetooth stack and targets low-energy, low-cost devices.

Its focus on resource-constrained devices has made BLE highly suited for IoT applications [18], including personal

health/fitness monitoring [22], asset tracking [8], vehicular management [13], and home automation [27]. Most of these use cases augment the functionality of the BLE device with a mobile application. This application may need to read or write sensitive or critical data on the BLE device (for example, glucose measurement values stored by a continuous glucose meter, or a field that controls a door's locking mechanism in a smart home security system). To ensure privacy and security/safety, measures should be taken to protect such data from being accessed by unauthorized entities.

The Bluetooth specification provides means for restricting access to BLE data via *pairing* and *bonding*, which are mechanisms for establishing an authenticated transport between two communicating devices. However, when multiple applications reside on a single host, as is the case with mobile devices, there is potential for a malicious application to abuse a trusted relationship between the host and the device that was initiated by an authorized application [31].

In this work, we show how a malicious application could take advantage of the BLE communication model on Android to read and write pairing-protected data on a BLE device without the user's knowledge. We also show that these unauthorized applications may be able to do so while requesting minimal permissions, thereby making them appear less invasive than even an authorized application.

We discuss various strategies, in terms of the different stakeholders involved, that can be used to secure BLE data against such unauthorized access. We argue that in the current landscape, it is up to the BLE device/application developers to implement application-layer security to protect the data on their devices. We perform a large-scale static analysis of 18,929 BLE-enabled Android applications (filtered down from an original dataset of over 4.6 million applications) to determine how many of them currently employ such protection mechanisms. While the results vary for BLE reads vs. writes, overall they show that more than 45% of the tested applications do not provide cryptography-based application-layer security for BLE data. This number rises to about 70% for those applications that are categorized under "Medical". This information,

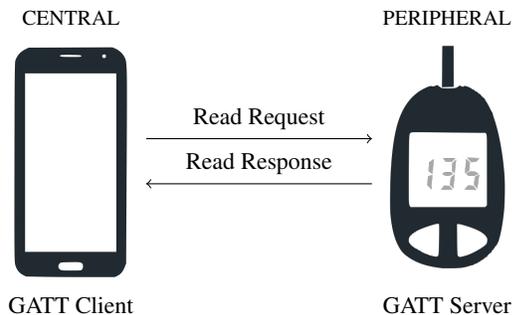

Figure 1: GATT communications between a mobile phone and a BLE-enabled glucometer.

when combined with the download counts for each application, allows us to estimate a lower bound for the number of BLE devices that may be vulnerable to unauthorized data access.

The rest of this paper is structured as follows: Section 2 provides an overview of key BLE concepts, particularly with regard to data access mechanisms and restrictions. We demonstrate unauthorized BLE data access in Section 3. This section also discusses stakeholders and possible mitigation strategies. Section 4 details our marketplace application analysis and examines the results. Related work is described in Section 5, and Section 6 provides our concluding remarks.

## 2 Background

Two devices that communicate using BLE will operate in an asymmetric configuration, with the more powerful device, referred to as the *central*, taking on most of the resource-intensive work. The resource-constrained device is termed the *peripheral* and performs tasks that are designed to consume fewer resources.

### 2.1 Data Access on BLE Devices

BLE, unlike Classic Bluetooth, can only handle discrete data known as *attributes*. Attributes are stored and accessed according to rules specified by the *Attribute Protocol* (ATT) and the *Generic Attribute Profile* (GATT), both of which are defined in the Bluetooth standard. There are different types of attributes, of which *characteristics* are the most relevant for our analysis, as they hold the actual data of interest. Related characteristics are grouped into *services*, which are exposed to connected devices [11].

When one BLE-enabled device wants to access attributes on another BLE device, the device that initiates the exchange takes on the role of *GATT client* and the other acts as the *GATT server*. In this paper, we focus on the scenario where the BLE peripheral (e.g., a glucose meter), acts as the server, and a mobile phone acts as the client, as shown in Figure 1.

### 2.2 BLE Attribute Permissions

Every attribute has associated with it three permissions that control how it may be accessed: (1) *Access permissions* define whether an attribute can be read and/or written. (2) *Authentication permissions* indicate the level of authentication and encryption that needs to be applied to the transport between the two devices before the attribute can be accessed. (3) *Authorization permissions* specify whether end-user authorization is required for access.

When a GATT client sends a read or write request for an attribute to a GATT server, the server will check the request against the permissions for that attribute, to determine whether the requested access mechanism is allowed and whether the client is authenticated and/or authorized, if required. An attribute is only readable or writable if its access permissions specify it to be so. In the case of authentication permissions, if the attribute requires an authenticated or encrypted link before it can be accessed (referred to as a “pairing-protected” attribute in this paper), and if such a link is not present when the access request is made, then the server responds with an `Insufficient Authentication/Encryption` message. At this point, the client can initiate the pairing process to authenticate and encrypt the transport. If this process completes successfully, the server will fulfill subsequent requests made by the client. This procedure for handling authentication requirements is well-defined in the Bluetooth specification. Authorization requirements, on the other hand, are implementation-specific and largely left up to developers.

Once two devices complete the pairing process, they typically go through an additional *bonding* process, during which long-term keys are established. This prevents the need for going through the pairing process again if they disconnect and subsequently reconnect, provided they retain the long-term keys. Upon re-connection, the link encryption process will be initiated using the stored keys. Keys normally remain on the devices unless the devices are reset or manually unpaired by the user.

## 3 BLE Co-located Application Attacks

In this section, we show how *any* application on an Android device can access pairing-protected attributes from a BLE peripheral, even when the pairing process was initiated by a different application. We then explore various mitigation strategies that are available to different stakeholders in the BLE ecosystem.

These attacks were also explored by Naveed et al. in 2014, for Classic Bluetooth [31]. We show that the problem remains on newer versions of Android, and also that the situation is worse for BLE, as one of our attacks enables fewer restrictions for access and requires fewer permissions of the malicious application than even of the official application.

### 3.1 Attack Mechanisms

We describe two attacks: the first shows that pairing-protected data can be accessed by unauthorized applications, while the second refines the attack and reduces the number of permissions required by the unauthorized application. We use two Android applications to describe the attacks: One application that is expected to be able to connect to the BLE device and access its data (“OfficialApp”), and a different application that should *not* be able to access pairing-protected data from the device (“AttackApp”). We conducted our experiments on an Alcatel Pixi 4 mobile phone, running Android 6.0, and on a Google Pixel XL, running Android 8.1.0. Version 6.0 was the most widely-deployed release [2], while 8.1.0 was the latest stable release, as of 01 Aug 2018.

#### 3.1.1 Attack 1: System-wide Pairing Credentials

This attack demonstrates that the BLE credentials that are stored on an Android device are implicitly available to *all* applications on the device, rather than just the application that originally triggered the pairing.

When the OfficialApp connects to the BLE device and attempts to access a pairing-protected characteristic, the resulting exchange will trigger the Android OS into initiating the pairing and bonding process (as depicted in the upper block in Figure 2). The resultant keys are associated with the link between the Android and BLE devices, rather than between the BLE device and the OfficialApp (which actually triggered the pairing). Therefore, once bonding completes, when the AttackApp scans and connects to the BLE device, the Android OS completes the connection process and automatically initiates link encryption with the keys that were generated during the previous bonding process (lower block in Figure 2). This enables the AttackApp to have the same level of access to the pairing-protected data on the device as the OfficialApp, but without the need for initiating pairing.

A key point to note here is that, not only is the unauthorized AttackApp able to access potentially sensitive information from the BLE device, but also the user is likely to be unaware of the fact that this data access is taking place, as there is no indication during link re-encryption and subsequent attribute access.

#### 3.1.2 Attack 2: Reuse of Connection

Our second attack exploits the fact that, on Android, a BLE peripheral can be used concurrently by multiple applications [32]. In this attack, the AttackApp does not scan for BLE devices. It instead searches for connected BLE devices using the `BluetoothManager.getConnectedDevices()` API call, with `BluetoothProfile.GATT` as the argument. If the OfficialApp happens to be in communication with the BLE device at the same time, this call will return a list with a reference to the connected BLE device. The AttackApp is then

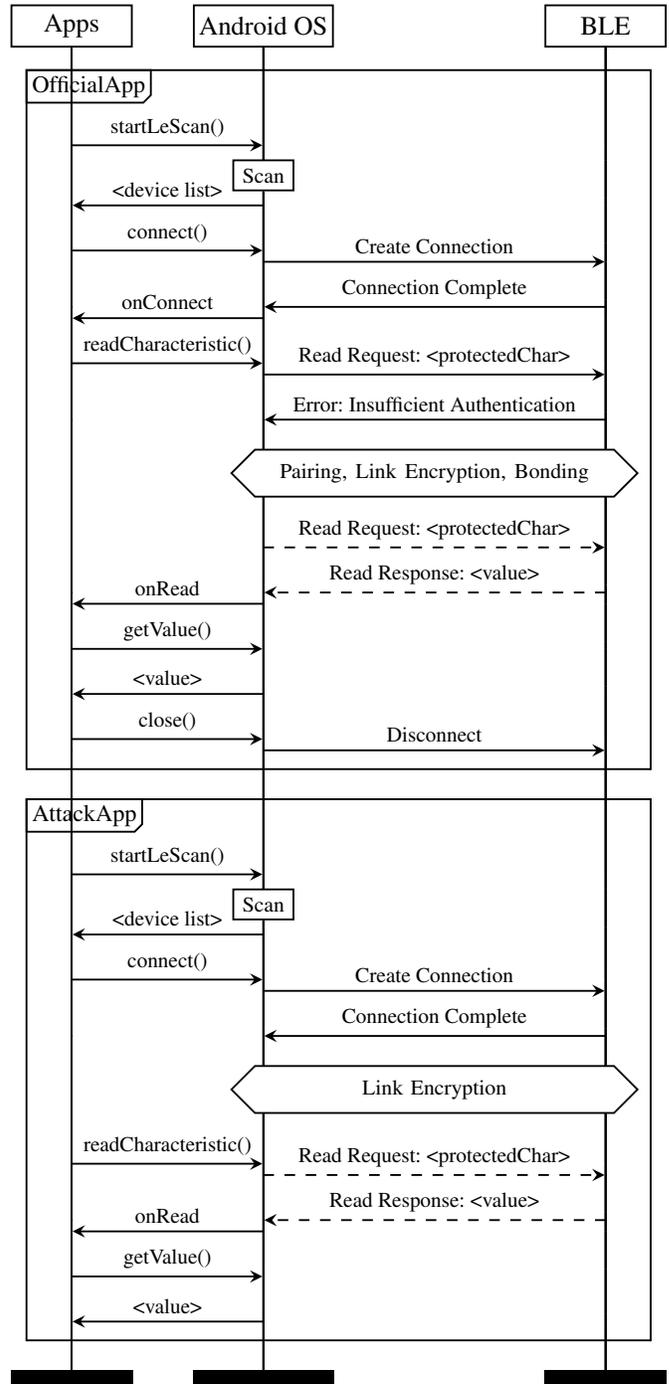

Figure 2: Attack 1 - Illustrative message exchange depicting access of pairing-protected data by unauthorized application. Note: Dashed lines indicate encrypted traffic.

able to directly connect to the GATT server and read and write to the characteristics on it (including those that are pairing-protected), without the need for creating a new connection to

the peripheral. This again is done surreptitiously, without the user being aware of the data access. An illustrative message flow where the AttackApp writes to a protected characteristic on the BLE device (which the OfficialApp subsequently reads) has been depicted in Figure 3.

An interesting observation from this attack is a subtle but relevant impact it has on user awareness, due to the different permissions that need to be requested by the two applications. Since both applications access data from a GATT server, they both require `BLUETOOTH` permissions. In this attack scenario, because the OfficialApp scans for the BLE device before it connects to it, it also needs to request the `BLUETOOTH_ADMIN` permission. Both `BLUETOOTH` and `BLUETOOTH_ADMIN` are “normal” permissions that are granted automatically by the Android operating system after installation, without any need for user interaction. However, due to restrictions imposed from Android version 6.0 onward, the OfficialApp also needs to request `LOCATION` permissions to invoke the BLE scanner without a filter (i.e., to scan for all nearby devices instead of a particular device). These permissions are classed as “dangerous” and will prompt the system to display a confirmation dialog box the first time they are required. Because the AttackApp merely has to query the Android OS for a list of already connected devices, it does not require these additional permissions. This makes the AttackApp appear to be less invasive in the eyes of a user, since it does not request any permission that involves user privacy. This could play a part in determining the volume of downloads for a malicious application. For example, a malicious application that masquerades as a gaming application, and which does not request any dangerous permissions, may be more likely to be downloaded by end users as opposed to one that requests location permissions.

### 3.2 Discussion

In this section we discuss the impact of our findings, compare them with the Classic Bluetooth case, and mention some attack limitations.

#### 3.2.1 Implications of Attack

In both of our experiments, the AttackApp was able to read and write pairing-protected data from the BLE device. The simplest form of attack would then be for a malicious application to perform unauthorized reads of personal user data (as an example) and relay this to a remote server.

We verified the practicability of this attack by testing a BLE-enabled fitness tracker that implemented the Bluetooth Heart Rate Service. According to the service specification, characteristics within this service are only supposed to be protected by pairing [9]. However, we observed that the pairing employed by the device appeared to be a non-standard implementation, and also that access to the Heart Rate Measurement characteristic was “locked” and had to be “unlocked”

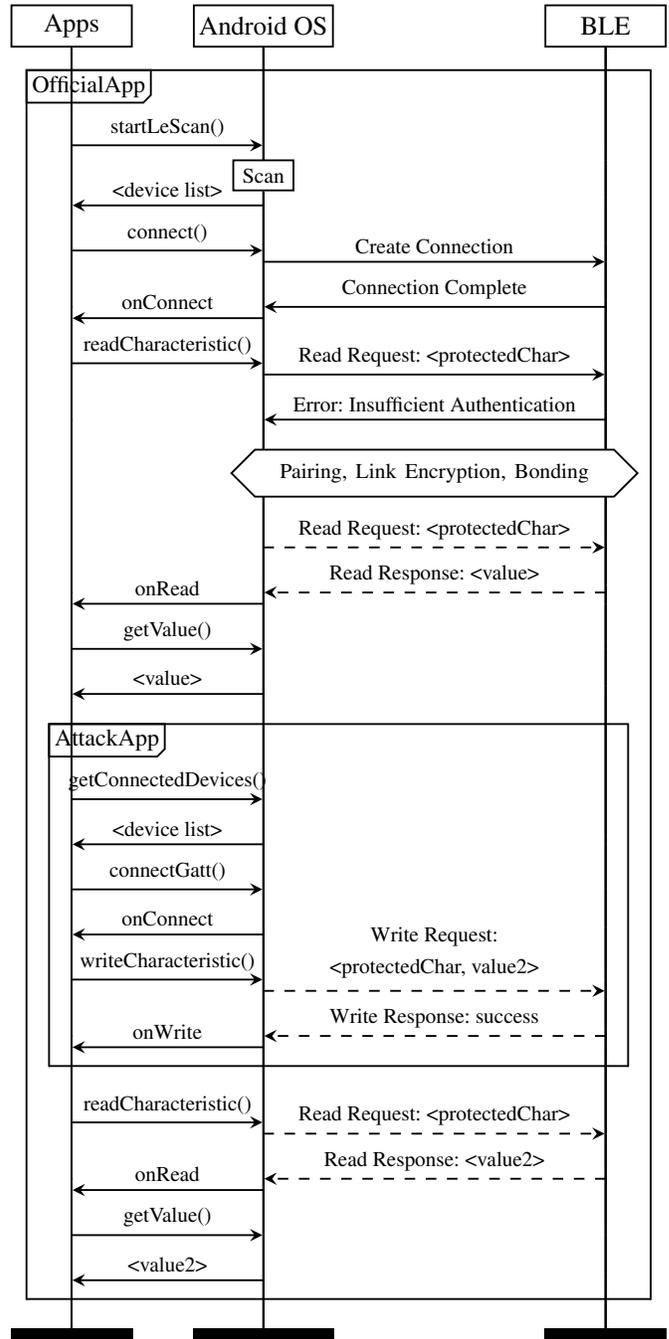

Figure 3: Attack 2 - Illustrative message exchange depicting the access of pairing-protected data by reusing an existing connection. *Note:* Dashed lines indicate encrypted traffic.

by first writing to certain other characteristics on the tracker. Despite this, we found that by deploying our second attack, our AttackApp was able to obtain Heart Rate Measurement readings without the need for performing any “unlocking”.

This is because the AttackApp connects to the GATT server by reusing an existing connection that was initiated by the official application. The unlocking procedure would therefore already have been performed for that connection by the official application. This result shows that artificially restricting access to data using non-cryptographic means will not be effective. We notified the device developer of this issue on 01 Nov 2018, but have not yet received a response.

It should be noted that the above attack could be used by a malicious application to target other sensitive health information such as ECG, glucose or blood pressure measurements from vulnerable BLE devices, to build up a profile on a user's health. Further, Smart Home devices and BLE-enabled vehicles may hold information on a user's habits and lifestyle (e.g., time at home, alcohol consumption, driving speed), and could be exploited. It may also be possible for a malicious application to overwrite values on the BLE device, such that the written data either causes unexpected behavior on the device, or is read back by the legitimate application, thereby giving the user an incorrect view of the data on the peripheral. For example, it may be possible to update the peripheral's firmware via GATT writes. If this mechanism is not suitably protected, then a malicious application could potentially install malicious firmware onto the BLE device, as we demonstrate in Section 4.6.

### 3.2.2 Comparison with Classic Bluetooth

In their experiments with Classic Bluetooth, Naveed et al. found that an unauthorized Android application would not be able to obtain data from a Classic Bluetooth device if the authorized application had already established a socket connection with the device, as only one application can be in communication with the device at one time. Therefore, a malicious application would either require some side-channel information in order to determine the correct moment for data access, or would need to interfere with the existing connection, thereby potentially alerting the user [31]. This limits the attack window for the malicious application. Our experiments show that this is not the case with BLE communication channels. With BLE, there are no socket connections and if the official application has established a connection with the BLE device, then this connection can be utilized by any application that is running on the Android device. That is, a malicious application does not have to wait for the authorized application to disconnect before it can access data.

### 3.2.3 Attack Limitations

The main limitation for the AttackApp in the case of the first attack is that it requires the `BLUETOOTH` and `BLUETOOTH_ADMIN` permissions in its manifest, and also needs to explicitly request `LOCATION` permissions at first run-time in order to be able to invoke the BLE scanner. This

enables the AttackApp to connect to the BLE device regardless of whether or not another application is also connected, but increases the risk of raising a user's suspicions.

In the second attack scenario, the obvious limitation for the AttackApp that requests only the `BLUETOOTH` permission is that the application will only be able to access data from the BLE peripheral when the peripheral is already in a connection with (another application on) the Android device. That is, data access will have to be opportunistic. This can be achieved, for example, by periodically polling for a list of connected devices.

## 3.3 Stakeholders, Mitigation Strategies and Awareness

In this section, we discuss potential mitigating strategies that different stakeholders within the BLE ecosystem could implement in order to prevent the attacks detailed in Section 3.1. We consider the Bluetooth Special Interest Group (SIG), Android (i.e., Google), and BLE device/application developers as stakeholders.

### 3.3.1 Bluetooth SIG

The Bluetooth SIG is the group that is responsible for defining and maintaining the Bluetooth standard, which provides details on pairing, bonding and BLE attribute permissions. The SIG also defines various BLE services, including some that handle user health information, e.g., the Heart Rate Service and the Continuous Glucose Monitoring Service. The Bluetooth specifications for these services require only pairing as a protection mechanism for the characteristics that hold health-related measurements [9, 10]. This protection is intended to avoid man-in-the-middle attacks and eavesdropping. However, as shown in Section 3.1, pairing will not prevent unauthorized Android applications from accessing the sensitive data held in these characteristics.

This issue could be avoided by modifying the Bluetooth specification and introducing specific security measures for protecting data at higher layers. However, this would require changes to all devices within the ecosystem, which may not be feasible due to the sheer volume of devices and applications currently available, and which could lead to fragmentation and reduced interoperability. Despite this, we believe that developers accessing Bluetooth documentation should at least be made aware of the risks involved, and have therefore notified the SIG via their Support Request Form (17 Dec 2018). We were informed (19 Dec 2018) that the case had been assigned to the appropriate team for assessment.

### 3.3.2 Android

Allowing all applications on an Android device to share BLE communication channels and long-term keys may well be by

design, particularly since the BLE standard does not provide explicit mechanisms for selectively allowing or denying access to data based on the source application. This model may work in some situations, for example on a platform where all applications originate from the same trusted source. However, the Android ecosystem is such that, many of the applications on a device are from different and potentially untrusted sources. In this scenario, providing all applications with access to a common BLE transport opens up possibilities for attack, as we have demonstrated.

One option to eliminate the problem is to modify how Android handles BLE communication channels. The modification would require some form of association between BLE credentials and the application that triggers the pairing/bonding process. Each data access request would then be checked against the permissions associated with the requesting application. This approach is favoured by Naveed et al., who propose a re-architected Android framework which will create a *bonding policy* when an application triggers pairing with a Bluetooth device [31]. This strategy has the advantage that Bluetooth devices will be protected by default from unauthorized access to their data. Further, assuming a suitably strong pairing mechanism is used, a minimum level of security will also be guaranteed. However, not only will the operating system(s) need to be modified, but also a mechanism will be required for ensuring that all users' mobile devices are updated. Otherwise, it is fairly likely that this measure will result in a fragmented ecosystem, with some devices running the modified operating system with protection mechanisms, and others running older versions of the OS with no protection.

Regardless of whether or not the above measure is implemented, we believe that developers should be made aware of the possibility of unauthorized applications accessing their BLE device data. At present, Android does not mention the issue in its Developer Guide [3]. In fact, to the best of the authors' knowledge, there is only a single document, from a BLE chipset manufacturer, which explicitly references the fact that multiple Android applications can simultaneously use a connection to a BLE device [32]. Apart from this, the risks of "system-wide pairing" have been mentioned in a specification issued by the Fast ID Online (FIDO) Alliance, without specific reference to mobile platforms [20].

We submitted an issue to the Android Security Team on 02 Nov 2018, focusing on the need of clear documentation so that developers are aware of the need for implementing additional protection measures if they are handling sensitive BLE data. The issue was reviewed by the security team and rated as Moderate severity (16 May 2019), based on Android's severity assessment matrix [5].

### 3.3.3 BLE Device/Application Developers

Despite the BLE stack containing an application layer, it could be argued that BLE is commonly viewed as a lower-layer tech-

nology for providing wireless communication capabilities, on top of which higher-layer technologies operate [12, 38]. This would result in the responsibility of securing user data being transferred from the Bluetooth SIG or Android to the BLE application/device developers. At any rate, this is the only mechanism available at present for protecting data against access by co-located applications.

That is, rather than relying solely on the pairing provided by the underlying operating system, developers can implement end-to-end security from their Android application to the BLE peripheral firmware. It may be possible to achieve such behavior via BLE authorization permissions, because even though their purpose is to specify a requirement for end user authorization, the behavior of BLE devices when encountering authorization requirements is implementation-specific. Most modern BLE chipsets implement authorization capabilities by intercepting read/write requests to the protected characteristics, and allowing for developer-specified validation.

One advantage of this method is that it gives the developer complete control over the strength of protection that is applied to BLE device data, as well as over the timings of security updates. However, leaving the implementation of security to the developer runs the risk of cryptography being applied improperly, thereby leaving the data vulnerable [17]. For existing developments, retrofitting application-layer security would mean that both an update for the Android application and a firmware update for the BLE device would be required, and there is a risk that the BLE firmware update procedure itself may not be secure [6].

Due to the lack of clear guidelines regarding attribute security in both the Android Developer Guide and the Bluetooth specification, it is also possible that developers implement no security at all, due to an assumption that protection will be handled by pairing. In the next section, we test this assertion of a lack of developer awareness by exploring the current state of application-layer security deployments via a large-scale analysis of BLE-enabled Android applications.

## 4 Marketplace Application Analysis

As evidenced by our experiments, it is fairly straightforward for any Android application to connect to a BLE device and read or write pairing-protected data. As discussed in Section 3.3, the only strategy available at present is for developers to implement application-layer security, typically in the form of cryptographic protection, between the Android application and the BLE peripheral.

In this section, we identify the proportion of applications that do *not* implement such security mechanisms, to demonstrate a possible lack of awareness surrounding the issue, and to be able to estimate the number of devices that are potentially vulnerable to the types of attack shown in Section 3.1.

Table 1: APKs and Downloads per Google Play Category

Category	APKs [packages]	Downloads(mm)
Health & Fitness	3012 [1263]	344.95
Lifestyle	1501 [1006]	52.60
Business	1489 [950]	39.62
Tools	1428 [891]	6308.62
Sports	1268 [685]	17.74
Travel & Local	948 [545]	31.83
Productivity	526 [305]	43.05
Entertainment	446 [284]	128.41
Music & Audio	406 [239]	51.48
Education	313 [225]	3.35
Shopping	383 [190]	144.87
Maps & Navigation	348 [181]	33.21
Medical	407 [177]	5.68
Communication	395 [146]	755.89
Finance	259 [126]	96.38
Auto & Vehicles	236 [119]	4.13
Food & Drink	146 [87]	6.23
Photography	114 [80]	45.78
Social	203 [77]	663.43
Other	746 [516]	258.41

<sup>a</sup> We make the assumption that all versions of an application fall under the same category.

<sup>b</sup> Some APKs within the dataset are no longer available on Google Play and hence, have no corresponding category. These have not been included.

To identify the presence of application-layer security, there are two possible targets for analysis: BLE peripheral firmware or Android applications. At present, there is no public repository of BLE firmware, which means that the firmware would need to be obtained from the peripherals themselves. This would necessitate the purchase of a large number of devices and would not be financially viable. Further, reverse-engineering and analyzing BLE firmware is not straightforward, as the firmware image is usually a `.hex` file, which can typically only be converted to binary or assembly. Android APKs, on the other hand, are easier to obtain, and a number of decompilers exist that allow for conversion of APKs to a human-readable format.

We therefore target Android applications for our analysis and perform the following: (1) obtain a substantial dataset of BLE-enabled Android APKs, (2) determine the BLE method calls and the cryptography libraries of interest, and (3) define a mechanism to determine whether BLE reads and writes make use of cryptographically processed data. We then apply this mechanism to our dataset and analyze the results.

## 4.1 APK Dataset

We obtained our dataset from the AndroZoo project [1]. This is an online repository that has been made available for research purposes and which contains APKs from several different application marketplaces. We focus on only those APKs that were retrieved from the official Google Play store, which nevertheless resulted in a sizeable dataset of over 4.6 million APKs. This dataset includes multiple versions for each application, as well as applications that are no longer available on the marketplace. We performed our analysis over the entire dataset, rather than focusing on only those APKs that are currently available on Google Play. This was in part because older versions of an application may still be residing on users' devices, and in part to be able to identify trends in application-layer security deployments over time.

As we are only interested in those applications that perform BLE attribute access, and because such access always requires communicating with the GATT server on the BLE peripheral, the APKs were filtered by the `BLUETOOTH` permission declaration and by calls to the `connectGatt` method, which is called prior to performing any data reads or writes. 18,929 APKs, comprising 11,067 unique packages<sup>1</sup>, from the original set of 4,600,000+ APKs satisfy this criteria, and these formed our final dataset.

### Application Categories

Applications are categorized in Google Play according to their primary function, such as "Productivity" or "Entertainment", and it may be possible to gauge the sensitivity of the BLE data handled by an application based on the category it falls under. For example, "Health and Fitness" applications are probably more likely to hold personal user data than "Entertainment" applications.

The number of APKs per category has been listed in Table 1 for our dataset. Approximately 23% of the APKs (18% of unique applications) fall under the categories of "Health and Fitness" and "Medical", with a cumulative download count of over 350 million. Note that the disproportionately high volume of downloads for the category "Tools" is due to the Google and Google Play applications, which include BLE capabilities and are installed on most Android devices.

## 4.2 Identification of BLE Methods and Crypto-Libraries

We perform our analysis against specific BLE methods and crypto-libraries. When considering BLE methods, we focus on those methods that involve data writes and

<sup>1</sup>An Android application may have many versions, each of which will be a separate APK file (with a unique SHA256 hash), but all of which will have the same package name. We use the terms "unique applications" or "unique packages" to denote the set of APKs that contain only the *latest* version of each application.

Table 2: BLE Data Access Methods

Access	Method Signature <sup>a</sup>	#APKs	% of Total Methods <sup>b</sup>
Read	byte[] getValue ()	17896	61.58%
	Integer getIntValue (int, int)	8051	27.70%
	String getStringValue (int)	2313	7.96%
	Float getFloatValue (int, int)	800	2.75%
Write	boolean setValue (byte[] )	16198	70.49%
	boolean setValue (int, int, int)	5542	24.11%
	boolean setValue (String)	627	2.73%
	boolean setValue (int, int, int, int)	611	2.66%

<sup>a</sup> All methods are from the class `android.bluetooth.BluetoothGattCharacteristic`.

<sup>b</sup> “% of Total Methods” refers to the percentage of occurrences of a particular method for a particular data access type (i.e., read or write), with respect to all methods that enable the same type of data access.

reads. Such methods have been listed in Table 2, and function as the starting point for our analysis. For data writes, the `BluetoothGattCharacteristic` class within the `android.bluetooth` package has `setValue` methods that set the locally-stored value of a characteristic. This is then written out to the BLE peripheral. For data reads, the same class has `getValue` methods, which return data that is read from the BLE device. In a few APKs that we analyzed, BLE data access methods were also called from within other, vendor-specific libraries. However, we do not include these in our analysis as they are now obsolete.

For cryptography, Android builds on the Java Cryptography Architecture [33] and provides a number of APIs, contained within the `java.security` and `javax.crypto` packages, for integrating security into applications. While it is possible for developers to implement their own algorithms, Android recommends against this [4]. We therefore consider only calls to these two packages as an indication of application-layer security.

### 4.3 BLECryptracer

Identification of cryptographically-processed BLE data is in essence a taint-analysis problem. For instance, a call to an encryption method will taint the output variable that may later be written to a BLE device. For the purpose of this paper, when analyzing data that is read from a BLE peripheral, we consider the `getValue` variants in Table 2 as sources and the cryptography API calls as sinks. For data that is written to the BLE device, we consider the cryptography API calls as sources and the `setValue` methods as sinks.

There are a number of tools available for performing taint-analysis, such as Flowdroid [7] and Amandroid [40]. However, running a subset of our dataset of APKs through Amandroid (selected because of advantages over Flowdroid and other taint-analysis tools [34]), we found that analysis of a single APK sometimes utilized over 10GB of RAM and took several

hours to complete. We also found through manual analysis that many instances of cryptographically-processed data were not identified by Amandroid, especially when the BLE functions were called from third-party libraries. We therefore developed a custom Python analysis tool called BLECryptracer, to analyze *all* calls to BLE `setValue` and `getValue` methods within an APK.

BLECryptracer is developed on top of Androguard [16], an open-source reverse-engineering tool that decompiles an Android APK and enables analysis of its components. Our tool traces values to/from BLE data access functions and determines whether the data has been cryptographically processed. To achieve this, it employs a technique for tracing register values which is sometimes referred to as “slicing” and which has been utilized in several static code analyses [17, 24, 35]. It also traces fields, as well as messages passed via `Intents`<sup>2</sup> and certain threading functions, e.g., `AsyncTask`. It returns `TRUE` at the first instance of cryptography that it encounters and `FALSE` if it is unable to identify any application-layer security with BLE data.

Our tool analyzes BLE reads and writes separately, as the direction of tracing is different in the two cases. It performs three main types of tracing, in the following order:

1. Direct trace - Attempt to identify link between BLE and cryptography functions via direct register value transfers and as immediate results of method invocations.
2. Associated entity trace - If the direct trace does not identify a link between source and sink, analyze abstract/instance methods and other registers used in previously analyzed function calls.
3. “Lenient” trace - If the above methods fail to return a positive result, perform a search through all previously encountered methods (which would have originated from the BLE data access method), to determine if cryptography is used *anywhere* within them.

<sup>2</sup>By matching the `Extra` identifier within the calling method.

Table 3: Accuracy Statistics

Access	Tool	Confidence	App Set <sup>a</sup>	Detected <sup>b</sup>	TP	FP	TN	FN	Precision	Recall	F-measure
Read	Amandroid	N/A	92	49	44	5	10	33	90%	57%	70%
		High	92	62	58	4	11	19	94%	75%	83%
	BLECryptracer	Medium	30	11	7	4	7	12	64%	37%	47%
		Low	19	12	8	4	3	4	67%	67%	67%
Write	Amandroid	N/A	92	56	49	7	8	28	88%	64%	74%
		High	92	50	46	4	11	31	92%	60%	72%
	BLECryptracer	Medium	42	22	19	3	8	12	86%	61%	72%
		Low	20	10	5	5	3	7	50%	42%	45%

<sup>a</sup> Number of APKs tested. Note that, for confidence levels Medium and Low, we don't consider the APKs detected at higher confidence levels.

<sup>b</sup> The number of APKs that were identified as having cryptographically protected BLE data.

The first trace method will produce results that are most likely to actually have cryptographically-processed BLE data, as the coarse-grained analysis performed in the subsequent methods adds increasing amounts of uncertainty. For this reason, BLECryptracer assigns “confidence levels” of High, Medium and Low to its output, which correspond to the three trace methods above, to indicate how certain it is of the result. We evaluate these confidence levels against a modified version of the DroidBench benchmarking suite in Section 4.4.1. Note that BLECryptracer only looks for application-layer security in benign applications, and these confidence levels apply only when deliberate manipulations (i.e., malicious obfuscation techniques) are not employed to hide the data flow between source and sink.

Appendix A describes the tracing mechanism in greater detail, and also outlines how BLECryptracer combats the effects of obfuscation in benign applications.

## 4.4 Evaluation

We evaluated BLECryptracer, in terms of both accuracy and execution times. For comparison purposes, we have included test results from Amandroid as well.

### 4.4.1 Accuracy Measures

At present, there is no dataset of real-world APKs with known use of cryptographically-processed BLE data, i.e., ground truth. Therefore, in order to test our tool against different data transfer mechanisms, we re-factored the DroidBench benchmarking suite [21] for the BLE case.

Each DroidBench test application was cloned twice and modified so the data flow between the sources and sinks would be from `getValue` to a cryptography method invocation, and from the cryptography method invocation to `setValue`, to emulate cryptographically-processed reads and writes, respectively. Some DroidBench test cases were excluded as they

were found to be irrelevant due to differences in the objectives of DroidBench and our test set, e.g., applications that employ emulator detection or which leak contextual information in exceptions. Further, applications where BLE data is written to or read from files, or which contain data leaks in inactive code segments were not included (as our aim is to determine whether or not BLE data is cryptographically-processed). In total, we created 184 APKs: 92 for reads and 92 for writes.

We executed BLECryptracer against our benchmarking test set, analyzed the results and obtained performance metrics in terms of the three different confidence levels. The statistics differ based on the type of access that is analyzed (i.e., reads vs. writes) due to differences in the tracing mechanisms. The same test set was also used against Amandroid for comparison. Table 3 presents the performance metrics for both tools.

In the case of BLECryptracer results, the metrics are with respect to the total analyzed APKs at each confidence level. That is, because lower confidence levels analyze only those APKs that do not get detected at higher levels, accurate metrics can only be derived by considering the set of APKs that were actually analyzed at each level. For example, when considering the analysis of BLE reads, while the entire dataset of 92 APKs is relevant for confidence level High, only the 30 APKs that do *not* result in a TRUE outcome at level High will be analyzed for confidence level Medium. This also means that, when obtaining performance metrics for confidence level High, all TRUE results obtained at levels Medium and Low are taken to be FALSE.

The DroidBench test set, and hence our benchmarking suite, is an imbalanced dataset, containing far more samples *with* leaks (77) than *without* (15). For this reason, metrics such as accuracy are not suitable for analyzing the performance of our tool when executed against this test set, as they are more susceptible to skew [23, 26]. For our analysis, we compare the combined True Positive Rate (TPR) and False Positive Rate (FPR), and the combined precision-recall instead, in-line with

taint-analysis evaluations [36].

Table 3 presents the precision and recall (i.e., TPR) for both BLECryptracer and Amandroid. We further derive FPRs for both tools. With BLECryptracer, when analyzing reads, False Positive Rates steadily increase as the confidence level reduces, as expected, with values of 27% for confidence level High, 36% for Medium and 57% for Low. When analyzing writes, the values are 27%, 27% and 63%, respectively. Regardless of the data access mechanism being tested, BLECryptracer (considering only the results at High confidence, for a fairer comparison) performs better than Amandroid in terms of FPR, with 27% vs. 33% for reads and 27% vs. 47% for writes. Precision values are also better in the case of BLECryptracer for both reads and writes. In terms of the True Positive Rate, BLECryptracer performs better than Amandroid for reads at 75% vs. 57%, and slightly worse for writes at 60% vs. 64%. These results show that, overall, BLECryptracer performs better than Amandroid for analyzing the use of cryptography with BLE data.

It should be noted that three of the four False Positives obtained by BLECryptracer at the High confidence level were due to the order in which variables are assigned values (i.e., lifecycle events), which is not tested for by BLECryptracer. Other data transfer mechanisms not tested for are `Looper` and `Messenger` functions, which generate False Negatives. The remaining False Positive was due to the presence of method aliasing and was also identified as a False Positive by Amandroid. In addition, the unexpectedly low TPR (i.e., recall) at level Medium for reads is due to the relatively few cases analyzed at that level when compared to High.

#### 4.4.2 Execution Times

We also compared BLECryptracer and Amandroid in terms of speed of execution. For this, we ran the two tools against a random subset of 2,000 APKs and compared time-to-completion in both cases. We imposed a maximum run-time of 30 minutes per APK for both tools, and only compared execution times for those cases where Amandroid did not time out (approximately 40% of the tested APKs timed out when analyzed by Amandroid. In comparison, fewer than 2% of APKs timed out when analyzed by BLECryptracer).

Figure 4 plots the time taken to analyze BLE writes using BLECryptracer vs. Amandroid. The figure shows that analysis times with BLECryptracer were, for the most part, around 3-4 minutes per application. We observed no obvious correlation between the size of the application’s dex file and the execution time, for either tool. APKs that took longer to process with BLECryptracer were predominantly of confidence level “Medium”, which indicates that the longer analysis times may simply have been because of having to first go through the most stringent analysis (at the highest confidence level). For Amandroid, the execution times vary to a greater extent than with BLECryptracer, due to the difference in the mechanisms

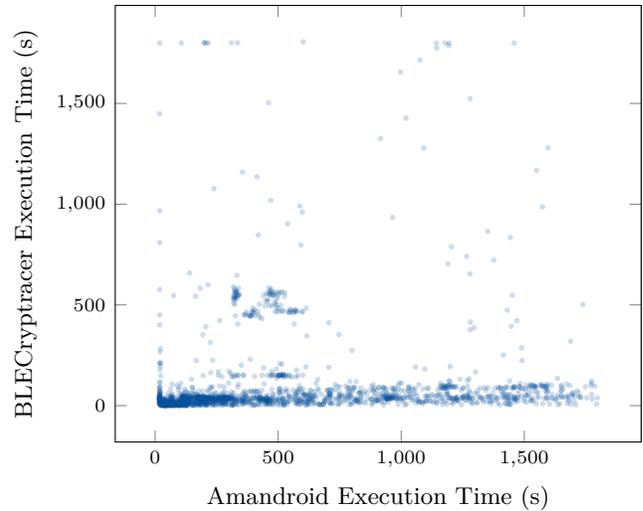

Figure 4: Comparison of time taken to execute BLECryptracer vs. Amandroid, when analyzing BLE writes.

employed for performing the analysis.

## 4.5 Results from Large-Scale APK Analysis

We executed BLECryptracer against our dataset of 18,929 APKs. 192 APKs timed out when analyzing reads and 220 APKs timed out when analyzing writes, when a maximum runtime of 30 minutes was imposed. These APKs were re-tested with an increased runtime of 60 minutes. However, even with the longer analysis time, 44 and 76 APKs timed out for reads and writes, respectively, and had to be excluded from further analysis. In addition, approximately 90 APKs could not be processed via Androguard’s `AnalyzeAPK` method and were excluded.

Due to the differences in performance metrics obtained for the three confidence levels during testing (as mentioned in Section 4.4), we focus on only those results that either identify cryptography at confidence level High or those where no cryptography was identified at all.

### 4.5.1 Presence of App-Layer Security with BLE Data

Our results show that approximately 95% of BLE-enabled APKs call the `javax.crypto` and `java.security` cryptography libraries *somewhere* within their code. While this is a large proportion of APKs, the results also indicate that a much smaller percentage of APKs use cryptographically processed data *with BLE reads and writes* (approximately 25% for both, identified with High confidence). In fact, about 46% of APKs that perform BLE reads and 54% of those that perform BLE writes (corresponding to 2,379 million and 2,075 million cumulative installations, respectively) do *not* implement security for the BLE data. Interestingly, of the 16,131 APKs that called

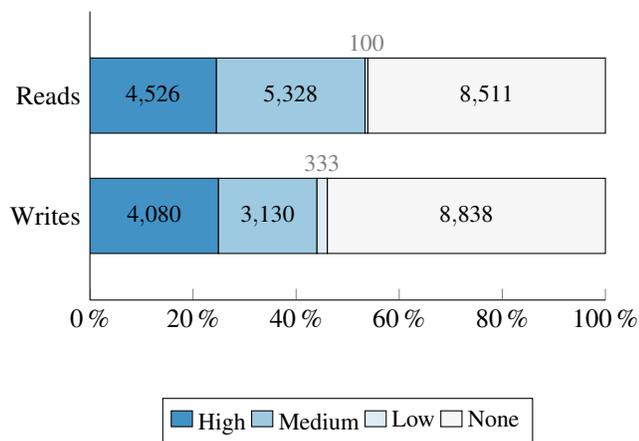

Figure 5: Analysis results depicting the presence of cryptographically-processed data with BLE writes and reads, with breakdown according to Confidence Level.

both BLE read and write functions, about 36% (i.e., more than 5,700 APKs), with a cumulative download count of 1,005 million, do not implement application-layer security for either type of data access. Figure 5 summarizes the proportion of APKs that were identified as containing cryptographically protected BLE data at the three different confidence levels.

#### 4.5.2 Libraries vs. App-Specific Implementations

We found that many BLE-enabled APKs actually use third-party libraries for incorporating BLE functionality. To get an idea of exactly how many APKs relied on libraries, we analyze all methods within an APK that called BLE data access functions. To do this in an automated way, we compare the method class name with the application package name. If the first two components (e.g., `com.packagename`) of each match, then we take it to be a method implemented within the application. If the components do not match, we take it to be a library method. If the package name uses country-code second-level domains (e.g., `uk.ac.packagename`), then we compare the third components as well.

Of the APKs that called the `setValue` method, 63% used BLE functionality solely through libraries, 32% used application-specific methods only, while 4% used both. Fewer than 1% of the APKs could not be analyzed due to very short method names. Within the APKs that used both application-specific methods and libraries, around 34% used an external library to provide Device Firmware Update (DFU) capabilities, thereby enabling the BLE peripheral to be updated via the mobile application. Of the APKs that utilized only application-specific methods to incorporate BLE functionality, 67% did *not* implement application-layer security with the BLE data. This proportion was lower at 48% for applications that relied on libraries.

In the case of the APKs that called `getValue` variants,

37% used only application-specific methods, 58% used only libraries, and 5% used both. As with the `setValue` case, a higher proportion of APKs that used only app-specific BLE implementations were found to not use cryptography (60%), when compared with those that used only libraries (39%).

Table 4 presents the ten most commonly-encountered BLE libraries, their functionality, the number of APKs that use them, and the presence of cryptographically-processed BLE data within the library itself. The table shows that the most prevalent third-party packages are libraries that enable communication with BLE beacons. In fact, a single such library (Estimote) made up more than 90% of all instances of cryptographically-processed BLE writes and 85% of cryptographically-processed BLE reads (identified with High confidence). An analysis of this library suggested that cryptography is being used to authenticate requests when modifying settings on the beacon.

Apart from beacon libraries, we identified five libraries that function as wrappers for the Android BLE API. For example, Polidea wraps the API so that it adheres to the reactive programming paradigm. The libraries `Randdusing`, `Megster` and `Evothings` enable the use of BLE via JavaScript in Cordova-based applications. Similarly, `Chromium` enables websites to access BLE devices via JavaScript calls. None of these libraries handle cryptographically-processed BLE data. It is expected that developers using these libraries will implement their own application-layer security (using either JavaScript or reactive Java as appropriate).

Of the two remaining libraries, `Flic`, which uses cryptographically-processed data, is a library offered by a BLE device manufacturer. This library allows third-party developers to integrate their services into the `Flic` ecosystem, to allow them to automate certain tasks.

Finally, `Nordicsemi` is a library provided by a BLE chipset manufacturer to enable DFU over the BLE interface. With the newest version of the DFU mechanism, the BLE peripheral verifies that the firmware has been properly signed. Devices using the legacy DFU mechanism will not verify the firmware. However, the mobile application (and by extension, the library) does not need to handle cryptographically-processed data in either case.

#### 4.5.3 Cryptographic Correctness

`BLECryptracer` identified 3,228 unique packages with cryptographically protected BLE data (with either reads or writes), with High confidence. However, the presence of cryptolibraries does not in itself indicate a secure system. We therefore further analyzed this subset of APKs to identify whether cryptography had been used correctly in them. The tool `CogniCrypt` [29] was utilized for this purpose. Although this tool does not formally verify the cryptographic protocol between the application and the BLE peripheral, it identifies various misuses of the Java crypto/security libraries.

Table 4: Top Ten Third-Party BLE Libraries

Library	Function	#APKs[unique]	Crypto
Estimote	Beacon	3980[2804]	Yes
Nordicsemi <sup>a</sup>	DFU	1238[847]	No
Kontakt	Beacon	1108[690]	No
Chromium	Web BLE	402[269]	No
Randdusing	Cordova Plugin	268[188]	No
Megster	Cordova Plugin	317[187]	No
Flic	BLE Accessory	173[164]	Yes
Polidea	BLE Wrapper	138[114]	No
Evthings	Cordova Plugin	142[84]	No
Jaalee	Beacon	102[79]	No

<sup>a</sup> Significant overlap present between Estimote and Nordic due to repackaging of the Nordic SDK into Estimote.

Among the 3,228 unique packages, we found that there was significant overlap between APKs in terms of the BLE libraries or functions<sup>3</sup> used. Removing such duplicates resulted in a set of 194 APKs. Of these, 68 were identified by CogniCrypt as having issues. However, because CogniCrypt identifies cryptography misuse within the entire APK, the results were filtered for BLE-specific functions. 24 APKs were found to have issues within or associated with the methods that cryptographically processed BLE data (as identified by BLECryptracer) and often, a single APK exhibited multiple issues. Table 5 shows the different types of misuse encountered and the number of unique packages that were identified as having such misuse. Note that because this analysis was performed over unique packages, the number of *APKs* that misuse crypto-libraries will be higher.

We manually analyzed the 24 APKs that were flagged by CogniCrypt as having BLE-relevant issues, and examined the identified instances of bad cipher modes and hardcoded keys/Initialization Vectors (IVs). With regard to insecure block cipher modes, we found that explicit use of ECB was prevalent (9 out of 10 cases), but there was also one case where `Cipher.getInstance("AES")` was used without the mode being specified, which may default to ECB depending on the cryptographic provider. When analyzing keys, we observed that several applications directly contained hardcoded keys as byte arrays or strings. Three applications retrieved keys from JSON files. In two cases, keys were generated from the `ANDROID_ID`, which is a system setting that is readable by all applications. We also observed one instance where a key was obtained from a server via HTTP (not HTTPS).

<sup>3</sup>There are instances where two applications may have unique package names, but which actually incorporate much the same functionality. This is often the case when the same developer produces branded variants of an application for different clients in a single industry. For example, two applications could have unique package names `com.myapp.app1` and `com.myapp.app2`, but their functionality may be derived from a common codebase `com.myapp`.

Table 5: Number of Packages with Cryptographic Misuse

Misuse Type <sup>a</sup>	#Unique Packages
ECB (or other bad mode)	10
Non-random key	6
Non-random IV	10
Bad IV used with Cipher	7
Bad key used with Cipher	11
Incomplete operation (dead code)	4

<sup>a</sup> Description of misuse based on [17, 30].

This analysis shows that several real-world applications contain basic mistakes in their use of crypto-libraries and handling of sensitive data, which means that the BLE data will not be secure despite the use of cryptography.

#### 4.5.4 Trends over Time

Figure 6 shows the trend of application-layer security over time for applications that incorporate calls to BLE reads or writes. The graph depicts the percentage of applications that do not have cryptographic protection for either type of access. The overall downward trend suggests that there has been some improvement in application-layer security between the years 2014 and 2017 (we refrain from making observations about APKs from 2013 as they were very few in number, and about APKs from 2018 as the dataset is not yet fully populated for this year). However, it should be noted that, even in 2017, which had the smallest percentage of APKs without cryptography, these APKs corresponded to 128 million downloads, which is a significant number.

#### 4.5.5 Application-Layer Security by Category

The percentage of applications that use cryptographically processed data from each major application category has been graphed in Figure 7. While it would be reasonable to expect that most “Medical” applications would implement some level of application-layer security, the results show that fewer than 30% of applications under this category actually have such protection mechanisms. However, it is possible that the reason for this is that the devices implement the standard Bluetooth SIG adopted profiles, which do not mandate any security apart from pairing, as mentioned in Section 3.3. In fact, of the APKs categorized under “Medical” and with no cryptographic protection for either reads or writes, we found that three of the top ten (in terms of installations) contained identifiers for the standard Bluetooth Glucose Service.

Perhaps surprisingly, APKs that are categorized under “Business”, “Shopping” and “Travel & Local” appear to be the most likely to incorporate application-layer security, with around 50% of all such applications being identified as having

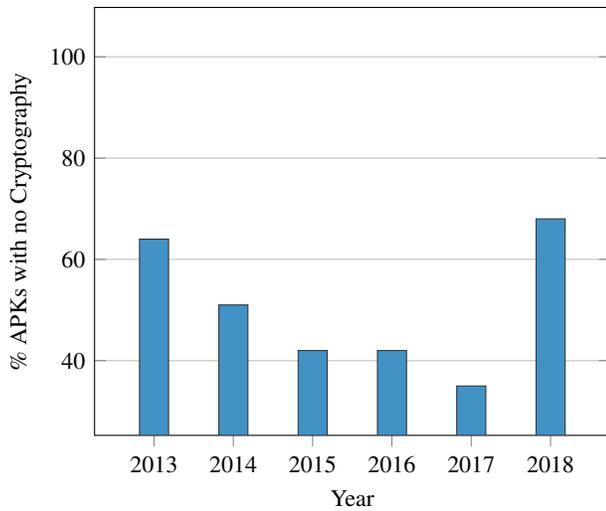

Figure 6: Application-layer security trends over time. *Notes:* Graph depicts APKs that perform BLE reads or writes, and have no cryptographic protection for either. APKs with dates that are invalid [39] or older than 2012 (when native BLE support was introduced for Android) have not been included.

cryptographically processed BLE data with High confidence. However, in over 85% of such occurrences, this was found to be due to the Estimote beacon library.

#### 4.5.6 Impact Analysis

While 18,929 BLE-enabled applications may seem like a relatively small number of applications when compared with the initial dataset of 4.6 million+, a single application may correspond to multiple BLE devices, sometimes even millions of devices as is the case with fitness trackers [25]. For example, even if we consider the slightly restrictive case of unique applications that do not use cryptography with either reads or writes, the cumulative install count is still in excess of 1,005 million. This shows that the attack surface is much larger than may be indicated by the number of APKs.

It is of course a possibility that the data that is read from a BLE peripheral has no impact on user security or privacy (e.g., device battery levels). Understanding the data within APKs would require a more complex static analysis and is left as future work.

#### 4.6 Case Study: Firmware Update over BLE

When analyzing our results, we found that one of the APKs that was identified as not having application-layer security was designed for use with a fitness tracker from our test device set. The tracker is a low-cost model that, based on the install count on Google Play (1,000,000+), appears to be widely used. An analysis of the APK suggested that the device used the Nordic BLE chipset, which could be put into the Legacy

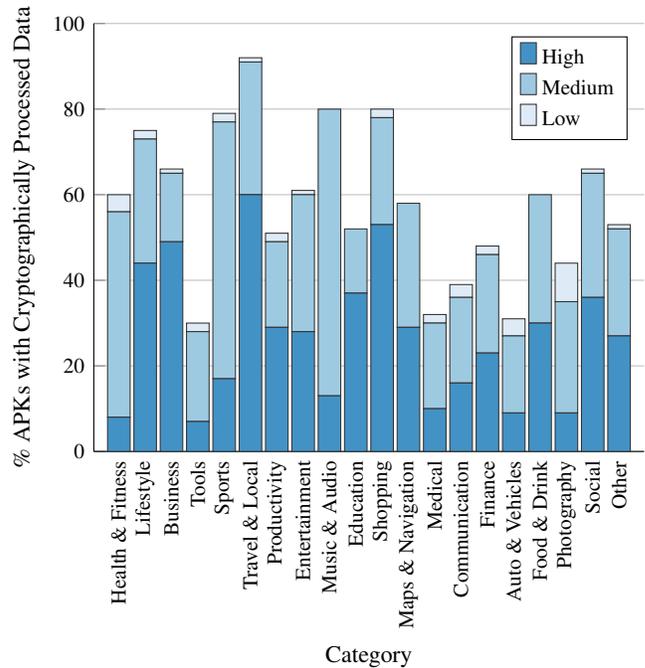

Figure 7: Presence of application-layer security in different categories of applications, averaged over BLE reads and writes, and broken down by confidence level. Only unique packages have been taken into consideration. APKs that do not currently have a presence on Google Play have been excluded, as their category cannot be identified.

DFU mode, which does not require the firmware to be signed. To exploit this, we developed an APK that, in accordance with the attacks described in Section 3.1, connects to the device, sends commands to place it in DFU mode, and then writes a new modified firmware to the device without user intervention. The updated firmware in this case was a simple, innocuous modification of the original firmware. However, given that the device can be configured to receive notifications from other applications, a malicious firmware could be developed in such a way that, for example, all notifications (including second-factor authentication SMS messages or end-to-end encrypted messages) are routed to the malicious application that installed the firmware.

This attack was possible because the BLE peripheral did not verify the firmware (e.g., via digital signatures) nor the source application (via application-layer security). We have informed the application developer of the issue (02 Nov 2018), but have received no response as of the date of submission of this manuscript (18 May 2019).

While our attack was crafted for a specific device, it does demonstrate that attacks against these types of devices are relatively easy. An attacker could easily embed several firmware images within a single mobile application, to target a range of vulnerable devices.

## 4.7 Limitations

In this section, we outline some limitations, either in our script or due to the inherent nature of our experiments, that may have impacted our results.

### 4.7.1 Unhandled Data Transfer Mechanisms

As mentioned in Section 4.4, BLECryptracer does not analyze data that is written out to file (including shared preferences), or communicated out to a different application, because it is not straightforward (and many times, not possible) to determine how data will be handled once it has been transferred out of the application under analysis. It is also possible that an application obtains the data to be written to a BLE device from, or forwards the data read from a BLE device to, another entity, such as a remote server. That is, the Android application could merely act as a “shuttle” for the data, which means that an analysis of the APK would not show evidence of usage of cryptography libraries. However, the transfer of data to/from a remote server does not in itself indicate cryptographically-processed data, as plain-text values can also be transmitted in the same manner. We therefore do not analyze instances of data transfers to external entities.

BLECryptracer also does not handle data transfers between a source and sink when only one of them is processed within an `Looper` function or when the data is transmitted via messages. However, when we logged instances of where such functions were called during a trace, we found that of the APKs that utilized such data transfer mechanisms, a large percentage were identified as having cryptographic protection via other data flows. In fact, of the 8,834 APKs where cryptography was not identified with BLE writes, only 501 APKs interacted with `Looper` or `Messenger`, and an even smaller percentage of APKs were affected for BLE reads.

### 4.7.2 Conditional Statements with Backtracing

When backtracing a register, BLECryptracer stops when it encounters a constant value assignment. However, it is possible that this value assignment occurs within one branch of a conditional jump, which means that another possible value could be contained within another branch further up the instruction list. To identify this, the script would have to first trace forward within the instruction list, identify all possible conditional jumps, and then trace back from the register of interest for all branches. This would need to be performed for every method that is analyzed and could result in a much longer processing time per APK file, as well as potentially unnecessary overheads.

## 5 Related Work

User privacy has received particular attention in the BLE research community because several widely-used BLE devices,

such as fitness trackers and continuous glucose monitors, are intended to always be on the user’s person, thereby potentially leaking information about the user’s whereabouts at all times. Some of the research has focused on the threats to privacy based on user location tracking [15, 19], while others explored the possibility of obtaining personal user data from fitness applications or devices [14, 28].

While our research *is* concerned with data access and user privacy, we focus more on the impact on privacy and security due to how the BLE standard has been implemented in mobile device architectures, as well as how it is applied by application developers in general, rather than due to individual BLE firmware design.

The work that is most closely related to ours is the research by Naveed, et al., which explored the implications of shared communication channels on Android devices [31]. In their paper, the authors discussed the issue of Classic Bluetooth and NFC channels being shared by multiple applications on the same device. They then demonstrated unauthorized data access attacks against (Classic) Bluetooth-enabled medical devices. The authors also performed an analysis of 68 Bluetooth-enabled applications that handled private user data, and concluded that the majority of them offered no protection against this attack. Finally, they proposed an operating-system level control for mitigating the attack.

Our work specifically targets pairing-protected characteristics on BLE devices, because BLE appears to slowly be replacing Classic Bluetooth in the personal health and home security domains. We demonstrate that the BLE data format and access mechanisms enable even easier attacks than in the case of Classic Bluetooth. Further, we identify the impact that the new Android permissions model (introduced in Android v6) has had on the user experience and on malicious applications’ capabilities. We also perform a much larger-scale analysis over 18,900+ Android applications, to determine how prevalent application-layer security is among BLE-enabled applications.

## 6 Conclusions

In this paper, we analyze the risks posed to data on Bluetooth Low Energy devices from co-located Android applications. We show the conditions under which an unauthorized Android application would be able to access potentially sensitive, pairing-protected data from a BLE peripheral, once a co-located authorized application has paired and bonded with a BLE peripheral, without the user being aware of the access. We also show that, in some cases, an unauthorized application may be able to access such protected data with fewer permissions required of it than would be required of an authorized application. We then discuss mitigation strategies in terms of the different stakeholders in the BLE ecosystem.

We present BLECryptracer, an analysis tool for determining the presence of application-layer security with BLE data.

We evaluate it against the taint-analysis tool Amandroid, and present the results from executing BLECrypttracer against 18,929 BLE-enabled Android APKs. Our results suggest that over 45% of all applications, and about 70% of “Medical” applications, do not implement cryptography-based application-layer security for BLE data. We also found, among the applications that *do* use cryptographically processed BLE data, several instances of cryptography misuse, such as the use of insecure cipher modes and hard-coded key values. We believe that, if this situation does not change, then as more and more sensitive use cases are proposed for BLE, the amount of private or critical data that may be vulnerable to unauthorized access can only increase. We hope that our work increases awareness of this issue and prompts changes by application developers and operating system vendors, to lead to improved protection for BLE data.

## 7 Availability

The code for our BLECrypttracer tool is available at

<https://github.com/projectbtle/BLERcrypttracer>

This repository also contains the SHA256 hashes of the APKs in our dataset, and the source/sink files used for the Amandroid analysis. In addition, it contains source code for the benchmarking applications, as well as a comprehensive breakdown of the results per DroidBench category.

## Appendix A: BLECryptracer Logic

We describe here the basic tracing mechanism employed by BLECryptracer in order to identify the presence of application-layer security for BLE data.

### Backtracing BLE writes

BLE writes use one of the `setValue` methods in Table 2 to first set the value that is to be written, before calling the method for performing the actual write. BLECryptracer identifies all calls to these methods, and then traces the origins of the data held in the registers that are passed as input to the methods.

Considering the smali<sup>4</sup> code in Figure 8 as an example, `setValue` is invoked at Line 13 and is passed two registers as input. As `setValue` is an instance method, the first input, local register `v3`, holds the `BluetoothGattCharacteristic` object that the method is invoked on. The second input, parameter register `p2`, holds the data that is to be written to the BLE device, and is the second argument that is passed to the method `a` (Line 1). BLECryptracer identifies `p2` as the register that holds the data of interest, and traces backward to determine if this data is the result of some cryptographic processing. To achieve this, the method(s) within the APK that invoke method `a` are identified, and the second input to each such method is traced. If the BLE data had come from a local register, rather than a parameter register, BLECryptracer would trace back *within* method `a`'s instructions, to determine the origin of the data. This backtracing is performed until either a crypto-library is referenced, or a `const-<>` or

<sup>4</sup>Android applications are typically written in Java and converted into Dalvik bytecode. The smali format can be considered an “intermediate” step between the high-level Java source and the bytecode.

Figure 8: Sample smali code for BLE attribute write.

`new-array` declaration is encountered (which would indicate that no cryptography is used). Note that calls to any method within the crypto-libraries mentioned in Section 4.2 are accepted as evidence of the use of cryptography with BLE data. The tool stops processing an APK at the first instance where such a method call is identified.

During execution, the BLECryptracer maintains a list of registers (set within the context of a method) to be traced, for each `setValue` method call within the application code. This initially contains a single entry, which is the input to the `setValue` method. A new register is added to the list if it appears to have tainted the value of any of the registers already in the list. This could be due to simple operations such as `aget`, `aput` or `move-<>` (apart from `move-result` variants), or it could be as a result of a comparison, arithmetic or logic operation (in which case, the register holding the operand on which the operation is performed is added to the trace list). Similarly, if a register obtains a value from an instance field (via `sget` or `iget`), then all instances where that field is assigned a value are analyzed. However, the script does not analyze the order in which the field is assigned values, as this would require activity life-cycle awareness.

Where a register is assigned a value that is output from a method invocation via `move-result`, if the method is not an external method, then the instructions within that method are analysed, beginning with the return value and tracing backwards. In some instances, the actual source of a register's value is obfuscated due to the use of intermediate formatting functions. In an attempt to overcome this, BLECryptracer traces the inputs to called methods as well. Further, if a register is used as input to a method, then all other registers that are

Figure 9: Sample smali code for BLE attribute read.

inputs to the method are also added to the trace list. While this captures some indirect value assignments, it runs the risk of false positives. For this reason, we have included the concept of *Confidence Levels* for the code output.

If, for an APK, the input to the `setValue` method can be backtraced to cryptography directly, via only register value transfers and as immediate results of method invocations, then a confidence level of “High” is assigned to the result. If a register cannot be traced back directly to a cryptographic output, but if an indirect trace identifies the use of a cryptography library, then a confidence level of “Medium” is assigned. Finally, in the event that no cryptography use is identified at High or Medium confidence levels, the script performs a less stringent search through all the instructions of the methods that it previously analyzed. This risks including instances of cryptography use with functions unrelated to BLE and is therefore assigned a “Low” confidence level.

### Forward-tracing BLE reads

With BLE reads, a `getValue` variant is invoked and the output, i.e., the value that is read, is moved to a register. To trace this value, BLECryptracer identifies all calls to `getValue` variants, then traces the output registers and all registers they taint until either a crypto-library is referenced or the register value changes. Such value changes can occur due to `new-array`, `new-instance` and `const` declarations, as well as by being

assigned the output of various operations (such as method invocations or arithmetic/logic operations).

With forward-tracing, the register holding the BLE data is considered to taint another if, for example, the source register is used in a method invocation, or comparison/arithmetic/logic operation, whose result is assigned to the destination register. The destination register is then added to the trace list. When a register is used as input to a method, then along with the output of that method, the use of the register *within* the method is also analyzed.

This method of analysis tends to result in a “tree” of traces. As an example, considering the smali code in Figure 9, the byte array output from the BLE read is stored in register `v0` (Line 4). This taints register `v3` via a format conversion function (Lines 10 and 11), which in turn taints `v2` via a `java.lang.StringBuilder` function (Lines 12 and 13). At this point, all three registers are tainted and will be traced until their values change.

The forward-tracing mode also assigns one of three confidence levels to its output. “High” is assigned when cryptographically-processed data is identified via the tracing mechanism above; “Medium” is when the use of cryptography is identified by tracing classes that implement interfaces. “Low” is assigned when a less stringent search through all encountered methods results in identification of a reference to a cryptography library (similar to the backtracing case).

### Handling obfuscation

APKs sometimes employ obfuscation techniques to protect against reverse-engineering, and the question then arises as to whether these techniques may impact the results of our analysis. We therefore briefly discuss different obfuscation techniques and why they do not impact our tool.

One of the most common techniques is *identifier renaming*, where identifiers within the code are replaced with short, meaningless names. However, because Androguard operates on smali (rather than Java) code, BLECryptracer is able to overcome the challenges posed by this technique. *String encryption* is another obfuscation mechanism, but it again does not affect the output of our tool as BLECryptracer does not search for hard-coded strings. Further, our tool was verified successfully against three out of four benchmarking applications that utilized *reflection*. The most complex obfuscation techniques are *packing* and *runtime-based obfuscation*, but these are typically employed by malware. Because we are looking for vulnerable (not malicious) applications, we do not consider these techniques. Therefore, in general, we believe our analysis to be unaffected by most benign obfuscation mechanisms.

# The CrossPath Attack: Disrupting the SDN Control Channel via Shared Links

## Abstract

Software-Defined Networking (SDN) enables network innovations with a centralized controller controlling the whole network through the control channel. Because the control channel delivers all network control traffic, its security and reliability are of great importance. For the first time in the literature, we propose the *CrossPath* attack that disrupts the SDN control channel by exploiting the shared links in paths of control traffic and data traffic. In this attack, crafted data traffic can implicitly disrupt the forwarding of control traffic in the shared links. As the data traffic does not enter the control channel, the attack is stealthy and cannot be easily perceived by the controller. In order to identify the target paths containing the shared links to attack, we develop a novel technique called *adversarial path reconnaissance*. Both theoretic analysis and experimental results demonstrate its feasibility and efficiency of identifying the target paths. We systematically study the impacts of the attack on various network applications in a real SDN testbed. Experiments show the attack significantly degrades the performance of existing network applications and causes serious network anomalies, e.g., routing blackhole, flow table resetting, and even network-wide DoS.

## 1 Introduction

Software-Defined Networking (SDN) becomes increasingly popular and is being widely deployed in data centers [32], cloud networks [13], and wide area networks [11]. In SDN, the control plane and data plane are decoupled. A logically centralized controller communicates with SDN switches to exchange control messages, e.g., routing decisions, via the control channel built upon a southbound protocol, e.g., OpenFlow [47]. SDN enables diversified packet processing and drives network innovation. A large number of network services and applications [26, 40, 33] benefit from it.

Unfortunately, the SDN control channel between the control plane and data plane is not well protected and can be

exploited though the confidentiality and integrity of the communication over the channel are protected by the TLS/SSL protocol. We find that the control channel is under the risk of the Denial-of-Service (DoS) attack. In particular, a small portion of traffic may tear down the communication over the control channel. Existing studies focus on many security aspects of SDN, including malicious or buggy applications [63, 48], attacks on crashing controllers [60, 49, 65], attacks on disrupting switches [22, 51], and information leakage in SDN [25, 56, 19, 45], but the security of the SDN control channel is still an open problem.

In this paper, we propose a novel attack named *CrossPath Attack*, which disrupts the SDN control channel by exploiting the shared links between paths of control traffic and data traffic. Our attack is stealthy and cannot be easily perceived by the controller since it does not directly send a large volume of control traffic to the controller. Instead, it generates well-crafted data traffic in the shared links to implicitly interfere with the delivery of the control traffic while the data traffic does not reach the controller. Thereby, real-time control messages delivered between the SDN controller and the switches are significantly delayed or dropped. In particular, since the controller performs centralized control over all network switches via the control channel, an attacker can easily break down all network functionalities enabled by various SDN applications running on the controller. The root cause of the vulnerability is the side effect incurred by shared links between paths of control traffic and data traffic in SDN. Such link sharing is a common practice in SDN with in-band control [21, 65], which can greatly reduce the cost of building a dedicated control network and simplify network maintenance, especially for large networks. However, it also opens the door for an attacker to disrupt the control channel by sending malicious data traffic to the shared links.

It is challenging to construct the attack in real networks. Unlike traditional IP networks where almost all links deliver both control traffic (e.g., OSPF or BGP updates [1, 2]) and data traffic at the same time, only a few number of links forward control traffic in SDN. For instance, an SDN network

with  $m$  switches can have  $O(m^2)$  links. However, there may be  $m$  links forming a spanning tree connecting  $m$  switches with a controller to deliver the control traffic. Thus, an attacker needs to find a target path that contains the shared links between control and data traffic to send the attack traffic. However, it is difficult to know since the network topology and the routing information are invisible to end users. Moreover, none of the information can be inferred by scanning tools used in traditional IP networks due to different forwarding actions in SDN. For example, Traceroute [17] cannot work well because SDN switches usually do not decrease the time-to-live (TTL) values in packet headers.

To address the above challenge, we present a probing technique called *adversarial path reconnaissance* to find a target path of data traffic that contains the shared links. The key observation is that the delays of control messages on the SDN control channel will become higher if a short-term burst of data traffic passes through the shared links. Meanwhile, such delays that indicate the path of the current data traffic has shared links with control traffic can be measured by a host. The reason one host can measure the delays is that the first packet of a new flow will be sent to the controller to query forwarding actions, which incurs extra delays of control messages other than that of the following packets directly processed in the data plane. Thus, by crafting timing packets to measure the latency variation of the control messages with/without injecting a short-term burst of data traffic, a path containing the shared links can be correctly identified. By conducting the above reconnaissances on each possible path, a target path can finally be found.

We note the probing technique may fail to identify a target path in rare cases. We study the conditions of successful probing, and our experiments with 261 real network topologies [4] demonstrate that these conditions can be easily met in practice. Moreover, we analyze the expected number of paths that need to be explored for an attacker to find a target path. Both theoretical analysis and experimental results show the high efficiency of our probing technique. For example, it only needs to explore less than 50 paths on average if there are 1,000 paths and only 2% of them contains shared links. Experimental results in a real SDN testbed show our reconnaissances can achieve more than 90% accuracy.

In order to ensure the stealthiness of the attack, we leverage the low-rate TCP-targeted DoS [41] to generate data traffic consisting of periodic pulses in the shared links, instead of directly flooding shared links to disrupt the network. The low-rate TCP targeted DoS incurs repeated TCP retransmission timeout for TCP connections of the control channel. Compared with direct link flooding on the shared links, it significantly reduces the volume of attack traffic. Note the TCP-targeted DoS cannot effectively disrupt SDN networks without the knowledge of shared links obtained by our probing technique. Moreover, our attack is significantly different from the packet-in flooding attacks [55, 60] that trigger a

huge volume of *control traffic* with bogus packets to saturate the SDN control channel. Instead, it leverages low-rate *data traffic* to disrupt the control channel and can thus succeed even in the presence of state-of-the-art SDN defenses, such as FloodGuard [60], FloodDefender [52], and SPHINX [27].

We systematically study the impacts of the attack on different SDN applications that achieve diversified network functionalities. We find that almost all SDN applications can be affected by our attack since our attack targets at disrupting the core services in SDN controllers that support these applications. In order to understand the impacts, we conduct experiments with four typical applications that have been widely deployed in SDN controllers, i.e., ARP Proxy [5], Learning Switch [6], Reactive Routing [9], and Load Balancer [7]. The results show (1) the performance of ARP Proxy can be significantly degraded, such as 10 times increase in the response delays and 95% reduction in the number of the ARP replies; (2) Learning Switch cannot successfully install forwarding decisions in the data plane and thus the throughput of the data plane is reduced to 0 Mbps; (3) Reactive Routing cannot update routing information in time and obtain incorrect topology information, which incurs various routing anomalies, e.g., routing loop, routing blackhole, routing path eviction, and flow table resetting; and (4) Load Balancer generates wrong decisions, resulting in link overloading.

In summary, our paper makes the following contributions:

- We present the CrossPath attack to significantly disrupt the SDN control channel by exploiting the shared links between paths of control traffic and data traffic.
- We develop a probing technique called adversarial path reconnaissance that can find a target path containing the shared links with a high accuracy.
- We prove the conditions of successful probing, analyze the expected number of explored paths to find a target path, and validate our analysis with experiments.
- We perform a systematical study and conduct extensive experiments on four typical SDN applications to demonstrate the impacts of the attack on various SDN network functionalities.

The rest of the paper is organized as follows. Section 2 provides background information about SDN and threat model. Section 3 presents the CrossPath attack along with an effective probing technique. Section 4 evaluates the feasibility and effectiveness of the attack both in large-scale simulations and real SDN testbeds. Section 5 further studies the impacts of the attack on different SDN applications by detailed analysis and extensive experiments. Section 6 discusses defense mechanisms that can be immediately deployed in practice to mitigate the attack. Section 7 reviews related work. Section 8 concludes the paper.

## 2 Background and Threat Model

### 2.1 Background

In this section, we briefly review the SDN architecture and a typical protocol of SDN, i.e., the OpenFlow protocol [47]. SDN enables network innovations by decoupling the control and data planes and provide programmability as well as flexibility. The control plane is logically centralized and can be deployed on commodity servers. The SDN architecture can be divided into three layers. The control layer and the application layer constitute the control plane, which runs as a network operating system, a.k.a. a controller. Various network applications can be deployed in the application layer to enable diversified network functions, such as routing, network monitoring, anomaly detection, and load balancing. The data plane layer, which consists of “dumb” SDN switches, performs low-level packet processing and forwarding based on the decisions generated by the control layer.

The dominant communication protocol between the control and data planes is OpenFlow, which has been standardized by the Open Networking Foundation (ONF) [14]. OpenFlow allows a controller to dynamically specify SDN switches’ forwarding behaviors by installing flow rules. Each flow rule contains *match fields* to match against incoming packets, a set of *instructions* that describe how to process the matched packets, and *counters* that count the number and the total bytes of matched packets. OpenFlow also defines how to handle packets in a switch. When a switch receives a packet, it processes the packet based on the rule that matches the packet with the highest priority. If no rules match the packet, the switch sends the packet to the SDN controller through the control channel with a *packet.in* message. Applications running on the controller analyze the packet and make decisions. Once the decisions are made, the packet will be sent back to the switch with a *packet.out* message. The corresponding flow rules will be installed into all switches forwarding the packet with *flow\_mod* messages. Such a packet processing procedure is called reactive rule installation, which has been widely used in OpenFlow networks [60, 52]. Moreover, to reduce the cost of building a dedicated control network and operating networks, in particular in large-scale networks [21, 65], OpenFlow allows the control and data traffic to share some links in the network, which is called in-band control.

### 2.2 Threat Model

In this paper, we consider an SDN network deployed with the OpenFlow protocol. The network uses a reactive approach to install flow rules, which is widely adopted in practice [60, 52], over an in-band control channel [21, 65]. We assume that an attacker has or compromises at least one host attached in the network, which can be easily achieved, e.g.,

by renting a virtual machine in an SDN-based cloud network. The goal of the attacker is to craft data traffic to disrupt the SDN control channel that delivers control traffic.

An attacker does not need to have prior knowledge on the network and any privileges of network operation. The CrossPath attack does not require the attacker to compromise the controllers, applications, and switches, or to construct man-in-the-middle attacks on the control channel to manipulate the control messages. The control channel can be protected with TLS/SSL. Furthermore, we assume that controllers, switches, and applications are well protected. For example, the network applies strict access control policies to prevent communication between controllers and attackers.

## 3 The CrossPath Attack

In this section, we present the CrossPath attack on disrupting the SDN control channel. Particularly, we develop a probing technique called *adversarial path reconnaissance* to accurately find a target path containing shared links.

### 3.1 Overview

The CrossPath attack aims to disrupt the SDN control channel by exploiting the shared links between paths of control traffic and data traffic. An attacker interferes with the transmission of control traffic by generating data traffic passing through the shared links. Thereby, the real-time control messages delivered in the control channel are delayed or dropped. As the SDN controller performs centralized control over all switches via the control channel, an attacker can almost break down all network functionalities enabled by SDN by constructing the attack. To achieve this, an attacker needs to use a host attached in the network to generate probing traffic so as to identify which path of data traffic (i.e., a target path) shares links with paths of control traffic. Then, the attacker can send attack traffic to the target path to disrupt the control channel. In order to decrease the attack rate, the attack utilizes the low-rate TCP-targeted DoS (LDoS) [41] to generate periodic on-off “square-wave” traffic, which leads to repeated TCP retransmission timeout for the TCP connections of the control channel.

Now let us use a simple example to illustrate the attack. For the ease of explanation, we use *data path* to denote the path where the data traffic is delivered and *control path* to denote the path where the control traffic is delivered. As shown in Figure 1, the network has five switches  $\{s_1, s_2, s_3, s_4, s_5\}$ . Host  $h_1$  and  $h_3$  communicate with each other via the data path  $h_1 \rightarrow s_2 \rightarrow s_3 \rightarrow s_4 \rightarrow h_3$ , while the control path between  $s_2$  and the controller is  $s_2 \rightarrow s_3 \rightarrow s_5 \rightarrow c$ . We can observe that the link between  $s_2$  and  $s_3$  is shared by the control and data path. Assume host  $h_1$  compromised by an attacker sends crafted LDoS traffic to  $h_3$ . Since the link and corresponding queues of switch ports are also used by the control

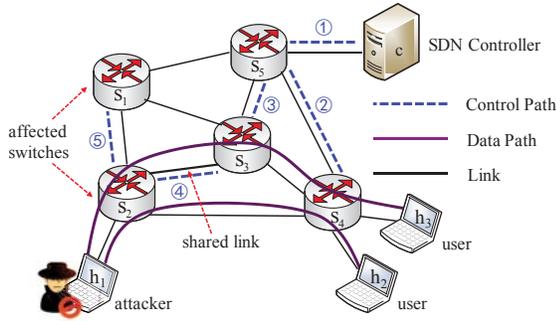

Figure 1: An example of disrupting the SDN control channel.

paths of  $s_2$  and  $s_1$ , the control messages delivered between the switches and the SDN controller can be significantly delayed or dropped, resulting in abnormal network behaviors.

In order to successfully launch the attack, an attacker should correctly choose a target path that contains shared links. However, it is challenging to find target paths in SDN. Different from traditional IP networks that almost each link delivers data and control traffic at the same time, there are only a few number of links delivering control traffic in SDN. For instance, given an SDN network with  $m$  switches, there may be  $m^2/2$  links.  $m$  links may be used to deliver control traffic so that the connectivity between the controller and all SDN switches can be ensured. Thus, only a limited number of data paths include the links shared with control paths. To identify such data paths, the attacker needs to know the network topology and routing information. Nevertheless, they are stored in the SDN controller and are invisible to the attacker. Moreover, existing scanning tools cannot be used in SDN to infer the network topology and routing information because SDN has different forwarding behaviors compared to traditional IP networks. For example, Traceroute [17] cannot infer the routing path of the packets, as SDN usually does not decrease the time-to-live (TTL) values in packet headers.

### 3.2 Adversarial Path Reconnaissance

To address the challenges above, we develop a probing technique called *adversarial path reconnaissance* to find target data paths that have links shared with control paths. The technique inspired by the key observation that the delay of a control path is higher if a short-term burst of the data traffic passes through the shared links. Thus, an attacker can use a host in SDN to identify the key data paths by generating data traffic and measuring the delay variations of the control paths. To achieve the goal, our adversarial path reconnaissance consists of two phases: measuring the delays of control paths and identifying a target data path.

**Measuring Delays of Control Paths.** In SDN, packets that cannot be matched in a switch will experience long forwarding paths and high delays, since they will be forwarded to the controller to request flow rules. We can analyze the delays

of these packets to calculate the delays of control paths that share links with data paths. Assume there are two hosts  $h_i$  and  $h_j$ , and the data path between them is a sequence of consecutive links  $P_d^{i,j} = \langle l_{h_i \rightarrow s_1}, l_{s_1 \rightarrow s_2}, \dots, l_{s_\omega \rightarrow h_j} \rangle$ . Figure 2a shows the forwarding path and delay for a packet that is sent from  $h_i$  to  $h_j$ . The packet cannot be matched by flow rules in  $s_1$ . We can know the end-to-end delay for the packet is:

$$d_{i,j} = d_{prop}^{h_i} + \sum_{k=1}^{\omega+1} d_{trans}^k + \sum_{k=1}^{\omega} (d_{queue}^k + d_{proc}^k) + \delta_{i,j}, \quad (1)$$

where  $d_{prop}^{h_i}$  is the propagation delay at host  $h_i$ ,  $d_{trans}^k$  is the transmission delay at the  $k^{th}$  link,  $d_{queue}^k$  is the queuing delay at the  $k^{th}$  switch, and  $d_{proc}^k$  is the processing delay at the  $k^{th}$  switch.  $\delta_{i,j}$  is the delay of the control path, which is caused by querying controllers for rule installation. The delay pattern of such packet is shown in Figure 2a. However, if we send the same packet after the rule installation, the path and delay will become shorter, as shown in Figure 2b. The end-to-end delay can be expressed as follows:

$$d'_{i,j} = d_{prop}^{h_i} + \sum_{k=1}^{\omega+1} d_{trans}^k + \sum_{k=1}^{\omega} (\hat{d}_{queue}^k + d_{proc}^k). \quad (2)$$

Here, we change  $d_{queue}^k$  to  $\hat{d}_{queue}^k$  because the queuing delay depends on the current network traffic and is time-varying. Based on equation (1) and (2), the delay of the control path is:

$$\delta_{i,j} = d_{i,j} - d'_{i,j} + \sum_{k=1}^{\omega} (\hat{d}_{queue}^k - d_{queue}^k) \quad (3)$$

However, if we send two packets with a short time interval, e.g., sending the same packet immediately once we receive a response to the last packet, the queuing delay  $d_{queue}^k$  and  $\hat{d}_{queue}^k$  can be approximately equal. Thus, we have  $\delta_{i,j} \approx d_{i,j} - d'_{i,j}$ . Similarly, we have  $\delta_{j,i} \approx d_{j,i} - d'_{j,i}$ . We use  $\delta$  to denote the sum of  $\delta_{i,j}$  and  $\delta_{j,i}$ . We have the following equation:

$$\delta \approx (d_{i,j} + d_{j,i}) - (d'_{i,j} + d'_{j,i}). \quad (4)$$

Note that,  $d_{i,j} + d_{j,i}$  is the round-trip-time (RTT) of the packet that is not matched by rules, and  $d'_{i,j} + d'_{j,i}$  is the RTT of the same packet matched by rules. Thus, we can infer the delay of control paths between two hosts by subtracting RTTs of these two crafted packets.

**Identifying a Target Data Path.** An attacker needs to send two packet streams for each possible data path in order to find a target data path crossing with some control paths, i.e., a data path containing shared links. The first packet stream is a *timing stream*, which aims to measure the delay  $\delta$  shown in equation (4). The timing stream must trigger responses from the destination host in the current data path. Fortunately, many types of packets meet the requirement, such as ICMP packets, TCP SYN packets, and HTTP request packets. Moreover, each timing stream must contain a pair of

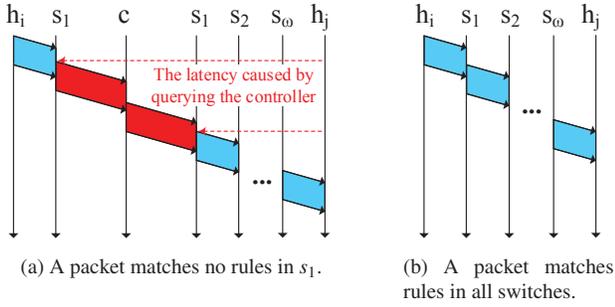

Figure 2: Different forwarding paths and delays for packets sent from  $h_i$  to  $h_j$ .  $c$  denotes the controller and  $s_i$  denotes the  $i^{th}$  switch in the packet path.

packets. The first packet must trigger new rule installation and the second packet must match the newly installed rules. This can be achieved by waiting a long enough time before sending the first timing packet to the destination, and then immediately sending another same packet after receiving a response from the first packet. The first packet can guarantee new rule installation, since old rules will be expired due to timeouts as we mentioned in Section 2. According to the previous study [44], the timeouts are usually configured as small values in order to save space of flow table and waiting for 30 seconds is enough for most cases.

The second packet stream is a *testing stream*. It contains a short-term burst of packets sent to the destination host in the current data path. These packets in the stream can be typically UDP packets. TCP packets can also be chosen if we send them with raw sockets [15] to eliminate the automatic rate control in TCP. The testing stream can be used to test whether the current data path crosses with some control paths or not in collaboration with the testing stream. An attacker can first measure the delay  $\delta$  by the timing stream without transmitting the testing stream to the destination. After waiting enough time to ensure that old flow rules expire, an attacker can measure the delay again (denoted by  $\delta'$ ) with the testing stream being transmitted at the same time. By comparing these two delays, an attacker can obtain:

- (i) If  $\delta'$  is significantly higher than  $\delta$ , the short-term burst of packets affects the delays of some control paths. Thus, the data path currently being explored crosses with some control paths.
- (ii) If  $\delta'$  is similar to  $\delta$ , no available evidence indicates that the data path crosses with some control paths.

Thus, we are able to find a target path by testing each path if it exists.

### 3.3 Improved Reconnaissance

In order to efficiently and accurately find a target data path, we apply two methods to improve our reconnaissance.

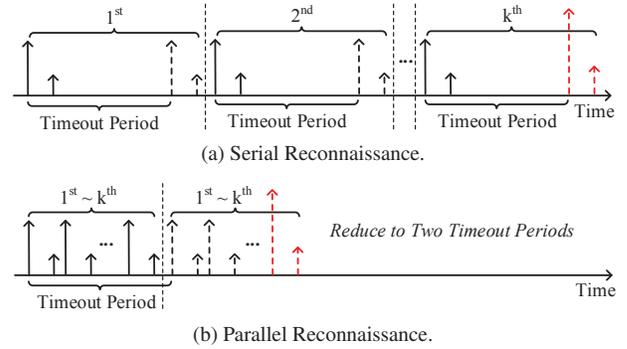

Figure 3: Two different reconnaissances of finding a target data path. Each arrow denotes a timing packet and the height of it denotes the RTT of a timing packet. A dashed arrow denotes testing packets are sent at the same time. The red arrows denote a target path is found when conducting a reconnaissance on the  $k^{th}$  data path.

**Improving Accuracy with *T*-test.** Although our reconnaissance allows an attacker to know whether a data path crosses with control paths by sending only four packets, it may achieve low accuracy in practice. Various network noises can affect the reconnaissance. For example, a burst of benign traffic can also cause high latencies of control paths, which makes a non-target data path misidentified as a target data path. We find that t-test [20] can be a straightforward approach to eliminate the influences of network noise as much as possible. T-test is a statistical method that compares whether two groups of samples with random noises belong to the same distribution. It produces a  $p$  value to denote the likelihood that the two groups of samples belong to the same distribution. Typically, if  $p$  is less than a predetermined value, i.e., the significance level  $\alpha$  [20], the two groups are considered significantly different. Thus, we can collect two groups of latencies with or without a testing stream for a data path, and apply t-test to determine whether a data path crosses with control paths according to the  $p$  value.

**Improving Efficiency with Parallelization.** Basically, an attacker can try to test each data path one-by-one, which is shown in Figure 3a. However, it is time-consuming. An attacker has to wait for at least a timeout value before conducting next round of testing, as obtaining the latencies of control paths with testing stream requires that the old rules have been removed. Suppose that a network has 100 data paths and the timeouts in flow rules are configured to 10s. Moreover, we assume 10 repeated reconnaissances are conducted for each path in order to apply t-test. We can calculate that finding a target path needs approximate 10,000s at the worst case, which is unbearable in practice. Fortunately, different flow rules matching specific packets make up different data paths in SDN, which means the installation and expiration of rules in two different paths are independent. Thus, the reconnaissance can be parallelized to reduce

the time. As shown in Figure 3b, an attacker can choose  $k$  pending paths. The latencies of their crossed control paths can be measured in turn by sending two timing packets for each data path. After waiting for only one timeout value, an attacker can measure the latencies again in turn while transmitting corresponding testing streams, since the old rules of each data path will expire in turn. The parallel reconnaissance allows an attacker to explore  $k$  data paths within two timeout values, which significantly improves efficiency. The maximal  $k$  depends on the maximal timeout values of flow rules and the maximal RTT of timing packets. In order to find a target data path as fast as possible,  $k$  should be subject to the inequation:  $2 \cdot k \cdot RTT_{max} < timeout_{max}$ . It ensures that an attacker can check whether there is a target path among  $k$  data paths within two timeout periods. If the maximal RTT of the timing packets is 20 ms in the target SDN, the parallel reconnaissance can dramatically reduce the time used by the previous example from 10,000s to less than 100s.

Based on the above designs, the algorithm of improved adversarial path reconnaissance can be easily implemented. Due to space constraints, for further details, we refer the reader to see the pseudo-code in Appendix A.

### 3.4 Theoretical Analysis

To understand the feasibility and efficiency of the adversarial path reconnaissance in SDN, we perform theoretical analysis to answer the following two questions:

- If there exists target data paths crossing with control paths in the network, which conditions the network must meet so that our reconnaissance can identify a target data path?
- How many data paths should be explored in order to find a target data path?

Firstly, we use an example to illustrate the network conditions that must meet for identifying a target data path before presenting the theory results. Figure 4 shows the target network where an attacker conducts reconnaissances. Each switch connects the controller through the shortest control paths. Switch  $s_2$  and  $s_3$  both have two different shortest control paths that can be chosen. We first consider the case where  $s_2$  connects the controller via  $\langle l_{s_2 \rightarrow s_5}, l_{s_5 \rightarrow s_6}, l_{s_6 \rightarrow c} \rangle$  and  $s_3$  connects the controller via  $\langle l_{s_3 \rightarrow s_2}, l_{s_2 \rightarrow s_1}, l_{s_1 \rightarrow s_6}, l_{s_6 \rightarrow c} \rangle$ . Obviously, the data path from  $h_1$  to  $h_2$  crosses with the control path of  $s_3$ . However, an attacker cannot identify it. Measuring the delay of the crossed control paths is infeasible, since an adversary cannot trigger rule installation into  $s_3$ . If we consider another case where  $s_2$  connects the controller via  $\langle l_{s_2 \rightarrow s_1}, l_{s_1 \rightarrow s_6}, l_{s_6 \rightarrow c} \rangle$  and  $s_3$  connects the controller via  $\langle l_{s_3 \rightarrow s_2}, l_{s_2 \rightarrow s_5}, l_{s_5 \rightarrow s_6}, l_{s_6 \rightarrow c} \rangle$ , the target data path from  $h_1$  to  $h_2$  crossing with the control path of  $s_2$  can be identified. The main difference between

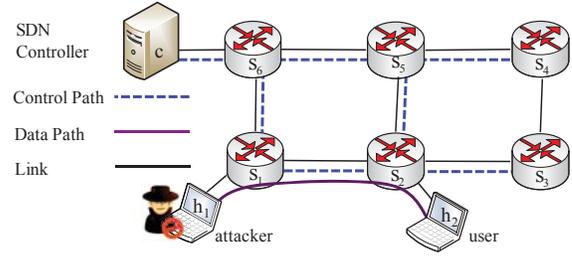

Figure 4: The target network where an attacker conducts reconnaissances.

the two cases is whether the target data path crosses with a control path of a switch belonging to the data path.

We consider a set of all the hosts in the target network  $H = \{h_1, h_2, \dots, h_n\}$ , a set of compromised hosts  $\tilde{H} = \{\tilde{h}_1, \tilde{h}_2, \dots, \tilde{h}_q\}$ , and a set of all the switches in the network  $S = \{s_1, s_2, \dots, s_m\}$ . Let  $p_d^{i,j}$  be the data path from host  $i$  to host  $j$ , let  $p_c^i$  be the control path of switch  $i$ , and let  $S_{i,j} = \{s_1, s_2, \dots, s_r\}$  be the set of switches belonging to the data path from host  $i$  to host  $j$ . Here,  $\tilde{H} \subset H$  and  $S_{i,j} \subset S$ .  $p_d^{i,j}$  and  $p_c^i$  both is a set that contains a sequence of consecutive links. In fact, we have the following theorem:

**Theorem 1.** *If and only if the target SDN network meets the condition:  $\exists (p_c^i \cap p_d^{j,k} \neq \emptyset)$ , where  $i \in S_{j,k}$ ,  $j \in \tilde{H}$ ,  $k \in H$  and  $j \neq k$ , then there exists a target data path which can be identified by the adversarial path reconnaissance.*

*Proof.* We prove the theorem in two steps. We first prove the sufficient condition, i.e., if the target network meets the conditions in Theorem 1, then a target data path can be identified by the adversarial path reconnaissance. According to the conditions, we can know that a data path  $p_d^{j,k}$  from a compromised host  $\tilde{h}_j$  to another host  $h_k$  crosses with a control path  $p_c^i$ . The crossed control paths belong to the switches  $S_{j,k}$  along the data path. An attacker can conduct the adversarial path reconnaissance on the data path. Basically, four timing packets will be sent to the data path. The first timing packet will trigger rule installation into all switches along the data path. Only after all switches finished installing rules according to the messages of the controller, the packet can reach the destination and a response packet will be sent to the compromised host. Thus, the RTT of the timing packet contains total latencies of control paths of all switches in  $S_{j,k}$ . The second timing packet will be sent after rule installation. The total latencies of control paths can be obtained by subtracting the RTTs of these two timing packets. After waiting at least a timeout value, another two timing packets can be sent to the data path with testing stream. The total latencies of control paths can be obtained again in a similar way; however, crossed control path  $p_c^i$  will be affected by the test stream. The reconnaissance will notice that the total latencies will be significantly higher than the previous latencies.

Thus, a target data path  $p_d^{j,k}$  is identified.

We next prove the necessary condition, i.e., if a target data path can be identified by the adversarial path reconnaissance, then the target network meets the conditions in Theorem 1. We assume that a target data path  $p_d^{j,k}$  is identified. Since  $p_d^{j,k}$  is a target data path, it at least crosses with a control path  $p_c^i$ . Obviously, the reconnaissance can only be launched by the compromised hosts. Thus,  $j \in \tilde{H}$ ,  $k \in H$ , and  $j \neq k$ . We only need to prove that the crossed control path belongs to a switch along with the data path  $p_d^{j,k}$ , i.e.,  $i \in S_{j,k}$ . Let us consider the opposing case  $i \notin S_{j,k}$ . Note that the timing packets in our reconnaissance trigger rule installation into switches  $S_{j,k}$  along the data path. Thus, only the latencies of control paths belonging to the switches in  $S_{j,k}$  can be measured. When  $i \notin S_{j,k}$ , the delay variation of  $p_c^i$  cannot be noticed by our reconnaissance. Thus, there must be  $i \in S_{j,k}$  if a target data path can be identified.  $\square$

Theorem 1 indicates that our reconnaissance can find a target data path only if the network meets the conditions. Fortunately, it only requires at least one data path which crosses with a control path of switches that are in the data path. Such conditions can be easily met in practice. We will show that our reconnaissance can find a target data path with various real network topologies for most cases in Section 4.1.

In order to estimate the average number of explored data paths for finding a target data path, we introduce a parameter  $\gamma$  denoting the total number of target data paths which can be identified in a network. In addition to the notations we used in Theorem 1, let  $\rho$  be the total number of data paths between a compromised host in  $\tilde{H}$  and a host in  $H$ , and let  $X$  be a random variable denoting the number of explored data paths for finding a target data path. Obviously, if we find a target data path at the  $k_{th}$  exploration, then we have already failed to find a target data path for  $k-1$  times. Thus, the probability of finding a target data path at the  $k_{th}$  exploration for the first time is:

$$P(X = k) = \frac{\gamma}{\rho - (k-1)} \prod_{j=0}^{k-2} \frac{\rho - \gamma - j}{\rho - j}, \quad (5)$$

where  $1 \leq k \leq \rho - \gamma + 1$ . Here, we define  $\prod_{j=x}^y a = 1$ , when  $x > y$ . The average number of explored data paths can be calculated as:

$$\begin{aligned} E(X) &= \sum_{k=1}^{\rho - \gamma + 1} k \cdot P(X = k) \\ &= \sum_{k=1}^{\rho - \gamma + 1} \frac{k\gamma}{\rho - (k-1)} \prod_{j=0}^{k-2} \frac{\rho - \gamma - j}{\rho - j}. \end{aligned} \quad (6)$$

If we consider the case where there is only one compromised host in the network and each of the data paths between two hosts is different, then  $\rho = n - 1$ .  $n$  is the number of hosts in

the network. Equation (6) can be simplified as:

$$E(X) = \sum_{k=1}^{n-\gamma} \frac{k\gamma}{n-k} \prod_{j=0}^{k-2} \left(1 - \frac{\gamma}{n-1-j}\right). \quad (7)$$

Equation (7) indicates the average number of explored data paths  $E(X)$  totally depends on  $n$  and  $\gamma$ . We will show that  $E(x)$  gets small values with proper parameters and the theoretical values are consistent with our experimental values in Section 4.1. In reality, our reconnaissance can quickly find a target data path by exploring several data paths (see Figure 6 in Section 4.1).

## 4 Attack Evaluation

In this section, we perform large-scale simulations to demonstrate that the CrossPath attack can be launched with various network topologies. Moreover, we conduct experiments to evaluate the feasibility and effectiveness of the attack in a real SDN testbed.

### 4.1 Large-Scale Simulation Experiments

**Simulation Setup.** We perform simulations with 261 real network topologies [4] around the world. As these network topologies do not contain hosts and routing information, we generate 100 hosts<sup>1</sup> in each topology and apply Dijkstra's algorithm [28] to generate the shortest data path between two hosts. Note that shortest path forwarding is commonly used in the intra-domain routing system. We add another host in each network topology as the SDN controller. The controller can connect switches via shortest paths (SP) to minimize delays, a minimum spanning tree (MST) to minimize costs, or randomly searching available paths (RS). We conduct experiments with different types of connection in turn. Moreover, for simplicity and without loss of generality, we assume that the attacker only controls one host in the network and we attach such a host to each network topology.

We note that the positions of hosts in a network will affect our experimental results. Thus, we conduct 1,000 experiments for each network topology and randomly changes the positions of all hosts in each experiment. We show the average results over 1,000 experiments for each topology.

**Average Percentage of Identified Target Paths.** Figure 5a shows the CCDF of the average percentage of identified target paths with 261 various network topologies. From the results, we can see all the network topologies have at least 5% identified target paths among total data paths in a network regardless of types of connections. More than 98% of the network topologies have at least 30% identified target paths. Moreover, the network tends to have more identified data paths when the controller connects switches via MST.

<sup>1</sup>In reality, we also conduct our experiments with 50, 500, 1000 hosts, respectively. The results are similar to those in Figure 5.

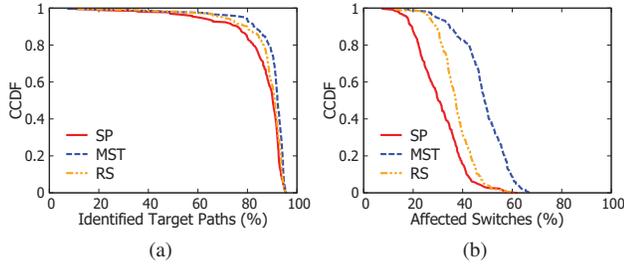

Figure 5: Complementary Cumulative Distribution Function (CCDF). (a) shows the CCDF of the average percentage of identified target paths with 261 real topologies; (b) shows the CCDF of the average percentage of affected switches by attacking a target path with 261 real topologies.

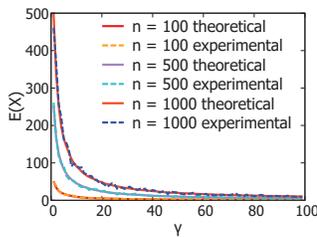

Figure 6: Comparison of theoretical values and experimental values of  $E(X)$  with different  $n$  and  $\gamma$ .

The results demonstrate that the conditions in Theorem 1 can be easily met. An attacker can use our reconnaissance to find some target data paths to launch the CrossPath attack.

**Average Percentage of Affected Switches.** As attacking different target paths will affect the average percentage of switches in a network topology, we randomly attack a target path in the 1,000 experiments for a network topology and calculate the average percentage of affected switches. Figure 5b shows that more than 20% of the switches can be affected by attacking a target path for 90%, 99% and 99% of the 261 network topologies with SP, MST and RS connections, respectively. For some network topologies, attacking a target path can even affect half of the whole switches. Thus, it is possible for an attacker to attack multiple target paths to cause damages for the whole switches and incur network-wide DoS.

**Average Number of Explored Data Paths.** Equation (7) denotes the average number of explored data paths  $E(X)$  for finding a target path totally depends on the number of data paths  $\gamma$  containing shared links and the number of hosts in a network  $n$ . We draw the theoretical values of  $E(X)$  in Figure 6. We can see that  $E(x)$  declines quickly when  $\gamma$  increases from 0 to 20. When there are 1,000 hosts and 40 data paths (2% of the 1,000 total data paths) containing shared links,  $E(X)$  is less than 50. Moreover,  $E(x)$  tends to be the same with the growth of  $\gamma$ . The results demonstrate that our reconnaissance can fast find a target data path and has a good

scalability with a different number of hosts in the network. The experimental values of  $E(x)$  are also plotted in Figure 6. Each experimental value with different  $n$  and  $\gamma$  is obtained by conducting 1,000 experiments to get the average number of explored data paths. The results show that the experimental values are consistent with the theoretical values.

## 4.2 Experiments in a Real SDN Testbed

**Experiment Setup.** Our testbed contains a popular SDN controller Floodlight [12], five hardware SDN switches (AS4610-54T [10]), and three physical hosts. The controller is deployed on a server with a quad-core Intel Xeon CPU E5504 and 32GB RAM. Each physical host has a quad-core Intel i3 CPU and 4GB RAM. All hosts run Ubuntu 14.04 server LTS. The network topologies, control paths and data paths are illustrated in Figure 1. An attacker first compromises host  $h_1$  to conduct the algorithm of adversarial path reconnaissance (see Appendix A for details) for the data paths of the other hosts. The burst rate of short-term testing packets is 1 Gbps, which is the maximal rate the host can send.

The attacker then generates LDoS data traffic to disrupt the control channels of switches  $s_1$  and  $s_2$  by attacking the data path between  $h_1$  and  $h_3$ . Basically, there are three parameters for the LDoS flows: burst length, inter-burst period, and peak magnitude. The previous study [42] has conducted comprehensive experiments on how different parameters determine the attack impacts of LDoS flows and how to better choose these parameters. As our paper mainly focus on studying the impacts for the SDN functionalities after the control channel is attacked by the data traffic, we apply fixed parameters in our attack. We choose the burst length as 100 ms, inter-burst period as 200 ms, and peak magnitude as the maximal speed 1 Gbps that the host can send for our all experiments in the paper. These parameters show how an attacker can affect the SDN functionalities to the maximum extent by generating data traffic to disrupt the control channel. Moreover, compared to simply flooding the target paths, which needs to send traffic with 1 Gbps all the time, the rate of our LDoS flow is only approximate 0.33 Gbps on average.

**Accuracy of Reconnaissances.** We first collect the delay variations in delivering control messages. The delay variation is defined as the absolute difference between the delays of control messages measured with and without testing stream. We collect 5,000 records both for two data paths in the network. We wait up to 20 seconds for each timing packet to get a response in order to obtain possible maximum delays. Figure 7 shows the distribution of the probability of the delay variation. The results demonstrate that the target data path has a significantly different probability distribution compared with the non-target data path. In particular, most delay variations with the non-target data path are less than 2 ms, while most delay variations are much larger for the target data path. These results illustrate that the discrimination

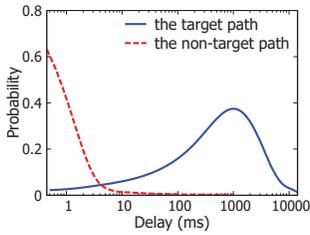

Figure 7: Probability distribution of delay variations.

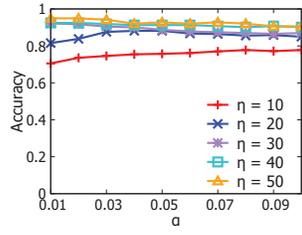

Figure 8: Accuracy of reconnaissances with different parameters.

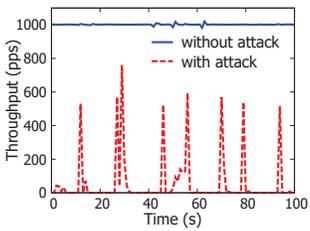

Figure 9: Throughput of control packets.

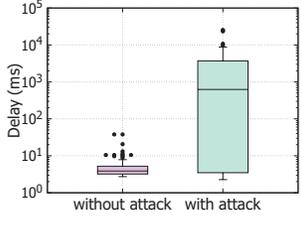

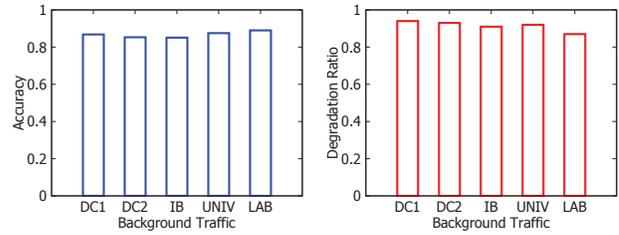

Figure 10: Delays of control packets.

between target data paths and non-target data paths can be easily identified according to the delay variations.

We then calculate the accuracy of our reconnaissance by conducting 1,000 repeated experiments with different settings of  $\eta$  and  $\alpha$ . Here,  $\eta$  denotes the number of measured delays for each data path, which is also the size of each group in the t-test used to identify a target path.  $\alpha$  is the significance level used in the t-test. As shown in Figure 8, the accuracy increases with the increase of  $\eta$ . Moreover, we can observe that the accuracy increases with the increase of  $\alpha$  when  $\eta$  is smaller, e.g., 10 or 20. However, the accuracy tends to be stable when  $\eta$  becomes large. The reason is that two different groups will statistically differ from each other and two similar groups will be statistically closer to each other with more data. It is easier to distinguish the two types of paths if we have enough data, which is not significantly impacted by the setting of  $\alpha$ . The accuracy always reaches more than 90% with different settings of  $\alpha$  when  $\eta$  is 40 or 50.

**Effectiveness of the Attack.** To evaluate the impact of the attack on the control packets, we configure the controller to generate 1,000 control packets per second<sup>2</sup> to the switch  $s_2$ . Figure 9 shows the throughput of control packets. The throughput can achieve 1,000 packets per second. However, it almost drops to 0 under the attack though there are short-term peaks of throughput. The reason is that our attack triggers TCP of control flows to periodically enter the phase of retransmission timeout. In this case, no packets will be sent within the retransmission timeout. Figure 10 shows the delay

<sup>2</sup>There can be thousands of control packets per second [29]. For simplicity but without loss of generality, we choose a practical value, 1,000.

(a) Accuracy of Reconnaissances. (b) Degradation Ratio of Control Traffic.

Figure 11: Robustness of the attack with different background traffic.

of control packets. The median value of delays for control packets under the attack is 687 ms, which is more than about 100 times higher than that in absence of the attack. Moreover, the delays under the attack vary within a large range from below 10 ms and to more than 10,000 ms. Note that, most delays without the attack are less than 10 ms. The results above demonstrate our attack can significantly degrade the throughput of control packets and incur high delays.

**Robustness of the Attack.** As background traffic may affect the reconnaissances and attack effects, we inject different background traffic into our network with TCPReplay [16] in turn. Such traffic traces comes from two Data Centers (DC1 and DC2) [3], an Internet Backbone (IB) [8], a University (UNIV) [18] and our Laboratory (LAB). Moreover, due to the limited flow table capacity in switches, we randomly choose flows from the trace to ensure that the number of rules generated by flows do not exceed the table capacity.

Figure 11a shows the accuracy of reconnaissances with different background traffic. The parameters of reconnaissances  $\alpha$  and  $\eta$  are set to 0.01 and 50, respectively, which are the best parameters to get the highest accuracy (93% in Figure 8) without background traffic. When the background traffic is injected, the accuracy drops to below 90%, ranging from 85% to 89%. However, such accuracy is still satisfactory for an attacker to conduct reconnaissances. Figure 11b shows the degradation ratio of control packets. The degradation ratio is the fraction of the control packets reduced by the attack over the total control packets without the attack. We can see that the attack always causes more than 90% degradation ratio with different background traffic. Above results demonstrate that our attack achieves high robustness.

## 5 Attack Impacts on Network Functionalities

In this section, we perform a systematical study on the impacts of the attack on various network functionalities. We first review the common core services enabled in SDN controllers that generate different types of OpenFlow control messages and are used by various SDN applications. We then study four typical SDN applications, which use these common core services, so that we measure the impacts of

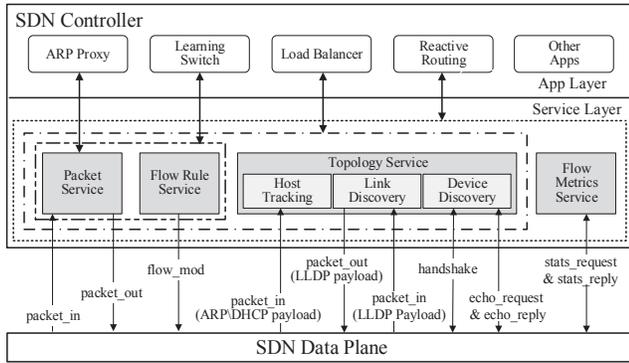

Figure 12: The core services of SDN controllers.

the attack on SDN functionalities.

## 5.1 Core Services of SDN

SDN controllers can be abstracted as a two-layer architecture though different controllers have different implementations. Applications can be deployed in the top layer to enable different network functionalities, while the low layer provides different core services that interact with switches and provide basic functionalities for the top-tier applications. As shown in Figure 12, there are four major core services:

**Packet Service.** The service manages packets exchanged between the control and data planes. It paraphrases *packet\_in* messages containing data packets received from switches and dispatch them to applications. Meanwhile, it sends data packets back to switches via *packet\_out* messages.

**Flow Rule Service.** The service manages flow rules. It installs or updates rules in switches via *flow\_mod* messages according to the results computed by applications.

**Topology Service.** The service maintains the topology of end hosts, links, and switches. It discovers new hosts and tracks their locations via *packet\_in* messages embedded with an ARP or DHCP payload. It periodically sends and receives LLDP packets encapsulated in *packet\_in* or *packet\_out* messages to maintain link information. Besides, it establishes the control channel between switches and controllers via several *handshake* messages. The liveness of switches is periodically checked via *echo\_request* and *echo\_reply* messages. Applications obtain network topologies through the service.

**Flow Metrics Service.** The subsystem is responsible for collecting flow statistics. It periodically queries the flows on network devices via *stats\_request* and *stats\_reply* messages, and then provides various statistics to applications.

We note that almost all applications enabling network functionalities in SDN is built on at least one of the four services. Our attack thus can affect various SDN functionalities by disrupting the transmission of control messages exchanged between these core services and switches. We will choose four typical applications that are widely deployed in

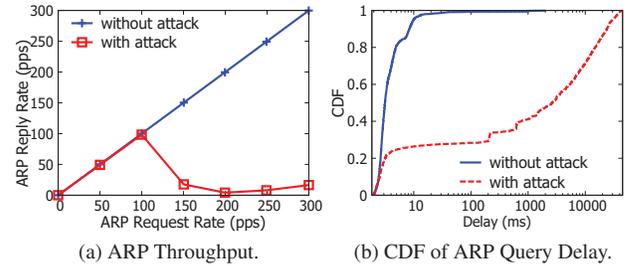

Figure 13: Attack impacts on ARP Proxy.

SDN controllers to show the impacts of the attack on various network functionalities. The implementations of the four applications [5, 6, 9, 7] are from Floodlight [12].

## 5.2 ARP Proxy

SDN enables Address Resolution Protocol (ARP) similar to IP networks, which finds the association between a destination IP address and its corresponding hardware (MAC) address so that hosts can correctly send and receive IP packets. In IP networks, layer two switches flood an ARP request sent from a host to get an ARP reply. If the target IP address in the ARP request is not in the local network, a router acts as an ARP proxy to send back an ARP reply with the hardware address of its own interface. In SDN, ARP packets are handled by an *ARP proxy* application [5] in the SDN controller. When an ARP request sent by a host arrives at a switch, it will be sent to the controller via *packet\_in* messages. The packet service extracts the ARP request packet from *packet\_in* messages and dispatches the packet to the ARP proxy application. The application extracts the sender IP address and the source MAC address to store them into the ARP table. Meanwhile, it finds an entry that the IP address matches the target IP address in the ARP request. A corresponding ARP reply packet is created and will be sent back to the ingress switch via *packet\_out* messages. Thus, the original host obtains an ARP reply.

Our attack can completely disrupt the functionality of ARP proxy by interfering with the exchange of the messages between the packet service and switches. Figure 13a shows the ARP throughput. The ARP reply rate is proportional to the ARP request rate in absence of the attack. However, under the attack, the ARP reply rate falls below 10 pps when the ARP request rate exceeds 100 pps. The reason is that the TCP flows of control traffic frequently enter the retransmission timeout phase under the attack due to the congestion. Figure 13b shows the CDF of ARP delays. More than 90% delays are less than 10 ms without the attack, while more than 70% delays are higher than 10 ms and more than 50% delays are higher than 1,000 ms with the attack. Delays under attacks significantly increase. Particularly, some delays exceed 10,000 ms, which can cause connection failures between two hosts because hosts cannot get MAC addresses.

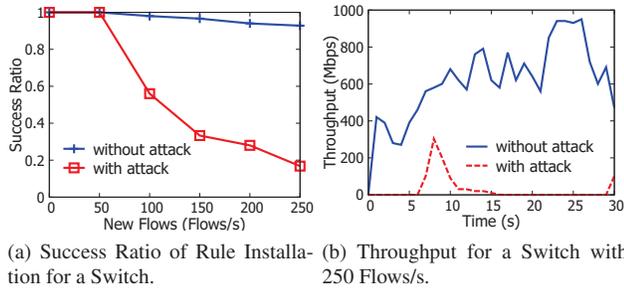

Figure 14: Attack impacts on Learning Switch.

### 5.3 Learning Switch

The *learning switch* application [6] allows SDN switches act as normal switches in IP networks. The application examines a packet matching no rules in a switch and looks up the recorded mapping between the source MAC address and the port. If the destination MAC address has already been associated with a port, the packet will be sent to the port and corresponding rules will be installed to match subsequent packets. Otherwise, the packet will be flooded on all ports. As shown in 12, the application relies on two services. The packet service sends the packet to the controller via *packet\_in* messages and back to the switch via *packet\_out* messages, and the flow rule service installs rules in the switch via *flow\_mod* messages.

Our attack can effectively block installation of forwarding decisions generated by the application by disturbing the messages exchanged between the core services and switches. Figure 14 shows the impacts of the attack on the functionalities of *learning switch*. Here, we define the success ratio of rule installation as the number of successfully installed rules over the number of rule requests within a second. As shown in Figure 14a, the success ratio of rule installation in a switch always maintains over 90% with various numbers of new flows without our attack. However, it drops significantly in presence of our attack. When the rate of new flows reaches 250 flows per-second, the success ratio reduces to below 20%. Thus, *learning switch* cannot work correctly. As shown in Figure 14b, the throughput of a switch is 0 Mbps for a long time with attack when there are 250 flows/s.

Figure 16: Attack impacts on Reactive Routing.

### 5.4 Reactive Routing

The *reactive routing* [9] application enables flexible and fine-grained routing decisions for different flows, which is enabled in almost all controllers. When a new flow matching no rules is generated, the first packet of the flow will be sent to the *reactive routing* application. The application analyzes the packet and calculates routing paths for the new flow. Besides depending on the packet service processing data packets and flow rule service installing rules, the application also queries the topology service that provides the information of the locations of hosts, the state of switches and links.

In order to demonstrate the effectiveness of our attack, we build a network topology with four hosts and three switches, as shown in Figure 15. The IP addresses of the four hosts  $h_1$ ,  $h_2$ ,  $h_3$  and  $h_4$  are 10.0.0.1, 10.0.0.2, 10.0.0.3, and 10.0.0.4, respectively. The hosts  $h_1$  and  $h_2$  send packets to the host  $h_3$ . The default routing path of packets from  $h_1$  to  $h_3$  is  $\langle l_{h_1 \rightarrow s_1}, l_{s_1 \rightarrow s_2}, l_{s_2 \rightarrow s_3}, l_{s_3 \rightarrow h_3} \rangle$ . The default routing path of packets from  $h_2$  to  $h_3$  is  $\langle l_{h_2 \rightarrow s_2}, l_{s_2 \rightarrow s_3}, l_{s_3 \rightarrow h_3} \rangle$ . Also, a flow with TCP port 1111 from  $h_2$  to  $h_3$  has a different path due to a QoS requirement. Here, the compromised host  $h_4$  sends attack (i.e., LDoS) traffic to  $h_3$  in order to exploit the control path of switch  $s_2$ .

Figure 16 shows the impacts of the attack on *reactive routing*. As shown in Figure 16a, our attack incurs long-term routing rule inconsistency, which makes the link utilization reach 100%. The reason is that SDN exists transient rule inconsistency [36] which can be leveraged by our attack. In the network shown in Figure 15, packets with an IP destination address 10.0.0.3 and a destination port 1111 loop between  $s_1$  and  $s_2$  when the application deletes rule “10.0.0.3 : 1111, to  $s_3$ ” while rule “10.0.0.3 : 1111, to  $s_1$ ” remains. The rule inconsistency normally lasts for a very short period before all the commands of deleting corresponding rules of the flow are issued. However, our attack can delay the commands exchanged between the flow rule service and  $s_2$  for tens of seconds. Thus, the packets loop between  $s_1$  and  $s_2$  for a long period and the link utilization between the two switches increases with more packets injected.

Figure 16b shows the long-term routing blackhole when  $h_3$  is migrated from  $s_3$  to  $s_2$ . The migration is finished within five seconds without the attack, as the topology service can track the new location via *packet\_in* messages containing the DHCP payload when the host moves to  $s_2$ . However, the messages are significantly delayed under our attack, and thereby the routing between other hosts and  $h_3$  cannot be updated in time, causing more than 10 seconds routing blackhole. Moreover, by blocking LLDP packets between the topology service and switches, our attack can deactivate links in the topology database and thus the corresponding routing paths will be removed. In the Floodlight controller, a link will be deactivated if no LLDP packets pass through the links within 35s. Figure 16c shows the original routing path from  $h_2$  to  $h_3$  is removed since our attack deactivates the link from  $s_2$  to  $s_3$ . Moreover, our attack can reset the connections between switches and the controller by delaying control messages. Figure 16d shows the connection of switch  $s_2$  is reset and all the flow tables are cleaned.

## 5.5 Load Balancer

Load balancing has been widely used to improve resource usage and throughput as well as reduce response delays, which balances the workload among multiple nodes. SDN controllers deploy the *load balancer* [7] application to achieve the goal. The application in the Floodlight controller can balance requests of clients in two way, i.e., round robin and statistics-based scheduling. Round robin scheduling randomly chooses a server from a server pool to serve a new request each time. The statistics-based scheduling chooses a server that has the lowest utilization to serve a new request, where the utilization is calculated according to the real-time statistics of the switch ports. The *load balancer* application relies on the flow metrics service to collect the statistics.

We configure the *load balancer* application in Floodlight to enable statistics-based scheduling, as it can provide better load balancing under different flow distribution of clients. In

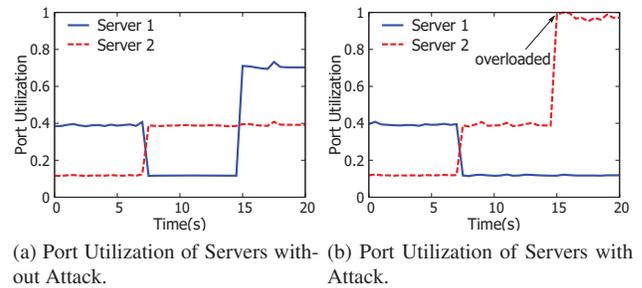

Figure 17: Attack impacts on Load Balancer for misallocating the workloads across servers.

our experiments, two hosts consist of a server pool and another two hosts send flows to the servers. Figure 17a shows the utilization of switch ports connecting the two servers over time without our attack. Initially, two different elephant flows are sent to the servers, which causes the port utilization to increase to 40% and 10%, respectively. At the 7th second, the rate of the two flows exchanges. The utilization of one server reduces from 40% to 10% while another server increases from 10% to 40%. At the 14th second, a new elephant flow starts, and the application directs the flow to server #1 that has the lowest port utilization. The port utilization of server #1 reaches 70%. Unfortunately, the application will mistakenly direct the flow to server #2 under our attack. As shown in Figure 17b, the port utilization of server #2 reaches 100%. The reason is that our attack can significantly delay the *stats\_request* and *stats\_reply* messages exchanged between the flow metrics service and switches, and thus the applications cannot know the port utilization in time. Actually, the application considers that the port utilization of server #2 is still 10% when the new flow comes.

## 6 Defense Schemes

In this section, we discuss possible countermeasures that network administrators can be used to mitigate the attack.

**Delivering Control Traffic with High Priority.** To defend against the attack, one way is to ensure forwarding control traffic with high priority, which thus can protect control traffic from being congested by malicious data traffic. According to our analysis, such a defense scheme can be enforced by carefully configuring Priority Queue (PQ) or Weighted Round Robin Queue (WRR) in switches. We note that many commercial SDN switches support at least one of the two queueing mechanisms (see Appendix C). We implement the defense scheme based on PQ and WRR in our hardware switches to deliver control traffic with high priority. The evaluation shows it can effectively protect control traffic against malicious data traffic. The detailed implementations and evaluations can be found in Appendix B.

**Proactively Reserving Bandwidth for Control Traffic.**

Another way to defend against the attack is to proactively reserve proprietary bandwidth for control traffic. Such a defense scheme is suitable for SDN switches that do not support PQ and WRR mechanisms. We implement the defense scheme with OpenFlow meter table in our hardware switches. We have demonstrated that control traffic can be well protected by reserving enough bandwidth. We refer the reader to Appendix B for details. The main disadvantage of the defense scheme is that the reserved bandwidth cannot be used by other traffic even there is massive free bandwidth. Our future work will focus on how to dynamically reserve the bandwidth for control traffic to make full use of it.

**Disturbing Path Reconnaissances.** The necessary condition to successfully launch the CrossPath attack is to find a target path containing shared links. Thus, we can prevent the attack by disturbing path reconnaissances. One way is to deliberately add random delays when installing flow rules, which may result in incorrect delay measurements of control paths when conducting path reconnaissances. Our evaluation shows that the accuracy of path reconnaissances can drop to less than 30% by adding random delays ranging from 100 ms to 1,000 ms. However, adding random delays affects the rule installation of all flows in the network. It is especially harmful to mice flows that are delay-sensitive [30]. Designing a scheme to effectively disturb path reconnaissances and reduce the impacts on network flows is worth more future research.

## 7 Related Work

In this section, we review related security research in SDN and legacy networks, respectively.

**Reconnaissances in SDN.** SDN reconnaissances has been extensively studied. Shin et al. [54] designed an SDN scanner to determine whether a network is SDN by measuring response delays of pings. Cui et al. [25] further conducted experiments in real SDN testbed to demonstrate its feasibility. Klöti et al. [39] presented a reconnaissance technique to determine if an SDN has rules for aggregated TCP flows by timing the TCP setup time. Achleitner et al. [19] designed SDNMap to reconstruct composition of flow rules by analyzing probing packets with specific protocols. Liu et al. [45] developed a Markov model to reveal rule distribution among switches. John et al. [56] presented a sophisticated inference attack to learn host communication patterns and ACL entries even if injected packets do not trigger replies. However, none of the methods can be applied to find target paths containing shared links with control paths.

**Attacks on SDN and Related Defenses.** SE-Floodlight [48] and SDNShield [63] are developed to provide permission control for malicious SDN applications. Some studies focus on the security of controllers, including network poisoning [31], identifier binding attacks [35], subverting SDN controllers [49], and exploiting harmful race conditions in SDN

controllers [65]. Other studies focus on data plane security, including low-rate flow table overflow attacks [22], SDN teleportation, and detection on abnormal data plane [51]. Our paper focuses on the security of control channel, which is orthogonal to the existing work. Particularly, we uncover a new type of attack, which has not been discovered by existing automatic attack discovery tools [34, 43, 59] in SDN.

The packet\_in flooding attack [55, 60] is mostly closest to ours. It saturates the control channel with a large amount of packet\_in messages. To trigger the control messages, the attack requires generating massive bogus packets matching no rules in switches. Different from it, our attack generates low-rate data traffic to implicitly disrupt control traffic in the shared links instead of directly generating massive control traffic. Our attack can bypass the previous defenses [55, 60, 52, 27] against packet\_in flooding attacks since they detect attacks by identifying and throttling malicious control traffic.

**LDoS Attacks in Traditional IP Networks.** Kuzmanovic et al. [41] developed low-rate TCP-targeted DoS attacks to disrupt TCP connections. Zhang et al. [66] demonstrated the attack has severe impact on the Border Gateway Protocol (BGP) by conducting real experiments. Schuchard et al. [50] extended the attack developed by Zhang et al. and designed the Coordinated Cross Plane Session Termination attack (CXPST) that allows an attacker to attack the Internet control plane by using only data traffic. Our attack differs from the previous work in three aspects. First, our attack focuses on disrupting the SDN control channel that shares a limited number of links with data paths. Second, probing techniques are required in the attack to identify target data paths containing shared links, which is necessary to ensure the effectiveness of the attack. Third, our attack in SDN has more significant impacts on diversified network functionalities including layer 2, 3 and 4 functions.

To defend against LDoS, some countermeasures have been provided in traditional IP networks, such as randomizing RTO [42] and complex signal analysis [58, 53, 23, 64, 46, 24]. However, randomizing RTO cannot fully mitigate the attack [66], and none of the methods are shown to be sufficiently accurate and scalable for deployment in real networks. Besides, they are general defenses against LDoS in traditional IP networks and are not designed to protect the SDN control channel. Defenses against LDoS attacks on BGP was described in [50], such as BGP Graceful Restart. However, it is not suitable to protect the SDN control channel with “dumb” SDN switches.

**Link Flooding Attacks in Traditional IP Networks.** Studer et al. [38] and Kang et al. [57] introduced link flooding attacks, which generate large-scale legitimate low-speed flows to flood and congest network critical links. They use traceroute to find critical links in traditional IP networks. Our crosspath attack also congests the critical links that deliver control traffic and data traffic in SDN at the same time. However, one major difference is that our crosspath attack

identifies the critical links with the unique SDN reconnaissance technique. Moreover, the crosspath attack can incur various damages in the whole network by disrupting the control channel due to the centralized control in SDN. Though there exist some SDN defense systems [67, 61, 62, 37] that detect link flooding attacks, they cannot defend the crosspath attack that disrupts the control channel, which these SDN defense systems depend on.

## 8 Conclusions

In this paper, we present a novel attack in SDN. It disrupts the control channel by crafting data traffic to implicitly interfere with control traffic in the shared links. We develop the adversarial path reconnaissance to find a target data path containing shared links for the attack. Both theoretic analysis and experimental results show that our reconnaissance works in real networks. We demonstrate that the attack can significantly disrupt various network functionalities in SDN. We hope this work attract more attention to SDN security, especially the possible attacks on the SDN control channel when deploying SDN to innovate network applications.

## A The Algorithm of Adversarial Path Reconnaissance

Algorithm 1 shows the pseudo-code of improved adversarial path reconnaissance, which can be performed by any host in the network. The input  $\eta$  is the number of repeated reconnaissances for each data path and is also the number of data in each group used in the t-test. The input  $t_{wait}$  is the waiting time for rules to expire. The input  $t_{max}$  is the maximal waiting time for each timing packet to get a response in the target network, and  $\alpha$  is the significance level used in the t-test. Here,  $t_{wait}$  must be larger than the timeouts of flow rules and  $t_{max}$  must be large enough so that most RTTs in the network do not exceed it. Step 1 gets all hosts in the network in order to explore the data paths between the compromised host and them. Step 2 initializes the maximal number of data paths that can be explored within two timeout values. The main loop is from Step 4 to Step 29. In each loop iteration, the algorithm tests  $k_{max}$  data paths. Step 5 to Step 20 collects  $2\eta$  latencies of the crossed control paths for each of the  $k_{max}$  data paths. The delay of crossed control paths when the testing stream is not transmitted is obtained in Step 7 to Step 10. Step 13 to Step 18 obtain the delay while transmitting the testing stream. Step 11 and Step 19 both make the program paused for enough time so that old rules can expire before conducting the next reconnaissance. After obtaining all the latencies of possible crossed control paths for the  $k_{max}$  data

6:      $t_{start} \leftarrow \text{time}()$ 
7:     for  $k = i \rightarrow \min(i + k_{max}, |H|)$  do
8:        $d_1 \leftarrow \text{sendTimingStreamTo}(H[k])$ 
9:        $\delta_1[k].\text{add}(d_1)$ 
10:    end for
11:     $\text{sleep}(t_{wait} - (\text{time}() - t_{start}))$ 
12:     $t_{start} \leftarrow \text{time}()$ 
13:    for  $k = i \rightarrow \min(i + k_{max}, |H|)$  do
14:       $\text{startSendTestingStreamTo}(H[k])$ 
15:       $d_2 \leftarrow \text{sendTimingStreamTo}(H[k])$ 
16:       $\text{stopSendTestingStreamTo}(H[k])$ 
17:       $\delta_2[k].\text{add}(d_2)$ 
18:    end for
19:     $\text{sleep}(t_{wait} - (\text{time}() - t_{start}))$ 
20:  end for
21:  for  $k = i \rightarrow \min(i + k_{max}, |H|)$  do
22:    if  $t\text{Test}(\delta_1[k], \delta_2[k]) < \alpha$  and  $\text{sum}(\delta_1[k]) < \text{sum}(\delta_2[k])$  then
23:      /* The data path from the compromised host to
24:        $H[k]$  crosses with control paths. */
25:       $\text{output}(H[k])$ 
26:       $\text{exit}()$ 
27:    end if
28:  end for
29:   $i \leftarrow i + k_{max}$ 

```

---

paths, the t-test is applied to determine whether a data path crosses with control paths in Step 21 to Step 27. If the group of latencies with testing stream is dramatically higher than the other group, the algorithm outputs the destination host of the data path and terminates. Otherwise, the algorithm prepares for the next round of iteration in Step 28.

In our experiments on a real SDN testbed,  $t_{wait}$  is set as 30s which is larger than the default values of timeouts in the Floodlight controller in order to leave enough time for rules to be expired, and  $t_{max}$  is set to 1s for each timing packet to get a response. The settings of  $\eta$  and  $\alpha$  are varied.

## B Defense Against the CrossPath Attack

We explore two defense schemes to mitigate the CrossPath attack. The first is delivering control traffic with high priority. Hence, any malicious data traffic cannot disturb the delivery of control traffic. Such a defense scheme can be enforced with Priority Queue (PQ) or Weighted Round Robin

Table 1: The Settings for Flow Rules to Enforce Defense Strategies.

Defense Strategy	Rule	Match	Actions
Control traffic delivery with high priority <sup>1</sup>	#1	control flows	OutPort(x), ..., SetQueue(ID=highPriQueue)
	#2	data flows	OutPort(x), ..., SetQueue(ID=lowPriQueue)
Proactive bandwidth reservation for control traffic <sup>2</sup>	#1	data flows	OutPort(x), ..., SetMeter(ID=RateLimit)

<sup>1</sup> It requires SDN switches to support PQ or WRR queuing mechanism.

<sup>2</sup> It is used when SDN switches fail to enable PQ or WRR mechanism.

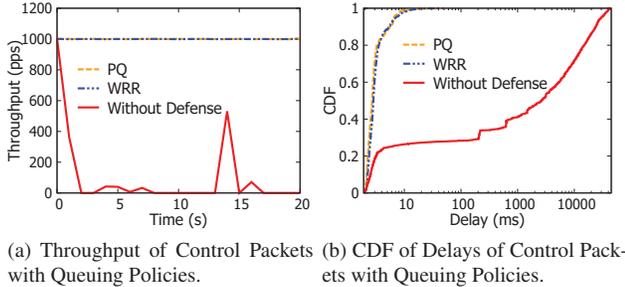

Figure 18: Evaluation on the defense scheme of delivering control traffic with high priority via PQ or WRR mechanism.

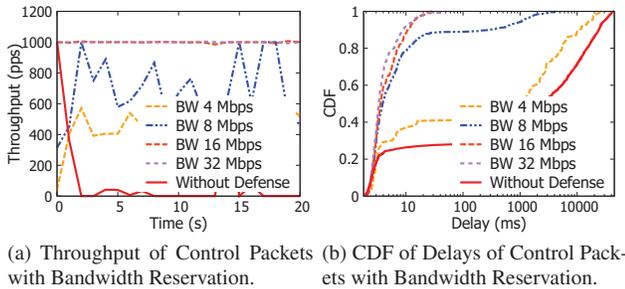

Figure 19: Evaluation on protecting control traffic with the defense scheme of proactive bandwidth (BW) reservation.

(WRR) <sup>3</sup> scheduling mechanism in SDN switches. Specifically, network administrators can inform controllers to add *SetQueue* actions to flow rules associated with switch ports in the control paths. Packets matching a flow rule with the *SetQueue* action will be directed to a queue with an *ID* set by the action. As shown in Table 1, we can set a flow rule matching control flows with a high priority queue and set a flow rule matching data flows with a low priority queue. In this way, the control traffic will always be forwarded in advance with no disturbances of other traffic.

We note that some switches in the market do not support PQ or WRR mechanisms. However, we can still mitigate the CrossPath attack by proactive bandwidth reservation for control traffic with OpenFlow meter table. A meter entry belonging to a meter table associates with various flow rules so that it can measure the total rate of packets matching the flow rules and enforce rate limiting. We can assign each flow rule

<sup>3</sup>By configuring different weighted values to queues with WRR, similar results like PQ can be achieved.

matched by the data traffic a meter entry with the *SetMeter* action (see Table 1). Therefore, by limiting the maximal rate of the total data traffic, we reserve proprietary bandwidth for control traffic.

We evaluate above two defense schemes with AS4610-54T commercial hardware SDN switches in our testbed. For simplicity, we trigger 1,000 new flows per second to generate the control traffic and generate the attack traffic to disrupt the transmission of control packets. Figure 18a and 18b shows that defense schemes with PQ or WRR mechanism effectively protect the control traffic. The throughput always reaches approximate 1,000 pps over time even with the attack. The delays of more than 99% of the control packets are less than 10 ms with either of the two queuing mechanisms. Figure 19a and 19b show that proactive bandwidth reservation with meter table can also protect control traffic. The larger the reserved bandwidth is, the higher the throughput is, and also the better the delay is. In our experiments, 16 Mbps reserved bandwidth is enough to ensure forwarding control traffic. Note that compared with the queuing mechanism, it requires proactively reserving enough bandwidth for control traffic. In a large network, it may require reserving bandwidth in the order of several Gbps.

Table 2: SDN Switches with PQ or WRR Support.

Brand	Model	Queue Support	
		PQ	WRR

## Abstract

Apple Wireless Direct Link (AWDL) is a key protocol in Apple's ecosystem used by over one billion iOS and macOS devices for device-to-device communications. AWDL is a proprietary extension of the IEEE 802.11 (Wi-Fi) standard and integrates with Bluetooth Low Energy (BLE) for providing services such as Apple AirDrop. We conduct the first security and privacy analysis of AWDL and its integration with BLE. We uncover several security and privacy vulnerabilities ranging from design flaws to implementation bugs leading to a man-in-the-middle (MitM) attack enabling stealthy modification of files transmitted via AirDrop, denial-of-service (DoS) attacks preventing communication, privacy leaks that enable user identification and long-term tracking undermining MAC address randomization, and DoS attacks enabling targeted or simultaneous crashing of all neighboring devices. The flaws span across AirDrop's BLE discovery mechanism, AWDL synchronization, UI design, and Wi-Fi driver implementation. Our analysis is based on a combination of reverse engineering of protocols and code supported by analyzing patents. We provide proof-of-concept implementations and demonstrate that the attacks can be mounted using a low-cost (\$20) micro:bit device and an off-the-shelf Wi-Fi card. We propose practical and effective countermeasures. While Apple was able to issue a fix for a DoS attack vulnerability after our responsible disclosure, the other security and privacy vulnerabilities require the redesign of some of their services.

## 1 Introduction

With deployments on over one billion devices, spanning several Apple operating systems (iOS, macOS, tvOS, and watchOS) and an increasing variety of devices (Mac, iPhone, iPad, Apple Watch, Apple TV, and HomePod), Apple Wireless Direct Link (AWDL) is ubiquitous and plays a key role in enabling device-to-device communications in the Apple ecosystem. The AWDL protocol is little understood, partially due to its proprietary nature, especially when it comes to security and privacy. Considering the well-known rocky history of wireless protocols' security, with various flaws being re-

peatedly discovered in Bluetooth [7], WEP [74], WPA2 [88], GSM [12], UMTS [57], and LTE [51], the lack of information regarding AWDL security is a significant concern given the increasing number of services that rely on it, particularly Apple's AirDrop and AirPlay. It is also noteworthy that the design of AWDL and integration with Bluetooth Low Energy (BLE) are (1) driven by optimizing energy and bandwidth and (2) the devices do not require an existing Wi-Fi access point (AP) with secure connections but are open to communicating with arbitrary devices, thus, potentially exposing various attack vectors.

We conduct the first, to the best of our knowledge, security analysis of AWDL and its integration with BLE, starting with the reverse engineering of protocols and code supported by analyzing patents. Our analysis reveals several security and privacy vulnerabilities ranging from design flaws to implementation bugs enabling different kinds of attacks: we present a man-in-the-middle (MitM) attack enabling stealthy modification of files transmitted via AirDrop, a denial-of-service (DoS) attack preventing communication between devices, privacy leaks allowing user identification and long-term tracking undermining MAC address randomization, and targeted DoS and blackout DoS attacks (i. e., enabling simultaneous crashing of all neighboring devices). The flaws span AirDrop's BLE discovery mechanism, AWDL synchronization, UI design, and Wi-Fi driver implementation. We demonstrate that the attacks can be stealthy, low-cost, and launched by devices not connected to the target Wi-Fi network. We provide proof-of-concept (PoC) implementations and demonstrate that the attacks can be mounted using a low-cost (\$20) micro:bit device and an off-the-shelf Wi-Fi card. The impact of these findings goes beyond Apple's ecosystem as the Wi-Fi Alliance adopted AWDL as the basis for Neighbor Awareness Networking (NAN) [19, 94] which, therefore, might be susceptible to similar attacks. Moreover, Google Android provides a NAN API since 2017 pending manufacturer support [38].

Specifically, our contributions are threefold. *First*, we discover security and privacy vulnerabilities in AWDL and AirDrop and present four novel network-based attacks on iOS

and macOS. These attacks are:

- (1) A long-term device tracking attack which works *in spite* of MAC randomization, and may reveal personal information such as the name of the device owner (over 75% of experiment cases).
- (2) A DoS attack aiming at the election mechanism of AWDL to deliberately desynchronize the targets' channel sequences effectively preventing communication.
- (3) A MitM attack which intercepts and modifies files transmitted via AirDrop, effectively allowing for planting malicious files.
- (4) Two DoS attack on Apple's AWDL implementations in the Wi-Fi driver. The attacks allow crashing Apple devices in proximity by injecting specially crafted frames. The attacks can be targeted to a single victim or affect all neighboring devices at the same time.

*Second*, we propose practical mitigations for all four attacks. *Third*, we publish open source implementations of both AWDL and AirDrop as the byproducts of our reverse engineering efforts to stimulate future research in this area.

The rest of this paper is structured as follows. Section 2 provides background information on AWDL. Section 3 shows the results of reverse engineering AirDrop. Section 4 presents an attack to activate AWDL on devices in proximity, while Section 5 shows how we leverage this activation mechanism for user tracking attacks. Sections 6 and 7 feature the desynchronization DoS attack and the MitM attack, respectively. Section 8 reports implementation security vulnerabilities and Section 9 concludes this work. We discuss mitigation techniques and related work in subsections of the respective sections describing the attacks.

## 2 Background on Apple Wireless Direct Link

AWDL is a proprietary wireless ad hoc protocol based on the IEEE 802.11 standard. In this section, we rely on the reverse engineering efforts of the Open Wireless Link project [81] and summarize the operation of AWDL as presented in [79, 80]. At its core, AWDL uses a channel hopping mechanism to enable "simultaneous" communication with an AP and other AWDL nodes on different channels. This channel hopping is implemented as a sequence of so-called Availability Windows (AWs). For each AW, a node indicates if it is available for direct communication and, if so, on which channel it will be. The channel value can be the channel of its AP, one of the dedicated AWDL social channels (6, 44, or 149), or zero indicating that it will not be listening on any channel. Each node announces its own sequence  $s$  consisting of 16 AWs<sup>1</sup> regularly in AWDL-specific IEEE 802.11 Action Frames (AFs). We call the length of such a full 16-AW sequence a *period*  $\tau$ . Each AW

<sup>1</sup> Actually, [79] differentiates between AWs, Extension Windows (EWs), and Extended Availability Windows (EAWs) where one EAW consists of one AW and three EWs. In this work, we abstract from the smaller entities and simply use the term AW to refer to an EAW.

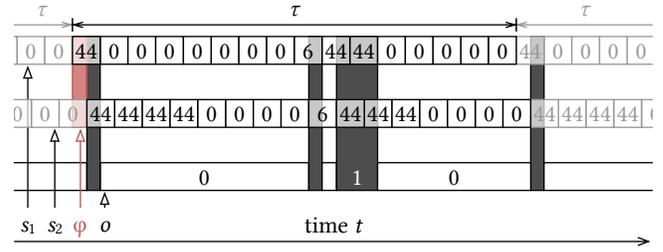

Figure 1: AWDL synchronization depicting period, phase offset, and the overlap function of two channel sequences.

has a length of 64 Time Units (TUs) where  $1 \text{ TU} = 1024 \mu\text{s}$ , so  $\tau \approx 1 \text{ s}$ . Figure 1 depicts these and the following concepts.

To allow nodes to meet and exchange data on the same channel, they need to align their sequences in the time domain. AWDL nodes elect a common master and use its AFs as a time reference to achieve *synchronization*. Each master node transmits *synchronization parameters* which consist of the current AW sequence number  $i$  ( $0$  to  $2^{16} - 1$ ) and the time until the next AW starts based on its local clock  $t_{\text{AW}}$ . When receiving an AF from its master at time  $T_{\text{Rx}}$ , a node approximates  $T_{\text{AW}}$ , the start of the next AW  $i + 1$  in local time as:<sup>2</sup>

$$T_{\text{AW}} \approx t_{\text{AW}} + T_{\text{Rx}} \quad (1)$$

and correct its clock accordingly. Eq. (1) does not achieve perfect alignment as it ignores the transmission delay as well as delays in the sender's Tx and receiver's Rx chains. The phase  $\phi$  denotes the effective clock offset between two nodes. Typically,  $\phi \leq 3 \text{ ms}$  in practice [79].

A node transmits frames to another AWDL node during AWs where the channels of both nodes are the same. We denote the *overlap* as the relative communication opportunities during one period: an overlap of one means that two nodes are on the same AWDL channel during all 16 AWs, while zero means that they are never on the same channel. Formally, we define the *overlap*  $O$  as the integral over the overlap function  $o$  of two sequences  $s_1$  and  $s_2$  taking into account the phase where  $s(t)$  is the  $\tau$ -periodic continuation of a sequence, i. e.,  $s(t + n\tau) = s(t), \forall n \in \mathbb{N}$ . Then,

$$o(s_1, s_2, \phi, t) = \begin{cases} 1 & \text{if } s_1(t) = s_2(t - \phi) \neq 0 \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

and

$$O(s_1, s_2, \phi) = \int_{t=0}^{\tau} o(s_1, s_2, \phi, t) \quad (3)$$

## 3 Reverse Engineering AirDrop

AirDrop is an application that allows iOS and macOS users to exchange files between devices using AWDL as transport.

<sup>2</sup> Simplification of [79, Eq. (1)].

We reverse-engineered the AirDrop protocol by employing a MitM HTTPS proxy [20] and using a popular disassembler on macOS' `sharingd` daemon and `Sharing` framework where AirDrop is implemented. Based on our findings, we reimplement AirDrop in Python and make it available as open source software [78]. Next, we discuss how different discoverability settings affect the user experience. Then, we describe the technical protocol flow and, finally, explain the difference between authenticated and unauthenticated connections.

### 3.1 Discoverability User Setting

When opening the sharing pane (see left screenshot in Fig. 2) in AirDrop, nearby devices will appear in the user interface depending on their discoverability setting [2]. In particular, devices can be discovered (1) by *everybody* or (2) by *contacts only*. Alternatively, (3) the *receiving off* setting disables any AirDrop connection requests. AirDrop requires Wi-Fi and Bluetooth to be enabled. By default, Wi-Fi and Bluetooth are enabled, and AirDrop is set to *contacts only*. In addition, we found that devices need to be unlocked to be discovered. Based on a user study that we present in Section 5.2, we found that 80% of the participants enable AirDrop (59.4% in *contacts only* and 20.6% in *everybody* mode) while the other 20% disabled it. For the rest of the paper, we assume that a target device has AirDrop enabled and is unlocked.

### 3.2 Protocol and User Interaction

We describe all mechanisms involved in AirDrop including discovery, authentication, and data transfer with a visual aid in Fig. 2. The *sender* initiates the discovery procedure and transfers the data while the *receiver* responds to requests: (1a) The sender emits BLE advertisements including its hashed contact identifiers (see Section 4.1 for details), while the prospective AirDrop receiver regularly scans for BLE advertisements. (1b) The receiver compares the sender's contact hashes with contact identifiers in its own address book if set to *contacts-only* mode. If there is at least one match or if the receiver is in *everyone* mode, the receiver activates its AWDL interface. (1c) Using mDNS/DNS-SD, the sender starts to look for AirDrop service instances via the AWDL interface. (2) For each discovered service, the sender establishes an HTTPS connection with the receiver and performs a full authentication handshake (*Discover*). If authentication is successful, the receiver appears as an icon in the sender's UI. (3) When the user selects a receiver, AirDrop sends a request containing metadata and a thumbnail of the file (*Ask*). The receiver decides whether they want to accept. If so, the sender continues to transfer the actual file (*Upload*).

Next, we discuss the client and server TLS certificates and explain their usage in combination with the sender's and receiver's record data to establish an authenticated connection.

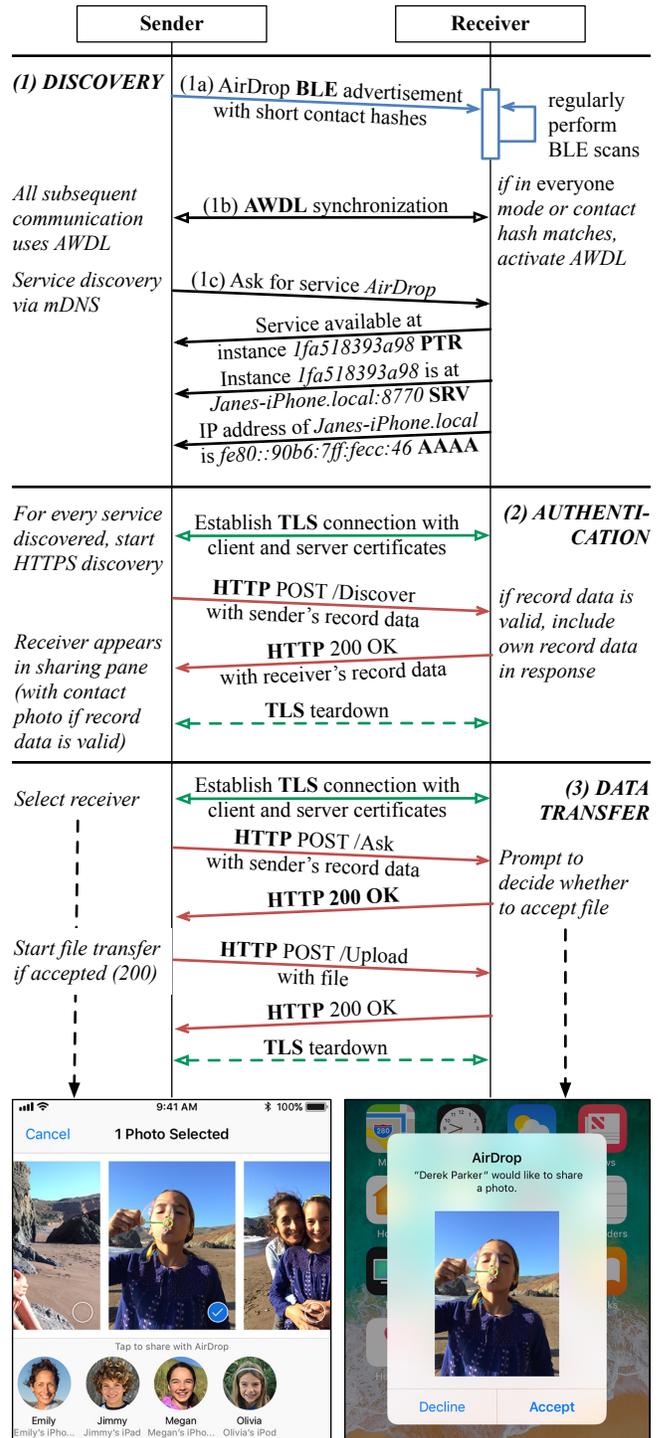

Figure 2: Typical AirDrop protocol workflow including screenshots [2] where user interaction is required.

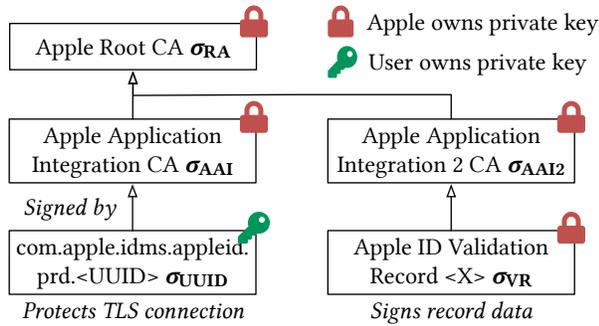

Figure 3: Certificates and CAs involved in AirDrop. Boxes contain the certificates’ *common names*.

### 3.3 (Un)authenticated Connections

AirDrop will always try to set up what we call an *authenticated* connection. Such a connection can only be established between users with an Apple ID and that have each other in their address books. Authentication involves multiple certificates and CAs that we depict in Fig. 3. In order to authenticate, a device needs to prove that it “owns” a certain contact identifier  $c_i$  such as email address or phone number associated with its Apple ID, while the verifying device checks whether it has  $c_i$  in its address book. When establishing a TLS connection, AirDrop uses a device-specific Apple-signed certificate  $\sigma_{\text{UUID}}$  containing a *UUID*.  $\sigma_{\text{UUID}}$  is issued when a user logs into the device with its Apple ID. The UUID is not tied to any contact identifiers, so AirDrop uses an Apple-signed *record data* “blob”  $RD$  containing the UUID and all contact identifiers  $c_1, \dots, c_n$  that are registered with the user’s Apple ID in a hashed form. This record data is retrieved once from Apple and then presented for any subsequent AirDrop connection. Formally,  $RD$  is a tuple:

$$RD = \text{UUID}, \text{SHA2}(c_1), \dots, \text{SHA2}(c_n) \quad . \quad (4)$$

The signed record data  $RD_\sigma$  additionally includes a signature and a certificate chain (Fig. 3):

$$RD_\sigma = RD, \text{sign}(\sigma_{\text{VR}}, RD), \sigma_{\text{VR}}, \sigma_{\text{AAI2}} \quad , \quad (5)$$

where  $\text{sign}(\sigma, X)$  is the signature of  $\sigma$  over  $X$ . When authenticating, a node computes SHA2 over each contact identifier in its address book and compares them with the hashes contained in the presented  $RD_\sigma$  and verifies that the UUID matches the certificate of the current TLS connection. The latter effectively prevents reuse of  $RD_\sigma$  by an attacker using a different TLS certificate.

AirDrop transparently treats a connection as *unauthenticated* if the sender or receiver fails to provide an Apple-signed TLS certificate or valid record data. This means that AirDrop will establish an unauthenticated connection with devices that use a self-signed certificate and provide no record data. While AirDrop’s authentication mechanism appears to be crypto-

graphically well-designed, we show in Section 7 how to downgrade an authenticated connection to an unauthenticated one and launch a MitM attack on the data transfer.

## 4 Activating AWDL on Devices in Proximity

Some of the attacks demonstrated in this work require the targets’ AWDL interface to be active, which is typically not the case since an application has to request activation explicitly [79]. We have found that the BLE discovery mechanism integrated with AirDrop (see Section 3) can be exploited to activate all AWDL devices in proximity. Devices in *everyone* mode will enable AWDL immediately after receiving any AirDrop BLE advertisement. We analyze the theoretical performance of brute forcing the truncated contact hash values in AirDrop’s BLE advertisements (Fig. 2) to activate the AWDL interfaces of targets in the default *contacts-only* mode. Finally, we build a PoC leveraging a low-cost (\$20) BBC micro:bit device and experimentally confirm that the attack is feasible in practice with a target response time of about one second for devices that have 100 contact identifiers in their address book.

### 4.1 AirDrop BLE Advertisements

We show the actual BLE advertisement frames [17, Vol. 3, Sec. 11] that AirDrop uses including four contact identifier hashes in Fig. 4. They are broadcast as non-connectable undirected advertising (`ADV_NONCONN_IND`). The frames use manufacturer-specific data fields that have fixed values except for the contact hashes. In fact, we found that the contact hashes are the first two bytes of the SHA2 digest of the sender’s contact identifiers that are also included in the record data (see Section 3.3). If the sender has less than four identifiers, the remaining contact hash fields are set to zero. Due to the short length, it appears feasible to use brute force to try all possible values.<sup>3</sup>

<sup>3</sup>Note that the sender still has to provide the complete hash during the HTTPS handshake before the receiver accepts the data on an *authenticated* connection.

Table 1: Symbols

SYMBOL	DESCRIPTION
$\mathbb{S}$	Contact hash search space
$\mathbb{C}$	Contacts in the target’s address book
$w$	Target’s BLE scan window
$i$	Target’s BLE scan interval
$i_{\text{PHY}}$	Attacker’s BLE PHY injection interval
$r$	Effective contact hash brute force rate
$n$	Tried hash values per scan window
$p(p_j)$	Hit probability after one (or $j$ ) scans

## 4.2 Brute Force Analysis

We assume that the attacker does not know the target’s contacts and, thus, attempts to enable the target’s AWDL interface using brute force. As the target has at least one contact identifier (the address book contains at least the user’s own Apple ID), the attacker needs to try  $\mathbb{S} = 2^{16} = 65\,536$  hashes in the worst case. Thus, the challenge for the attacker is to quickly send a large number of BLE advertisements *while* the target is conducting a BLE scan. In the following, we analyze *how fast* the attacker can deplete the search space and *how successful* they would be. We start investigating the results for a single BLE scan window and then extend our analysis to multiple scan intervals.

**One Scan Window.** Let the attacker inject BLE advertisement frames at the physical layer with an interval of  $i_{\text{PHY}}$ . Further, consider that the attacker has a single radio and that BLE uses three advertisement channels [17]. Also, recall that an AirDrop BLE frame has room for four contact hashes. Then, the attacker’s effective brute force rate  $r$  can be calculated as:

$$r = \frac{4}{3 \cdot i_{\text{PHY}}} . \quad (6)$$

Now, we can compute the number of hash values  $n$  that the attacker can inject per scan window  $w$  [17] as:

$$n = w \cdot r . \quad (7)$$

Let  $X$  be a random variable, and  $P(X = k)$  denote the probability that the target “sees”  $k$  known contact hashes during one scan window. Since the attacker moves through the search space sequentially, we can formulate the problem using the *urn model* in *drawing without replacement* mode which results in a hypergeometric distribution. We get:

$$P(X = k) = \frac{\binom{n}{k} \binom{\mathbb{S}-n}{\mathbb{C}-k}}{\binom{\mathbb{S}}{\mathbb{C}}} . \quad (8)$$

In particular, the attacker only requires one hit to activate the

target’s AWDL interface whose probability we call  $p$ :

$$\begin{aligned} p &= P(X \geq 1) = 1 - P(X = 0) \\ &= 1 - \frac{\binom{n}{0} \binom{\mathbb{S}-n}{\mathbb{C}-0}}{\binom{\mathbb{S}}{\mathbb{C}}} = 1 - \frac{\binom{\mathbb{S}-n}{\mathbb{C}}}{\binom{\mathbb{S}}{\mathbb{C}}} . \end{aligned} \quad (9)$$

Using the Stirling’s approximation  $\binom{n}{k} \approx \frac{n^k}{k!}$  for  $k \ll n$ , we can simplify Eq. (9) as:

$$\begin{aligned} p &\approx 1 - \frac{\frac{(\mathbb{S}-n)^{\mathbb{C}}}{\mathbb{C}!}}{\frac{\mathbb{S}^{\mathbb{C}}}{\mathbb{C}!}} = 1 - \frac{(\mathbb{S}-n)^{\mathbb{C}}}{\mathbb{S}^{\mathbb{C}}} \\ &= 1 - \left(\frac{\mathbb{S}-n}{\mathbb{S}}\right)^{\mathbb{C}} = 1 - \left(1 - \frac{n}{\mathbb{S}}\right)^{\mathbb{C}} . \end{aligned} \quad (10)$$

**Multiple Scan Intervals.** BLE devices perform scans regularly at a fixed interval  $i$  [17]. Let  $Y$  be a random variable indicating that the attacker has a hit ( $Y = 1$ ) or not ( $Y = 0$ ) during one scan. We assume that the attacker does not know when the target’s scan window starts and, therefore, that  $Y$  is i.i.d. between scans.<sup>4</sup> Let  $j$  indicate the target’s  $j$ th scan since the attacker started their brute force attack. Then, the probability that the attacker had  $k$  hits after  $j$  scans is given by a binomial distribution:

$$P(Y = k) = \binom{j}{k} p^k (1-p)^{j-k} . \quad (11)$$

Again, the attacker needs at least one hit whose probability we denote as  $p_j$  (note that  $p_1 = p$ ):

$$p_j = P(Y \geq 1) = 1 - P(Y = 0) = 1 - (1-p)^j . \quad (12)$$

With Eq. (10), we get:

$$p_j \approx 1 - \left(1 - \frac{n}{\mathbb{S}}\right)^{j\mathbb{C}} . \quad (13)$$

We know that  $j$  depends on the time since the attack started and the target’s BLE scan interval  $i$  (the target performs one BLE scan of length  $w$  per interval). Let  $t$  denote the attack duration, then  $j \leq \lfloor t/i \rfloor$ . Finally, we denote the success probability at time  $t$  as

$$p(t) \approx 1 - \left(1 - \frac{wr}{\mathbb{S}}\right)^{t\mathbb{C}/i} . \quad (14)$$

## 4.3 Jailbreaking BLE Advertisements

The Bluetooth standard imposes a minimum advertisement interval<sup>5</sup> of 100 ms for non-connectable undirected advertising [17, Vol. 6, Sec. 4.4.2.2], which we found is usually

<sup>4</sup>If the attacker knew the start of each scan window, they could follow a better strategy by only sending advertisements while the target is performing a scan. This way, they would deterministically succeed after they had gone through  $\mathbb{S}$  once.

<sup>5</sup>The BLE advertisement interval accounts for a frame transmission on each of the three advertisement channels.

```

uint8_t *le_adv = airdrop_init_template()
for (uint16_t h = 0; /* loop */; h += 4) {
    airdrop_set_hashes(le_adv, h, h+1, h+2, h+3);
    for (uint16_t chan = 37; chan < 40; chan++) {
        le_adv_tx(le_adv, chan);
        sleep(0.625 /* in milliseconds */); } }

```

Figure 5: C pseudo code of our BLE brute force attack

enforced in the BLE firmware. By complying to the standard, the attacker would need at least  $2^{16} = 27$  minutes to iterate through the entire search space once. If the attacker had access to the BLE physical layer to control and schedule individual transmissions, they could circumvent the standard’s restrictions and, thus, iterate through the search space much faster. To this end, we extend an open source BLE firmware [65] for the Nordic nRF51822 [63] chipset to implement our brute force attack. In principle, our attack implementation is very simple and shown in Fig. 5. We use a send interval of  $i_{PHY} = 0.625$  ms resulting in  $r = 2133.3$  s<sup>-1</sup> which allows the attack to iterate through  $\mathbb{S}$  in only  $2^{16}/f = 30.72$  s. By using three BLE radios (one for each advertisement channel), we could reduce this time to 10.24 s. However, we show that using one radio is sufficient in practice.

#### 4.4 Target Response Times Micro Benchmark

We measure the target response time, i. e., the time it takes for a target to turn on its AWDL interface when being exposed to our attack. In particular, we measure the response time for a *contacts-only* receiver that has 10, 100, and 1000 contact identifiers in their address book. In addition, we include reference measurements for a receiver in *everyone* mode under the same attack.

**Setup.** For the experiment, we use a Wi-Fi sniffer (Broadcom BCM4360) to receive AWDL AFs and a \$20 micro:bit device [58] to inject BLE advertisements. To get the response times, we start a brute force attack and measure the time until we receive the first AF from the target. We then stop the attack and wait until the target stops sending AFs which means that the AWDL interface has turned off. Then, we start over to collect 50 measurements per setting.

**Results.** We show the results for an iPhone 8 (iOS 12) in Fig. 6. The plot also includes the analytical response time distribution based on Eq. (14), assuming a BLE scan window  $w$  and interval  $i$  of 30 ms and 300 ms, respectively.<sup>6</sup> We can make several observations: (1) Our analytical model does not capture our experimental results precisely but approximates them within an order of magnitude which is sufficient for our purposes. (2) The median response time of targets with only 10 contact identifiers in their address book is 10 seconds and

<sup>6</sup><https://lists.apple.com/archives/bluetooth-dev/2014/Sep/msg00001.html>

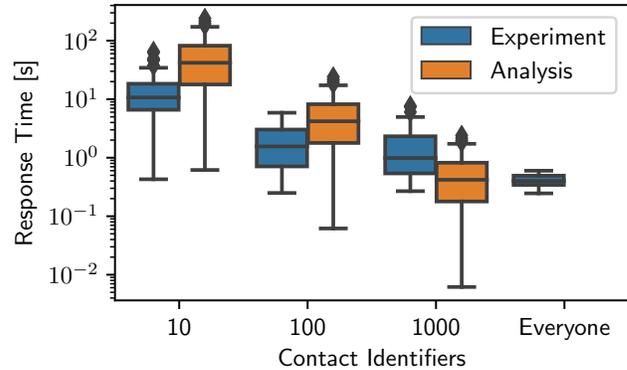

Figure 6: Time it takes until target turns on its AWDL interface after being exposed to our brute force attack.

decreases to about 1 second when more contacts are available. We found that a user has more than 136 contacts on average based on a user study that we describe in Section 5.2. (3) This means that the brute force attack is feasible for scenarios where the target will be in the attacker’s communication range for a few seconds.

## 5 Privacy: Tracking Apple Device Users

In this section, we assess privacy issues in AWDL and find that AWDL devices are easily trackable. First, we discuss protocol fields that enable tracking. Then, we leverage the attack presented in Section 4 to perform an experimental vulnerability assessment at different locations and compare the results with a user study spanning 500 participants. Finally, we discuss possible mitigations.

### 5.1 Identifying Devices and Users via AWDL Protocol Fields

Even though AWDL implements MAC randomization for the IEEE 802.11 header, AWDL-specific fields contain long-term device identifiers that disclose sensitive information about the user, undermining MAC randomization. In particular, AWDL includes the following sensitive fields in the AFs which devices broadcast *in the clear* multiple times per second when the AWDL interface is active:

- The *hostname* may include parts of the user’s *name*, e. g., “Janes-iPhone,” which is the default when setting up a new device.
- The *real MAC address* as well as the AP the device is currently connected to.
- The *device class* differentiates between devices running macOS, iOS/watchOS, and tvOS.
- In combination with the *protocol version*, this can be used to infer the OS version, e. g., AWDL v2 is used in macOS 10.12 while AWDL v3 is used in macOS 10.13. The attacker could exploit the OS information during

reconnaissance to mount attacks on vulnerable driver implementations.

Targets need to broadcast AFs to make these vulnerabilities exploitable, which an attacker can practically enforce by mounting the attack presented in Section 4.

## 5.2 A Survey on the Potential of Apple Device User Tracking

The hostname set by default during Apple iOS and macOS device installation includes the user’s name [3]. Due to its frame structure, the AWDL protocol aids an adversary in mapping a hostname with the MAC address of the device. This enables them to track users even if users change this hostname on their device. The combination also enables more sophisticated threats as the person’s name can be combined with information from public databases (e. g., US census [86]) to infer their home and work locations, while the MAC address can be used to track them in real-time. To assess what percentage of device hostnames contain parts of the owner’s name, we conducted a survey among 500 Apple device users on Amazon Mechanical Turk. This survey contained questions<sup>7</sup> relevant to the attacks demonstrated in this paper, and we report the statistics in the relevant sections. In particular, in the context of tracking, we asked the surveyors if it was easy for other users to find their device because their hostname contained parts of their real name. We report the results of this question along with the results of an experimental evaluation in the next section.

## 5.3 Experimental Vulnerability Analysis

To demonstrate the feasibility of user tracking using AWDL, we collect the number of discovered devices and check whether that device’s hostname includes a person’s name in four different locations within the US. We selected the locations to reflect static as well as dynamic environments. In particular, we recorded at a departure gate of an airport, in the reading section of a public library, in a moving metro train, and in the food court of a university.

**Determining Whether a Hostname Contains a Person’s Name.** We use two databases to determine whether a hostname contains a person’s name: the 2010 US Census [85] containing 162 253 family names, and the 1918–2017 baby names from the US Social Security Administration [87] containing 96 743 given names. When detecting a new AWDL node, we check string segments separated by hyphens against these two databases.<sup>8</sup> Note that when one segment matches

<sup>7</sup>The survey questionnaire is available at <https://goo.gl/forms/0okC4UphTQBnQ0FB3>

<sup>8</sup>If a segment ends with the letter “s,” we also check the segment without a trailing “s.” In addition, we ignore segments containing common device names such as “iPhone,” “Mac,” etc. For example, for the hostname “Johns-iPhone,” we try to match the strings “Johns” and “John” to our name databases.

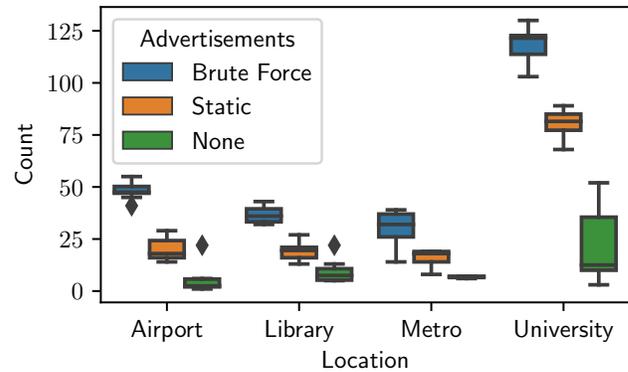

Figure 7: Discovered AWDL devices at one location during one minute.

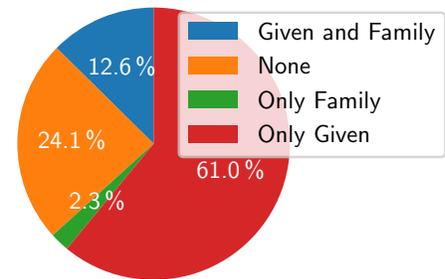

Figure 8: Persons’ names distribution in hostnames.

the given name database, it is not matched again as a family name because it is more likely that an Apple device will include a person’s given name [3].

**Ethical Statement.** To preserve user privacy and not having to store any sensitive user information, we fully automated the name matching procedure. In particular, we only stored salted hashes of the discovered hostnames (to differentiate between devices) together with two bits indicating whether the hostname contained a given or a family name. The salt was generated randomly, kept in memory only, and discarded after the completion of each experiment.

**Setup.** We do the measurements (a) without an attack (passive), (b) with static BLE advertisements containing only the “zero” contact hash, and (c) with our BLE brute force approach. With (b), only devices in the *everyone* mode should respond, with (c) we also capture those that are in *contacts-only* mode. We run each setting for 60 seconds and repeat it 10 times per location. To avoid statistical bias, we cycle through the (a) to (c) settings back to back in each iteration and use a cooldown time of 40 seconds between them. The cooldown ensures that all devices in proximity have turned off their AWDL interfaces again.

**Experimental Results.** Fig. 7 shows the number of discovered AWDL devices in the different locations. By using the

brute force approach, we can discover about twice as many devices compared to sending only regular advertisements. This means that in our experiments, approximately 50 % of the Apple devices are in AirDrop’s *everyone* mode. Our survey complements our experimental results by indicating that 20 % of Apple device users have AirDrop turned off and, thus, are not trackable via AWDL. It is interesting to note that we are able to pick up AWDL devices even when not sending any advertisements. This can happen if a device (not controlled by us) sends out advertisements itself, for example, when a user opens the AirDrop sharing pane which apparently occurred regularly at the university location. Finally, we found that among all discovered devices, more than 75 % contain a person’s name in the hostname. Most devices contain only a given name which is the default for freshly set up Apple devices [3], some contain a combination of a given and family name, and very few contain only a family name. Our survey confirms these results as 68 % answered that it was “easy” or “very easy” for others to recognize their device because it contained their name.

**Outlook for Large-Scale Attack.** In this analysis, we show what kind of information a motivated attacker would be able to collect. We used a single fixed physical location for each experiment and did not attempt to track any user movement. However, given that we can receive unique identifiers of Apple devices (Wi-Fi MAC address and hostname), mounting a large-scale tracking attack should be trivial for an adversary that can deploy multiple low-cost Wi-Fi and BLE nodes throughout an area.

## 5.4 Mitigation

We present a short-term solution and then propose two mitigation techniques that remove stable device identifiers to prevent user tracking via AWDL.

**Disable AirDrop.** Until Apple fixes the problem, the only way to thwart user tracking is to disable AirDrop completely. This presents a countermeasure to our attack presented in Section 4, i. e., the AWDL interface cannot be remotely activated via BLE advertisements.

**Hide Real MAC Address When Not Connected to an AP.** When a device connects to an AP it uses its real MAC address for communication, in which case AWDL does not disclose new information. However, we have found that the MAC address is occasionally included in AFs even when the device is not connected to an AP. This appears to be unintended behavior and should be fixed via a software update.

**Randomize Hostname for AWDL.** Apple devices transmit their hostname in AWDL AFs as well as the mDNS responses during service discovery that are used to find AirDrop instances (see Section 3). As a countermeasure, we propose to use randomized hostname with AWDL similar to MAC address randomization. If an application such as AirDrop needs the real hostname for identification, it should only be

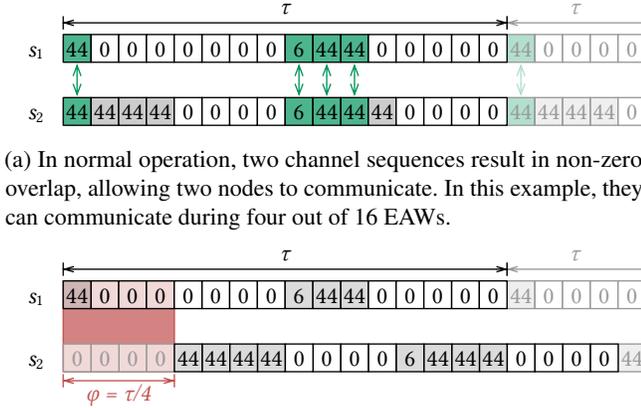

transmitted via an encrypted and authenticated channel such as TLS. In fact, AirDrop already transmits the device name in the HTTPS handshake and uses this name in the UI ignoring the hostname from mDNS responses. Therefore, hostname randomization would not require any changes to the AirDrop implementation which would retain backward compatibility.

## 5.5 Related Work: User Tracking

Several related works have studied the topic of user tracking from mobile devices. Some common attack vectors include using the GPS sensor [35, 48, 55, 83, 95], cellular [5, 44, 50, 67], Wi-Fi [15, 40, 69, 96, 97], radio interface fingerprinting [90], and motion sensors [25, 39, 59, 61, 62]. We believe that the above works are orthogonal to our approach, and could be used in conjunction with our approach to improve tracking performance. Many countermeasures have also been proposed to prevent tracking from the above vectors. Some of them include recommending new location frameworks and privacy metrics [9, 28, 29, 30, 49, 64], location obfuscation [1, 6, 18, 72, 92], location cloaking [42, 43], synthesizing locations [16, 46, 53, 82, 98], sensor data obfuscation [22, 23], and permission analysis [32, 45, 68]. Along with resource permissions on mobile devices, these countermeasures limit the practicality of some of the above attacks.

Some device-specific identifiers have also been used for tracking, e. g., IMEI [36, 93], BLE addresses [24, 31, 47], and MAC addresses [21, 33, 54, 60]. While IMEI-based tracking can be easily mitigated by protecting access to this information, BLE is a dominant standard for fitness trackers and smartphone communication and their addresses must be exposed. Tracking using BLE identifiers has been demonstrated to be easy. However, our approach has the added benefit for an attacker that the hostname is exposed. This allows inferring additional user information such as home and work locations, family members, or movement patterns, which are useful for more targeted tracking [34, 84]. Like BLE addresses, MAC addresses are also essential as they form the backbone of layer 2 network communication and must be exposed for networking (e. g., Wi-Fi probe requests).

MAC address randomization has been proposed to prevent device tracking through Wi-Fi probe requests [11, 26]. Today, both Apple and Google implement MAC address randomization in their mobile operating systems. Randomization does improve user privacy; however, some works have demonstrated that devices are still trackable. For example, [89] implemented an algorithm using probe request fingerprinting that has a 50 percent success rate for tracking users for 20 minutes. Another work [56] demonstrated that MAC randomization could be defeated through timing attacks, where a signature based on inter-frame arrival times of probe requests can be used to group frames coming from the same device with distinct MAC addresses. Their framework could group random MAC addresses of the same device up to 75% of cases for about 500 devices. Our work advances the scalabil-

(a) In normal operation, two channel sequences result in non-zero overlap, allowing two nodes to communicate. In this example, they can communicate during four out of 16 EAWs.

(b) A phase shift of a quarter period ( $\phi = \tau/4$ ) results in zero overlap preventing the two nodes from communicating with each other.

Figure 9: Sketch of the desynchronization attack.

ity, tracking time and accuracy of the prior works. We show that, owing to implementation nuances in the AWDL protocol, an adversary can track millions of Apple device owners globally with 100% accuracy.

## 6 DoS: Impairing Communication with Desynchronization

AWDL does not employ any security mechanisms. Instead, Apple decided to leave security mechanisms to the upper layers. Thus, while end-to-end confidentiality and integrity can be achieved using a secure transport protocol such as TLS, AWDL frames are vulnerable to forgery which renders any upper layer using AWDL susceptible to attacks on availability. In this section, we present a novel DoS attack that targets AWDL’s synchronization mechanism (Section 2) to prevent two nodes from communication with each other. In the following, we describe a novel *desynchronization* attack which aims to minimize the channel sequence overlap of two targets. Next, we evaluate the attack’s performance and present an effective mitigation method. Finally, we discuss related work.

### 6.1 Desynchronizing Two Targets

We exploit AWDL’s synchronization mechanism to reduce the channel overlap by inducing an artificial *phase* offset between two targets. In order to succeed, the attacker needs to (1) get recognized as the master by both targets, (2) communicate with each target separately to (3) send different sets of synchronization parameters that result in zero (or minimal) channel overlap. Figure 9 depicts the non-zero overlap in normal operation and the zero overlap as the result of the desynchronization attack. We describe the three steps in the following.

(1) **Winning the Master Election.** The master election in AWDL is based on a numeric comparison of two values that are transmitted in the *election parameters*. The first value

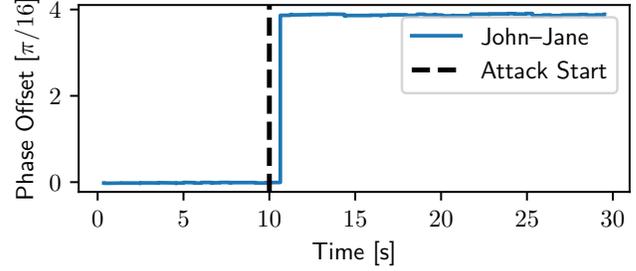

Figure 10: Phase offset between two targets before and after mounting a desynchronization attack which induces a phase shift of  $\phi = \tau/4$ .

is called *metric*, and each node draws one randomly upon initialization. The numeric range of the *metric* is bounded and depends on the AWDL version that runs on the node [79]. The second value is called *counter* which is initialized to a random value and increases linearly over time while the node is elected as a master. Given the metric and counter values of two nodes *A* and *B* as  $(m_A, c_A)$  and  $(m_B, c_B)$ , respectively, then, *A* wins the master election if

$$c_A > c_B \vee (c_A = c_B \wedge m_A > m_B) \quad (15)$$

and loses otherwise. To consistently win the election, the attacker sets *c* and *m* to their maximum values.

(2) **Unicasting AFs.** The attacker needs to send the synchronization parameters to each target without the other one noticing. We have found that while AFs are typically sent to the broadcast MAC address `ff:ff:ff:ff:ff:ff`, AWDL nodes also accept unicast AFs. Therefore, the attacker can unicast their AFs to make sure that only the intended target receives them.

### (3) Phase Shift: Different Synchronization Parameters.

To desynchronize two targets, the attacker needs to send incompatible synchronization parameters that will result in a controllable offset. We explain how the attacker calculates the relevant parameters *i* and  $t_{AW}$  for both targets. Let us assume that the attack starts at some time  $T_s$ . An AF sent to the *first* target at some time  $T_{Tx}$  with  $t = \left\lfloor \frac{T_{Tx} - T_s}{1024} \right\rfloor$  (in TU) will include the following parameters:

$$i = \left( \left\lfloor \frac{t \bmod 64}{16} \right\rfloor + 4 \left\lfloor \frac{t}{64} \right\rfloor \right) \bmod 2^{16} \quad \text{and,} \quad (16)$$

$$t_{AW} = 64 - t \bmod 64 \quad . \quad (17)$$

For the *second* target, the attacker will calculate *t* as  $t^\phi = \left\lfloor \frac{T_{Tx} - T_s - \phi}{1024} \right\rfloor$  and compute  $i^\phi, t_{AW}^\phi$  analogously to Eqs. (16) and (17). We verify the correctness of these calculations experimentally and show the resulting phase offset between two targets for a target phase  $\phi = \tau/4$  in Fig. 10.

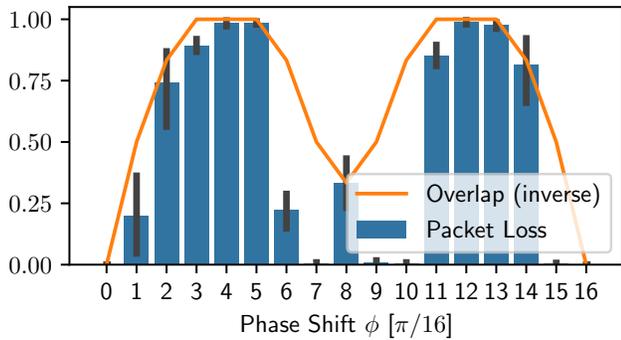

Figure 11: Packet loss for different phase shifts.

## 6.2 Evaluating Packet Loss

We evaluate the impact of our desynchronization attack by measuring the packet loss via the `ping` program. In particular, we use an APU board [66] equipped with a Qualcomm Atheros AR928X Wi-Fi card to act as an attacker which can inject AWDL AFs. The ICMP echo requests are sent from a MacBook Pro (Late 2015, macOS 10.13) to an iPhone 8 (iOS 12). The attacker induces different phase shifts spanning one period. The sender emits 100 ICMP echo requests per experiment which we repeat 10 times and plot the resulting packet loss in Fig. 11. The error bars indicate the standard deviation. In addition, we include the inverse channel overlap (see Section 2) which is calculated for two identical sequences which we have observed were the most common ones during our experiment: 44, 44, 44, 0, 0, 0, 0, 0, 6, 44, 44, 0, 0, 0, 0, 0.

At  $\phi = 0$ , there is no attack, while at  $\phi = 16$ , the targets are desynchronized by a full period which unsurprisingly does impair communication reliability. The other results indicate that the desynchronization attack significantly degrades communication between the targets, peaking at phase shifts where the targets are off by a quarter ( $\phi = 4$ ) and three-quarter period ( $\phi = 12$ ) which is where the channel overlap has its minima (and the inverse overlap its maxima). At these settings, the packet loss is almost 100%. Surprisingly, some phase shifts (e.g.,  $\phi = 6, 7, 9, 10, 15$ ) result in less packet loss than the overlap predicts. We suspect the reason to be retransmissions on the MAC layer (up to 7 times in Wi-Fi [73]) which, at the cost of longer latency, increase the chance that a frame will be received in a subsequent AW.

## 6.3 Mitigating Desynchronization

Devices can mitigate our desynchronization attack by discarding unicast AFs. Not accepting unicast frames is an extremely effective and practical countermeasure because it will cause all nodes in range to process the same information exclusively. While this does not prevent an attacker from winning the master election and, thus, sending invalid synchronization parameters, as all nodes process the same frames, it becomes much harder to create a deterministic offset between two tar-

gets. A more sophisticated attacker could employ attacks on the PHY layer (e.g., using directional antennæ) to achieve a similar effect as that of unicasting. However, such attacks are difficult to carry out in practice.

## 6.4 Related Work: Reactive Jamming

At first glance, our desynchronization attack achieves a similar effect as a *reactive jammer* [37, 52, 70, 91]. However, the desynchronization attack can be more attractive for two reasons: first, desynchronization in principle needs less energy than a jamming attack. The desynchronization attacker only needs to emit one frame every 1.5 s to maintain their position as a master node because AWDL nodes elect a new master if they have not received an AF for more than 1.5 s from their current one. In contrast, a reactive jammer needs to emit a jamming signal for every packet that the target sends. Second, it allows intercepting frames from its targets which enables to mount more sophisticated MitM attacks as presented in Section 7. In contrast, a normal jammer *kills* the frame in transit disallowing anyone (even the attacker themselves) to decode the frame [70]. There exist more sophisticated receiver designs that cancel out the jammer’s own signal, but this typically requires special hardware [37]. Our desynchronization attack only requires a system with an off-the-shelf Wi-Fi chip and, thus, could even be implemented in a smartphone [71].

## 7 MitM: Planting Malware via AirDrop

This section describes a MitM attack on the popular AirDrop service which allows iOS and macOS devices to exchange files directly via AWDL. First, we assess the security of AirDrop and find that poor UI design choices enable an attacker to masquerade as a valid receiver. Then, we describe a complete MitM attack on AirDrop which prevents any sender to discover a valid receiver using a DoS attack and subsequently can intercept and modify any AirDrop file transmission. Finally, we discuss possible mitigations for the attack.

### 7.1 Ambiguous Receiver Authentication State

We have observed that AirDrop employs two different kinds of connections which we term *authenticated* and *unauthenticated* (see Section 3). Further, the user can set its device to be discoverable by *contacts only* or *everyone*. Counter-intuitively, the discoverability setting *only applies to the receiver side*. In particular, while a receiver in *contacts-only* mode will only accept files from authenticated senders, a sender will see all discoverable receivers irrespective of whether they are authentic or not. This ambiguity has profound implications for security because it is up to the user of the sending device to decide whether a connection is authenticated or not which can be non-trivial. The only visual cue to differentiate between an authenticated and unauthenticated connection is that an authenticated connection will show the receiver’s name and photo from the sender’s address book. Neither provides sufficient evidence to unambiguously decide whether a receiver

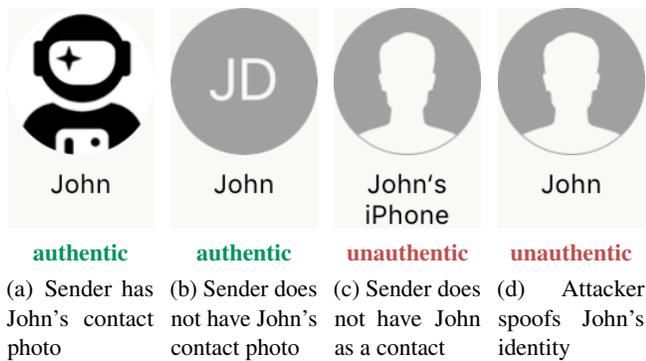

Figure 12: UI representation of a receiver.

is authentic. First, if no contact photo is available (users augment only 27% of their contacts with a photo according to our survey), the icon contains the receiver's initials in a grey circle which is similar to that of an unauthenticated receiver (a grey circle with a head's silhouette). Second, the name that is displayed underneath unauthenticated receivers is the receiver's device name. Based on our results in Section 5, a device name contains the user's given name in the majority of the cases (more than 70% according to our experimental evaluation in Section 5), which the attacker can exploit to create a trustworthy-looking device name. Unless users are sensitive to such subtle UI changes, an attacker can easily trick them into sending files via an unauthenticated connection. Figure 12 compares the different receiver icons including a spoofed identity by the attacker. We want to highlight the similarity between an authenticated identity (Fig. 12b) and a spoofed identity (Fig. 12d).

## 7.2 The Complete AirDrop MitM Attack

Our MitM attack on AirDrop is carried out in three phases. First, we break the discovery process to put ourselves in a privileged position. Second, we wait until the target receiver becomes discoverable by *everyone*, effectively forcing the user to downgrade the connection. Third, we relay and manipulate the actual data transfer to plant arbitrary files at the receiver. We illustrate the attack in Fig. 13 and explain each phase in more detail below. Also, we provide a video PoC of the attack [77].

**(1) Breaking Discovery via DoS.** The most crucial part of the attack is preventing the sender to discover the receiver such that it appears as an icon in the sharing pane. In particular, we need to prevent that the *Discovery* handshake via HTTPS completes successfully. In principle, such a DoS attack could be carried out via our desynchronization attack (Section 6). However, we found that it could not reliably prevent the short *Discovery* request and responses from being received. This is due to the fact that AirDrop senders increase the channel allocation when starting the discovery process, thus, increasing the overlap with the receiver even when desynchronized.

As an alternative, we used the well-known TCP reset attack which sends TCP segments including an RST flag to the targets which, in turn, immediately drops the connection. For this attack, the attacker sends out an RST reply for every TCP segment that is not addressed to itself and effectively prevents any reconnection attempts from the sender to the receiver.

**(2) Downgrading an Authenticated Connection.** For a complete MitM attack, we need to authenticate to the receiver. Otherwise, it will deny any *Ask* or *Upload* requests. If the receiver is discoverable by *everyone*, this is trivial, since it accepts all authentication attempts, even those with a self-signed certificate which the attacker can easily generate (see Section 3.3). The receiver indicates a successful authentication attempt from a non-contact by including its device name in the *Discover* response. However, we have found that in most cases (59.4% in our survey), users set their device to *contacts only*. In such cases, we leverage the ongoing DoS attack to force the receiver to try the *everyone* setting.

**(3) Relaying and Modifying Data Transfer.** Once the receiver becomes discoverable (we can check when a receiver is discoverable by *everyone* by periodically sending *Discovery* requests), we advertise our own AirDrop identity via mDNS and wait until the sender tries to perform the authentication handshake via HTTPS for discovery which we let succeed. We relay the sender's *Ask* request to the receiver including the original file thumbnail to make the request appear valid. After the receiver accepts the transmission request, we relay the answer back to the sender which—in turn—starts to send the actual file. We can now decide whether to relay a modified version of the file or send an entirely new one possibly containing malware to the receiver.

## 7.3 Implementation

Our PoC of the MitM attack consists of two components. First, we re-implement AWDL such that we were able to overhear and parse data frames not addressed to us which is required to mount a TCP reset attack. Second, we implement an AirDrop-compatible client and server which we use to probe the discoverability status of the receiver target and finally implement the MitM attack as depicted in Fig. 13. We make both projects available as open source software [76, 78].

**AWDL.** Our AWDL implementation [76] is written in C and runs on Linux as well as on macOS. On macOS, the implementation can be used as a drop-in replacement for Apple's own AWDL interface. We use the monitor mode and frame injection of the system's Wi-Fi card to receive and inject raw IEEE 802.11 frames. In addition, we provide a virtual network interface (via *tuntap*) to the system such that any IPv6-capable application can use AWDL. Internally, our implementation takes care of frame parsing, synchronization, election, and scheduling data frames in the correct AWs.

**AirDrop.** Our AirDrop implementation [78] is written in Python and implements an unauthenticated AirDrop sender

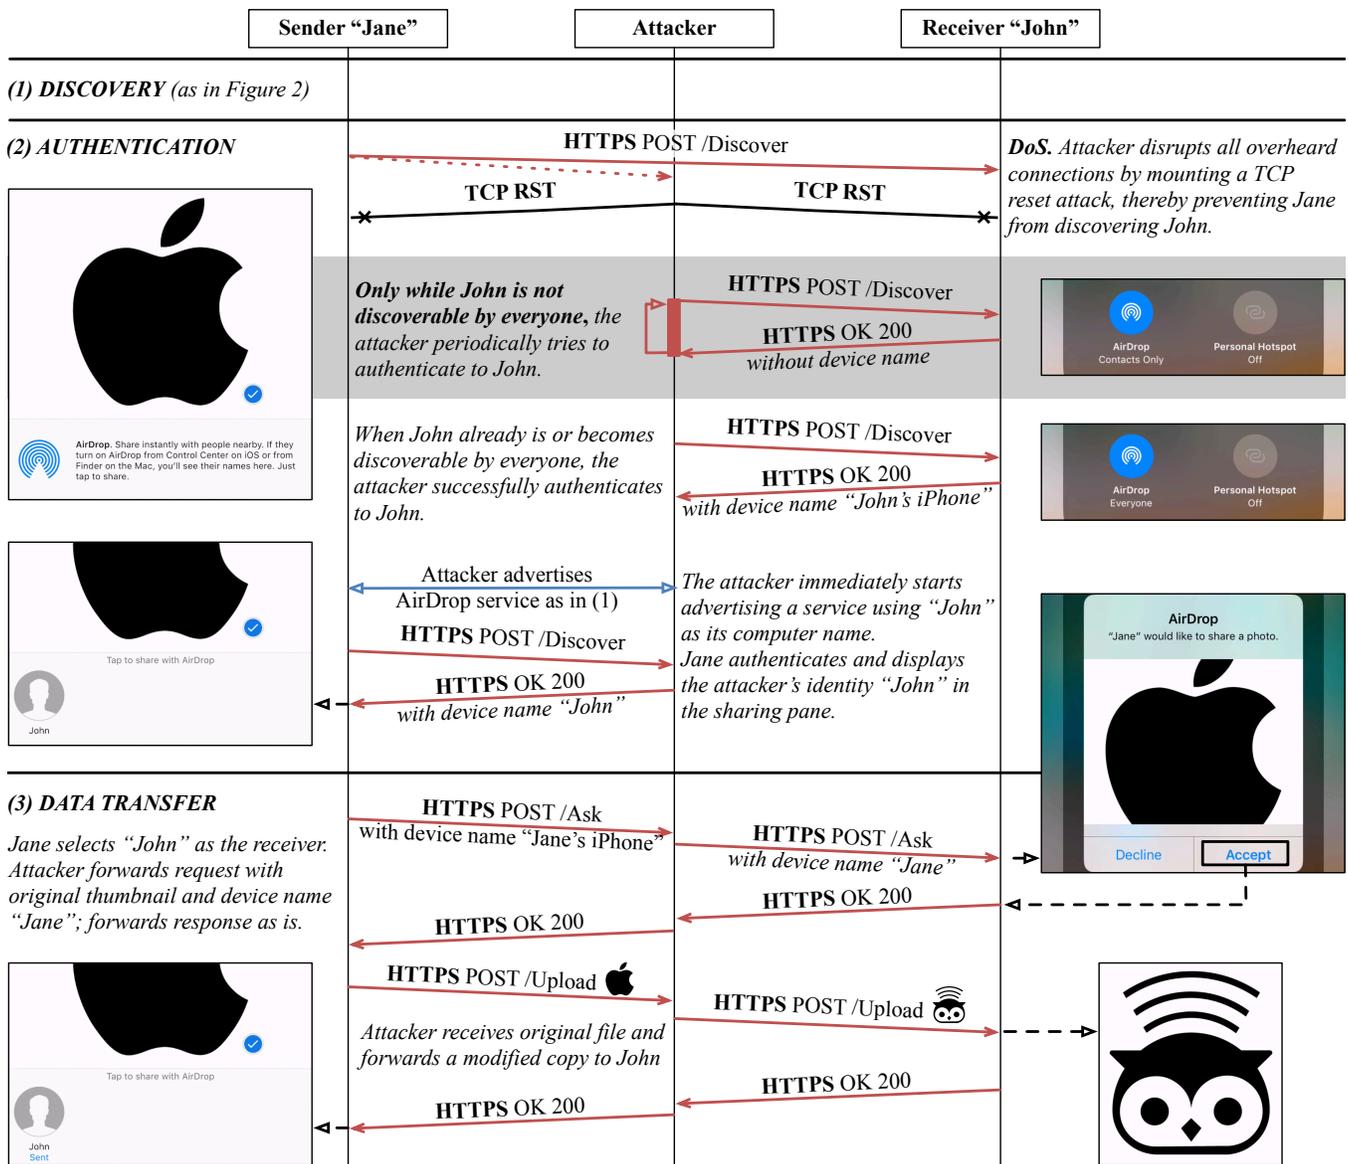

Figure 13: Protocol flow and user interaction of our MitM attack on AirDrop.

and receiver. The code exposes a command line interface which allows to *find* discoverable receivers, *send* files to them, and *receive* files from any sender.

## 7.4 Mitigation

We discuss possible mitigation strategies. We examine them according to complexity to implement, starting with the mitigation requiring the least number of changes to existing AirDrop implementations.

**Provide Stronger Visual Cues for Authenticated Receivers.** One of the core problems of the current design of AirDrop is that a user might have a hard time to differentiate between authenticated and unauthenticated receivers (see Section 7.1 and Fig. 12). Currently, the only cues to decide

whether a receiver is authenticated are the display of a contact photo and contact name. We have shown that the former is not commonly available (users augment 27.4 % of their contacts with photos) and the latter can be spoofed. Therefore, we propose to provide stronger visual cues that unambiguously tell the user if a receiver is authenticated or not. This is already customary in web browsers where HTTPS-protected websites are augmented with a green (lock) symbol telling the user that the website they are visiting is authentic.

**Reset Everyone to Contacts Only After a Timeout.** Users might set the discoverability setting of their device to *everyone* for convenience or if they used it for one occasion and then forgot to reset it. In either case, we believe that the *everyone* setting should only be used except when it is required,

i. e., if one wants to receive a file from a non-contact. To protect negligent users, we propose to use a timeout after which the discoverability setting is reset to *contacts only*. Alternatively, one could reset the setting the next time the device is locked. This would also prevent past cases where people would receive inappropriate photographs from strangers in public places [13, 41] because, in *contacts-only* mode, devices will transparently reject all request from unauthenticated senders.

**Introduce Secure AirDrop Mode for Non-Contacts.** Our last proposal involves deprecating unauthenticated connections and instead establish authentication with a non-contact via an out-of-band (OOB) channel. AirDrop could transmit one-time cookies with similar functionality as the *record data* (see Section 3.3) during the initial HTTPS authentication handshake (see Section 3.2). The one-time cookies could be validated via an OOB channel such as NFC or via QR codes. After one transfer (or after a specific timeout), each device deletes its one-time cookie. By committing to the one-time cookie in the TLS handshake, a MitM attack on the OOB channel would be fruitless because the attacker could not establish a TLS connection with the same key. Unfortunately, such a mode would require one more manual step by both parties and, therefore, would impair usability.

## 7.5 Related Work: Attacks on AirDrop

Other attacks on AirDrop have been presented before. An impersonation attack [10] exploits mDNS/DNS-SD to redirect file transmissions to an attacker for unauthenticated connections. In particular, the attack uses forged SRV and AAAA responses to redirect an AirDrop ID to the attacker. In contrast to our work, [10] does not differentiate between *authenticated* and *unauthenticated* connections and claims that the UUID certificate (see Section 3.3) could not be bound to any contact identifiers, which we have found to be untrue. Also, the attack only works on unauthenticated connections, while our attack also targets authenticated connections via a downgrade attack and we present a complete MitM attack which allows an attacker to send malicious files to the receiver stealthily. Finally, [10] proposes a conflict detection mechanism for Multicast DNS (mDNS) to prevent their attack, which is based on the assumption that “disrupting two parties’ communication through a Wi-Fi direct link or a local network is difficult for the adversary without access to the routing infrastructure of the network.” In this work, we show that it is indeed practical to mount a DoS on the link layer since AWDL does not employ any security mechanisms. An earlier work [27] targeted a vulnerability in AirDrop’s implementation which allowed the attacker to install files in arbitrary directories on the target’s system. Apple fixed this bug in 2015.

## 8 Implementation Security

During our AWDL analysis and building an AWDL prototype, we found two implementation flaws in Apple’s OSes that

allow an attacker to crash devices in proximity.

**DoS: Kernel Panic and System Crash.** These flaws can be exploited by sending corrupt AFs. In particular, we can trigger kernel panics by setting invalid values in the synchronization parameters (affecting macOS 10.12) and the channel sequence (affecting macOS 10.14, iOS 12, watchOS 12, and tvOS 5), respectively. To showcase our findings, we provide a video of our PoC which exploits the second vulnerability on iOS devices [75]. The video demonstrates how an attacker mounts a targeted DoS attack that crashes a single device and a black-out DoS attack that crashes all devices in range of the attacker at the same time.

**Outlook: Remote Code Execution.** While not critical by themselves, the mere existence of these vulnerabilities creates a new class of threats to Wi-Fi devices as an attacker can exploit them *without any authentication towards the target*, i. e., they do not have to be on the same network. In light of past discovered remote code execution in implementations of standardized Wi-Fi procedures [8, 14], we think that a determined attacker can find similar flaws for AWDL.

## 9 Conclusion

The deployment of open Wi-Fi interfaces enables new types of applications for mobile devices. They allow devices in proximity to communicate with each other without being connected to the same Wi-Fi network. On the downside, this also opens new opportunities for an attacker as they no longer have to provide any kind of authentication (e. g., access to a secure Wi-Fi network). In this paper, we investigate the first protocol of this kind, i. e., Apple’s proprietary AWDL. In particular, we find three distinct protocol-level vulnerabilities that allow for DoS, user tracking, and MitM attacks. In addition, we discovered two implementation bugs in Apple’s OSes that cause DoS. Given the complexity of the protocol and implementations, we conjecture that more severe vulnerabilities will be found in the future. To build PoCs for these attacks, we have reverse-engineered AirDrop, a system service that runs on top of AWDL, and have implemented open versions of both AWDL and AirDrop which we make available as open source software. Finally, our findings have implications for the non-Apple world: NAN, commonly known as Wi-Fi Aware, is a new standard supported by Android which draws on AWDL’s design and, thus, might be vulnerable to the similar attacks as presented in this work. This is pending further investigation.

## Responsible Disclosure

We have contacted Apple about our findings on December 17, 2018. We have shared a draft of this paper as well as our PoC code and support Apple in fixing the privacy leaks (Section 5) and desynchronization issue (Section 6) in AWDL as well as the ambiguous authentication state in AirDrop (Section 7). We have reported the two implementation vulnerabilities (Section 8) earlier on August 14 and 27, 2018, respectively. Apple will not fix the first one affecting only macOS 10.12, but

has released software updates addressing the second one on October 30, 2018, for all Apple OSes [4].

## Acknowledgements

This work is funded by the LOEWE initiative (Hesse, Germany) within the NICER project and by the German Federal Ministry of Education and Research (BMBF) and the State of Hesse within CRISP-DA. The work was partially supported by NSF grant 1740907. We thank the Apple Product Security team for feedback on the paper.

## Availability

We release the source code of our AWDL [76] and AirDrop [78] implementations as part of the Open Wireless Link project [81] (<https://owlink.org>).

## Abstract

Long-Term Evolution (LTE) communication is based on an open medium; thus, a legitimate signal can potentially be counterfeited by a malicious signal. Although most LTE signaling messages are protected from modification using cryptographic primitives, broadcast messages in LTE have never been integrity protected. In this paper, for the first time, we present a signal injection attack that exploits the fundamental weaknesses of broadcast messages in LTE and modifies a transmitted signal over the air. This attack, which is referred to as signal overshadowing (named `SigOver`) has several advantages and differences when compared with existing attacks using a fake base station. For example, with a 3 dB power difference from a legitimate signal, the `SigOver` attack demonstrated a 98% success rate when compared with the 80% success rate of attacks achieved using a fake base station, even with a 35 dB power difference. Given that the `SigOver` attack is a novel primitive attack, it yields five new attack scenarios and implications. Finally, a discussion on two potential countermeasures leaves practical and robust defense mechanism as a future work.

## 1 Introduction

Long-Term Evolution (LTE) technology utilizes broadcast signals to transmit essential information from a cellular network to user devices. At minimum, the information broadcasted by an LTE base station, which is referred to as an evolved NodeB (eNB), includes the synchronization information and radio resource configurations required for a User Equipment (UE) to access the cellular network. Based on the received broadcast signals, a UE registers with the network by performing an Authentication and Key Agreement (AKA) procedure. After registration, the UE monitors the broadcast signals for various objectives. For example, when the UE does not have a connection with an eNB due to its inactivity, it needs to listen to paging messages regularly to check the messages transmitted to it. Even when the UE has an active connection with an eNB, the UE keeps listening broadcast signals to determine poten-

tial changes in system-wide radio configurations which are required to be updated, and to identify the arrival of messages intended to multiple UEs.

Despite its various practical applications, the broadcast signal is not security-protected at all. In LTE, communication between a UE and network is secured only after successful authentication and security handshake procedures, namely Non-Access Stratum (NAS) and Access Stratum (AS) security mode procedures for the protection of *unicast* messages. Unprotected broadcast signals may be unavoidable to a certain extent in wireless communication; however, they subject the system and UEs to various vulnerabilities that can be exploited.

Previous studies [21, 26, 36, 39, 40] reported on several attacks that exploit *unprotected* broadcast signals. In general, such attacks employ a fake base station (FBS) that attracts UEs to be connected to itself by transmitting a signal stronger than those of the legitimate base stations. The attacks mainly exploit the paging messages, resulting in undesirable effects on the UE, e.g., out-of-service and battery drains. Notably, such FBS-based attacks entail noticeable characteristics (e.g., high signal power) and/or outcomes (e.g., service denial) that enable the victim UEs to identify the presence of the FBS (see Section 3.5 for details).

In this paper, we propose a new approach referred to as the `SigOver` attack, which injects a manipulated broadcast signal into UEs without employing an FBS. The `SigOver` attack overwrites a portion of the legitimate signal using the manipulated attack signal. The `SigOver` attack is based on the fact that the UE decodes a stronger signal when it concurrently receives multiple overlapping signals, which is referred to as the *capture effect* [51]. The main technical component of the attack is to synchronize the timing of the attack signal with that of the targeted legitimate signal so that the UE only decodes the attack signal (see Section 3). This attack is both stealthy and far-reaching. It is stealthy because the attack signal, which is transmitted at a significantly low power level, only overshadows the targeted signal; whereas the other signals/messages between the victim UEs and network remain intact. It is far-

reaching because the attack signal can simultaneously affect a large number of nearby UEs with low signaling and a low computational cost. Note that the SigOver attack does not require any active communication with the UEs, and it does not relay messages between UEs and an eNB.

The SigOver attack is the first practical realization of the signal overshadowing attack on the LTE broadcast signals using a low-cost Software Defined Radio (SDR) platform and open source LTE library [43]. The SigOver attack was made practical by addressing the following challenge: *time and frequency synchronization*. To overshadow the legitimate signal using the malicious signal, the SigOver attack needs to be tightly time-synchronized with the eNB’s downlink physical channel to which the victim UE is listening. To achieve time synchronization, we leverage the synchronization signals of the eNB that are transmitted periodically with a fixed time gap. For accurate frequency synchronization, we employ a Global Positioning System (GPS) disciplined oscillator.

The feasibility of the SigOver attack was verified by testing it against 10 smartphones (listed in Section 5) connected to an operational network<sup>1</sup>. For the experiments, we introduced five new attack scenarios, which included the signaling storm, denial of service (DoS) against UEs, network downgrade, and UE location tracking (Section 5). The experimental results reveal that the SigOver attack overshadows the target signal and causes the victim device to decode it with a 98% success rate and a power difference of only 3 dB from a legitimate signal. On the other hand, attacks utilizing an FBS have only 80% success rate even with a 35 dB power difference. This implies that the SigOver attack is significantly more efficient than the attacks using the FBS.

Finally, two potential countermeasures against the SigOver attack are discussed in Section 6: (1) digital signature based solution and (2) channel estimation based detection. Moreover, a practical and robust solution to the SigOver attack is left as a future work.

Our contribution are summarized as follows:

- **First signal overshadowing attack on LTE:** To the best of our knowledge, the SigOver attack is the first realization of a signal overshadowing attack on LTE broadcast signals.
- **Implementation and evaluation:** We demonstrate the practicality and stealthiness of the SigOver attack via extensive real world experiments with high attack success rate.
- **Novel attack scenarios and implications:** We present novel attack scenarios and analyze their implications in detail based on the experiments.
- **Countermeasures:** We investigate prevention and detection strategies against the SigOver attack, e.g., the digitally signing on broadcast signals for prevention, and leveraging the changing nature of the physical signal for detection.

<sup>1</sup>All the experiments were conducted based on the permission of the operators.

## 2 Background

In this section, we present a brief description of the LTE network architecture and the essential procedures of radio connection establishment, mobility management, and security setup between a device and an LTE network. (See the table in Appendix B for the acronyms used in this paper.)

### 2.1 LTE Network Architecture

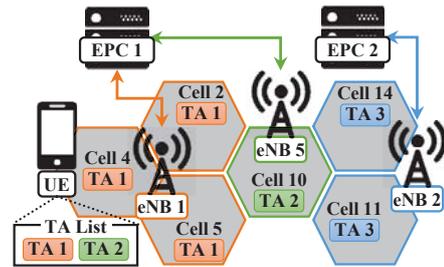

Figure 1: LTE network architecture

An LTE network consists of a UE, eNB, and Evolved Packet Core (EPC) components as illustrated in Figure 1.

A UE is an end device that provides various LTE services (i.e., voice and data services) to a subscribed user. It includes a smart card referred to as the Universal Subscriber Identity Module (USIM), which stores a permanent identity (International Mobile Subscriber Identity, IMSI) or a temporary identity (Globally Unique Temporary Identity, GUTI) for user identification, and a cryptographic key for encryption and integrity protection.

An eNB is an LTE base station, which provides a wireless connections for UEs to receive services enabled at the LTE network. A single eNB covers multiple sites (referred to as cells in LTE), which are identified by a Physical layer Cell Identity (PCI).

An EPC network is responsible for control functions such as authentication, mobility and session management, and user plane services. For mobility management, a Mobility Management Entity (MME) in the EPC network manages a set of Tracking Areas (TAs), each of which contains several eNBs.

### 2.2 LTE Physical Layer Initial Access

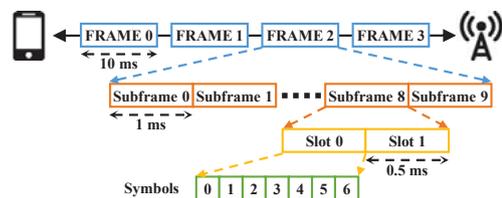

Figure 2: LTE frame structure type 1 [2]

**LTE frame.** The UE and eNB communicate with each other based on the radio frame structure, as shown in Figure 2<sup>2</sup>.

<sup>2</sup>The LTE-Frequency Division Duplex (FDD) mode was employed in this study, as used by the majority of operators in the world [18].

Each frame has a duration of 10ms and comprises 10 subframes, each of which has a duration of 1ms. A single subframe is further divided into two slots of equal duration and each slot comprises seven Orthogonal Frequency Division Multiplexing (OFDM) symbols.

**Downlink Scheduling.** In LTE, radio resources are allocated in the unit of the Physical Resource Block (PRB) [2] that contains 12 subcarriers (each with a bandwidth of 15 KHz) and consumes one slot in time (0.5ms). The number of available PRBs in a frequency band is determined by the system bandwidth. Depending on the size of the data, an eNB allocates PRBs within a subframe (1ms), which is the smallest scheduling time interval.

**Channel estimation.** When a signal travels through a wireless channel, the signal gets distorted due to several factors, e.g., attenuation, phase-shift, and noise. To accommodate those factors, wireless devices estimate the channel using the following equation:  $Y(k) = H(k)X(k)$ , where  $Y(k)$ ,  $H(k)$  and  $X(k)$  represent a signal received by a UE, the channel coefficient, and the signal transmitted by an eNB, respectively. In LTE, a UE performs channel estimation based on the Reference Signal (RS) transmitted by the eNB. The UE calculates  $H(k)$  from  $H(k) = \frac{Y(k)}{X(k)}$  as it already knows  $X(k)$  and  $Y(k)$  value of RS. To minimize the effects of noise in the channel estimation,  $H(k)$  of RS is averaged using an averaging window.

**Cell search.** When a UE is turned on, it has to find a suitable cell to establish radio connections. To this end, it first attempts to measure the Received Signal Strength Indication (RSSI) of the candidate frequency channels. The UE selects the channel with the highest RSSI based on the measurement. Thereafter, the UE obtains time synchronization on a subframe basis and the PCI of the cell by listening to a Primary Synchronization Signal (PSS) and a Secondary Synchronization Signal (SSS). The UE then decodes the Master Information Block (MIB) to acquire the System Frame Number (SFN) and other physical channels.

**System information acquisition.** After completing the cell search procedure, the UE decodes a Physical Control Format Indicator CHannel (PCFICH) and a Physical Downlink Control CHannel (PDCCH) to decode downlink data. The UE knows the number of OFDM symbols used to carry the PDCCH at each subframe through the PCFICH. The UE then decodes the PDCCH that contain the information on the resource blocks that the data and the demodulation scheme required by the UE. After decoding the two channels, the UE decodes the other system information broadcasted through a Physical Downlink Shared CHannel (PDSCH). There are 22 System Information Blocks (SIBs), each of which contains different cell-related system information [3]. Among them, SIB1 and SIB2 are essential for a UE to connect to a cell. The availability of other SIBs is indicated in SIB1.

**Random access.** A UE performs a Random Access CHannel (RACH) procedure to establish a radio connection with the

eNB. To this end, the UE randomly chooses a Random Access (RA) preamble sequence and transmits it to the eNB. Unless the same preamble sequence is simultaneously transmitted from a different UE, the UE successfully completes the RA procedure.

## 2.3 Mobility Management

**Radio Resource Control (RRC).** When all the steps above have been completed, the UE carries out a connection establishment procedure with the eNB (called RRC connection establishment procedure). Upon the completion of the procedure, the UE enters the *RRC Connected* state in which it can communicate with the eNB. When there are no incoming and outgoing data for a certain time period, the radio connection between the UE and eNB is released, and the UE enters the *RRC Idle* state, to reduce battery consumption.

**Non-Access Stratum (NAS).** NAS is a network layer protocol between the UE and MME for mobility and session management. To register with the LTE network, the UE carries out an ATTACH procedure. After the UE is successfully registered with the LTE network, the MME knows the TA to which the UE belongs and provides the UE of a list of TA identifiers (TAIs). This TAI list is used by the UE to report its location to the MME.

**Idle state behavior.** In the *RRC Idle* state, the UE periodically wakes up to read paging messages and SIB 1. When there is incoming message to the UE, the MME that tracks the UE sends a paging to all eNBs in the entire TAs assigned to the UE, and those eNBs broadcast a paging message to inform the UE of the arrival message. The paging message contains either the temporary or permanent identity of the UE. If the UE receives the paging message, it sends a *RRC connection request* and a *Service request* message to the LTE network. Paging is also used to notify the system information change or provide emergency alerts such as the Earthquake and Tsunami Warning System (ETWS) and Commercial Mobile Alert System (CMAS). The UE also reads the SIB1 to identify the current TA. If the UE enters into a new TA that is not in the TAI list, the UE sends a *Tracking Area Update (TAU) request* to the MME to report its location. In addition, the UE periodically measures the power and quality of the serving cell and neighboring cells by calculating the Reference Signal Received Power (RSRP) and Reference Signal Received Quality (RSRQ). When the RSRP of a neighboring cell is higher than that of the serving cell by a certain threshold, the UE selects new cell and camps on it (i.e., cell re-selection).

## 2.4 Establishing Security Context

When a UE establishes a wireless connection with an eNB, it registers with the LTE network to achieve a full connection with the network (this behavior is called ATTACH) by providing its permanent identity, IMSI. Then, the MME and the UE mutually authenticate each other and carry out a key

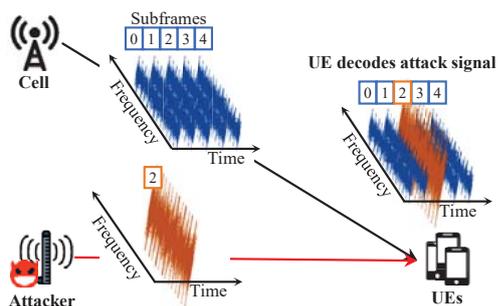

Figure 3: Overshadowing attack at a glimpse: By exploiting the fixed transmission timings of LTE subframes, the attacker injects a crafted subframe (in brown) that precisely *overshadows* the legitimate subframe (in blue) without errors.

agreement procedure to create a *security context* (i.e., NAS security context) for encryption and integrity protection. After the Authentication and Key Agreement (AKA) procedure, most messages between the UE and the MME are encrypted and integrity protected with cryptographic primitives. On the other hand, all initial procedures before establishing a security context in the AKA procedure are not encrypted and integrity protected by design. Those unprotected messages include paging, SIBs and several network layer initial messages specified in the LTE standard [5].

### 3 Overshadowing LTE Broadcast Message

In this section, we present the attack model, followed by a description of the SigOver attack. The SigOver attack is demonstrated by using an SDR that is widely used today (i.e., Universal Software Radio Peripheral (USRP) [16]). Lastly, we compare the SigOver attack with typical FBS attacks to show the effectiveness of the former.

#### 3.1 Attack Model

We assume an active adversary with minimum privilege. The proposed attack model can be described as follows: (i) The adversary does not know the LTE key of the victim UE. (ii) The adversary is able to eavesdrop on the downlink broadcast messages transmitted from the legitimate LTE cell to the victim UE(s). However, as the victim key is unavailable, the encrypted messages cannot be decrypted. Note that (ii) is trivially achievable because messages are transmitted through the open medium. Under the above assumptions, we show that an active adversary can inject malicious messages into the victim UE(s) by overwriting the legitimate messages. This is achieved by carefully crafting a message that overlaps a legitimate message with respect to time and frequency. In Section 3.5, we discuss the fundamental differences between the proposed attack model and typical FBS attacks [21, 22, 36, 37, 39].

#### 3.2 SigOver Attack Overview

This section briefly outlines the design of the SigOver attack. As discussed in Section 2, the LTE downlink is scheduled in a subframe granularity with a duration of 1ms. Each subframe is encoded separately by the base station, and is therefore decoded accordingly by the UE. Under this frame structure, Figure 3 conceptually illustrates the SigOver attack, where the attacker injects a crafted subframe (brown color) that precisely *overshadows* the legitimate subframe (blue color). Since the subframes are decoded independently from one another, the legitimate (non-overshadowed) subframes are generally not affected. At the same time, the injected subframe is crafted such that the UEs that have received and decoded the subframe behave based on the included information, which typically yields an abnormal or malicious behavior - an intended behavior by the attacker. The inherent vulnerability of LTE broadcast messages enables an attacker to launch various types of attacks using legitimately-looking messages (i.e., insidiously).

In principle, the SigOver attack leverages the capture effect [51], wherein the stronger signal is decoded when multiple simultaneous wireless signals (i.e., legitimate and crafted subframes) collide in the air. This is true for signals with a slight power difference of 3 dB [29]. Two technical challenges to launch the SigOver attack are (i) carefully crafting the overshadowing message to be decoded by the victim UEs (Section 3.3), and (ii) the stringent requirement of the transmission timing and frequency for precise overshadowing (Section 3.4).

#### 3.3 Crafting a Malicious Subframe

Here we illustrate how to craft a subframe that can be successfully decoded at the victim UE for a successful attack.

**Communication configuration matching.** For the SigOver attack, the attacker must first identify the physical configuration of the legitimate cell on which the victim UEs are camping, to determine the structure of the attack subframe. The necessary physical configuration information for valid subframe construction includes the PCI, channel bandwidth, PHICH configuration, and transmission scheme (or the number of antenna ports); all of which are available to the attacker once the attacker camps on the same legitimate cell. In particular, PCI is calculated from the PSS/SSS, and the remaining information is obtained from the MIB. Furthermore, the attacker must synchronize with the SFN of the legitimate cell, which is also available in the MIB, to determine the injection time of the attack subframe.

**Subframe structuring and injection.** In LTE, when a UE reads a broadcast message, it decodes the following information from a subframe: i) a Control Format Indicator (CFI) that contains the control channel structure, ii) Downlink Control Information (DCI) that contains the allocated resource (i.e., resource blocks) for the message, and iii) the resource blocks (RBs) that contain the message itself. The CFI and DCI are

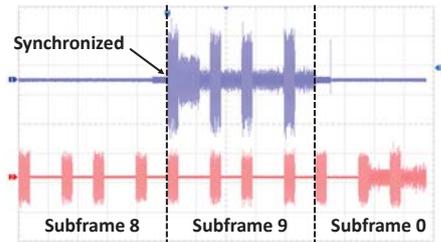

Figure 4: Oscilloscope snapshot showing precise time synchronization between a legitimate (in red) and a crafted signal (in blue).

transmitted over the PCFICH and PDCCH respectively; and the message is transmitted over the PDSCH. Therefore, to inject a subframe, the attacker needs to craft a subframe that contains the PCFICH, PDSCH and PDSCH. However, the injected subframe containing those values may not be decoded correctly at the UE due to a channel estimation error. Note that the UE estimates the channel from the RS transmitted by the legitimate eNB, yet the estimation result may be inappropriate to decode the injected subframe correctly. To address this issue, the RS is included in the subframe for the SigOver attack, which significantly increases the robustness of the SigOver attack.

The last technical challenge related to the decoding of the crafted subframe is with respect to wireless channel estimation and equalization, for recovery from the signal distortion due to the channel. In the SigOver attack, the channel is estimated either dominantly (even solely depending on the paging occasion) from the crafted subframe (*RRC Idle*), or it is averaged from consecutive subframes (*RRC Connected*) along with multiple legitimate subframes. In the former, a single injection is sufficient for the attack (i.e., decoding of the crafted subframe). In the latter, repeated injections are needed to effectively reflect the wireless channel between the attacker and the victim UE. According to our measurement (Section 4) which injected one subframe for every SFN, SigOver attack reaches over 98% success rate in less than a second while maintaining reliable communication for legitimate subframes. In Appendix A, we present empirical results showing that legitimate communication is minimally affected by SigOver attack using several services including web browsing and streaming.

### 3.4 Accurate Overshadowing

Overshadowing requires the crafted subframe to overlap the legitimate signal precisely in both the time and frequency domains. This subsection discusses how this is achieved.

**Time synchronization.** To precisely overshadow legitimate subframes, an attacker needs to know the subframe timing (to determine when a subframe starts) and SFN (to determine when to inject the subframe with respect to the frame number) from the legitimate cell. The attacker obtains the subframe timing from the synchronization signals (i.e., PSS/SSS) and the SFN from the MIB of the legitimate cell. The attacker

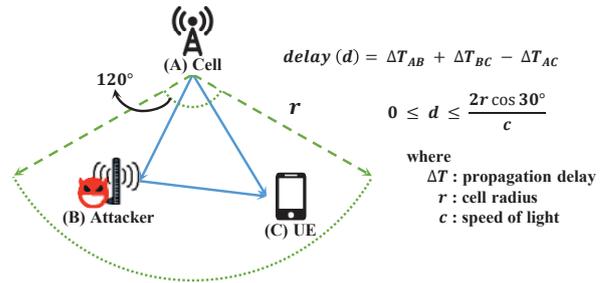

Figure 5: Propagation delay in the 3-sector cell configuration according to the location of the victim UE and the attacker. The attacker and victim UE are assumed to be within a cell coverage (the green sector form)

continuously obtains the subframe timing and the updated SFN, as the values vary over time depending on the channel condition. With the knowledge of the subframe timing and the SFN, the SigOver attack precisely synchronizes the transmission time of the crafted subframe with that of the target broadcast message (see Figure 4).

As shown in Figure 5, however, the crafted subframe transmitted at the acquired subframe timing may still arrive at the UE with a slight timing offset (with reference to the legitimate subframe) due to the propagation delay. Although the delay ( $d$ ) is unavoidable (as the propagation delay is immeasurable by the attacker), its impact is minimal. This is because the baseband processor in the UE is designed to compensate the delay due to mobility and environmental effects [48]. Since the maximum delay that can be compensated is dependent on the baseband processor of the UE, we perform the following experiments to measure the delay. We assumed the typical three-sector cell configuration wherein the transmission angle of the cell is  $120^\circ$  [10]. The delay ( $d$ ) is maximized when the attacker and the victim UE are located at both ends of the arc. This translates to  $d = 8.66\mu\text{s}$  under a typical cell radius of approximately 1.5km in urban environments. We measured the offset tolerance on two devices with different basebands (Qualcomm and Exynos), and the tolerance was larger than the maximum delay (i.e.,  $8.66\mu\text{s}$ ) (see Section 4 for detailed experimental results).

**Frequency synchronization.** The operating frequency of a radio device is determined by the oscillator, where it inevitably suffers from a device-specific offset that is randomly imposed during manufacturing and generated during operation due to environmental effects (e.g., temperature). Such an imperfection in the oscillator is reflected in the radio signal as carrier frequency offset. In LTE, there are a number of readily available techniques [27, 50] to compensate for offsets up to a certain level (e.g., Up to  $\pm 7.5\text{KHz}$  for PSS based compensation in the LTE 15KHz subcarrier spacing [38]). Therefore, for the reliable implementation of the SigOver attack, the offset should be maintained below that level in the UE, at all times.

The LTE standard defines the minimum frequency accu-

message should be selected such that the attack sustains even if the UE makes a cell change (e.g., TAU Reject [39]) or has an immediate impact on the UE (e.g., emergency warning message [21]). Thus, it is not an appropriate attack vector to exploit broadcast messages (e.g., SIB messages) that are refreshed when the serving cell changes. This makes the FBS attack either limited in terms of attack scope (as exploitable messages are very limited) or less sustainable in its duration.

### 3.5.2 MitM attacks

Recently, a new type of FBS attack referred to as the aLTER [37] attack was discovered. This is an MitM attack that employs an FBS with eNB and UE capabilities. The eNB component of the FBS impersonates a legitimate eNB by relaying the messages from the eNB to a victim UE. In addition, the UE component of the FBS impersonates the victim UE by relaying the messages from the UE to the eNB. By sitting between the victim UE and the eNB, the MitM attacker manipulates user plane messages since the messages are not integrity-protected in LTE. The MitM attack inherits two aforementioned limitations of the FBS attack, namely, a high power consumption and low stealthiness, since the MitM attacker should attract the victim UEs in the same manner. Meanwhile, in principle, the MitM attack does not affect the connection between the victim UE and the eNB, thereby making the attack sustainable. However, we noticed that it is non-trivial to implement a MitM attacker for various reasons. First, to maintain the connection with a victim UE, the MitM attacker should relay all uplink and downlink messages exchanged between the victim UE and the eNB. To this end, the attacker must know the UE's radio resource settings configured by the eNB and configure the radio resource for the UE accordingly. Otherwise, the radio connection between the UE and the eNB may become unstable or fail. However, since the message that contains the radio resource setting (i.e., RRC reconfiguration) is encrypted, the attacker cannot properly configure the UE's radio resource. We note that the RRC reconfiguration contains a large number of PHY, MAC, RLC, and PDCP configurations for the UE.

To address this issue, the aLTER attack used the radio configuration in a heuristic manner under the following conditions: (i) a victim UE receives the service using the *default radio configuration*, and (ii) the default radio configuration of an operator is stable. That is, only a few parameters (e.g., scheduling request (SR) and channel quality indicator (CQI) configuration) are changed for each radio configuration; whereas the others are the same. Thus, the attacker only needs to guess the CQI and SR configurations. However, in the real world, the eNB frequently changes the UE's radio configuration depending on the service that the UE is using and/or the current channel condition (e.g., initiating carrier aggregation, starting a Voice/Video call service, service priority, or channel quality change due to mobility). We observed that when a UE watched a YouTube video for 2 minutes under a bad chan-

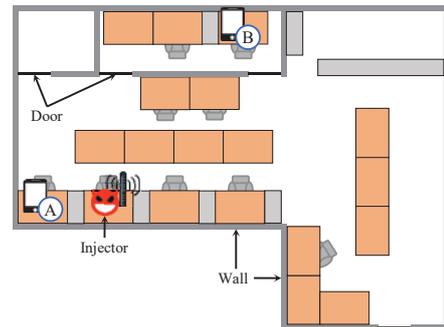

Figure 7: Experiments are conducted at two UE locations, A and B: A is 2m away from the attacker with line of sight. B is 10m away from the attacker, separated by a wall (i.e., non-line of sight). We refer to the former and the latter as LOS and NLOS, respectively.

nel condition, it received 9 RRC reconfiguration messages from the eNB, where the length of each message varied from 18 bytes to 109 bytes. Note that, as the attacker is only able to know the message length and the sequence of message delivery, it may not correctly guess the configuration. We also observed that 8 out of 9 messages have different CQI configurations which also need to be guessed.

These limitations apply to all MitM attacks, even when the attacker attempts to manipulate the broadcast message. However, the SigOver attack does not suffer from such limitations, as it only utilizes a persistent radio configuration acquired from the MIB of the legitimate cell (see Section 3.3).

## 4 Real World Experiment

In this section, we perform SigOver attack in the wild, and analyze the reliability of the attack.

### 4.1 Experimental Setup

We implement the SigOver attack based on the *pdsch\_enodeb*, which contains a basic transmission function as part of srsLTE [43]. We add a custom-built receive function for time synchronization with the legitimate cell. The subframes were crafted using the srsLTE library. Moreover, an USRP X310 [16] equipped with a UBX [15] daughter board and GPSDO [14] was employed, which was connected to an Intel Core i5-3570 machine with an Ubuntu 14.04. To overshadow the signal from a legitimate eNB, the USRP was augmented with ZVE-2W-272 amplifier [28], if needed. Victim UEs are commercial smartphones that camp on a legitimate LTE cell with a 20MHz bandwidth. In addition, the diagnostic monitor tools (e.g., SCAT and XCAL [8, 42]) were used for the analysis of the transmitted and received messages at the UE.

Figure 7 illustrates the two locations within a university office, where two sets of experiments were conducted, as follows: (LOS) The victim UE and the attacker were in the same room, separated by a distance of 2m. (NLOS) The victim UE and the attacker were in different rooms separated by a

wall and distance of 10m. These two environments were used for experiments throughout the study.

**Implementation details.** An attacker acquires the information of the target benign cell (PCI, MIB) using *pdsch\_ue* or diagnostic tools [8, 42]. She acquires time synchronization with the target cell (mimicking the procedure for a benign UE to camp on a cell by getting the PSS/SSS and MIB). After she obtains the arrival timing and SFN information of the LTE frame transmitted by the benign cell, she transmits the malicious message to the target SFN. Thereafter, she continuously receives the PSS/SSS (every 5ms) and MIB (every 10ms) transmitted by the benign cell and updates the synchronization information. Self-interference may cause synchronization problems, because Rx and Tx are in the same frequency. However, due to the precise overshadowing, the *SigOver* attack can minimize the effects on the legitimate PSS/SSS and MIB (there was no case of losing synchronization due to the self-interference).

As a minor issue, the USRP X310 generated an unintended high peak signal at the beginning and end of the signal when carrying out a burst transmission which *SigOver* attack does. This is due to the state change of the front-end components of the SDR. When there was no transmission, it was in the idle state. When transmission occurred, the transition to the transmitting state caused unwanted noise. We resolve this problem by simply padding zero to the front and back ends of the signal to separate the unwanted noise from the original signal, and by compensating the delay due to the zero padding during transmission.

**Ethical considerations.** As the attacker, we use a downward-facing dome-shaped antenna to minimize upward interference. In addition, we perform the experiments on the first basement level, which is the lowermost floor of the building. The basement floor was restricted during the experiments to prevent normal users from receiving the crafted signal. The experimental results with respect to the impact of the crafted signal revealed that the users upstairs and outside the building normally communicate with the legitimate base station without being affected by the signal. The signaling storm attack explained in Section 5.1.1 was run in a carrier’s shielded testbed network, since the attack may cause a DoS on an operational network.

## 4.2 Practicality

In this section, we evaluate the practicality and robustness of the *SigOver* attack in the LOS/NLOS environment. We use an LG G7 ThinQ smartphone with SnapDragon845, which is the latest Qualcomm LTE chipset. We inject a paging message with the S-TMSI<sup>4</sup> intentionally set as an invalid value of 0xAAAAAAAA, to differentiate the injected subframe from the legitimate subframes.

<sup>4</sup>S-TMSI is the shortened form of GUTI.

Table 2: Success rate of *SigOver* and FBS\* attack

Relative Power (dB)	1	3	5	7	9
<i>SigOver</i>	38%	98%	100%	100%	98%
Relative Power (dB)	25	30	35	40	45
FBS attack	0%	0%	80%	100%	100%

\* The FBS sets the same freq. band, PCI, MIB and SIB1 to the legitimate cell. If the victim UE camped on the FBS within 10s after it operates, the attack was considered a success. The FBS experiment was run 10 times for each power level. The *SigOver* experiment was performed with 100 paging messages for each power level.

Table 3: Success rate of *SigOver* attack in various conditions.

	LOS	NLOS
<i>RRC Connected</i>	97%	98%
<i>RRC Idle</i>	100%	98%

**Power cost.** The *SigOver* attack exploits the capture effect, where it injects a stronger signal to overshadow the legitimate signal, which is at a lower power level. Moreover, we inject 100 paging messages into a victim UE in the *RRC Idle* state, and measure the success rate of the attack depending on the relative power between the injected and legitimate signals in the LOS environment. Table 2 shows that the *SigOver* attack achieves the success rate of 98% at 3 dB.

**Attack robustness.** Table 3 summarizes the success rates of the *SigOver* attack for different combinations of experimental settings (LOS/NLOS) and RRC states (Idle/Connected). Each measurement was an average of 120 injected paging messages. In the *RRC Idle* state, we inject a paging message at the exact paging occasion (e.g., Subframe 9) and paging frame (e.g.,  $SFN \% 256 = 144$ ) of the victim UE. As discussed in Section 3.3, in the *RRC Idle* state, the channel estimation is carried out solely on the injected signal; whereas in the *RRC Connected* state, the average of the channel estimated from a set of the injected and legitimate signals is considered. In other words, in the *RRC Idle* state, injected signals are individually decoded without the impact of the legitimate signals; thus successful attacks (i.e., correct decoding) can be achieved with a single injection. However, in the *RRC Connected* state, repeated injection is required to overcome the influence of the legitimate signals. To achieve this, we inject a paging message at the exact paging occasion/frame of the victim UE. Simultaneously, we also inject a subframe with RS at every SFN, to reflect the channel of the injected signal and enable a successful attack. As shown in Table 3, the *SigOver* attack maintained a success rate greater than 97% in different RRC states and the LOS and NLOS setups, thus validating the robustness of the *SigOver* attack with respect to operating modes and environmental factors (e.g., multipath). Finally, during the experiments the victim UE neither reported any radio link failures nor initiated radio connection re-establishment (i.e., RRC Reestablishment request). This implies that the *SigOver* attack is non-disruptive to the victim UE and its service. Furthermore, we verify that the *SigOver* attack maintains 100% success rate for over 100 SIB 1 and SIB 2 messages in the *RRC Idle* state and LOS setup.

Table 4: Time tolerance of two smartphones.

Time ( $\mu\text{s}$ )	LG G7 (Qualcomm)	Galaxy S9 (Exynos)
Min.	-2.93	-2.60
Max.	9.77	8.46
Max. tolerance*	12.7	11.06

\* Note that the `SigOver` attack succeeds if  $d < \text{Max. tolerance}$ , regardless of the cell radius; where  $d$  is defined in Section 3.4

**Attack coverage.** As described in Section 3.4, a crafted subframe may arrive at victim UE with a slight timing offset due to the propagation delay of the injected signal from the attacker to the victim UE. The decoding of the crafted subframe requires the offset to be bounded within the tolerance range of the UE LTE chipset. Hence, the largest tolerable offset determines the maximum propagation delay; or equivalently, the maximum distance between the attacker and the UE (i.e., the attack coverage). The attack coverage was experimentally evaluated, wherein the propagation delay between the attacker and the UE was emulated by time-shifting the transmission timings of the crafted subframes. We gradually changed the shift in the unit of 10 samples ( $=0.33\mu\text{s}$  at 30.72Mps), until the crafted subframes were not decoded; which indicates the maximum delay tolerance. Table 4 presents the tolerance measured from two smartphones with different basebands – LG G7 (Qualcomm), and Galaxy S9 (Exynos). The tolerance offset was consistently higher than  $8.66\mu\text{s}$  across all the devices. With reference to the tolerance-distance relationship discussed in Section 3.4, the results indicate that the `SigOver` attack can cover the entire urban cell (typical radius of 1.5 km) at all times, irrespective of the relative positions of the UE and attacker.

## 5 Attack Scenarios and Implications

This section presents several attack scenarios using the `SigOver` attack, in addition to their practical implications. The `SigOver` attack can be used to exploit two broadcast messages; SIB and paging. All the attacks were run in the LOS setup presented in Section 4, with the exception of the signaling storm attack. To validate the proposed attacks on the various baseband chipset types, ten LTE capable smartphones were employed: one Intel (iPhone XS), six Qualcomm (Galaxy S4/S8/S9, LG G2/G6/G7), and three Exynos (Galaxy S6/S8/S9) chipset equipped smartphones.

### 5.1 Attacks Exploiting SIB

In this section, a discussion on two types of attacks via SIB injection, namely, signaling storm and selective DoS, is presented.

#### 5.1.1 Signaling Storm

**Attack mechanism.** When a UE moves to a new cell, the UE retrieves the Tracking Area Code (TAC<sup>5</sup>) contained in the SIB1 from the new cell and validates it using the TAI list in the

<sup>5</sup>TAC is the shortened form of TAI.

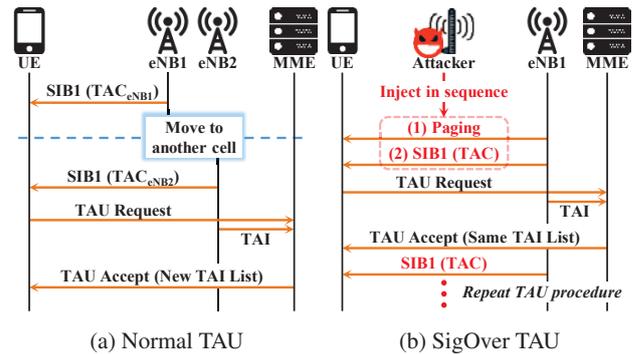

Figure 8: Normal and attack case for TAU procedures

UE. If the TAC is not included in the list of TACs on the UE, the UE initiates a TAU procedure to notify the LTE network of the updated TAC. The `SigOver` attack incurs the signaling storm by repeatedly triggering invalid TAU. Figure 8 illustrates the attack process when compared with the normal (i.e., without attack) operation. The attacker first overshadows a paging message with the `system_Info_Modification` field set as true, thus forcing the UEs to read SIB1. The SIB1 is then overshadowed using a spoofed TAC, thus leading to the TAU. It should be noted that the TAU request messages are directed to the legitimate eNB, because the `SigOver` attack preserves the radio connection between the victim and the legitimate eNB. Repeating this procedure results in the signaling storm on the LTE network. On the contrary, under normal circumstances, the TAU is performed only once each time the UE moves to another TA not included in the TAI list.

**Validation.** This attack was validated using a carrier’s testbed LTE network with nine LTE devices<sup>6</sup> registered to the testbed network. Each device was running the diagnostic monitor tools (e.g., SCAT, XCAL [8, 42]) for the analysis of the UE-side signaling messages throughout the attack. Figure 9 reveals that a single UE carries out an average of seven TAU procedures per second, which is unlikely under the normal conditions without the attack. Moreover, the UE-side signaling messages were analyzed to better understand the behavior of the network under the attack. When the victim UE carries out the TAU with the spoofed TAC (irrespective of the validity of the TAC value), the network returns the same list of TACs previously provided during the legitimate registration. This is because the serving cell is unchanged. That is, the list of TACs still does not include the victim UE’s spoofed TAC. Hence, the victim UE repetitively carries out the TAU upon receiving the SIB1 message from the attacker. Nokia reports [31] that a UE generates approximately 45 service requests<sup>7</sup> during a peak busy hour. However, the signaling storm via the `SigOver` attack induces a more significant network traffic, e.g., an attacker is able to trigger an average of 25,200 TAUs per UE per

<sup>6</sup>The iPhone was excluded because our monitoring tool does not support it

<sup>7</sup>UE sends a `Service request` during the connection initiation to the LTE network.

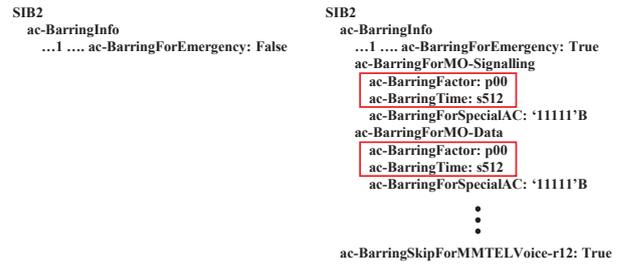

Figure 9: Wireshark snapshot of TAU Request messages generated by the SIB1 spoofing.

hour. Given that the number of signaling messages generated through the TAU and service request is similar, the attacker can generate more traffic than that generated during a peak hour by a factor of 560. This clearly demonstrates the significant impact of the signaling storm attack, which imposes a heavy signaling load on the network and causes severe battery drainage for the UE.

**Boosted impact of Qualcomm chipset.** A sustained signaling storm attack requires the attacker to continually inject SIB1 messages. However, the smartphones equipped with the Qualcomm baseband (e.g., Galaxy S4/S8/S9, LG G2/G6/G7) malfunctioned, thus generating TAUs indefinitely after a single SIB1 injection. In particular, the UE continued to perform the TAU procedure, even after the attacker stopped injecting SIB1<sup>8</sup>. The malfunctioning UE exhibits a normal behavior to the user, which indicates that the data/call service can be used without disrupting the user. Although the malfunction can be fixed by setting the UE in airplane mode, the user is unlikely to do so without noticing any problems. This indicates that the attack is sustained, even with the low-cost efforts to further strengthen its impact.

**Infeasibility of the FBS or Rogue UEs.** The signal storm attack seems to be achievable with an FBS. However, the injection of malicious SIB1 (containing the spoofed TAC) via the FBS does not lead to the signaling storm attack. This is because under the FBS, the TAU request from the victim UE is directed to the FBS, instead of the legitimate LTE network. In other words, the signals do not reach the LTE network; thus, the signaling storm attack is inherently unachievable for the FBS. Moreover, exploiting a number of rogue UEs may induce the signaling storm on the network. However, this approach is limited with respect to its scalability, wherein it requires multiple radio devices and SIM-cards for each device, to induce the same effect as the SigOver attack. On

<sup>8</sup>The root cause of this malfunctioning is the implementation logic of the Qualcomm LTE chipset, which did not read the SIB1 after completing the TAU. As a result, they could not recognize the legitimate SIB1 that contained correct TAC, and the TAU was carried out until the legitimate SIB1 was re-read.

(a) Original SIB2 (b) Malicious SIB2

Figure 10: Access control feature in SIB2 message

the other hands, the SigOver attack uses a single radio device that covers an entire cell and forces several authentic users camping on the cell to initiate the TAU procedure.

### 5.1.2 Selective DoS through Access Barring

**Attack mechanism.** The cellular network has control over the number of UEs that can access the network. This feature is to manage the amount of traffic and maintain the stability of the network under specific conditions, e.g., a disaster. The control is realized using the *BarringFactor* parameter in SIB2, which is exploited by the SigOver attack to block the victim UE. By setting *BarringFactor* as 0 (via overshadowing), an attacker can restrict all data traffic and signaling from the UE (i.e., mobile originating)<sup>9</sup>, which leads to DoS.

Figure 10 presents the configuration of the malicious SIB2 in the crafted subframe in comparison with the original SIB2 in a legitimate subframe. To maximize the impact of the attack, the SigOver attack sets the *BarringTime* to 512s, which is the maximum value as per the standard. Note that *BarringTime* can be refreshed if the attacker repeats the attack within the remaining *BarringTime*; thus, a persistent DoS can be achieved. To properly inject the crafted subframe (similarly to the signaling storm), the attacker first overshadows a paging message with *system\_Info\_Modification*. Thereafter, she overhears the legitimate SIB1 to extract the SFN, from which the attacker can obtain the schedule of the next SIB2 for overshadowing. A potential extension of this attack is service-specific DoS to *selectively* block only the targeted services (e.g., voice call, video conference, and SMS). This leverages a new service-specific barring feature introduced in 3GPP specifications [7].

**Validation.** This attack was validated using 10 different smartphone models. Upon the successful SigOver attack (i.e., injected paging and SIB2 are received); entire data services, which include web browsing and video streaming were blocked on all 10 devices. From the analysis of the device logs, it was found that all the devices failed to initiate any connection when applications made multiple connection requests. This confirms the feasibility of the barring via the SigOver attack. Moreover, the service-specific DoS was validated using

<sup>9</sup>The attacker can also block the mobile terminating traffic by overshadowing the paging channel of the victim UE.

the Samsung Galaxy S9 based on the Exynos chipset.

**Comparison with the FBS.** An FBS can also inject malicious SIB2. However, the attack is only valid when the FBS is turned on, and immediately stops when the FBS is turned off. This is because the victim UE connects to the legitimate cell shortly after disconnection from the FBS. During the connection to the legitimate cell, the victim UE reads the legitimate SIB2, which recovers UE services. Conversely, the services of the victim UE remain blocked after SigOver attack stops, as this does not incur cell reselection. Furthermore, the FBS cannot achieve the service-selective DoS, as it cannot provide the LTE service.

## 5.2 Attacks Exploiting Paging

In this section, we present three attacks through the SigOver attack on the paging message: DoS attack, network downgrading, and location tracking.

### 5.2.1 DoS Attack by Overshadowing Paging with IMSI

**Attack mechanism.** When the GUTI of the UE is unavailable, the network sends paging message with IMSI as an identifier of UE. As defined in the 3GPP standards, upon receiving the paging that contains the IMSI, the UE terminates all service sessions and initiates the registration procedure using the IMSI as the identifier [5]. This implies that the DoS attack can be realized by injecting the paging message with IMSI<sup>10</sup>. Specifically, the attacker injects a paging message that contains the IMSI of the victim UE at the paging occasion/frame of the victim UE. This attack detaches a UE from the cellular network services, which include voice call and data services, thus indicating a DoS at the UE. As the registration procedure (which follows the service termination) automatically recovers the services, the attack is sustained by the repeated injection of the paging message.

**Validation.** This attack was validated using 10 different smartphone models in two different operation states (*RRC Idle* and *RRC Connected*). Specifically, in the *RRC Idle* state, we confirmed that the UEs successfully received the overshadowed paging message. Furthermore, the internal logs in the UEs confirmed the expected impact of the attack, i.e., detachment from the network followed by the registration procedure, thus leading to DoS.

For following experiment, we launched the attack on the UE in the *RRC Connected* state. Note that the SigOver attack enables the attacker to convey the crafted message to the UE on the existing radio connection between the UE and the eNB. We first make a voice call on the victim UE to force the UE to enter the *RRC Connected* state. We then transmitted the paging message with IMSI to the UE. Interestingly, we observed that not all UEs handled the paging messages in the *RRC Connected* state. In particular, the Samsung Galaxy S8/S9, LG

G6/G7 (Qualcomm), Samsung Galaxy S8/S9 (Exynos), and Apple iPhone XS (Intel) properly handled the paging message with IMSI, after which the call was immediately aborted (service termination). Meanwhile, the Samsung Galaxy S6 (Exynos), and Galaxy S4, LG G2 (Qualcomm) did not respond to the attack in the *RRC Connected* state.

The inconsistencies between the devices stem from the ambiguity of the 3GPP standards. The mechanism used to handle paging in the *RRC Connected* state is loosely defined, without specific direction on paging with IMSI, e.g., only information on paging with the system information notification or CMAS/ETWS [3] is provided. In summary, by injecting the paging message with IMSI, the SigOver attack can realize a DoS on the victim UE in *RRC Idle* and *RRC Connected* states, depending on the device.

**Comparison with the FBS.** This attack scenario was extensively discussed in the previous work [21, 35] leveraging the FBS. Although the impact and the attack vectors are equivalent, the applicability of the existing attacks is limited when compared with the SigOver attack. This is because the SigOver attack uniquely enables the attacker to deliver the paging message to the UE which has an active radio connection with the network, whereas other works are only applicable to UEs that use no services; thus indicating the wider applicability of the SigOver attack.

### 5.2.2 Network Downgrading Attack via CS Paging

**Attack mechanism.** In this attack, an attacker injects a paging message with a Circuit Switched (CS) notification (with the S-TMSI of the victim UE) to intentionally downgrade victim UEs to the 3G network. Upon the reception of the CS paging, the UE initiates the Circuit Switched Fall-Back process and transits to the 3G network. That is, the SigOver attack enables the attacker to force the UE to a slower connection.

**Validation.** We experimentally confirmed that the victim UE in the *RRC Idle* state immediately switched to the 3G network when the attacker's CS paging was received, after which it soon reverted back to the LTE network because there was no actual service in the 3G network. The attack was effective for the state-of-the-art smartphones, e.g., the Samsung Galaxy S8/S9, LG G6/G7 (Qualcomm), and Samsung Galaxy S8/S9 (Exynos), as they were able to respond the CS paging message the both *RRC Idle* and *RRC Connected* states. However, similar to the paging attack with IMSI, some smartphones did not respond to the CS paging in the *RRC Connected* state, and were therefore immune to the attack. Interestingly, when the Samsung Galaxy S8 (Qualcomm) dropped to the 3G network due to the attack, the LTE connection was never restored while using data service.

**Comparison with the existing attack.** Tu *et al.* demonstrated the throughput degradation attack against a victim UE by invoking the CS paging, which is similar to our attack [47]. However, in this study, the network was driven to send the paging message on behalf of the attacker, by establishing a

<sup>10</sup>Acquiring IMSI is extensively discussed in the previous work [11, 44]

call with the UE in the 3G network. It should be noted that, in the `SigOver` attack, the paging message is directly transmitted by the attacker. This attack inherently exposes the attacker's phone number, thus making the attack easily detectable by the operator. In comparison, the `SigOver` attack silently transmits the CS paging to the victim UE. Furthermore, the existing work cannot downgrade the victim UEs in the `RRC Connected` state to the 3G network, since the network does not send a paging message to the victim UE in the `RRC Connected` state; whereas the `SigOver` attack can deliver the paging message.

### 5.2.3 Coarse-grained Tracking of a UE

**Attack mechanism.** As explained in Section 2, following the completion of the RA procedure, the UE attempts to establish an RRC connection by sending a `Connection request` (containing UE identity) to the cell. If the UE holds the previously assigned temporary identity (i.e., S-TMSI), this identity is included in the `Connection request` as well. Otherwise, a random value is selected. Upon the receipt of the UE's request, the cell replies with the `Connection setup` that contains the UE's identity (the S-TMSI or the random value). By checking this identity, each UE is able to recognize if its RA procedure was successful. If the procedure fails, the UE retries the RA procedure. The abovementioned procedure used to resolve connection conflicts is referred to as a *contention resolution*.

In this attack, an attacker exploits the contention resolution technique to perform coarse-grained location tracking of the target victim. First, the attacker with the knowledge of the S-TMSI of the victim UE injects a paging message with the S-TMSI<sup>11</sup>. The attacker then eavesdrops on the `Connection setup` messages transmitted from the legitimate cell<sup>12</sup>. When the `Connection setup` message that contains the S-TMSI of the victim UE is received, the attacker confirms that the victim UE resides within the coverage of the cell by sniffing the downlink messages.

**Validation.** We validated this attack using all the smartphone models in this work. We confirmed that the attacker is able to identify the presence of the victim UE by injecting a single paging message and eavesdropping on the `Connection setup` message sent to the victim UE.

**Comparison with the FBS.** An FBS can achieve the same results by monitoring the IMSI in `Identity Response` message. However, the FBS requires an active connection to the target victim to transmit the message. Therefore, the attack is limited by the FBS with respect to its stealthiness and power efficiency. In a previous study, it was reported that RNTI-TMSI mapping can be applied to passively monitor the victim's TMSI [37]; however, the `SigOver` attack provides an active method by which the victim can be located.

<sup>11</sup>Due to the space limit, a detailed discussion on how an attacker acquires the S-TMSI of the target UE was omitted. However, this has been extensively investigated in previous studies [19, 22, 23, 37].

<sup>12</sup>Since the RRC connection procedure is not encrypted, the attacker can eavesdrop on any downlink messages during the connection procedure of the UEs.

## 6 Defending Against SigOver Attack

In this section, we present an outline of two possible defense strategies against the `SigOver` attack. We start the feasibility of the fundamental solution as a prevention measure, in which all the broadcast signals were digitally signed by adopting the Public Key Infrastructure (PKI). We then discuss a short-term solution for the detecting `SigOver` attack, which leverages the changing nature of the physical signal during the processing of the overshadowing signal.

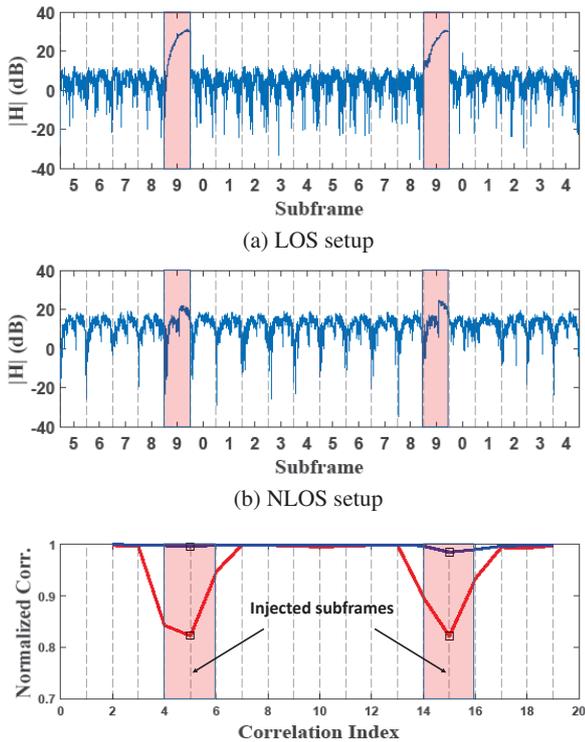

### 6.1 Digitally Signing Broadcast Messages

As the `SigOver` attack exploits the lack of integrity protection in broadcast messages, one natural defense against `SigOver` attack is to employ integrity protection in the messages using a digital signature scheme. For this, each base station needs to have a certificate issued by its operator and a UE needs to be provisioned with a root certificate (e.g., self-signed one by the operator) to verify the certificate of the base station. However, this natural defense has at least several deployment and technical challenges.

**Deployment challenges:** In 5G, the 3GPP introduced a public key encryption for IMSI in the initial registration, to provide privacy protection for the permanent identifier. For this, each UE is provisioned with its home operator public key, thereby it was assumed that a public key provisioning mechanism to the UE is in place. This provisioning mechanism could also be used to provision a public key (or a signing certificate) for base station certificate verification. However, in roaming scenarios, the UE need to acquire the public key of the visited network operator, which is trusted by the home operator. This essentially requires a PKI for the global cellular networks that span the world and non-trivial trust relationships among multiple operators in different jurisdictions. Furthermore, managing certificate revocation lists are another obvious burden.

**Technical challenges:** Signing every single broadcast message may incur a substantial computational overhead at the base station, considering the low periodicity of essential broadcast messages such as MIB (40ms) and SIB1/2 (80ms). Furthermore, message size increases due to the signature and certificate broadcasting (e.g., using a new SIB) would result in a higher power consumption at the base station. Similarly, from UE's perspective, verifying certificate and signature would require additional power consumption, resulting in a faster battery drain. Such a power consumption may be prohibitive to low-power Internet of Things devices that need to survive many years without battery replacements.

**An ID-Based Signature scheme (IBS)** [9, 41] can be considered as a cost-effective alternative, as it has substantially low key management overhead and eliminates the certificate broadcast and verification overhead. However, the IBS requires UEs to get synchronized with the public parameters from KMS [17]. This is problematic to UEs that do not have a

(c) Normalized cross-correlation on LOS (Red line) and NLOS (Blue line)

Figure 11: Fluctuation of the channel estimation magnitude after the SigOver attack: Sudden magnitude changes could be used for detection metric.

subscription as they may not be able to get the public parameters from the network. Note that the unsubscribed devices are also supposed to receive the ETWS or CMAS messages as long as they have cellular capabilities.

## 6.2 Leveraging the Channel Diversity

According to communication theory, a wireless channel varies significantly with a displacement of only a quarter of the wavelength, which is 3.57cm for 2.1GHz LTE [46]. This is referred to as the channel diversity, and it is highly applicable to the attacker and victim UE, which are expected to be at different locations – i.e., the wireless channel between the attacker and UE is likely to be disparate from that between the eNB and UE. Therefore, the injection of the attack signal, which reflects the channel between the attacker and UE, naturally forces the channel information recovered at the UE to deviate from when only the legitimate subframes are present (without attack). In other words, the detection of such a variance in the channel could serve as a defense technique.

The wireless channel can be conventionally represented as  $H$  [46] in complex representation. The magnitude  $|H|$  uniquely defines different wireless channels depending on how efficiently the signal power is delivered. Hence, an abrupt change in  $|H|$  is an effective metric to detect SigOver attack.

Figure 11a presents  $|H|$  of the injected (Subframe 9) and legitimate signals measured during the experiment in LOS setup, where the attacker is located 2m away from the victim UE. This clearly demonstrates the severe fluctuation of  $|H|$  when the attack occurs, indicating effortless detection.

Despite its effectiveness, the robustness of leveraging the channel is problematic. In particular, the general application of the technique to various scenarios is not trivial, due to the various factors that have a potential influence on  $H$ . Figure 11b shows a detection failure example in NLOS setup, when the power of the injected signal was low. That is, the impact of the attack signal to  $H$  gradually fades out as the energy decreases, down to the point where it is difficult to detect. Figure 11c clearly demonstrates this challenge, wherein the drop in the correlation was fuzzy in NLOS setup, unlike in the LOS setup (strong injection signal). In summary, leveraging the channel is a potential solution, where we leave the design of robust techniques as future work.

## 6.3 Discussion on Potential Solutions

Both approaches discussed in the previous sections present challenges to be addressed and/or limitations. However, we note that the exploits demonstrated in Section 5 are only a few examples rather than an exhaustive list. The effects of the SigOver attack would be broader and more damaging if the cellular network is utilized for critical domains, e.g., vehicular networks and industrial systems. Therefore, in principle, the intrinsic broadcast vulnerabilities of the cellular system should be addressed. Meanwhile, it is recommended that critical services should have their own security protection instead of relying on those of other protocol layers. For example, the issue of the ETWS or CMAS may be better addressed at the application level<sup>13</sup>, instead of being based on SIB protection, since the SIB is only a transport mechanism for those critical application messages.

## 7 Related Work

In this section, we describe previous work that exploits the signal overshadowing concept. We then present the signaling storm, in addition to attacks that exploit the non-integrity protection.

**Signal overshadowing in wireless channel.** The signal overshadowing attack, which exploits the use of an open medium and the capture effect, has been widely conducted in the wireless systems such as GPS [20, 45] and Low-Rate Wireless Personal Area Networks (LR-WPANs) [52]. Pöpper *et al.* presented a symbol flipping attack on the Additive White Gaussian Noise (AWGN) channel [34], with a fine-grained overshadowing of the signal at the symbol level. However, it requires exact information with respect to the timing, amplitude, and phase, which is difficult to achieve in the real

<sup>13</sup>The 3GPP already conducted a study on the security aspects of Public Warning System (PWS) [4].

world. Similar to this study, Wilhelm et al. demonstrated the possibility of signal overshadowing and its impact on IEEE 802.15.4 [52]. In comparison, the SigOver attack is the first comprehensive study in which the signal overshadowing attack on the LTE was realized, in addition to the validation of its practicability. Moreover, we present the novel attack scenarios by leveraging the SigOver attack.

**Message manipulation in LTE.** The LTEInspector [21] conducted a paging channel hijacking attack and paging message injection attack, which seems similar to this study. However, this study has two key differences: 1) the definition of the injection attack and 2) its realization method. First, the SigOver attack silently injects the victim with malicious messages while making the victim keep being synchronized with the legitimated eNB. As a result, during the SigOver attack, the uplink response message of the victim naturally goes to the legitimated eNB. However, the victim UE in LTEInspector transmitted its uplink response message to the malicious eNB after receiving the manipulated message, which is the general response action for the attack with the FBS. Thus, it is more similar to existing attacks using FBS. Second, the SigOver attack overwrites the target signal with malicious signals without requiring a connection to the malicious base station. To this end, we investigate various requirements of the SigOver attack as described in Section 3. Despite other requirements, LTEInspector only considered the paging cycle and its occasion, which are the part of timing synchronization requirements.

**Attacks exploiting non-integrity protection.** Extensive research has been conducted on the manipulation of messages with no/weak-integrity protection [21, 22, 26, 36, 39, 40]. As discussed in Section 3.5, such attacks mainly leverage an FBS. Although they exploited the broadcast messages in LTE, but the attacks have limited implications. This is because their operational logic inevitably produces limitations with respect to stealthiness, power efficiency, and attack sustainability.

## 8 Concluding Remarks and Future Work

Signal overshadowing is an intuitive method for the manipulation of LTE broadcast messages with no integrity protection, which was not addressed in previous studies. In this paper, we present the SigOver attack, which outlines the first realization of a signal overshadowing attack on the LTE network. We implement the SigOver attack using a low-cost SDR and open source LTE library, while resolving the challenges in satisfying the stringent transmission requirements and crafting a malicious frame. The feasibility and effectiveness of SigOver attack was demonstrated in five novel attacks, and an extensive analysis of the relative advantages of the SigOver attack over those of the FBS and MitM attacks was carried out. The key features of the SigOver attack are stealthiness, power-efficiency, and sustainability, which have not been achieved simultaneously by previous attacks. The evaluation revealed that the SigOver attack achieves a 98% success rate with low

power cost.

Finally, two potential approaches to defending against the SigOver attack were proposed, which leveraged the digital signature and channel diversity. As acknowledged, both approaches have challenges and limitations to be addressed; however, they can be used as a basis for the development of a reliable and robust solution.

The cellular industry is rapidly transitioning to the 5G network of cellular systems equipped with advanced radio technologies and enhanced security features. However, the fundamental broadcast security issues discussed in this paper have not addressed in design. Considering significant changes made in the 5G New Radio (NR), it is left as a future study to evaluate 5G NR against the SigOver attack. As this paper turns on the spotlight on the security of broadcast messages, we believe that 3GPP standard body and cellular network community need to consider the design of broadcast messages seriously.

## Acknowledgments

We sincerely thank Dr. Soo Bum Lee for his detailed and valuable comments on the earlier version of the draft. In addition, we would like to thank the anonymous reviewers for their insightful comments. This work was supported by Institute for Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) (2018-0-00831, A Study on Physical Layer Security for Heterogeneous Wireless Network).

## Appendix

### A Impact on Quality of Services

We measure the impact of the quality of services under the SigOver attack, where the malicious paging messages are transmitted at the every subframe 9. This implies that legitimate subframes at subframe 9 are overshadowed and lost, whereas non-overshadowed legitimate subframes may also be affected by crafted subframes. Specifically, the RS of the crafted subframes perturbs the channel estimation averaged among crafted and non-overshadowed legitimate subframes (in *RRC Connected* state), which may disturb the equalization and incur errors. Despite such factors, the impact of SigOver attack is validated to kept minimal, as demonstrated in this section under a range of common, but distinct services of voice call, web surfing, FTP download, and live streaming. We note that measurements were carried out under a reliable SigOver attack (>97% success rate) for the UE in the *RRC Connected* state.

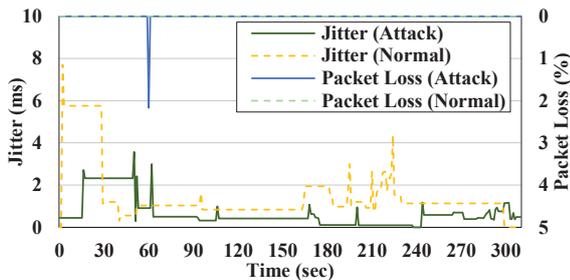

Figure 12: Call jitter and packet loss

**Voice call.** The UEs camping on LTE network use Voice over LTE (VoLTE) as a call service. We evaluate the impact of the SigOver attack on the key factors with respect to the VoLTE performance [13]; or equivalently, the call quality, e.g., data rate, jitter, and packet loss. Such metrics were measured before and after the attack for comparison. The data rate was kept stable after the attack, and omitted for brevity. Figure 12 illustrates the jitter and the packet loss. The jitter was consistently less than 10ms, and the packet loss is mostly kept as zero. Moreover, both were sufficient to support high quality call services [24]. This keeps the SigOver attack stealthy without degrading user experience.

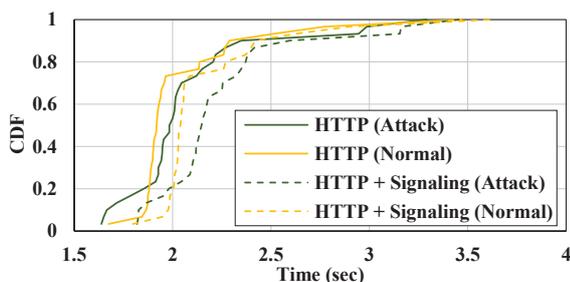

Figure 13: Webpage loading time

**Web-browsing.** We extend the measurements to web browsing, which is one of the most frequently used services. Specifically, the time required to load multiple identical web pages with and without the attack. Figure 13 presents the results, with ‘HTTP’ representing the total duration of HTTP data exchange for page loading. ‘Signaling’ is the time required for RRC connection establishment. Under the SigOver attack, the time from the RRC connection initiation to the web page downloading is delayed by an average of only 80ms when compared with the case without the attack. Previous studies [12] have shown that the impact of such lag on the quality of the experience is negligible.

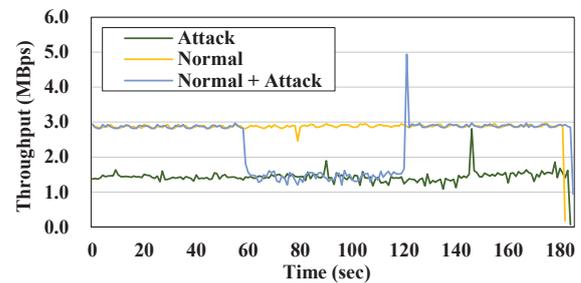

Figure 14: FTP throughput

**FTP downloading.** Figure 14 reveals that the FTP exhibited a significantly different performance under the SigOver attack. This is due to dynamically controlled modulation, to overcome the bit error in the communication. The SigOver attack incurs bit errors, which force the UE to use a robust modulation of QPSK, which has a limited throughput. Conversely, without the attack, the bit error is kept low. In this case, the UE used 64QAM which is less robust but supports higher throughput than QPSK. However, this impact is less likely to be experienced by the users and FTP rarely used on smartphones.

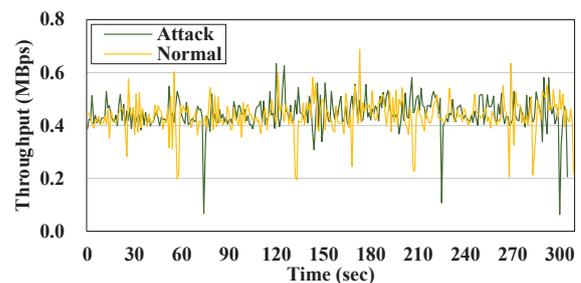

Figure 15: YouTube Live throughput: The average was 0.445 and 0.436Mbps for attack and normal case, respectively.

**Live streaming.** Figure 15 shows the throughput of the YouTube live streaming at a resolution of 1080p. In summary, neither buffering nor interruption occurred under the SigOver attack during a 5-min video clip. The result of the live streaming differs from that of the FTP downloads, as streaming throughput was not as high as that of the FTP.

## Abstract

Mobile autonomous systems, robots, and cyber-physical systems rely on accurate positioning information. To conduct distance-measurement, two devices exchange signals and, knowing these signals propagate at the speed of light, the time of arrival is used for distance estimations. Existing distance-measurement techniques are incapable of protecting against adversarial distance enlargement—a highly devastating tactic in which the adversary reissues a delayed version of the signals transmitted between devices, after distorting the authentic signal to prevent the receiver from identifying it. The adversary need not break crypto, nor compromise any upper-layer security protocols for mounting this attack. No known solution currently exists to protect against distance enlargement. We present *Ultra-Wideband Enlargement Detection* (UWB-ED), a new modulation technique to detect distance enlargement attacks, and securely verify distances between two mutually trusted devices. We analyze UWB-ED under an adversary that injects signals to block/modify authentic signals. We show how UWB-ED is a good candidate for 802.15.4z Low Rate Pulse and the 5G standard.

## 1 Introduction

Ranging and positioning information is often necessary for mobile autonomous systems, robots and cyber-physical systems to operate successfully. These systems are used in security and safety critical applications. Drones are becoming more popular for transportation and rescue [24], and autonomous systems are being increasingly tested and integrated as part of the ecosystem. The 5G community emphasizes the importance of designing the wireless protocols for the safety of the autonomous vehicles [33]. A stringent requirement for these systems is to avoid crashing into, *e.g.*, buildings, pedestrians, properties, or each other [25]. For example, keeping drones and autonomous vehicles on their intended paths

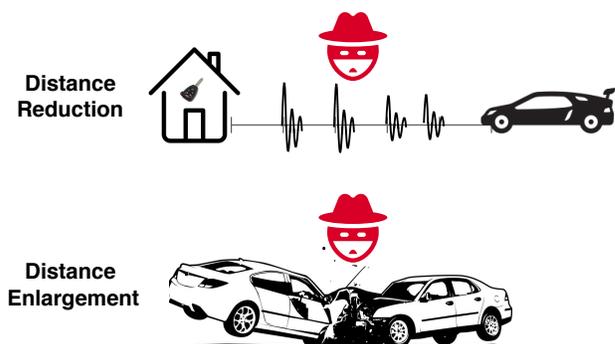

Figure 1: Ranging systems are vulnerable to distance reduction and enlargement attacks.

and preventing their collision can be achieved only if they are able to calculate their relative positions accurately and securely. Figure 1 shows that an adversary can manipulate the perceived distance between two mutually trusted devices by the distance reduction and enlargement attacks.

Conventional ranging systems, such as GPS and WiFi Positioning Systems (WPS) [34], are useful for benign environments and coarse-granular geolocation. However, they provide insufficient precision for accurate distance estimations (*e.g.*, *cm*-level granularity), suffer availability constraints (*e.g.*, indoors, outdoors), and are relatively slow to calculate locations for fast and mobile autonomous systems. More importantly, the aforementioned ranging systems are susceptible to various spoofing attacks [4, 14, 28].

Two-way time-of-flight (ToF)-based ranging systems (which map ToF to distance as signals propagate at the speed of light) have the potential to conduct accurate, fast, and secure distance measurements. Examples include high precision Ultra-wide Band (UWB) ranging systems, some of which are now available off-the-shelf [1, 9, 13, 35]. Numerous previous efforts were directed towards protecting these systems from distance-reduction attacks, *e.g.*, for access control. These mainly rely on the principle that propagation speeds

Version: February 18, 2019.

are bounded by the physical characteristics of the media, and cannot be sped-up. For example, distance bounding protocols return an upper bound on the measured distance, armed by the fact that an adversary would not succeed in guessing (secret) bit level information [5, 6]. Other techniques are based on tailoring modulations to prevent distance-reduction attacks at the physical layer [26]. None of these approaches prevent distance enlargement attacks.

Distance enlargement attacks can deviate vehicles from their intended paths, or cause physical collisions. Existing protection approaches rely on dense, and often fixed, verification infrastructures, *e.g.*, towers. These may not exist, and often do not; installing them in outdoor settings is a costly affair, and not necessarily feasible (*e.g.*, in drone-based military missions behind enemy lines). Distance enlargement is a more devastating attack than distance shortening because an adversary in the communication range only needs to annihilate (cancel) [23] or distort the authentic signals to prevent the receiver from identifying them and using their time-of-arrival (ToA) for ranging. The adversary then simply replays a delayed version of the authentic signals, which it has already received by positioning itself in the vicinity of the sender or the receiver. The adversary need not guess these signals, nor compromise any upper-layer protocols to do that. The amount of delay corresponds to the adversary-intended distance to enlarge. In a collision-avoidance system of automobiles or self-driving cars for example, a few meters ( $\sim$  a few nanoseconds) could be catastrophic.

We present *Ultra-Wideband Enlargement Detection* (UWB-ED)—the first known modulation technique to detect distance enlargement attacks against UWB ranging based on ToF. UWB-ED relies on the interleaving of pulses of different phases and empty pulse slots (*i.e.*, on-off keying). Unable to perfectly guess the phase, this leaves the adversary with a 50% chance of annihilating pulses (similarly for amplification). As a result, some of the affected (authentic) pulses will be amplified, while others will be annihilated. Unaffected pulses will remain intact, while positions that originally had no pulses may now have adversary-injected ones. The technique presented herein gets the receiver to seek evidence indicating whether such a deformed trail of pulses in the transmission was indeed authentic, albeit corrupt.

Similar to Singh *et al.* [26] (which addresses distance-reduction attacks), we leverage a randomized permutation of pulses. However, unlike [26], we cannot simply look for whether these are out of order, and ignore them if so because that is precisely the adversary’s objective in distance-enlargement: misleading the receiver to ignore the authentic signals. Instead, UWB-ED checks the *energy distribution* of pulses: comparing the aggregate energies of a subset of pulses at the positions where high energy was expected (as per the sender-receiver secret pulse-permutation agreement), with others where low energy was expected. To subvert this, the adversary would be forced to inject excessive energy throughout

the whole transmission, which could then be detected using standard DoS/jamming-detection techniques.

We derive the probability that an adversary succeeds in a distance-enlargement attack against UWB-ED. This is also useful in setting input parameters, *e.g.*, balancing an application’s security requirements and ranging rate, while accounting for channel conditions. For example, we show how proper parameterization of UWB-ED limits an adversary’s success probability in enlarging distances to  $< 0.16 \times 10^{-3}$ .

In summary, the paper’s contributions are twofold.

- UWB-ED—a novel, readily-deployable modulation technique for detecting distance enlargement attacks against UWB ToF ranging systems, requiring absolutely no verification infrastructure, and making no impractical assumptions limiting adversarial capabilities.
- Analytical evaluation to UWB-ED, where the probability of adversarial success is derived as a function of input parameters and channel conditions. This evaluation is also validated using simulations.

The sequel is organized as follows. Sections 2 and 3 provide background and detail the threat model. The new distance enlargement detection technique is explained in Section 4, and evaluated in 5. Section 6 complements with a related discussion, and 7 is related work. Section 8 concludes.

## 2 Background and Motivation

A device’s position can be estimated using the distances between itself and other landmarks with known locations; or it could be expressed using a coordinate system, *e.g.*, in a Cartesian plane. The distance between two devices can be measured using radio signal properties, such as received signal strength [3], phase [30], or the signal’s propagation time including ToF and ToA [15]. Reduction or enlargement of the calculated distances can lead to wrong positioning.

Adversarial distance reduction has been analyzed in previous literature [31], but limited work was performed on enlargement attacks. Preventing enlargement is achieved when a node is inside a polygon determined by an infrastructure of devices/towers, where verifiable multilateration [31] is applied. Enlargement attacks are harder to detect without an infrastructure. Signal strength-based systems do not provide strong security guarantees during high variations of signal strengths in some channel conditions. For distance reduction attacks, the adversary can amplify a degraded signal but for enlargement, degradation is in the adversary’s favor.

One-way ToF systems, such as GPS, can be spoofed to reduce/enlarge distances [4, 14]. Two-way ToF, such as UWB, provides secure upper bound by using distance bounding along with secure modulation techniques [5, 6, 26]. This provides strong guarantees against reduction attacks, but is still susceptible to enlargement attacks.

## 2.1 UWB

IEEE 802.15.4a and IEEE 802.15.4f have standardized impulse radio UWB as the most prominent technique for precision ranging. IEEE 802.15.4z [2] is in the process of standardizing UWB to prevent attacks on the ranging systems. Off-the-shelf UWB ranging systems were recently developed [1, 9, 13, 35], and the research community/industry has expressed tremendous interest in these systems (*e.g.*, for autonomous vehicles). Because current standards do not prevent enlargement attacks, it is important to mitigate them before standards are deployed in practice.

**Symbol Structure.** UWB systems operate over wide segments of licensed spectrum. They have to be compliant with stringent regulatory constraints. Firstly, the power spectral density should not exceed  $-41.3\text{dBm/MHz}$ , averaged over a time interval of 1ms. Secondly, the power measured in a 50MHz-bandwidth around the peak frequency is limited to 0dBm. Due to these constraints, the power per pulse is limited. To support longer distances, the energy of multiple pulses is aggregated to construct meaningful information. Figure 3 shows On-Off-keying (OOK) modulation, as used in IEEE 802.15.4f-based UWB ranging systems. Each symbol has two pulses and two empty slots. The symbol length is represented as  $T_b$  and the spacing between consecutive pulses is  $T_s$ . Information bits are encoded in the position of the pulse.

**Symbol Detection.** Figure 2 shows a conventional non-coherent energy detector (ED) receiver [32]. The energy detector receiver consists of a square-law device to compute instantaneous received signal power and an energy integrator. For the received signal  $r(t)$ , the output of the receiver can be expressed as:

$$E(k) = \int_{T_s * k}^{T_s * k + T_l} [r(t)]^2 dt \quad (1)$$

where  $T_s * k$  is the integration start time,  $T_l$  the integration window size, and  $T_s$  the spacing between consecutive pulses.

These receivers perform squaring and integration, making phase information irrelevant for pulse detection. In the case of multi-pulse per symbol, the energies of multiple pulses are aggregated. For the orthogonal hypothesis tests  $H_1$  and  $H_0$  for bit 1 and 0 respectively, the decision of the ED receiver is made in favor of the positions with higher energy.

$$b(i) = \begin{cases} 0 & E_{H_0}(i) \geq E_{H_1}(i) \\ 1 & E_{H_0}(i) < E_{H_1}(i) \end{cases} \quad (2)$$

## 2.2 Distance-Enlargement Attack

In contrast to reduction attacks, to enlarge the distance, the adversary need not predict the authentic signal. Instead, it replays the authentic signal by replaying an amplified version of

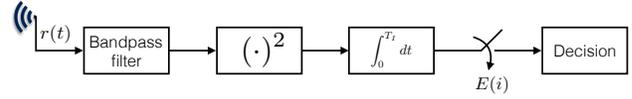

Figure 2: Non-coherent energy detector receiver.

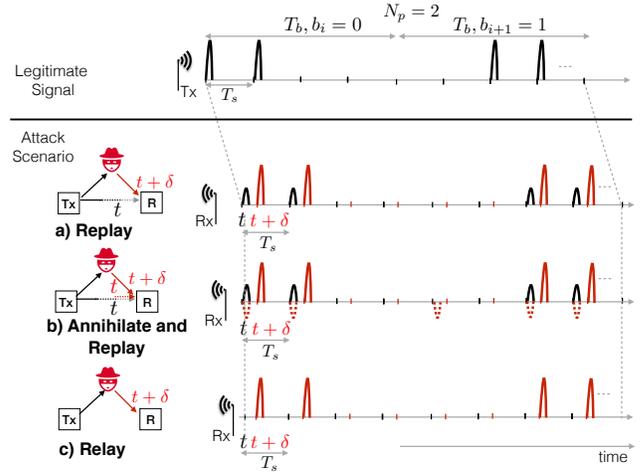

Figure 3: Various attack scenarios on UWB. Black and red colors represent authentic and adversary signals respectively. Dotted red represent adversarial signal-annihilation attempts.

it after some delay. The receiver gets both, authentic and adversary's signal superimposed. Because these authentic signals also reach the receiver, the adversary cannot control how the receiver processes them. None of the existing ranging systems is secure against enlargement attack- be it UWB -802.15.4z, WiFi- 802.11, or GPS. Signal replay is a typical strategy to mount distance enlargement attacks. Other enlargement attacks, such as jamming, alters the output of the receiver's automatic gain control (AGC), and are likely to expose the adversary [22, 27]. Complementing signal replay by signal annihilation prevents the receiver from detecting the authentic signal. Annihilation is possible due to the predictable symbol structure.

In Fig. 3, the devices know each other's communication range, and could verify that they are within that range, *e.g.*, using secure ranging (see Fig. 4). For short LoS distances, a symbol length of  $N_p = 1$  (*i.e.*, one pulse-per-symbol) could suffice. Longer distances are attained by longer symbols ( $N_p = 2$  in Fig. 3). Pulses are separated by time  $T_s$ , which should be more than the channel's delay spread. The length of the symbol ( $T_b$ ) is determined by the number of pulses per symbol, and the interval between two consecutive pulses ( $N_p \cdot T_s$ ). Figure 3 also shows instances of replay attacks on these symbols. When an adversary replays authentic signals after some delay ( $\delta$ ), both authentic and replayed signals are received. To deceive the receiver, the adversary needs to annihilate authentic signals.

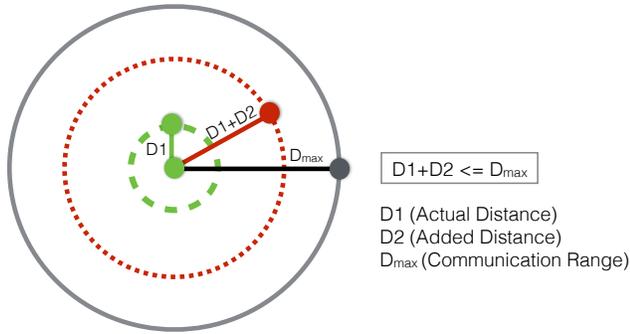

Figure 4: If  $D1 + D2 > D_{max}$ , the devices realize they are outside each other’s communication range without the need to run distance-enlargement detection protocol.

In Fig. 3a, an authentic signal reaches the receiver at time  $t$ , and the adversary’s signal at  $t + \delta$ . If the receiver backtracks in time (searching for earlier-received signals), the authentic signal will be encountered. Figure 3b shows how the predictability of the symbol structure enables an adversary to annihilate its pulses (by emitting a reciprocal pulse phase), preventing the receiver from detecting it. Figure 3c shows the case when nodes are not in the communication range (or signal is attenuated by channel condition); the receiver does not get authentic signals, just adversary-relayed (and delayed) signals.

### 3 Threat Model

We focus on the scenario where there are two devices in a wireless network that are interested to securely measure the physical distance between them, and protect the measurements from a third-party adversary. The devices know their maximum communication range. The adversary’s objective is to enlarge the distance that the devices measure. The adversary cannot directly block or modify messages on the channel (*cf.* Dolev-Yao’s adversary [10]); it can rather inject signals, and through such injection it can block/modify the authentic signals. If successful, this injection can lead to jamming, signal annihilation, and/or content modification. This model captures the capabilities of man-in-the-middle (MITM) attacks in wireless settings, and is typical in previous literature [7, 12]. The model also fits well with our target application scenario: the communicating devices are typically mobile and move (drive or fly) in formation. In such scenarios, it is unlikely that an adversary prevents the signals of one device from reaching the other by physical obstacles, and is thus limited to injecting signals.

We assume the adversary is able to communicate and listen on any channel the devices use. However, because the devices are communicating over UWB, the adversary is unable to deterministically annihilate pulses without knowing their phase

(positive or negative). Existing hardware is not fast enough to enable the adversary to sample a pulse’s phase and react by injecting the reciprocal pulse promptly due to the very narrow UWB pulse width of  $\approx 2$  ns. We therefore assume that the adversary will not be able to deterministically annihilate pulses from the channel, only with some probability  $< 1$ . It succeeds in annihilating pulses if it guesses the phase of the pulse correctly. We over-approximate the adversary by providing the capability to synchronize attack signal with the authentic transmission. Signal synchronization is a hard problem, but an adversary can achieve it by using stable clock and distance information.

We assume the adversary knows the actual physical distance between the two devices at any point in time. The adversary can calculate this using several means, *e.g.*, by eavesdropping on unencrypted position announcements the devices make. The adversary can also position itself along the direct path between the two devices, measure the distance between itself and each from that position, and add both distances. To measure these distances, the adversary’s device can perform two-way ranging with each device independently, pretending to be the other device; or even without such impersonation, it could perform one-way ranging after synchronizing its clock with each device separately.

We assume the devices themselves are not compromised; the adversary cannot attach a physical cable to their interfaces, nor hijack their firmware. However, the adversary can have multiple network cards and antennas, and is not energy-bounded. It can be stationary or mobile.

UWB-ED (Section 4) involves transmitting, between the victim devices, a code of  $n$  pulses,  $\alpha$  of which are data-representing, and the remaining  $\beta$  are absent of energy, where  $n = \alpha + \beta$ . We assume the adversary knows the values of  $\alpha$  and  $\beta$ , but not the positions of these pulses in the transmission. (Their positions are determined by both devices pseudo-randomly in each transmission.) The adversary can learn these parameters by remaining passive in the vicinity of the victim devices, silently observing their transmissions.

Finally, we assume that it is not in the adversary’s interest to prevent the devices from communicating, *e.g.*, by shielding them, or jamming the channel.

### 4 UWB-ED Design

UWB-ED consists of two phases conducted between both devices: Distance Commitment and Distance Verification. Figure 5 shows a timing diagram of both phases. In the first, the devices measure the distance between them using a two-way ranging protocol. The distance measured in this phase ( $t_{tof}^c$ ) should not exceed the supported communication range ( $t_{tof}^{max}$ ). In the distance verification phase, the devices measure their distance by exchanging verification codes (generated using a special UWB-ED modulation). To detect enlargement attacks, devices look for distorted traces of that code. The

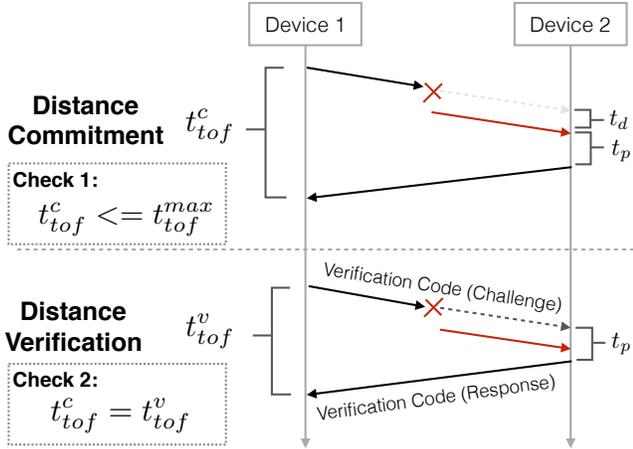

Figure 5: Timing diagram of UWB-ED operation. See inline (Section 4) for notation.

attack is detected when such traces are found,  $t_{tof}^c > t_{tof}^{max}$ , or when  $t_{tof}^c \neq t_{tof}^v$  (Fig. 5). By enlarging distance in the commitment phase, the adversary increases  $t_{tof}^c$  by  $t_d$ , but fails to enlarge the distance in the verification phase. Annihilation attempts on the challenge frame are shown, but the adversary can also attack responses from both devices.

**Distance Commitment Phase.** The devices measure secure upper bound by using distance bounding along with secure modulation techniques [5, 6, 26]. This provides strong guarantees against reduction attacks but is susceptible to enlargement attacks. The distance committed in this phase should not exceed the communication range (*i.e.*, an enlargement attack is detected when  $t_{tof}^c > t_{tof}^{max}$ ). This check ensures that the nodes can communicate without a relay. An adversary enlarging distance by more than the communication range is also exposed using this check.

**Distance Verification Phase.** In this phase, the committed distance is verified, *i.e.*, an enlargement attack is detected when  $t_{tof}^c \neq t_{tof}^v$ . To achieve this, the devices measure their distance using round-trip time-of-flight, with both challenge and response messages protected using specially crafted *verification codes* (*i.e.*, special UWB-ED modulation). In this exchange, the sender initiates the distance verification phase by transmitting a verification code; the receiver tries to detect the presence of that code, or traces thereof, in the transmission, despite the adversary’s efforts to *trail-hide* its existence from the channel (Section 2.2). The verification code and its check is applied to both time-of-flight messages. Both devices first agree on the code’s structure as follows.

#### 4.1 Modulation/Verification Code Structure

**Code length.** The code consists of  $n$  positions,  $\alpha$  of which have energy, and the remaining  $\beta = n - \alpha$  are empty, *i.e.*, absent of pulses (conceptually similar to OOK modulation,

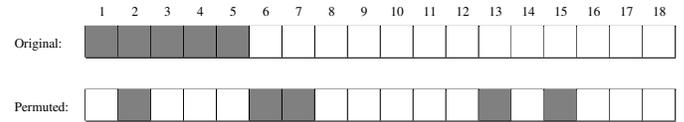

Figure 6: An example verification code with a randomly-looking pulse reordering, where  $\alpha = 5$ ,  $\beta = 13$ , and the code contains  $n = \alpha + \beta = 18$  pulses. Upon receiving the permuted code pulses as per the secret agreement between the sender and receiver, the receiver knows that  $\text{Bin}_\alpha$  will contain the received energies at the positions (gray) {2, 6, 7, 13, 15}, which are the expected high-energy pulses.  $\text{Bin}_\beta$  will contain the rest: {1, 3, 4, 5, 8, 9, 10, 11, 12, 14, 16, 17, 18}.

where  $\alpha = \beta$ ). The code length affects the performance and security of the presented modulation technique. Larger  $\alpha$  and  $\beta$  values improve the security by reducing the probability of adversarial success in mounting undetectable distance-enlargement attack. However, increasing the code length reduces the frequency of conducting two-way ranging. Additionally, the Federal Communications Commission (FCC) imposes restrictions on the number of pulses with energy, effectively limiting  $\alpha$  per unit of time. As such,  $\beta$  could be independently increased to compensate for the loss of code length. Setting these parameters is discussed in Section 5.

**Pulse phase.** The sender uses a random-phase for the  $\alpha$  pulses it transmits. Each phase is equally likely. The phase will be irrelevant for the receiver because ED receivers are agnostic to the phase, as explained in Section 2.1. The sender need not share this information with the receiver since the receiver measures the energy, not the polarity of the pulse.

**Pulse permutation.** The sender and receiver secretly agree on a random permutation of the  $n$  positions, obtained from a uniform distribution. Figure 6 shows an example before and after the permutation. The verification code can thus be considered a sequence of  $\{-1, 0, 1\}$  pulses, where  $\{-1, 1\}$  represent the phase, and  $\{0\}$  pulse absence.

**Spacing between pulses.** The time between two consecutive pulses,  $T_s$ , is normally lower bounded by the delay spread of the channel. We submit that  $T_s$  should be such that  $T_s > 2d/c$ , where  $d$  is the distance between the two devices. If the adversary replays the authentic signal delayed by more than the equivalent RTT, the attack will be detected by the mismatch between the measured RTT and the one equivalent to the committed distance. To avoid being detected, the adversary would thus replay its delayed version of a pulse within the  $T_s$  time window. As such, authentic pulse  $i$  will not overlap with the adversary’s delayed version of pulse  $i - 1$ , or any further adversary pulses  $i - 2$ ,  $i - 3$ , *etc.*

An example code structure, and adversarial attempts to corrupt and replay it, is shown in Fig. 7.

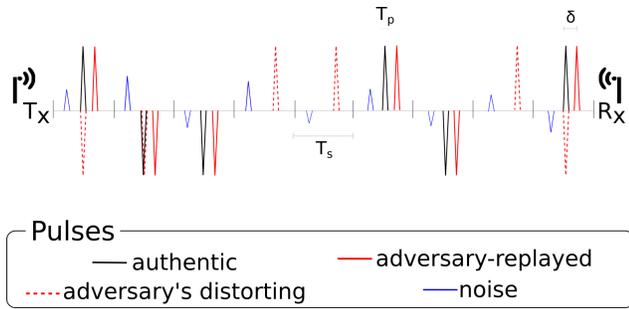

Figure 7: An example verification code of  $n$  slots (9 of which are shown), the spacing  $T_s$  between consecutive pulses is  $1\mu s$  and pulse width  $T_p$  is  $2ns$ . An adversary transmits a pulse to distort the legitimate pulse (dashed red). The adversary also replays the authentic signal with the delay  $\delta$  (solid red). Best viewed in color.

## 4.2 Verification Code Identification

Upon receiving a transmission, the receiver starts processing the code associated with the highest preamble's peak. The code associated with a peak is the train of  $T_s$ -spaced pulses that start at a fixed time interval (e.g., agreed upon between the sender and receiver) after the peak. This peak however may not be authentic, and could be the adversary's replayed version. The receiver thus backtracks at fixed time steps corresponding to the pulse width  $T_p$  (e.g.,  $2ns$ ), trying to identify if another version of the code (or a possible distorted imprint of it) was present in the transmission at an earlier time. The receiver does not need to backtrack further beyond some time  $T_0$ , knowing the maximum communication range. If the last distance verification occurred recently, the verified range could be used (in combination with the devices' upper bound motion speeds) to reduce the backtracking time.

Backtracking requires the receiver to record transmissions. If an earlier version of the code is found (and their difference exceeds the receiver's standard precision, e.g.,  $\pm 10cm$  for DecaWave [9]), it is used for ToF estimation.

As shown in Fig. 8, the receiver performs Attack Plausibility check and Robust Code Verification to detect attacks until the maximum backtracking time is reached. For each code, the receiver does not look for an exact match of the transmitted pulses in their positions simply because that could be easily bypassed with minimal adversarial efforts (as explained in Section 2.2). Instead, the receiver proceeds as follows. Knowing the mapping of the pulse positions, the receiver distributes the received powers of each pulse among two bins,  $\text{Bin}_\alpha$  and  $\text{Bin}_\beta$ . The former will have the values of the received power (e.g., in Watts) of the energy-present pulse positions, the latter energy-absent positions (Fig. 6).

**Attack Plausibility check.** For each candidate verification code obtained during backtracking, the overall received signal power (the aggregate of  $\text{Bin}_\alpha$  and  $\text{Bin}_\beta$ ) is measured, and

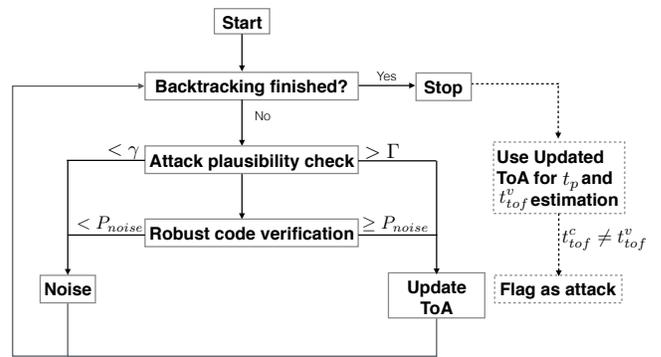

Figure 8: The receiver backtracks to detect enlargement attacks. An event is flagged as an attack when the aggregate energy is higher than  $\Gamma$  (e.g., DoS, jamming), i.e., the data looks more similar to a verification code than noise. The last flagged position is used for the ToF estimation.

compared to a predefined threshold,  $\gamma$ . This threshold is based on the receiver's noise figure. If the aggregate exceeds  $\gamma$ , a potential verification code has been found. Otherwise it gets discarded as noise. The aggregate energy is then compared to another threshold,  $\Gamma$ . This is calculated based on the overall aggregate energy the receiver expects to receive based on the measured distance in the commitment phase, following the path loss model. Artificial distance enlargement caused by the adversary in the commitment phase lowers the receiver's calculated  $\Gamma$  (because of the higher path loss), thus increases the likelihood of the actual received aggregate to exceed  $\Gamma$ . If the aggregate exceeds  $\Gamma$ , an adversary may possibly be injecting energy into the channel to distort the authentic code. If the verification code is neither discarded as noise ( $< \gamma$ ) nor exceeds  $\Gamma$ , the receiver proceeds to the Robust Code Verification check.

**Robust Code Verification.** Now the receiver checks the verification code content. If the receiver simply flags the presence of one or more pulses (above noise) in  $\text{Bin}_\beta$  as an attack, false positives increase because such pulses could occur for many legitimate reasons (e.g., noise spikes, reflections, interfering transmissions, antenna orientation, or multipath).<sup>1</sup> Instead, the receiver performs a sequence of binary hypothesis tests on random pulse samples. It tests if the candidate code is more similar to an authentic code than noise. It chooses  $r \leq \alpha$  random pulses from the  $\alpha$  in  $\text{Bin}_\alpha$  (where  $r$  is the number of pulses per symbol), aggregates their received powers and compares that to the aggregate of another  $r$  pulses randomly chosen from the  $\beta$  in  $\text{Bin}_\beta$ . If the aggregate of those selected from  $\text{Bin}_\alpha$  is larger, the receiver identifies this as a candidate authentic code, and records its ToA. Finally, the distance is calculated based on the recorded ToA of the most recently

<sup>1</sup> If the receiver instead interprets a pulse in  $\text{Bin}_\beta$  as an indication that the code is not authentic and continues backtracking, it may very well skip the authentic code thus helping the adversary.

received code, and a mismatch with the committed distance is flagged as an attack.

A candidate verification code could be again noise, which has slipped the Attack Plausibility check perhaps due to some sporadic noise spikes in the transmission. Noise has a probability of  $\leq P_{\text{noise}}$  to satisfy the Robust Code Verification check, where  $P_{\text{noise}}$  is derived as (32) in Section 5.1.4. As such, the receiver estimates the probability that the above condition is satisfied. This is done by repeating the random sampling  $\upsilon$  times, and checking if the ratio of the number of times the condition is satisfied to  $\upsilon$  exceeds  $P_{\text{noise}}$ . This would indicate the code is not noise, and is either authentic or adversary-replayed. Regardless, the receiver uses the ToA of the most recent code found.

### 4.3 Setting the Energy Thresholds.

**Setting the upper-bound threshold,  $\Gamma$ .** To set  $\Gamma$ , the receiver relies on the committed (unverified) distance between itself and the sender. This dictates the path loss—the amount of power loss per pulse as pulses propagate the medium. Larger committed distance causes the receiver to expect less power, thus setting a lower  $\Gamma$ . Thus, by increasing the committed distance, the adversary helps divulge its malice.

The path loss function  $f(\cdot)$  for outdoor UWB LoS is [20]:

$$f(d) = PL_0 + 10 \cdot n \cdot \log\left(\frac{d}{d_0}\right) \quad (3)$$

where  $d$  is the distance in meters, and  $PL_0$  is a constant representing the path loss at the reference distance  $d_0$ . For UWB LoS channel model, these constants are set to [20]:

$$f(d) = -46.3 - 20 \log(d) - \log\left(\frac{6.5}{5}\right) \quad (4)$$

This is calculated in the standard signal ratio unit,  $dB$ , where:

$$\text{Power ratio (in } dB) = 10 \log(\text{ratio}) \quad (5)$$

The path loss function thus expresses the power loss as

$$f(d) = 10 \log\left(\frac{(\lambda_b)^2}{(\lambda_{\text{sent}})^2}\right) \quad (6)$$

or

$$\frac{(\lambda_b)^2}{(\lambda_{\text{sent}})^2} = 10^{f(x)/10} \quad (7)$$

where  $(\lambda_b)^2$  is the pulse instantaneous power the receiver expects, and  $(\lambda_{\text{sent}})^2$  is that the sender has actually sent, *e.g.*, both in Watt. Knowing the constant pulse power of the sender, then the pulse power is expected to be received as:

$$(\lambda_b)^2 = (\lambda_{\text{sent}})^2 10^{f(x)/10} \quad (8)$$

The receiver then calculates  $\Gamma$  as follows:

$$\Gamma = \alpha (\lambda_b + N)^2 + \beta (N)^2 \quad (9)$$

where  $d$  is the (unverified) distance in meters between the sender and receiver obtained at commit stage, either true or artificially enlarged in case of an attack.  $N$  is an instantiation of zero-mean Gaussian noise at the receiver, *i.e.*, the noise present in the receiver’s channel and cannot be removed [19].

There are other factors that contribute to the degradation of power. These factors could cause further power loss  $E$ , typically up to  $E = -8$   $dB$  more [17, 21]. If the receiver sets  $\Gamma$  as that after the expected further degradation (*i.e.*, too small  $\Gamma$  value), false positives may increase because such additional signal-degradation factors may or may not occur—if they do not, the receiver would then falsely assume such relatively “too high” aggregate energy is due to an attempted attack. Accordingly, the receiver sets  $\Gamma$  based only on the (almost certain) path loss deterioration. Any further power loss would then be added benefit to the adversary, as it allows the adversary to inject more pulses into the channel to corrupt the authentic code without exceeding  $\Gamma$ .

**Setting the lower-bound threshold,  $\gamma$ .** If the aggregate energy is  $< \gamma$ , it would be either due to noise or a substantial deterioration of the authentic signal where no meaningful information could be recovered during the Robust Code Verification. Too high  $\gamma$  leads to false negatives; too low triggers Robust Code Verification even for noise. For critical applications seeking to prevent false negatives,  $\gamma$  could be set conservatively based on the receiver’s noise variance  $\sigma_N^2$ :

$$\gamma = (\alpha + \beta) \cdot \sigma_N^2 \quad (10)$$

## 4.4 Attack Resilience

Here we explain how UWB-ED resists standard enlargement attacks. More complex attacks are discussed in Section 6.

### 4.4.1 Detecting Signal Replay

An adversary that simply replays authentic pulses does not win because the receiver backtracks to detect earlier copies of the code. UWB-ED provides resilience to benign signal distortion, *e.g.*, due to channel conditions or antenna orientation, because the receiver looks for similarities between the code and the received signal (versus exact data match), allowing for a higher bit error rate. In general, poor channel conditions (low SNR) can be compensated for by increasing the symbol length,  $r$ , minimizing the bit error rate.

### 4.4.2 Complicating Signal Annihilation

The unpredictability of the pulse phase means an adversary must either wait to detect it and immediately inject the reciprocal pulse for annihilation, or inject a random-phased pulse hoping it is the reciprocal. The former is infeasible in practice for UWB (see Section 3). The latter results in amplifying or annihilating the authentic pulse, each with a 50% chance. Amplification is unfortunate to the adversary, as the adversary

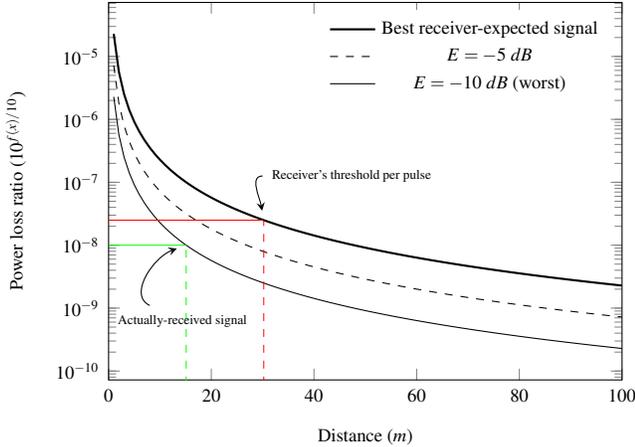

Figure 9: The best expected signal power as calculated by the receiver using the path loss function in (4), the signal at  $E = -5$  db of further power loss, and at  $E = -10$  db (worst expected). If the distance is  $D_1 = 15.11$  m (green line), and the adversary doubles it, *i.e.*, by adding  $D_2 = 15.11$  m to make it  $D_1 + D_2 = 30.22$  m (red line), the receiver will set the threshold following the fake distance, at  $10^{f(D_1+D_2)/10} = 10^{-7.6}$ . The adversary’s room is the difference between the red and green lines on the y-axis. At  $D_2 = 32.68$  m, the adversary has no room. Best viewed in color.

now needs to compensate with an equivalent amplitude,  $A$ . Amplification doubles the amplitude. The estimated energy of the pulses will thus amount to  $\sim A^2$ , and the adversary-contributed amplification to  $\sim (2A)^2$ .

Since the result is indeterministic for the adversary, it leads us to the next discussion: how successful would the adversary be in “contaminating the evidence” that an authentic verification code existed, and how much energy room does the adversary have to do that before exceeding  $\Gamma$ ?

#### 4.4.3 Mitigating Evidence Contamination

To hide the authentic code, the adversary tries to inject energy into the channel, hoping it annihilates as many of  $\text{Bin}_\alpha$  pulses as possible. We thus calculate the room available to the adversary here, and use that to derive the probability of adversarial success in distance enlargement in Section 5.

Figure 9 shows the path loss function in (7) as used by the receiver to detect the threshold  $\Gamma$ , as well as the worst receiver-expected signal after additional deterioration. The receiver sets the threshold based on the best expected signal. The room available for the adversary to add energy depends on the actual signal received. The most favorable situation to the adversary is when the received signal power is the worst (lowest  $E$ ), which allows the adversary to inject pulses without exceeding  $\Gamma$ . For example, in Fig. 9, if the actual distance between the sender and receiver is  $D_1 = 15.11$  m (green line), and the

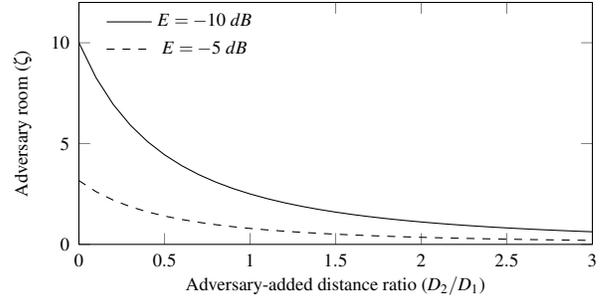

Figure 10: Adversary’s room to add energy,  $\zeta$  in (12), against the ratio of the adversary-added to true distance ( $D_2/D_1$ );  $E$  represents additional signal degradation beyond path loss.

adversary is trying to add  $D_2 = 32.68$  m to make the distance  $D_1 + D_2 = 47.79$  m (red line), the receiver will set  $\Gamma$  using the fake distance,  $D_1 + D_2$ . At such a relatively large added distance,  $D_2$ , the received pulse power is unlikely to fall below  $f(D_1) + E = 10^{-8}(\lambda_{\text{sent}})^2$  at, *e.g.*,  $E = -10$  dB. The room available to the adversary to inject energy becomes too small, significantly reducing its chances of success.

The room-per-pulse,  $R$ , available to the adversary to enlarge the distance thus lies in-between the received signal and  $\Gamma$ , and is calculated in dB as:

$$R = f(D_1 + D_2) - (f(D_1) + E) \quad (11)$$

where  $E$  represents other channel degrading factors, and the distances  $D_1$  and  $D_2$  (in meters) are respectively the true distance between both devices, and the extra distance the adversary intends to add. This room is thus expressed as:

$$\zeta = 10^{R/10} \quad (12)$$

Figure 10 plots  $\zeta$  at various distance ratios  $D_2/D_1$ .

Recall that the adversary may succeed to annihilate some of the pulses falling in  $\text{Bin}_\alpha$ . But since  $\text{Bin}_\beta$  in the authentic code have nothing but noise, adding pulses into those will result in an increase in the overall aggregate energy. As such, this available energy room in (11) by itself does not give a perfect indication to the adversary’s chances of success.

#### 4.5 A Numerical Example

Figure 11 shows an example verification code, expanded from Fig. 6, where the adversary injects  $k = 10$  random-phased pulses. For simplicity, the figure assumes  $N = 0$ . If the distance between the sender and receiver is  $D_1 = 4$  m, and the adversary is trying to enlarge it by  $D_2 = 4.5$  m to make it  $D_1 + D_2 = 8.5$  m, and assuming  $(\lambda_{\text{sent}})^2 = 7.6 \mu\text{W}$ , then the receiver expects a best case received power of:

$$\begin{aligned} (\lambda_b)^2 &= (\lambda_{\text{sent}})^2 10^{f(D_1+D_2)/10} \\ &= 7.67 \times 10^{f(8.5)/10} = 2.4 \mu\text{W} \end{aligned} \quad (13)$$

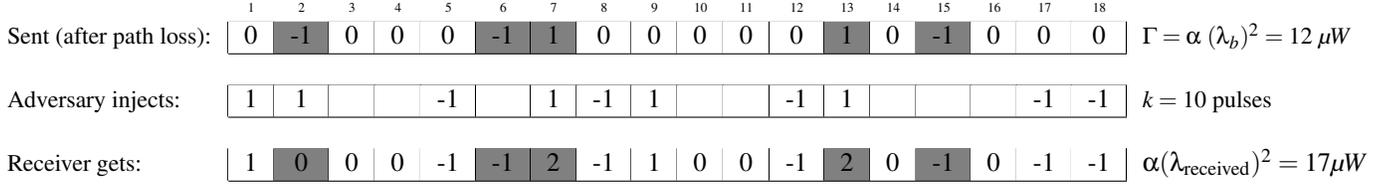

Figure 11: An example of the random-phased  $\text{Bin}_\alpha$  pulses (dark gray) reordered following the permutation in Fig. 6. After the adversary injects  $k = 10$  random-phased pulses at random positions, the receiver will get the summation at each pulse position.

From (10) at  $N = 0$  and  $\alpha = 5$  (as in Fig. 11), it then calculates the threshold as:

$$\Gamma = \alpha (\lambda_b)^2 = 12 \mu W \quad (14)$$

At  $E = -10$  dB, the actual signals are received as:

$$(\lambda_w)^2 = (\lambda_{\text{sent}})^2 10^{(f(D_1)+E)/10} \approx 1 \mu W \quad (15)$$

Now assuming the adversary is  $D_3 = 6$  m away from the receiver, and uses a random-phased pulse with transmission power of  $(\lambda_{\text{sent}}^{\text{adversary}})^2 = 15.77 \mu W$ . At  $E = -10$  dB, the receiver would receive the adversary's signals as:

$$(\lambda')^2 = (\lambda_{\text{sent}}^{\text{adversary}})^2 10^{(f(D_3)+E)/10} \approx 1 \mu W \quad (16)$$

So in the best case for the adversary, where the signal is highly deteriorated, the adversary would then have a per-pulse room of  $R = 3.45$  dB to add energy, which amounts to  $7 \mu W$  more, *i.e.*, up to  $\Gamma = 12 \mu W$ . In Fig. 11, after the adversary injects its  $k = 10$  pulses at the example random positions and with the random phases shown, it results in annihilating a single pulse (at position 2), amplifying two pulses (at positions 7 and 13), and adding seven more  $1 \mu W$  pulses for an increase of the overall aggregate to be  $17 \mu W$ . This exceeds  $\Gamma = 12 \mu W$ , and this attack would thus be detected.

## 5 Evaluation

We evaluate UWB-ED by deriving the probability of success for an adversary enlarging the distance. We also validate that model using simulations in Section 5.2.

### 5.1 Probability of a Successful Attack

The adversary hides the authentic code by having the aggregate of the  $r$  pulses that the receiver chooses from  $\text{Bin}_\beta$  exceed  $\text{Bin}_\alpha$ . The adversary must also avoid injecting too much energy to not exceed  $\Gamma$ . Not knowing which pulse belongs to which bin, the adversary injects  $k$  pulses at random positions thus affecting  $k$  of the  $n$  pulses in the code.

To that end, the probability of mounting a successful attack,  $P_{sa}$ , is the intersection of the probability of two events (the checks in Fig. 8): the aggregate of the energy pulses chosen

from  $\text{Bin}_\beta$  ( $b\beta$ ) exceeds that of  $\text{Bin}_\alpha$  ( $b\alpha$ ), and the added energy is  $\leq \Gamma$ :

$$P_{sa}(\alpha, \beta, r, \Gamma, k) = P_{b\beta > b\alpha}(\alpha, \beta, r, k) \cap P_{\leq \Gamma}(\alpha, \beta, k) \quad (17)$$

#### 5.1.1 Probability of successfully evading the Robust Code Verification check ( $P_{b\beta > b\alpha}$ )

To evade this, the adversary must have an energy aggregated from  $\text{Bin}_\beta$  exceed  $\text{Bin}_\alpha$ . When the adversary injects  $k$  pulses into the channel,  $x$  will fall into  $\text{Bin}_\alpha$ , and the remaining  $k - x$  into  $\text{Bin}_\beta$ .  $P_{b\beta > b\alpha}$  is then the probability of this distribution occurring multiplied by the probability of the attack succeeding under this distribution, for all possible such distributions  $0 \leq x \leq \alpha$  and  $0 \leq k - x \leq \beta$ . To calculate the probability of the distribution occurring, consider the general case of a bucket containing two types of objects (*e.g.*, colored pearls):  $I$  of the first type, and  $J$  of the second. If  $\psi$  objects are selected at random, the probability that  $i$  and  $j$  of the  $\psi$  are respectively of the first and second type ( $i + j = \psi$ ) is:

$$\frac{\binom{I}{i} \binom{J}{j}}{\binom{I+J}{i+j}} \quad (18)$$

where  $\binom{n}{r}$  denotes  $n$  choose  $r$  and is given by:

$$\binom{n}{r} = \begin{cases} \frac{n!}{r!(n-r)!}, & 0 \leq r \leq n \\ 0, & \text{otherwise} \end{cases}$$

Similarly, the probability that  $x$  and  $k - x$  of the adversary's  $k$  pulses respectively affect the  $\alpha$  in  $\text{Bin}_\alpha$  and  $\beta$  in  $\text{Bin}_\beta$  is:

$$\frac{\binom{\alpha}{x} \binom{\beta}{k-x}}{\binom{\alpha+\beta}{k}}$$

For all possible such distributions, we have:

$$P_{b\beta > b\alpha}(\alpha, \beta, r, k) = \sum_{x=0}^{\alpha} \left( p_{\alpha, \beta, r, k}(x) \cdot \frac{\binom{\alpha}{x} \binom{\beta}{k-x}}{\binom{\alpha+\beta}{k}} \right) \quad (19)$$

where  $p_{\alpha, \beta, r, k}(x)$  is the probability  $b\beta > b\alpha$  given the adversary affected  $x$  and  $k - x$  pulses in  $\text{Bin}_\alpha$  and  $\text{Bin}_\beta$  respectively.

To derive  $p_{\alpha, \beta, r, k}(x)$ , we assume for simplicity a unity power-per pulse, *i.e.*, the sender's and the adversary's pulses

reach the receiver after path loss and other factors at a constant energy of  $\pm 1\mu W$ .<sup>2</sup> This is similar to the example given in Fig. 11. Every adversary-added pulse in  $\text{Bin}_\beta$  will result in a  $1\mu W$  of added energy from the receiver's point of view since the receiver's aggregation is agnostic to a pulse's phase. For  $\text{Bin}_\alpha$ , after the adversary affects  $x$  pulses, some will be annihilated while others will be amplified. From the receiver's point of view, after the adversary's pulses are injected,  $\text{Bin}_\alpha$  will have a mix of  $2^2 = 4\mu W$  and  $0\mu W$  (adversary-affected) pulses, as well as the original  $1\mu W$  unaffected pulses.

More  $0\mu W$  (annihilated) pulses in  $\text{Bin}_\alpha$  raises the chances that  $b\beta > b\alpha$ , which is in the adversary's favor. Since every affected pulse in  $\text{Bin}_\alpha$  will either result in a  $0\mu W$  or a  $4\mu W$  pulse, there are  $2^x$  possible outcomes. Of those, there are  $\binom{x}{g}$  ways that  $g$   $0\mu W$  pulses will occur. The probability that the  $x$  adversary-injected pulses that fell in  $\text{Bin}_\alpha$  result in an annihilation of  $g$  pulses is thus  $\binom{x}{g}/(2^x)$ . For all possible numbers of annihilated pulses  $0 \leq g \leq x$ , the adversarial success probability in the event that  $x$  fell in  $\text{Bin}_\alpha$  is:

$$p_{\alpha,\beta,r,k}(x) = \sum_{g=0}^x \left( p_{\alpha,\beta,r,k,x}(g) \cdot \frac{\binom{x}{g}}{2^x} \right) \quad (20)$$

where  $p_{\alpha,\beta,r,k,x}(g)$  is the probability  $b\beta > b\alpha$  given  $g$  annihilated pulses in  $\text{Bin}_\alpha$ .

When  $\text{Bin}_\alpha$  has  $g$  annihilated ( $0\mu W$ ),  $x-g$  amplified ( $4\mu W$ ), and  $\alpha-x$  unaffected pulses ( $1\mu W$ ), the probability of  $b\beta > b\alpha$  in the event  $x$  fell in  $\text{Bin}_\alpha$ , and  $g$  of the  $x$  pulses were annihilated is the probability that an aggregate of  $m-1$  is chosen from  $\text{Bin}_\alpha$  and an aggregate of  $\geq m$  is chosen from  $\text{Bin}_\beta$ . For each possible  $0 \leq y_1, y_2 \leq r$ , we have:

$$p_{\alpha,\beta,r,k,x}(g) = \sum_{y_1=0}^r \sum_{y_2=0}^r \left( \frac{\binom{g}{y_1} \binom{x-g}{y_2} \binom{\alpha-x}{r-y_1-y_2}}{\binom{\alpha}{r}} \cdot \sum_{i=m}^r \frac{\binom{k-x}{i} \binom{\beta-(k-x)}{r-i}}{\binom{\beta}{r}} \right) \quad (21)$$

where  $m$  is:

$$m = 0^2 \times y_1 + 2^2 \times y_2 + 1^2 \times (r - (y_1 + y_2)) + 1 = r - y_1 + 3y_2 + 1 \quad (22)$$

At  $r = \alpha$  (i.e., selecting all  $\text{Bin}_\alpha$  pulses) and  $\alpha \leq \beta$ , we get:

$$p_{\alpha,\beta,r,k,x}(g) = \sum_{i=m'}^r \frac{\binom{k-x}{i} \binom{\beta-(k-x)}{r-i}}{\binom{\beta}{r}} \quad (23)$$

where  $m'$  is:

$$m' = 2^2 \times (x-g) + 1^2 \times (\alpha-x) + 1 = 4(x-g) + (\alpha-x) + 1 \quad (24)$$

Figure 12 plots  $P_{b\beta > b\alpha}$ , where  $\alpha = 50$ . From these results, increasing  $\beta$  is not necessarily effective for the Robust Code

<sup>2</sup>Analogous analysis applies for non-constant energy.

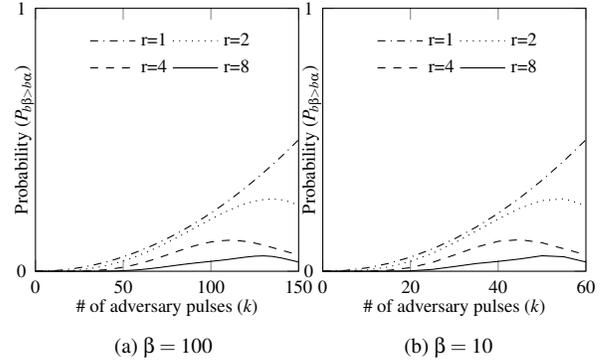

Figure 12: Probability that the Robust Code Verification check fails to detect the adversary's attack, plotted using (19) in Section 5.1.1, at  $\alpha = 50$  and  $0 \leq k \leq \alpha + \beta$ .

Verification check to detect attacks, since the adversary maintains its success probability by increasing  $k$  proportionally; there is a visually similar pattern of adversarial success probability in both Fig. 12a and 12b. As such, the advantage of the empty pulses in  $\text{Bin}_\beta$  does not quite manifest in the Robust Code Verification check, rather the Attack Plausibility check.

Another observation is that higher  $r$  lowers the adversary's success probability. For example at  $\beta = 100$  (Fig. 12a), the adversary has a 27% chance at  $r = 2$  (which occurs at  $k = 135$ ), versus 5.85% at  $r = 8$  (at  $k = 130$ ). In Section 5.1.3, we show that at  $r = \alpha$ , we get the optimal security results.

### 5.1.2 Final Probability of Adversary's Success

In (17), the event that the aggregate energy after the adversary's pulses is  $\leq \Gamma$  and the event that  $b\beta > b\alpha$  are dependent, and thus their intersection is not their product. Recall that in (20),  $g$  is the number of annihilated pulses,  $x-g$  is the number of amplified pulses in  $\text{Bin}_\alpha$ , and  $k-x$  is the number of added pulses in  $\text{Bin}_\beta$ . The aggregate-energy does not exceed  $\Gamma$  when the adversary's pulses satisfy the inequality:

$$(k-x)(\lambda' + N)^2 + (x-g)(\lambda' + \lambda_w + N)^2 + (\alpha-x)(\lambda_w + N)^2 + (\beta - (k-x) + g)(N)^2 \leq \Gamma \quad (25)$$

where  $\lambda'$  is defined as in (16), and  $\Gamma$  in (10).

If the adversary uses a variable pulse power randomly chosen from a distribution with a mean much different from  $\lambda_w$ , authentic pulses colliding with their reciprocal will not be fully annihilated. The adversary thus sets its power such that its mean at the receiver matches the sender, i.e.,  $(\lambda')^2 = (\lambda_w)^2$ . Assuming  $(\lambda_w)^2 = (\lambda')^2$  in (25), we get:

$$k + 2x - 4d + \alpha \leq \frac{\alpha \lambda_b^2 - \varepsilon}{\lambda_w^2} \quad (26)$$

where  $\varepsilon$  is a representation of noise, and evaluates to:

$$\varepsilon = N(\lambda_w(2k + 2\alpha - 4g) - \lambda_b(2\alpha))$$

As  $\varepsilon \rightarrow 0$ , (26) becomes:

$$k + 2x - 4d \leq \alpha \left( \frac{\lambda_b^2}{\lambda_w^2} - 1 \right) \quad (27)$$

From (13) and (15), we have:

$$\begin{aligned} \frac{\lambda_b^2}{\lambda_w^2} &= \frac{(\lambda_{\text{sent}})^2 10^{f(D_1+D_2)/10}}{(\lambda_{\text{sent}})^2 10^{(f(D_1)+E)/10}} \\ &= 10^{(f(D_1+D_2)-(f(D_1)+E))/10} \\ &= \zeta \end{aligned} \quad (28)$$

where  $\zeta$ , from (12), represents the room-per-pulse available to the adversary to add energy into the channel.

We now calculate  $p_{\alpha,\beta,r,k}(x,\Gamma)$ , similar to (20) as:

$$p_{\alpha,\beta,r,k}(x,\Gamma) = \sum_{g=0}^x \left( p_{\alpha,\beta,r,k,x,\Gamma}(g) \cdot \frac{\binom{x}{g}}{2^x} \right) \quad (29)$$

such that

$$p_{\alpha,\beta,r,k,x,\Gamma}(g) = \begin{cases} p_{\alpha,\beta,r,k,x}(g), & k + 2x - 4d \leq \alpha(\zeta - 1) \\ 0, & \text{otherwise} \end{cases} \quad (30)$$

Using (29), the final adversarial success probability is:

$$P_{\text{sa}}(\alpha, \beta, r, \Gamma, k) = \sum_{x=0}^{\alpha} \left( p_{\alpha,\beta,r,k}(x,\Gamma) \cdot \frac{\binom{\alpha}{x} \binom{\beta}{k-x}}{\binom{\alpha+\beta}{k}} \right) \quad (31)$$

Figures 13a and 13b plot  $P_{\text{sa}}$  in (31). At  $\zeta = 20$ ,  $\Gamma$  is too high to reduce  $P_{\text{sa}}$ , but the Robust Code Verification check enables the receiver to limit it to  $P_{\text{sa}} < 0.16 \times 10^{-3}$ . At  $\zeta = 10$ ,  $P_{\text{sa}}$  stops growing beyond  $0.73 \times 10^{-4}$ , which limits the adversary's pulses to  $k = 495$  for its highest success chance.

Figure 13c shows the effect of  $\beta$  on  $P_{\text{sa}}$ ;  $P_{\text{sa}}$  is almost constant with  $\beta$ , at around  $0.2 \times 10^{-3}$ , and only starts dropping when  $\beta$  is sufficiently large so that the aggregate energy after the adversary's pulses exceeds  $\Gamma$ . At a certain point, increasing  $\beta$  no longer helps. For example, at  $\zeta = 5$  and  $\beta \geq 400$ ,  $P_{\text{sa}} \approx 0$ .  $\beta$  should thus be set wisely, reflecting the application's sensitivity to distance increases and channel conditions, to avoid increasing transmission lengths unnecessarily.

### 5.1.3 Symbol length ( $r$ )

Figures 13d and 13e plot  $P_{\text{sa}}$  against the ratio of  $r : \alpha$ . As shown, longer symbol length (larger  $r$ ) is better for security; the best results are achieved when the ratio is 1 ( $r = \alpha$ ).

### 5.1.4 False positives: noise passing Robust Code Verification

Higher-than-usual noise in the channel might satisfy the Robust Code Verification check. Since the receiver backtracks,

it is imperative to calculate the probability,  $P_{\text{noise}}$ , that noise in the channel satisfies that check. Unlike the adversary's pulses targeted to alter the authentic code, such a candidate trail of noise pulses does not get added to the sender's code because they are at different positions. Without loss of generality, we can separate the noise-intervals in low-energy and high-energy, *e.g.*, across the median of the distribution of  $N^2$ . We refer to the number of high-energy intervals as  $\kappa$ . The probability that noise satisfies the Robust Code Verification check is the probability that  $x$  of  $\kappa$  pulses fell into  $\text{Bin}_{\alpha}$ , by the probability of satisfying the test in that event,  $p'_{\alpha,r}(x)$ :

$$P_{\text{noise}}(\alpha, \beta, r, \kappa) = \sum_{x=0}^{\alpha} \left( p'_{\alpha,r}(x) \cdot \frac{\binom{\alpha}{x} \binom{\beta}{\kappa-x}}{\binom{\alpha+\beta}{\kappa}} \right) \quad (32)$$

where,

$$p'_{\alpha,r}(x) = \sum_{y=0}^r \left( \frac{\binom{\alpha-x}{r-y} \binom{x}{y}}{\binom{\alpha}{r}} \cdot \sum_{i=0}^y \frac{\binom{\beta-(\kappa-x)}{r-i} \binom{\kappa-x}{i}}{\binom{\alpha}{r}} \right) \quad (33)$$

This is the probability that an aggregate of  $y$  is chosen from  $\text{Bin}_{\alpha}$ , and of  $\leq y$  from  $\text{Bin}_{\beta}$ . Since we separate along the median, the expected  $\kappa$  is  $(\alpha + \beta)/2$ . Figure 14 plots  $P_{\text{noise}}$  against  $\alpha$  using (32) at  $\kappa = (\alpha + \beta)/2$  and  $\beta = 100$ . Intuitively (and as the chart confirms),  $P_{\text{noise}} \rightarrow 0.5$  as  $\alpha \rightarrow \infty$ .

Since a candidate verification code is discarded as noise if the Robust Code Verification check is satisfied with a probability  $< P_{\text{noise}}$  (recall: Fig. 8), the adversary must have a success probability of at least  $1 - P_{\text{noise}}$  to hide the authentic code from the receiver. At  $r = \alpha$ ,  $P_{\text{noise}}(80, 100, 80, 40) = 0.53$ , and the adversary must thus have a success probability of at least 0.47. As this is much higher than the calculated probabilities in Section 5.1.2, the adversary will not be able to disguise authentic code as noise. The value 0.53 is a lower-bound; in practice  $P_{\text{noise}}$  should be set  $\geq 0.53$  depending on applications' requirements and channel conditions.

## 5.2 Validating the Probabilistic Model

The use of prototype implementation using Software Defined Radios (SDRs) and simulations are well-established methods for evaluating wireless systems. Existing SDRs do not support UWB. Therefore, we validate the probabilistic model above with simulations. The channel condition such as noise, multipath effect, and path loss are important factors to consider while designing a wireless system. The IEEE 802.14.4a [18] channel model for different environments is purposefully provided for UWB. The preamble and the verification code are converted into physical layer signals using this model for the outdoor LoS conditions. The model generates the pulse and multipath components to resemble the real world effect of the channel condition. We assume that upper layers, *e.g.*, Medium Access Control (MAC) layer, could decide on when to perform enlargement detection so that it doesn't interfere with

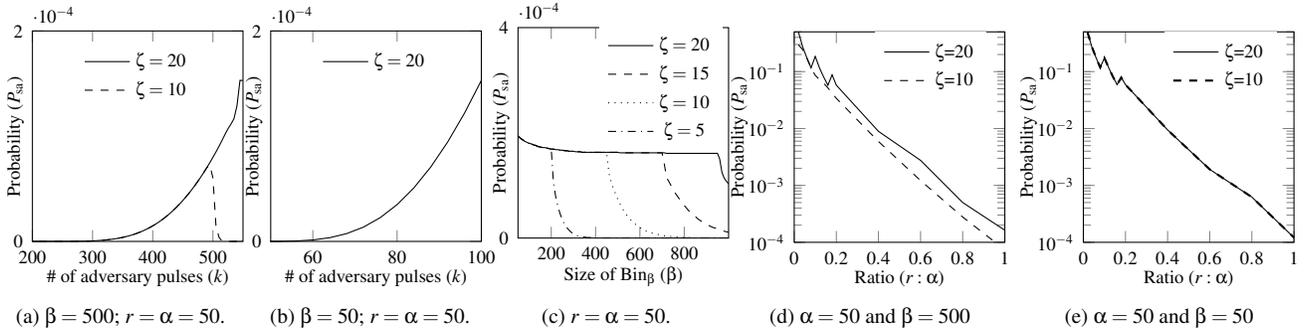

Figure 13: Adversarial success probability in (31).

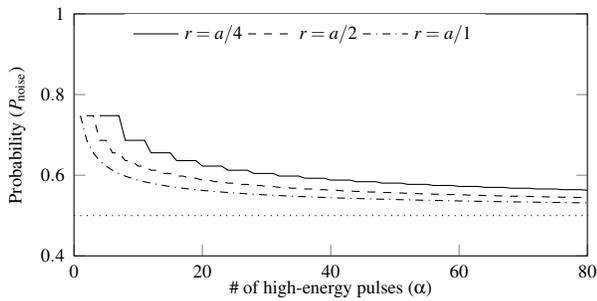

Figure 14: Probability that noise passes the Robust Code Verification check, calculated using (32);  $\kappa = \alpha/2$ ,  $\beta = 100$ .

other ranging applications. The simulations account for the noise and interference due to the noise figure of the receiver and multipath components. To verify the simulation setup, we performed a thorough evaluation to cross-check simulation metrics with previous proof-of-concept implementation [26]. Each pulse uses 500 MHz bandwidth, and the sampling time between consecutive pulses is 1  $\mu s$ . Transmission power is limited to -35 dBm/MHz, well under the limits applied by the FCC/ETSI regulations [11]. The energy is further reduced to adapt to path loss model and extra losses ( $E$ ; cf. Fig. 9).

An adversary is simulated to inject  $k$  signals to annihilate or distort the authentic code, and to replay a delayed and amplified versions of the authentic signals. Similar to our assumptions, the adversary in the simulator is capable of annihilating the pulse and its multipath if the phase is guessed correctly; it doubles the amplitude of the pulse otherwise. The time difference between authentic and delayed signals is  $\delta = 200ns$  in the simulations (see Fig. 7).

Before demodulation, additive white Gaussian noise (AWGN) is added to the signal. The receiver in Section 2.1 is implemented for code verification; it always locks on to the highest peak, *i.e.*, the peak generated by the adversary due to its replay attack. The communication range is considered 100m, and the backtracking restricted to 660ns.

The goal of our validation is to (1) confirm the probabilistic model’s correctness, and (2) analyze the effect of the parameters abstracted from the model, namely noise and the receiver’s ability to reconstruct the signal after long distance propagation. In practice, the latter point can be accounted for by increasing the number of pulses ( $n = \alpha + \beta$ )—see below.

**Validating  $P_{b\beta > b\alpha}$ .** Figure 15 shows the validation for  $P_{b\beta > b\alpha}$ , at a simulated distance between both devices of  $d = 10m$ . A boxplot is drawn at distinct  $k$ , where each scenario is run  $10^6$  times. The results confirm that abstracting noise from the model does not largely affect its accuracy. Next we show the effect of longer distances on the model.

**Validating  $P_{sa}$ .** Figure 16 shows the validation for  $P_{sa}$ , at  $r = \alpha$  and  $P_{noise} = 0.8$ . Results are shown for different  $k$ , at distances of 10m and 100m. Each scenario is run  $10^6$  times, and  $P_{sa}$  is calculated as the proportion of these where the adversary succeeded to hide the authentic code. Again the results show comparable patterns between the model and simulations. There is a slight horizontal shift at  $k$  due to the abstracted noise. In the simulator,  $\Gamma$  is set as in (9), which may be a bit too high or low depending on actual noise patterns. In Fig. 16a,  $\Gamma$  was relatively low, causing a drop in the simulated  $P_{sa}$  at smaller  $k$  compared to the model. In Fig. 16b,  $\Gamma$  was relatively high, replicating  $P_{sa}$  at higher  $k$ .

Another difference between simulations and the model manifests with increasing the distance  $d$  between both devices. In practice, in UWB, receivers increase their ability to reconstruct the signals (hence, the SNR) by aggregating over more pulses. We noticed that the model provides such comparable probability patterns when we decrease  $\alpha$  and  $\beta$  in the model proportionally with increasing  $d$  in simulations. For example in Fig. 16b where  $d = 100m$ ,  $\alpha$  and  $\beta$  in the simulator had to be increased from 15 and 158 to 50 and 500 respectively ( $\sim$  tripled) to account for the increased distance.

**Validating the false positives.** We also used simulations to confirm that noise would not be falsely mistaken for authentic code upon proper selection of  $P_{noise}$  and  $\Gamma$ . For various distances between 10m and 100m, the probability of a false positive was  $\sim 1 \times 10^{-6}$ , confirming the noise analysis in

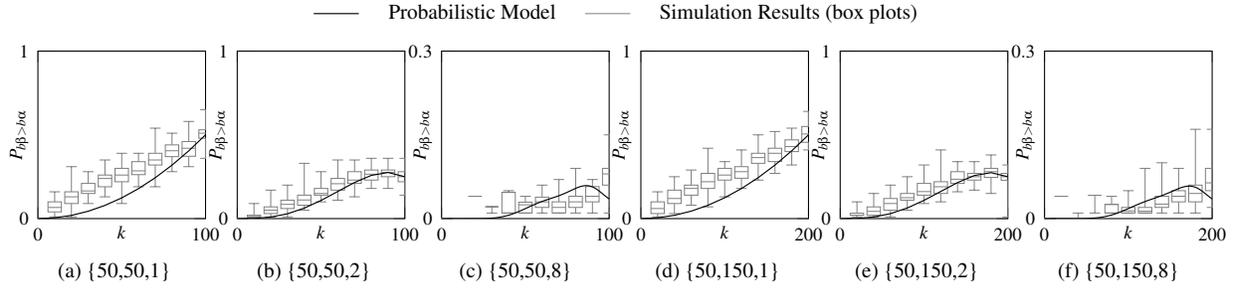

Figure 15: Probability of adversary’s failure calculated using (19), and simulations results validating the probabilistic derivations. Each scenario is run with the  $\{\alpha, \beta, r\}$  parameters shown in the charts’ individual captions.

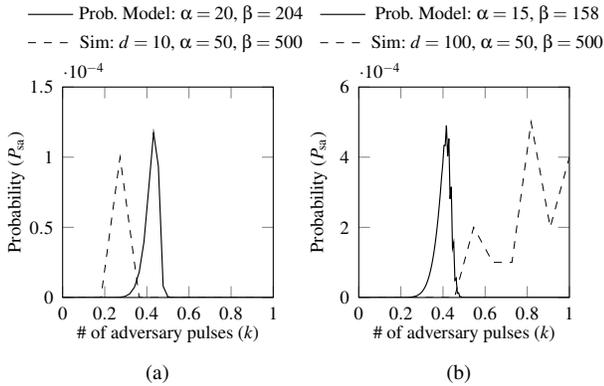

Figure 16: The attack is detected when the aggregate energy is between  $\gamma$  and  $\Gamma$ , but  $P_{\beta\beta > b\alpha}$  is more than  $P_{\text{noise}}$ . The attack is also detected when energy aggregate is more than  $\Gamma$ ;  $\zeta = 5$ .

#### Section 5.1.4.

In conclusion, the simulated probabilities follow comparable patterns with the model, and are in the same range. The model derived herein thus serves as a formal means for evaluating the efficacy and suitability of UWB-ED in practice. The results also show that the channel condition, such as path loss, noise, and interference due to multipath components, does not affect the performance and security of the system. An adversary can increase the noise level, which can increase false positives. High false positives may eventually cause DoS (which the adversary can mount anyway by jamming the channel), but the adversary remains unable to enlarge distances.

## 6 Discussion

**Adaptive attacks.** An adversary can notice the effect of each of its added pulses on the resultant energy, whether annihilated or amplified. It can then adapt its attack strategy by dynamically deciding  $k$  based on the number of pulses it has added/annihilated so far during the transmission. The adver-

sary can then utilize its knowledge of  $n$ ,  $\alpha$  and  $\beta$  in order to, not only decide the optimal value of  $k$  statically before the transmission begins, but also adjust their distribution in realtime. This attack does not succeed because the adversary cannot control the resultant pulse phase. Injecting excessive energy in  $\text{Bin}_\beta$  exceeds  $\Gamma$ ; injecting in  $\text{Bin}_\alpha$  does not guarantee annihilation because of the unpredictable phase.

**Varying energy levels.** To achieve perfect signal annihilation, an adversary uses the same amplitude expected at the receiver. Instead of injecting  $k$  pulses each with a constant energy of, *e.g.*,  $2\mu W$ , the adversary can inject one pulse with an energy of, *e.g.*,  $2k\mu W$ . If all  $k$  pulses fell in  $\text{Bin}_\beta$ , the aggregate energy would be the same as when that single high-energy pulse also falls in  $\text{Bin}_\beta$ . However, intuitively, the adversary is better off injecting multiple pulses with constant energies for two reasons. First, multiple pulses in  $\text{Bin}_\beta$  have higher chances of being selected than a single pulse, thus evading the Robust Code Verification check. Second, for those that fall in  $\text{Bin}_\alpha$ , any leftover energy after annihilating a pulse, regardless of the phase, will be counted towards the overall aggregate, thus hurts the adversary’s cause.

**Influencing  $\Gamma$  through distance shortening.** Instead of enlarging distances directly, the adversary can first mount a distance-reduction attack to trick the devices into using higher  $\Gamma$  (recall: smaller signal attenuation due to shorter path loss leads to higher  $\Gamma$  calibration). It is thus imperative to complement UWB-ED with a distance-reduction detection [5, 6, 26]. Devices should alternate between both techniques; *e.g.*, if distances of  $d_1$  and  $d_2$  are verified using respectively UWB-ED and a distance-reduction detection technique, it should be concluded that the actual distance,  $d$ , is in the range  $d_1 \leq d \leq d_2$  ( $d_1$  is a lower bound,  $d_2$  an upper).

**Influencing the number of pulses,  $n$ .** An adversary can inject a low stream of noise-like energy, not too high to be detected as jamming. However because  $\Gamma$  is set beforehand, it is not influenced by the adversary. By injecting noise, the adversary actually hurts its own cause as it reduces the amount of energy it can use strategically to prevent code detection.

**Integrating UWB-ED with 802.15.4z and 5G.** The 802.15.4z enhanced impulse radio task group is defining a

series of physical layer improvements to provide secure and precise ranging [2]. Those include additional coding, preambles, and improvement to existing modulations to increase ranging integrity and accuracy. UWB-ED is a potential candidate for enlargement detection in 802.15.4z. It adheres to the low pulse repetition (LRF) mode frequency (1-2 MHz), works with non-coherent receivers, and supports up to 100m.

The 3GPP technical specifications groups are designing the 5G-new radio technology, and it aims to include secure and precise ranging based on wireless signals [16,33]. Properties such as high carrier frequencies, large bandwidths, large antenna arrays, device-to-device communication, and ultra-dense networking will help attain this objective. It is early to say the exact modulation techniques 5G will use for distance measurement, but it is safe to assume that wideband will be used to attain position accuracy; beamforming techniques will achieve long distances. This system is equivalent to setting  $r = 1$  herein without restrictions on  $\alpha$ , as transmission power restrictions imposed on UWB do not apply to 5G. However, the security of 5G can be increased further, as it allows for the use of beamforming and coherent receivers.

## 7 Related Work

Detecting enlargement attacks has lately been a prominent research area. Previous literature explored timing acquisition at the preamble, and data ambiguity at payload. Taponecco *et al.* [27] show that the success of enlargement attacks using replay (or overshadowing) depends on the amount of delay the adversary introduces. Such success is harder for controllable attacks, where the adversary is required to position nodes at specific locations. Compagno *et al.* [8] provide a probabilistic model for the success of overshadowing attacks, which captures different channel conditions and leading edge detection techniques for ToA estimation. None of the above efforts considered adversarial signal annihilation.

Tippenhauer *et al.* [29] explored a theoretical approach to detect adversarial signal annihilation for distance enlargement: using a single pulse-per-symbol (consecutive integration windows represent a symbol). They found that modulation with a 2ns slot size, *i.e.*, mostly equivalent to a pulse width, might help detect signal annihilation. This, however limits the ranging technique to short distances. The effect of multipath on that scheme in practice is also unclear, since reflected signals would directly interfere with authentic ones causing distortion (no empty gaps between authentic pulses). In contrast, UWB-ED allows for increased distances by increasing the symbol length, and the sampling time between consecutive pulses is sufficient to handle the multipath effect.

## 8 Conclusion

We present UWB-ED—the first known technique to detect distance-enlargement attacks against standard UWB ranging systems. UWB-ED is readily deployable for current off-the-shelf receivers, requiring no additional infrastructure. Evaluation is performed by deriving the probability of adversarial success in mounting distance enlargement attacks. Results show that the verification code structure herein prevents signal annihilation. The code also allows the use of longer symbol length at the receiver, which is essential to achieve longer distance in the energy constrained UWB system. UWB-ED is thus a good candidate for enlargement detection in practice (*e.g.*, for 802.15.4z and 5G).

## Abstract

A victim service provider, or VSP, is a crucial partner in a human trafficking survivor’s recovery. VSPs provide or connect survivors to resources such as medical care, legal services, employment opportunities, etc. In this work, we study VSP-survivor interactions from a computer security and privacy perspective. Through 17 semi-structured interviews with staff members at VSPs and survivors of trafficking, we surface the role technology plays in VSP-survivor interactions as well as related computer security and privacy concerns and mitigations. Our results highlight various tensions that VSPs must balance, including building trust with their clients (often by giving them as much autonomy as possible) while attempting to guide their use of technology to mitigate risks around revictimization. We conclude with concrete recommendations for computer security and privacy technologists who wish to partner with VSPs to support and empower trafficking survivors.

## 1 Introduction

Human trafficking is a crime in which a perpetrator, or “trafficker”, preys on vulnerable individuals through atrocities such as sexual exploitation, forced labor, or the removal of organs [30]. As a conservative estimate, around 24.9 million individuals worldwide are being exploited in this manner [16]. Technology is playing an increasing role in this ecosystem, from enabling trafficking via online platforms (e.g., [2, 18]) to aiding in the detection and halting of trafficking (e.g., [6, 25]).

In this work, we focus on a previously understudied role that technology plays in the human trafficking ecosystem: technology in the interactions between trafficking survivors and organizations known as victim service providers, or VSPs. VSPs exist to support their clients by providing resources such as temporary shelter, help with employment and legal issues, and mental health support. In this work, we focus on VSPs providing resources to individuals who are exiting or recovering from a trafficking situation. These

resources are critical in protecting these individuals from former or future exploiters (“revictimization”).

Our research is driven by the following questions: How do VSPs communicate and interact with their clients (trafficking survivors), and, particularly, what role does technology play in that interaction? What are VSPs’ computer security concerns and threat models, both for themselves and on behalf of their clients? What technical (or non-technical) strategies do they use to mitigate these concerns? And, ultimately, what opportunities exist to better safeguard VSPs and their clients from a computer security perspective?

To investigate these questions, we conducted a qualitative interview study with 17 participants, including staff members at VSPs and several trafficking survivors. We analyzed these interviews using thematic analysis common in qualitative research. Our findings shed light on the general role of technology in VSP-survivor interactions (Section 4.1), the computer security concerns and threat models of VSPs and their clients (Section 4.2), and the corresponding defenses, where present (Section 4.3). We identify fundamental tensions and challenges that must be taken into account by technologists who wish to improve VSP and client security and privacy (Section 5).

At a high level, we find that VSPs make technology-related choices with the goals of protecting their clients from revictimization and other harm. Specific instances of how VSPs protect clients include helping clients lock down social media accounts and enforcing shelter rules restricting photos or social media posts (that may reveal the shelter’s location). We also find that, sometimes, the most effective means for VSPs and their clients to interact are not the most conducive to client safety. For example, despite the potential risk of trafficker-compromised accounts, some VSPs use Facebook to communicate with clients because it provides a reliable way to reach them even in the absence of cellular service. More generally, we find that our participants must balance building client trust and maintaining contact with imposing technology-related client safety rules.

From findings such as these, we distill concrete recom-

recommendations for those in the computer security and privacy community, and for technologists at large, wishing to help support survivor-VSP relationships. For example, we provide guidelines on securing communications in situations when the client's device is compromised by an adversary with physical access and raise awareness around the threat posed to survivors by publicly available information (e.g., public records) online. In investigating the interactions between survivors of human trafficking and VSPs from a computer security and privacy perspective, our work contributes to the larger push to leverage technology for good in the fight against human trafficking.

## 2 Background and Related Work

There is a growing body of research examining the role of technology in both facilitating and fighting human trafficking (e.g., [2, 12, 17–19, 24]). In the computer science community in particular, prior work has developed technology to aid investigators in examining online sex ads and online forums for trafficking activity [6, 25].

Focusing on the victim service provider ecosystem, there has been research that explores the ways anti-trafficking organizations utilize technology to collaborate with each other [29] as well as efforts within the VSP community to leverage technology in providing help to trafficking victims [20]. Work outside of the technical realm has examined how survivors of trafficking [4] or domestic violence [13] experience and react to the assistance provided by VSPs.

Beyond human trafficking, the computer security and privacy community has studied other specific (often at-risk) populations, including journalists [22], refugees [28], and undocumented immigrants [14]. Most relevant to our work is research studying computer security and privacy for survivors of intimate partner violence [5, 10, 11, 21]. Where relevant, we highlight similarities between our findings with these prior studies on related populations.

In this work, we focus on an aspect of the human trafficking ecosystem that has not been rigorously studied from an academic, technical perspective: the interactions *between* VSPs and trafficking survivors. We ask, from a computer security and privacy perspective: how does technology enable or hinder these relationships, and how do VSPs and their clients consider and mitigate the potential technology-related risks that may undermine the survivor's path to recovery?

## 3 Methodology

Between March and July 2018, we conducted 17 semi-structured interviews with staff members at victim service provider organizations and several trafficking survivors.

**Recruitment.** Recruitment took place through several primary methods: introductions facilitated by community

members and anti-trafficking leaders, the authors' personal connections, and snowball sampling. Our recruitment advertisements specified that we were looking for advocates who work with labor trafficking and/or sex trafficking survivors to speak about how they use technology in their work. We also specified that participants would be compensated \$30.

**Participants.** Table 1 provides an overview of the 17 study participants. The 17 participants represented 11 different organizations; survivors P14 and P17 were not affiliated with a specific organization at the time of the study. 16 participants were based in the U.S. and one participant was based in a Southeast Asian country. Most participants were based in urban areas.

As Table 1 shows, most participants currently focus on serving survivors of sex trafficking (though some participants may have previously helped labor trafficking survivors as well). To avoid confusion, we do our best throughout this paper to call out results that are specific to interactions with labor trafficking survivors or sex trafficking survivors. Finally, to be clear, note that some of the participants who focus on sex trafficking survivors naturally also serve individuals in the sex trade who may not technically fall within the parameters of sex trafficking (e.g. individuals who claim to be in the sex trade voluntarily).

**Study Protocol.** The interviews ran between 60-90 minutes. We began with groundwork questions to understand the participant's role in supporting clients and general thoughts on technology's influence on the trafficking ecosystem. We then asked questions that would help surface how VSPs use technology in their interactions with clients and what, if any, concerns exist around this technology usage. We asked about participants' experiences with technology with regards to first contact with clients, client intake, organization and client safety, and day-to-day interactions. To avoid priming participants to overemphasize their computer security and privacy concerns, most questions focused generally on technology in client-VSP interactions and related concerns but did not mention computer security and privacy in particular.

Finally, we showed participants two prototypes for secure communication (created by others): single-use URLs (a URL that leads to sensitive content, which gets changed to innocuous content when the same URL is accessed again) and disappearing messages [1, 8, 9]. Our goal was to elicit reactions and threat models using these concrete examples, not to propose these particular technologies as perfect solutions. To avoid participants giving inflated positive responses towards the tools (participant response bias), we stated these goals clearly for participants and also stated that we did not make the tools. We asked questions like: When, if at all, might you use this? How could it be helpful? How could it introduce more risk? The full interview protocol can be found in Appendix A.

ID	Job Title	Focus	Client Nationality	Client Age
P1	Advocate, Survivor Leader	Sex Trafficking	Domestic	Adult
P2	Advocate	Sex Trafficking	Domestic	Adult
P3	Director	Sex Trafficking	Domestic	All
P4	Director	Sex Trafficking	Domestic	Youth, TAY
P5	Advocate	Labor Trafficking	International	Adult
P6	Director	Sex Trafficking	Domestic	All
P7	Advocate	Sex Trafficking	Domestic	Youth, TAY
P8	Advocate	Labor and Sex Trafficking	Domestic, International	All
P9	Advocate	Sex Trafficking	Domestic	Youth, TAY
P10	Advocate, Survivor Leader	Sex Trafficking	Domestic	Youth, TAY (to 25)
P11	Advocate	Sex Trafficking	Domestic	Youth, TAY (to 30)
P12	Advocate	Labor and Sex Trafficking	International	Adult
P13	Advocate	Sex Trafficking	Domestic, International	TAY
P14	Survivor Leader	Sex Trafficking	N/A	N/A
P15	Advocate	Sex Trafficking	Domestic, International	did not disclose
P16	Director	Labor and Sex Trafficking	Domestic, International	Adult
P17	Survivor Leader	Sex Trafficking	N/A	N/A

Table 1: Summary of Participants. *Advocates* support clients one-on-one, *Directors* oversee the VSP’s human trafficking services (managing advocates as well as interacting with clients), and *Survivor Leaders* are survivors of trafficking (in this case, sex trafficking) who are raising awareness and leading trainings on the issue. Transition age youth (TAY) are individuals between the ages of 16 and 24 [32]; where specified, participants also worked with clients slightly outside of this range.

**Ethical Considerations.** Our study was declared exempt by the University of Washington human subjects review board (IRB). We obtained informed consent from participants to conduct and (optionally) to audio record the interview. As the interviews could touch on highly sensitive topics (especially for survivors), we ensured that participants knew that they could skip questions and request a break at any time. We also emphasized that participants should provide only as much detail in their answers as they felt comfortable with. All electronic files were password protected, and physical consent forms and notes were stored in a secure location.

**Data Analysis.** We continued conducting interviews until no new themes emerged (saturation). We analyzed the data thematically using a common methodology for qualitative data [3]. We conducted multiple passes through the data in which we iteratively identified and clustered themes, or codes, present in the data. Two researchers independently read through transcripts of several interviews, generated an initial set of codes, met in person to develop an initial codebook, and iteratively refined this codebook by applying it to additional interviews. Once the codebook was finalized, two researchers divided up the remaining interviews and coded them. We emphasize that the nature of our data is qualitative, not quantitative, so we do not report on raw numbers of participants who made certain statements in the results.

## 4 Results

We now turn to our results. After providing an overview of the general practices our participants and their organizations use in interacting with trafficking survivors, we will present the security and privacy concerns and mitigation strategies — and tensions and challenges — that arise in these interactions. We use the terms “survivor” and “client” interchangeably, depending on the context and following the norms described by our participants during the interviews. At times, we also use the term “victim” and note that VSP clients may not be fully removed from a trafficking situation when they are receiving services.

### 4.1 Client-VSP Interactions

This section provides background and context for the more in-depth security and privacy discussions in later sections.

#### 4.1.1 Role of VSPs

Though VSPs may help trafficking victims escape their situations, their primary role is to help clients with the many challenges they face on the path to stability, including looking for employment, applying for housing, dealing with legal matters, and coping with severe trauma. Importantly, as we investigate in this paper, VSPs protect clients and train

clients to protect themselves from revictimization into a trafficking situation.

Some of our participants work at VSPs that provide shelter for clients. These arrangements range from emergency shelters (with very low barrier to entry—e.g., a client can stay even if he or she is on drugs) to long-term homes (where the client must be committed to actively working towards goals and self-sustainability). As we discuss in Section 4.3, shelter locations are sometimes confidential to help protect clients.

As an overarching challenge in providing services to clients, participants described the delicate balance they must walk between building trust with their clients—so that they can best advise and maintain contact with them—and doing what they believe is best for the client. As clients have left (or as they are in the process of deciding whether to leave) a situation where they have had little control over their lives, participants often talked about how crucial it is to give clients as much autonomy as possible. For example, P13 talked about working with clients who want to find a job. While she would like her clients to go to school, she does not force her idea of what would be best on the client. Throughout our results, we will see this tension recur in the context of technology-related guidelines and choices that VSPs are hesitant to push on their clients.

#### 4.1.2 First Contact

Clients typically make their first contact with VSPs through referrals—e.g., from law enforcement, schools, or other VSPs—or via a phone hotline. Hotlines may receive emergency calls, playing a similar role to 9-1-1 for clients and trafficking victims. For example, P7 described answering hotline calls from individuals who are running for their lives at the moment, and P8 talked about how they will dispatch a Lyft or Uber to a caller who has just escaped.

Dispersal and discovery of hotline numbers happens in a variety of ways. Beyond relying on word of mouth (a common method), participants talked about posters with the hotline number placed in public locations such as hospitals, train stations, and rest stops. One organization has their hotline number on a local Spanish TV channel. Another mode of dispersal is through personal items (e.g., soap, essential oil, hats, etc.) handed out to at-risk individuals (e.g. farm workers) with the hotline number hidden discreetly on the object.

For individuals still in trafficking situations, calling the hotline can be dangerous (if the individual is constantly being monitored by their trafficker) or even impossible (if the individual does not have a device). In these situations, participants described the ingenuity of their clients in finding ways to access technology to get help. For example, one of P16's labor trafficking clients saved up enough money from tips to buy a burner phone from a gas station. While the burner phone did not have the capability to connect to the Internet, he had seen a hotline number earlier and committed

it to memory. As another example:

P8: I've had a few clients who, in escaping... [were] able to get access to a hidden phone or discretely (on an app that their trafficker isn't aware...is a messaging app)...send messages to a friend who helps them get help...

From advocates who work with sex trafficking survivors, we heard how clients will search the web for help:

P2: We've had a couple people. I'm like, "How did you learn about us?" She goes, "I googled prostitutes [city]."

At the same time, participants worried that lack of technical expertise could make it challenging for clients to find help online. For example:

P1: I think what people have a hard time with is search words. I think people don't understand how Google works, and how to search for things.

Mention of direct outreach by VSPs to potential clients was rare, but one participant uses the phone numbers in online sex ads to conduct text message campaigns to contact individuals who might want help leaving. Another participant, P3, said that her organization reaches out to people who like the organization's Facebook page to see if they need help.

#### 4.1.3 Continued Communication

Our participants typically communicate with clients via phone calls, SMS, social media (e.g., Facebook), email, and in person. Participants generally talked of using the communication method that their clients feel most comfortable with. P16 described how digital communication can help put clients at ease.

P16: I find that many of our clients are more comfortable engaging through technology because it's less raw. It's a step removed in some ways...

Communication methods that work over WiFi were often mentioned as important, as clients may not be able to afford reliable cellular service or even a reliable device:

P2: A client right now has a phone. It's not connected to any service, but she can connect to WiFi, so she and I can use Facebook Messenger instead of texting. That's true for a lot of our clients, because phones get turned off and on all the time, numbers change all the time. I can still reach them on Facebook, on Facebook Messenger. You can log in to any computer or any phone to access it.

As we will discuss further in Section 4.3, participants' and their clients' threat models also influence their choice of communication method.

## 4.2 Threat Models and Security Concerns

We now turn specifically to the threat models and computer security related concerns voiced by our participants, both for themselves as individuals and representatives of their organizations, and on behalf of their clients. We found that many of the security concerns or goals that our participants voiced ultimately revolved around preventing revictimization and protecting the physical safety of clients and VSPs. In this work, we focus primarily on technology-related issues, but highlight other concerns as well where necessary for context.

### 4.2.1 Trafficker as Primary Adversary

The most common adversary for VSPs and clients were the clients' former trafficker(s) or potential future trafficker(s).

**Compromising Online Accounts and Communications.** VSP clients' communications may be compromised by traffickers, either digitally or via physical access. In many cases, traffickers have access to account credentials directly. P5, who works with labor trafficking survivors, described one tactic traffickers use to gain such access and alludes to the way low digital literacy can harm international and/or labor trafficking victims:

P5: What if their trafficker has access to their email or helped them set up the email account. Just the client never knew that and now I'm communicating with the client and [the trafficker] is reading our information?...I feel with our clients, they're just so vulnerable and a lot of them were brain-washed...using a cell phone or using Facebook, a lot of them, their traffickers opened the account for them and they think, "Oh he was just being helpful. He wanted me to communicate with my family."

Traffickers may also compromise or intercept communications via physical access to clients' devices. For example, in the sex trafficking ecosystem:

P7: I've had different guys that'll pick up [my clients'] phone and pretend to be them, go through their messages.

Despite the risk that a trafficker might physically see or digitally intercept communication intended for a victim, P1 weighed such risks against the benefits of reaching trafficking victims in her text outreach work. Note that the term "pimp" is another way of referring to the trafficker.

P1: And I don't think it's at the expense of the victim, okay? I think, people ask this question because they're like, "Well don't you think that their pimp is gonna beat them up because they got this message?" Potentially. 100% yes...It's either, I get information out there that will potentially give them an out, or they just don't get anything.

**Tracking Location.** Another concern was traffickers tracking down former victims after their escape. P16 has had clients who found GPS trackers on their cars; P7 described the use of tracking apps on phones:

P7: It's usually...through [the victims'] device because most of the pimps get [the device], so they have the family tracking, different apps and stuff like that...One of my girls has shown me that they can pull it up on their computer and you can see where all of [the victims] are at one time.

### Using Online Information to Track Down Survivors.

Even if a survivor's devices or accounts are not directly compromised, participants worried about the use of online public information to track down survivors. This fear is exacerbated by the fact that the trafficker often knows key information (like birth date, social security number, etc.) that allows access even to protected information.

For example, P14 is herself a survivor, and she generalized from her own experiences the ways traffickers can utilize public information to relocate survivors. Specifically, she explained that traffickers can find where survivors have moved by searching publicly available Department of Motor Vehicles (DMV) records; they can use survivors' addresses and social security numbers to access and potentially lock them out of their own bank accounts; and they can then track survivors' activities by observing the details of bank transactions.

As another example, P17 described being found via medical records and an old Facebook page she had thought was gone. P16 talked about how shared rewards systems (like grocery rewards cards) can reveal to a trafficker where a survivor is shopping and what they are purchasing.

**Undermining VSP Operations.** Participants also discussed the ways that traffickers seek to undermine the efforts of VSPs. P7 talked about traffickers hanging out near VSPs to recruit, and P16 talked about a trafficker sending a victim into a survivor program to recruit others directly. P2 mentioned that traffickers have called her organization's hotline looking for survivors.

For shelters where the location is confidential, participants described various ways in which this confidentiality could be compromised. A common concern, for example, was that people living in the shelter might accidentally reveal its location (or the location of shelter guests) to traffickers via pictures or other posts on social media. P14 felt that location confidentiality was a challenging, if not impossible, goal:

P14: ...how confidential really is any kind of building? I mean, you're gonna see it on Google Maps eventually. Whether or not you see it this year or three years from now when they do their next picture, you're gonna see it. So it's not gonna be necessarily confidential for long.

On a related note, P14 talked about an organization she knows that did drone footage of their safe house as a cautionary tale to VSPs of how easily location confidentiality can be breached.

P14: Which to me, anybody who is logical, you're doing drone footage of a supposed safe house. Well, any good hacker is gonna be able to pinpoint on a map exactly where that safe house is. Now, you're no longer safe.

#### 4.2.2 Other Threats and Concerns

Beyond traffickers as direct adversaries, our interviews surfaced several other threats and concerns that VSPs and their clients may contend with.

**Availability of VSP Resources.** VSPs have limited resources which can come under intentional or unintentional contention. For example, several participants discussed ways in which the availability of the emergency hotline can be impacted, either by suspicious callers or by callers who misinterpret the function of the hotline. For example, P12 talked about how the hotline gets calls from people who need help with their subway cards because there are posters with the hotline number in the city's subway system.

**Post-Trafficking Limbo.** Several participants (P11, P13, P15) discussed how sex trafficking survivors can be at greater risk for abusive or unhealthy relationships:

P13: They'll minimize the [domestic violence] because "at least he's not selling me"...They'll minimize the psychological violence that they're causing them or the emotional.

P13 gave an example of the potential consequences, describing a client who has an abusive, controlling boyfriend:

P13: Like, within the last two months she's gotten like four new numbers, four new phones or five new phones. So I'm starting to think that this guy is breaking all her phones so that she doesn't have communication with anyone.

P13 described how this constantly changing communication environment severely limits the amount of help she can offer the client, e.g., prolonging the process of helping her find employment. Prior work [27] describes how domestic violence can serve as a "push factor" into sex trafficking. Our findings suggest that the push factor can also work in the opposite direction from sex trafficking to domestic violence. Computer security in the context of intimate partner violence has also been covered extensively in prior work [5, 10, 11, 21].

Labor trafficking survivors are especially desperate to get a job, and P5 described how they will sometimes even consider asking people in their community back home (who got them into labor trafficking in the first place) about jobs for

undocumented individuals. Furthermore, the internet is not always a safe place to look for re-employment. In describing ways that technology facilitates trafficking, P8 talked about online frauds that can lead to labor trafficking:

P8: We've had clients who respond to certain Craigslist ads for either a place to live or a job and then once they get into this suspect situation end up...getting trafficked.

**Online Triggers.** Several participants mentioned the risk of online triggers that may push a sex trafficking survivor towards revictimization. For example, survivors who are friends with individuals still in sex work (whether voluntarily or not) are constantly bombarded on social media with reminders of their past (e.g., a friend might post about the amount of money she made in a night):

P2: We talk about "environmental triggers," and you can avoid an area of town as part of a safety plan around relapse prevention, but do you also have to delete your Snapchat and maybe your Instagram? And maybe get a new Facebook? If you're still "friends," on any social media platform, with anyone from that life, you're gonna be seeing triggers constantly.

In a similar vein, P4 worried about all the things her (underage) clients might stumble across on the Internet. She told the story of a time one of her clients was doing homework and clicked on a Youtube video. Youtube's content suggestions led the viewer to increasingly explicit content. P4 was also fearful that images of past (digitized) exploitation might surface on the Internet and haunt her clients later in life.

**Concerns around Law Enforcement and Legal Systems.** Both VSP staff members and survivor leaders voiced concerns related to the interactions between victims/survivors and law enforcement. On one extreme, a survivor leader explained that local law enforcement was complicit in her trafficking. This is a real concern—e.g., police officers in New York City were recently charged for involvement in a prostitution enterprise [31]. Thus, this survivor worried that, if law enforcement ever came to the shelter (to help with some emergency), this could be triggering for shelter residents who may have had negative experiences with law enforcement. Participants also voiced concern over victims of trafficking being charged with crimes. For example, prostitution is largely illegal in the United States, and sex trafficking survivors may be charged under prostitution laws or with other crimes committed during the time they were being trafficked [26, 27].

Participants also expressed frustration over regulations that make it difficult to establish trust with clients, such as legislation in some states requiring advocates to report runaways who come to their shelter to parents and law enforcement. This disincentivizes minors to come to the shelter:

P10: If they're listed as missing or as a runaway, I'm obligated to let law enforcement know where they are...I do have a lot of professional protocols I have to follow as well. I adhere to those, as much as they suck. Our laws just don't always enable us to do what actually needs to be done.

As we discuss in Section 4.3, these concerns can drive the communication choices of clients and VSPs. We also want to note that some participants described strong partnerships with law enforcement, and one survivor leader described the immense support she received from law enforcement in her recovery.

**Authenticity of First Contact.** Finally, for VSPs who do direct outreach to potential clients, it is difficult to convince the recipient of their good intent. P1 reaches out to potential sex trafficking victims via text message, and those receiving her text messages are sometimes fearful that she is the police. P5 has heard about this kind of outreach, but has not started using it because she knows the individuals she would be reaching, potential labor trafficking victims, would be highly suspicious:

P5: It's like, "Should I trust this?"... "Should I respond to that or is it just another trap for me? Am I going to get in trouble?"

Victims' concern about both traffickers and potential legal ramifications, discussed above, may lead to this skepticism.

### 4.3 Technical Defenses and Mitigations

We now consider the concrete steps that VSPs take to mitigate their own and their clients' computer security and privacy related concerns (with the ultimate goals of avoiding revictimization and other harm, as discussed above). Overall, we observed four categories of technology-related defensive strategies: (1) guiding or explicitly restricting how clients use technology, (2) protecting communications with clients, (3) protecting data about clients, and (4) protecting the VSP's resources and employees. These strategies are in addition to physical and non-technological defenses, e.g., security cameras and bullet-proof windows in shelters, and heuristics that VSPs use to identify suspicious hotline callers.

#### 4.3.1 Guiding Client Technology Use

In order to protect clients from revictimization or other threats, VSPs guide—or in some cases, explicitly restrict—their use of technology. This guidance is typically done in the form of safety planning with a client, or through rules and guidelines about the use of technology in a shelter.

**Technology Safety Planning.** VSPs work closely with their clients to help them be safe and feel safe. Given our focus on computer security, we focus primarily on technology safety

planning here, but note that other forms of safety planning (e.g., for physical and emotional safety) are related.

One key goal of technology safety planning is to keep a client's whereabouts hidden from a former trafficker. Participants talked about a variety of strategies, including avoiding different parts of town, overhauling communication methods and social media accounts, and turning off location services on devices. For example:

P10: Some people, they need to create a whole new social media everything, change their phone number and email address, and they need to just like literally disappear... That means that your accounts are completely, 100% locked down and you have pseudonyms, and you don't use your face in any pictures that you post. You never post your location. You don't have location turned on on your phone. You get a brand new phone because you don't know what kind of app trackers there are.

Some participants simply give guidance to clients, while others, like P10, actively help clients configure their devices:

P10: I tell them . . . "Give me everything. Give me all the stuff." I sit down and lock everything down.

Our survivor leader participants described the precautions they take themselves and would recommend to other survivors. For example, P14 only uses location services when she needs help with navigation, changes her passwords regularly, and avoids making location-tagged posts on social media. Likewise, survivor leader P17 uses pseudonyms on her profiles and deactivates her Facebook regularly. In addition:

P17: When I'm at the store and they're like, "Can we please have . . . your zip code or your phone number," I always say no, my phone number is very private. When I check in at hotels, I always have a process so my name doesn't associate with the hotel. My medical information is protected like everybody else's but I always have to have a conversation, like look, there are people that have every piece of information about me and they will call to get my medical information so I need a code word or something associated with my account.

While a common sentiment was that location services on phones should be turned off, on the flip side, clients sometimes want location services *on* as part of the safety plan:

P2: We've had some clients...who want their location services on, so that I can use my iPhone and find them if something goes south, or to get an Uber sent to them in a crisis, or whatever the case may be. They want us to be able to track them.

Participants also helped their clients with general online safety best practices. For example, some participants (e.g., P11, P15) talked about helping their clients understand that folks on the Internet cannot always be trusted:

P15 (who works with sex trafficking survivors):

We've had some residents, when they're here, they start dating again. So they're on Facebook, they're on different websites, so I have candid conversations, "Okay, are you telling someone where you're gonna go? Are you telling another friend where you're meeting this new person online? What time can we expect you back?" Things like that. Trying to put that idea into their head that you should not trust people on the Internet.

Overall, there was the sense that safety planning is individualized rather than one-size-fits-all. For example, P14 mentioned that factors like how long someone was trafficked and where and whether or not the individual has made changes to personal appearance (e.g., dyeing hair) all impact safety planning. P15 also mentioned how age plays into technology use and, subsequently, technology safety planning: clients in their 40s and 50s tend to not have a large social media presence in the first place, while younger clients find it much more difficult to take a social media hiatus.

Stepping back, we observe a tension between granting autonomy to clients and providing maximum security:

P15: Because I always bring up to people, you probably should turn off location on your phone. But I do kind of leave it up to them. It's not mandatory that they turn it off. 'Cause we come from an empowering place. We don't want to be telling them what to do.

In addition, working through potential threats and how to defend against them can be highly stress-inducing — one of the challenges mentioned by our participants revolved around balancing the client's safety with their mental health. P8 talked about being careful in safety planning to not trigger the client and cause the client to become more fearful. P14 talked about the fine balance between making someone untrackable and keeping them sane. P15 pointed out that the survivor most likely is already safety planning and is in the best position to look out for himself or herself.

**Shelter Technology Rules.** Participants described sometimes enforcing technology-related rules in shelters. A number of rules or guidelines centered around attempting to protect the identity of people in the shelter and the confidentiality of its physical location. For example, some shelters disallow photos or videos:

P1: We have to think about all our clients and their privacy, especially we say, "If you're taking a photo, somebody could be walking behind you and you've breached their privacy because somebody could know who they are."

Similarly, P16's organization asks that shelter residents refrain from posting on social media and turn off location services on their devices. These rules aim to prevent accidental disclosure of the shelter location through, say, a Facebook post containing the resident's location. At P4's organization,

these rules hold for visitors as well: P4 mentioned that visitors have posted photos of general surroundings and staff asked them to take them down. P16 said that they also put up a sign notifying clients that if they use the VSP main office WiFi they are vulnerable to being tracked to that location — but overall considered providing WiFi to clients more important than mitigating this risk by not providing WiFi.

Additionally, some participants mentioned restricting or monitoring how clients use the computers provided in shelters, with the goal of shielding clients from content or activities that might put them at risk of revictimization. For example, at P3's organization, advocates ensure that clients are not using computers to post sex ads. In addition, clients can set up email accounts for employment, and they are told outright that the accounts are not private (i.e., the advocate may inspect the client's emails if there is cause to believe that the client is using the email account for other purposes).

In general, we found that organizations who work with younger clients (under 18) have more regulations around technology usage. For example, P4 checks the browsing history of the shelter's computers weekly. P6 was in the process of purchasing software to help manage computer usage. Her organization has an adult sit with clients who need to use a computer. At the under-18 shelter run by P9's organization, clients physically check in their phones when they enter.

The main challenge here lies in balancing technology rules with the fact that technology use is an increasingly crucial part of life for many people, helping them feel "normal." And, as P14 explains, strict restrictions on technology use can actually undermine security goals:

P14: If we deprive them of that technology, they're gonna do it behind our back. They're gonna find a way to get a burner phone, they're gonna find a way, and a friend, and whatever to get a phone ... whether we endorse it and give them a safe way to do it, or whether we let them do it behind our backs and potentially risk all of us ...

### 4.3.2 Protecting Communications with Clients

Given the potential for compromise—by traffickers or others—of communications with clients, VSPs carefully consider their choice and use of communication methods.

**Choice of Communication Medium.** Participants discussed two main goals when selecting communication methods: (1) protecting the content of communications from potential adversaries and (2) maintaining contact with clients. We summarize the pros and cons of communication methods from the perspectives of advocates and clients, with respect to both convenience and security, as reported by participants.

**SMS.** Participants described SMS, or texting, as common and useful. It gives survivors space to choose whether to respond to VSPs or not, allows for urgent communication and quick

access to resources, and is more discreet than phone calls.

P7 suggested that individuals in the sex trade (whether voluntarily or not) are moving away from using text due to concerns about law enforcement confiscating phones and searching text messages. From the advocate perspective, some participants expressed unease that, with texting, there is no authentication ensuring that you are communicating with the person you think you are communicating with.

*Phone.* Talking on the phone, by contrast, allows participants to authenticate communication partners via voice:

P15: Texting can be tricky. Even if I've worked with the client for a while and I'm still texting them. Sometimes it's like I'd rather just call and talk to them so that I know it's them talking to me and not someone else on their phone.

Phone calls were also generally considered a sufficiently secure communication method—as long as the line is not being tapped. However, clients were sometimes not comfortable talking on the phone when they were still in physically dangerous situations.

*Social Media.* Social media—especially Facebook—emerged as a very popular way for VSPs to communicate with clients. (Indeed, related work on technology in the trafficking ecosystem [2] has found that victims of domestic minor sex trafficking utilize Facebook in app and website form more frequently than any other online service.) We observe that this prevalence may cause challenges, as social media can blur the personal/professional boundary between VSPs and clients, and it may not be secure: our own findings as well as prior work on intimate partner violence [10, 11] suggest that abusers commonly access victims' Facebook accounts.

In our interviews, however, the benefits of using social media to communicate with clients seemed to outweigh these risks. A key benefit of Facebook was that clients could retain access to it when they switch devices or phone numbers, and that using it does not require a cell phone plan:

P7: Facebook. All the time. 'Cause they can always go to the library and get on it. They can always go somewhere and get on their Facebook.

Some clients consider Facebook to be a more discreet communication method compared to phone calls:

P7: And more of them use Facebook because they don't want somebody calling their phone or having access to their phone. I've had a couple people that are like, "Do not call this number ever. I will call you. Don't ever leave a message on this number, don't ever call it, don't ever do anything, 'cause I have this one chance to call you and if you call back, it's going to be bad for me."

Snapchat can play a similar role, with the additional benefit of supporting disappearing messages by default. P6 recounted the case of a client who ran away from foster care

but remained in touch with—and eventually asked to be rescued by—someone at P6's organization via Snapchat. Here, the client's use of Snapchat may have helped protect the communication from being discovered by the trafficker.

*Email.* By contrast, email was not mentioned as a common or convenient communication method, largely because of a lack of access by clients. For example:

P12: ...a lot of them don't have e-mail. If they do, they don't know how to access their e-mail. Somebody else helped them set up their e-mail and they forgot the password and their username...

Though (according to P4) email can be helpful as a last-ditch attempt to establish communication when a client's phone number has changed, participants generally described preferring Facebook Messenger in this situation.

*Secure Communication.* Despite the serious security and privacy concerns faced by our participants and their clients, we heard very few cases of VSPs using existing secure communication technologies with their clients. P16 was an exception:

P16: ...we like WhatsApp because it's encrypted and because it's a safe storage for the conversations. We cannot use Facebook or Instagram or Snapchat because it's not secure. I know a bunch of programs that will respond through Facebook Messenger and we're not going to do that especially with all the privacy concerns.

We hypothesize that the limited use of WhatsApp (and no mention of other secure communication tools, such as Signal) reflects the tendency of VSPs to choose communication methods that are already familiar to clients (e.g., Facebook or Snapchat in some cases, or texting and phone calls in the cases where professional boundaries preclude social media use).

*In Person.* Participants also used a non-technological strategy for mitigating digital security concerns: meeting their clients in person. Meeting in person has the benefits of avoiding communicating through any potentially compromised digital medium and allowing for the authentication of the client to the VSP (and vice versa). For example:

P15: I think in terms of texting with clients and what not, I really prefer to meet someone in person. Especially if I'm meeting someone new. If my first contact with someone is through text message, I don't know if it's that person talking to me. I don't know, it could be their trafficker, could be someone lying to me, making up a name to try to figure out where the house is.

We note that meeting in person cannot defend against the case where a client's phone has been compromised by an adversary who uses it as a remote microphone to eavesdrop on conversations. One participant took steps to mitigate this

risk: P8 obtained Faraday bags for the organization to use when there is concern that a client's device might be compromised (it blocks incoming and outgoing signals from the device). P8 talked about using it with a client and how it allowed them to talk more freely without fear of being monitored. The downside of meeting in person is that it can be challenging for survivors to get to the VSP. P16 stressed the importance of technology in this context:

P16: They are working three jobs, the kids are home alone, they want to be home with the kids so I think that's actually a nice example of how technology is so helpful for us. They like physically, economically, emotionally cannot get to an appointment but...if we can communicate through a text that could be the lifeline. Or email.

Meeting a client in person also means that the VSP knows, by definition, where the client is physically located. This can be at odds with a VSP's desire to avoid turning a client in to law enforcement, e.g., as would be required if the client is listed as missing or as a runaway. P7 discussed how communicating digitally can provide a loophole for this case:

P7: You can hit me up for services and tell me, "I need this, this, and that,"... But if I don't know your location, I can't report you... I don't know where you are. It kind of covers our back because we can still serve them without having the legality to report them.

**Message Content and Authentication.** No matter the chosen communication method, there is always the risk of the trafficker or another adversary monitoring communications in real-time or reading them later, e.g., by leveraging access to a client's account, or by simply overhearing a phone call. To mitigate such a threat, participants reported using ad-hoc techniques to obfuscate the content of their communications with clients. For example, P1 is very brief in her phone communications with clients and checks in beforehand to make sure it is a good time to talk. P10, P3, and P7 use predetermined codewords or code phrases when communicating with clients via SMS or social media. P7 described an authentication strategy in which her client asks or answers a specific question that they established previously to start off communication.

**New Devices.** P8 reported clients getting new devices as a safety precaution. Limited financial resources on the part of VSPs constrain how much VSPs can help clients acquire new devices. Typically the phones provided by VSPs come from sources such as government programs or Verizon's Hope-Line program (which provided recycled phones to domestic violence survivors but is now phasing out). P16's organization receives donated phones but does not have funds to purchase data plans. They still give the phones to clients as a way to call 9-1-1 in the case of an emergency.

### **Challenges and Tensions in Protecting Communication.**

In addition to learning about existing ways participants work to protect client communications, we also explored their reactions to other technologies: single-use URLs and disappearing messages [1, 8, 9]. These explorations surfaced several challenges and tensions.

First, a risk with securing a communication channel is that it may make it more difficult for a client to access information. For example, several participants pointed out that although single-use URLs may prevent an adversary from accessing sensitive information via an already-used link, they also prevent the client from *re*-accessing that information.

Second, participants explained that appearing to hide something can put a client in danger (e.g., causing the trafficker/exploiter to become violent):

P7: Any way that somebody can open the thing and tell that you're being secretive is a scary thing. 'Cause then you're hiding something from me. "What are you doing behind my back? Who are you telling?" There's a lot of paranoia...

The above quote came up in the context of disappearing messages that require a password to view the message, but we observe that this tension may arise for any communication tool that clearly has security as a goal. On a related note, participants described the strong psychological power traffickers have over their victims. P6 discussed how traditional security mechanisms (such as passwords) may fail as the trafficker has such power over the victim that he or she can easily compel the victim to reveal secrets.

P6: Because they have been so conditioned, so coerced, that it's [the victims] telling anything that they're asked...They're the ones that have a problem keeping a secret.

### **4.3.3 Protecting Data About Clients**

Participants talked about the strategies they use to secure the data that VSPs collect and store about clients.

**Access Control for Internal Databases.** Most participants talked about using databases to store client information. A few participants explicitly mentioned how each staff member at the organization has their own login credentials and also talked about access controls on the data.

P15: Someone working in our admin department, like a secretary, they shouldn't be able to open our case notes. There's that kind of protection.

P15 was concerned about the cloud-based nature of the case notes software her organization uses. She was worried that if staff members logged in at home, client information could be seen by the staff member's family or roommates.

**Interactions with External Organizations.** P7 described how technology aids the referral process and how protocol

dictates that sometimes meetings must take place in person:

P7: We have a secured email that people can send referrals to...so we get a lot of our referrals from social workers and different people like that. Or I'll have a teacher or a counselor be like, "I can't give you much information, but I'd like you to come in and meet with ..." 'Cause they can't send it over social media or emails, anything.

Several participants described strict protocols for sharing client information with external organizations:

P15: We have a very specific release form. So if someone wants me to connect with their substance abuse worker that they're working with, I need that form filled out with that substance abuse worker's name, my name, the client's name, the client's signature saying you can tell this substance abuse worker ... You can tell them my name and my date of birth. We ask them to be very specific.

**Securing Internal Communications.** P15's organization uses encrypted email internally. Other participants mentioned strategies for protecting client identities in internal communications more informally, such as using client initials or first names only in communications and files:

P8: We're also very careful about using client names. Even in inner work emails or text messages or anything like that. I have all my clients saved in my work phone just as initials. So even if someone is reading a text conversation, they wouldn't know who that was with. Within our database system, everyone is assigned a client number, so we do often use that when we're emailing.

**Minimizing Data Collection.** Finally, participants described a general principle of storing the least possible amount of client data:

P16: We intentionally don't write...detailed notes and don't jot down information that could potentially harm them. Not even casually because even if we make a note on the intake form or we write down on a post-it that's technically a part of the case now. ...Keep it brief, keep it vague, keep it objective because anything can be used against the client in court.

In some cases, though, collecting sensitive data is necessary or useful. For example, P13 described how other staff members at her organization make copies of a client's important documents during intake (e.g., birth certificate, Medicaid card, ID, etc.). P13 does not do so, because she considers this information to be sensitive — but she pointed out that the copies can be critical when a client loses the original document.

#### 4.3.4 Protecting VSP Resources and Employees

Finally, we turn to the strategies that VSPs use to protect their own resources and staff.

**VSP Location Confidentiality.** Participants described various strategies for keeping the location of the VSP's office or shelter confidential. In addition to the shelter technology rules described above, some participants described protecting the address of the shelter by not mentioning it in digital communications with clients. For example, P8 specified that the office address is never texted or emailed out. Likewise, P16 does not share the shelter address. Instead, clients are given the address of a neutral location several blocks away and staff meet them there and bring them to the shelter. Other non-technical strategies for protecting the VSP's location include requiring clients and visitors to sign a confidentiality form, asking clients arriving in a Lyft or Uber to be dropped off several blocks away, only meeting clients at the VSP office if absolutely necessary, and making the shelter look physically inconspicuous (e.g., like a vacant office building).

**Personal/Professional Boundaries.** Participants described attempting to separate their personal and professional lives, to protect their own physical and emotional well-being.

The primary technical strategies participants described involve separating personal and professional communications. Almost all participants mentioned having separate work emails and work cellphones. With respect to social media, some participants had a strict policy of not interacting with clients on social media (e.g., finding it unprofessional), while others found it invaluable for reaching and maintaining contact with clients (as discussed above).

Participants who do use social media to interact with clients often use separate personal and professional social media accounts. For example, P7 talked about how her personal Facebook account has strict privacy settings, and how she made her friends list inaccessible on her work account to protect those friends. P2, who generally works with individuals who (voluntarily or not) are in the sex trade, talked about carefully regulating when she looks at her work Facebook account because she does not know what she might be exposed to. Another possible concern is that Facebook may unexpectedly reveal to traffickers or others the connection between survivors and VSP staff members (e.g., by suggesting a VSP staff member as a friend to a trafficker through the "People You May Know" feature [15]), but this concern was not mentioned by our participants.

Participants also mentioned a variety of non-technical strategies for protecting themselves, including meeting clients in public locations, letting others know where the participant is going to meet a client, being vigilant of physical surroundings, and the importance of personal self-care and therapy. Ultimately, however, participants accepted the inherent risk in the work that they do:

P6: I don't make any claims that we're gonna protect [volunteers] from something bad happening. But then, it happens with these girls all the time. And if we're not willing to walk into that garbage in danger with them, to me it's kind of the same as throwing them out to the wolves. 'Cause they can't get out. They can't choose to not be at risk.

## 5 Discussion

We now take a step back from our findings, surfacing broader lessons and making concrete recommendations for technologists wishing to support VSP-client interactions.

### 5.1 Broader Lessons for Technologists

**Tensions and Challenges.** Our findings surface a number of tensions and challenges that influence how VSPs and their clients use technology. These must be understood and considered by technologists wishing to work in this space.

*Limited resources on the part of both clients and VSPs.* For example, clients may not have access to cell phone plans, limiting their communication technology choices to those that support WiFi (e.g., Facebook Messenger). They also may have limited memory on their devices, or may frequently change devices and phone numbers. Technology solutions must take into account these potential limitations.

*Limited and varied technology expertise.* We found that computer security and privacy literacy and practices varied widely among VSP staff and clients. Participants' defensive strategies ranged from technologically advanced (e.g., using Faraday bags) to abstaining from technology. Participants described knowledge gaps among clients (e.g., clients not realizing that their Facebook profiles can be found via a web search), but we also spoke with survivors who are going to extensive lengths to protect themselves digitally. Technology must be designed for this range of knowledge and expertise, and there may be a role for computer security education and training specifically designed for VSPs and their clients.

*Balancing client trust and technology access with safety.* VSPs must balance building client trust with enforcing rules intended to protect clients and the VSP. As one of our participants put it, a VSP that it is too strict in terms of rule enforcement risks becoming, in some ways, like a trafficker to its clients. Even well-intentioned rules and guidelines around technology use can ultimately reduce safety as clients figure out ways to circumvent the rules. Thus, our participants commonly gave clients space to make their own technology-related choices (echoing prior findings about journalists deferring to the choices of their sources [22]).

*Double-edged sword of technology.* Access to technology can be a critical part of recovery—survivors can connect

with new or former support networks, communicate with VSPs, and use technology for job searches and other critical tasks. However, this same access opens survivors up to potential risks, including being tracked down or monitored by former/future traffickers and being exposed to content that may make recovery harder. This tension echoes findings in the domestic violence context [21].

*Balancing safety planning with client mental health.* Finally, solutions must take into account the trauma and psychological challenges that survivors face—and avoid “triggering” survivors or causing them to be unnecessarily fearful.

#### **Lack of Systematization and Need for Personalization.**

Our findings suggest that there is little systematization among VSPs around technology in VSP-client interactions and safety planning. For example, one organization uses WhatsApp because they perceive it to be more secure than Facebook, while many other participants discussed commonly using Facebook to communicate with clients. These differences may stem from factors such as: differences in the technology expertise and experiences of the VSPs and their clients; the fact that, in some organizations, VSP staff work relatively independently without top-down restrictions; and the fact that different clients face different risks and thus different mitigation strategies are necessary or effective.

These observations lead us to two conclusions: First, there may be benefit in systematizing computer security related guidelines and trainings for VSP staff, to help inform them about potential risks and benefits with different technology choices. Second, technology-based interventions cannot be “one size fits all” but must enable personalized approaches for survivors and VSPs in different situations.

### 5.2 Directions for Technologists

**Authentication and First Contact.** Technology can help VSPs reach out to potential clients, e.g., through the text messaging program discussed by some of our participants. However, a challenge with directly contacting trafficking victims or survivors is how to authenticate the first contact and build trust. There may be opportunities for technology designers to help address this challenge, e.g., through the (re)design of messaging tools for this population or through rigorous A/B testing of different message content for direct outreach to potential clients.

In the other direction, some participants discussed how difficult it can be for clients to find or contact VSPs when they are looking for help. Possible technology-based improvements here include real-time chat systems to replace phone hotlines (as “sometimes picking up the phone...is not an option”, P7) and proactive help by search engines that suspect a user is attempting to find trafficking-related resources.

**Designing for VSP-Client Communications.** Based on our

findings, we recommend those designing for secure (i.e., hidden from the trafficker) client-VSP communications take into account the following lessons:

- Raising the trafficker’s suspicions can be dangerous, so sensitive messages should look innocuous or be easily hidden to provide plausible deniability around the content, intent, and/or recipient of the message.
- It is also important to account for the complex psychology of the victim-trafficker relationship, and how this makes it challenging for the victim to keep secrets (e.g., passwords) from the trafficker.
- Solutions must work with devices with varying levels of functionality (e.g., phones with limited memory) and in the face of changing phone numbers and devices.
- It is important to plan for adversaries (traffickers) with physical access to a client’s device.
- Solutions that can fit into existing popular communication platforms and/or existing VSP-client communication habits will have the greatest success in adoption.
- Prior work on domestic violence has shown that taking steps to remove an abuser’s access to an account can be dangerous [11]. We suggest research on ways to support secure communication *within* otherwise compromised accounts, e.g., via a hidden secondary messaging interface.
- Finally, the client’s ability to easily access and re-access the intended information is crucial — but must be balanced with protecting the same information from a potential local or remote adversary.

**Publicly Available Information.** The survivor leaders we spoke with are already extremely cautious in terms of digital security, yet there are data sources and tools/services that they have no control over that can compromise their safety. For example, traffickers utilize public records (e.g., DMV records) to track down former victims. To try to combat this, government address-confidentiality programs [23] provide qualified individuals with an alias mailing address. However, this is not a panacea; there are an unknown number of third-party services that pull public data and market themselves as an easy way to find people on the Internet. Even if a survivor qualifies for the confidentiality program, sensitive data could already exist on these people-finding services, and it is unclear how long it takes for new information to replace old.

Furthermore, this problem affects the general public as it enables a host of other crimes such as stalking and “doxing” (releasing sensitive information publicly). We suggest future work study this ecosystem and develop solutions for helping people protect themselves — for example, streamlining the process of opting out of these people-finding services and helping users renew the opt-outs when/if they expire.

**Supporting Safe Technology Use in Shelters.** We believe that the computer security and privacy community can work

with VSPs to develop ways for shelter residents to safely utilize technology. This is especially imperative for VSPs working with youth. These VSPs are in a difficult position as the youth they work with tend to be avid technology users but may not understand all the risks inherent in active technology use. In addition, they may be using technology to communicate with unsafe individuals such as their trafficker or potential trafficker. We found that, in response, VSPs tend to take an approach of strict regulation of technology use for young clients in particular, locking up phones at night and heavily regulating and monitoring computer use. While this is done out of the best intentions to protect the clients, it is (as discussed) commonly circumvented by clients.

Thus, it is clear that technology abstinence is not a reasonable solution for client safety planning. These findings highlight the need for members of the computer security and privacy community to work with VSPs to develop solutions and/or provide education to help strike the right balance.

### **Integrate VSPs and Survivors in Solution Development.**

Finally, echoing an increasingly common refrain in usable security, we note that it is critical to design technologies in a way that is deeply informed by the needs, constraints, and use cases of target populations. Though our work provides a foundation for technologists working in this space, future researchers should continue to connect with VSPs and survivors to design and evaluate any technology interventions.

P14: Getting advice from the people who are using the technology that y’all are creating is a big part of moving forward. Because the moment y’all stop listening...to those of us who us are on these front lines using this technology to help . . . the moment that that stops happening is the moment that y’all stop growing and being effective.

## **5.3 Limitations**

Our study is qualitative, not quantitative; thus, our sample size is small and does not allow us to draw quantitative, generalizable conclusions. Self-reported data also has limitations such as recall and observer bias. Additionally, our participants are based primarily in urban areas in the U.S. and our results relate mainly to sex trafficking and female survivors. Thus, our results do not represent all possible VSP-client interactions. We believe there is more to uncover with regards to providing services to survivors of labor trafficking and survivors of other genders. For example, P15 talked about how her organization opened a shelter for all genders, allowing them to take in labor trafficking survivors and families. These are areas that call for further exploration with regards to how technology plays into these new dynamics.

## 6 Conclusion

Victim service providers play a critical role in the recovery of survivors of human trafficking. In this work, we conducted 17 semi-structured interviews with VSP staff members and survivor leaders, surfacing the ways technology is involved in VSP-client interactions, as well as the computer security and privacy concerns and mitigation strategies associated with those interactions. Key contributions of this work include detailing the various tensions that VSPs face when using technology in their interactions with clients and providing concrete recommendations for technologists who wish to support VSPs and trafficking survivors.

## 7 Acknowledgements

We are deeply grateful to our participants for taking the time to share their experiences and perspectives. We thank Kirsten Foot and Tadayoshi Kohno from the University of Washington for their invaluable help and advice throughout this project. We thank Robert Beiser, Sherrie Caltagirone, Kelly Mangiaracina, Lauren Moussa, Taylor Naber, Johnna White and other members of the anti-trafficking community for their assistance in developing the interview protocol and facilitating connections within the VSP community. Tiffany Chen and Kiron Lebeck kindly read the draft of the paper. Finally, we thank the anonymous reviewers for their feedback. This work is supported in part by the National Science Foundation under Awards CNS-1463968 and IIS-1748903.

## A Interview Protocol

Our study involved qualitative semi-structured interviews. As such, the questions below served as a guide for our interviews, but individual interviews varied based on participants’ responses and specific experiences. We let the participant’s responses direct the conversation, asking relevant follow-up questions and skipping irrelevant questions as appropriate.

### General Background

1. What is your job title and role? In your job, what are the main services you provide to clients?
2. Would you describe your technology comfort level as high, medium, or low? Why?
3. How many years old is your organization? How many employees are there? What are the main services your organization provides?
4. How do you refer to the individuals you work with (e.g., clients, survivors, participants, guests, etc.)?
5. What kinds of clients do you mainly work with? What type of exploitation have they endured? What is their nationality, their age range?
6. What are the most common pathways you see for your clients to be exploited? How has the rise of technology made the situation worse or better? What are your fears and hopes looking ahead?
7. FOSTA (Allow States and Victims to Fight Online Sex Trafficking Act) just recently passed. It amends section 230 of the Communications Decency Act so that laws relating to sexual exploitation of children or sex trafficking can apply to third-party content providers. How do you think the legislation might affect your work, if at all? How do you think it might affect the broader trafficking ecosystem, if at all?
8. What are the key factors that cause revictimization? How do you think technology facilitates revictimization, if at all? If you are worried a client has been revictimized, how (if at all) do you stay in contact with them?
9. How do you get help when you encounter issues with technology and computer security at work?

### Client First Contact

1. How do cases typically come to your attention (e.g., law enforcement, community members, homeless shelters, victims directly reaching out, direct outreach, etc.)?
2. What means do you have for victims to directly contact your organization (e.g., phone, email, text, web form, online chat, etc.)?
3. Do clients ever reach out on their own? If so, how do you think they find you (e.g., word of mouth, Google, etc.)? What evidence do you have of this?
4. Walk me through what happens when an individual reaches out to your organization through any of those means. What do you do or not do to protect the individual's identity? How do you vet potential clients?
5. Is there an instance of someone contacting your organization that sticks out to you as particularly memorable?
6. Sometimes victims of trafficking are forced to recruit new victims. With that in mind, does your organization do anything to reach the traffickers, as some of them may be victims themselves?

### Client Intake

1. How do you record and store client information? What do you or your organization consider confidential? What worries you most in terms of the security and privacy or confidentiality of the information? Are you worried that the information may be subpoenaed?
2. What do clients usually have with them when they arrive (e.g., devices)? Are there any rules regarding what clients are or are not allowed to have with them before receiving services and/or entering the shelter?

### Day-to-Day Interactions

1. In your day to day work as you're interacting with clients, what are common (technology and non-technology) frustrations, worries, or fears? What would you say are the common frustrations, worries, or fears of your clients?
2. How do you communicate with clients in general (e.g., phone, email, SMS, social media, etc.)? For each mode of communication:
  - How did you choose this mode?
  - What do you commonly communicate about?
  - Have you ever been afraid that someone might be eavesdropping on the conversation?
  - Are there things you purposefully avoid talking about or don't feel comfortable talking about via this mode of communication?
3. What access to technology do survivors have through your organization? Do you provide any devices, apps, software, web programs, wifi access? If there is a computer for clients: What do people use it for?

### Additional Organization and Client Safety

1. Is the location of your organization and/or shelter confidential?
2. Do you have rules or guidelines about technology that clients have to follow (e.g., turning off location services on their phones)? Do you have rules or guidelines for visitors? How, if at all, do you enforce these rules?
3. What steps do you take to keep yourself safe? What are things you've noticed your clients doing to keep themselves safe?

### Reactions to Prototypes

When presenting these prototypes, in order to minimize participants response bias [7], we explicitly told participants that we had not created the prototypes, that we were interested in both positive and negatives reactions, and that our goal in presenting them was to make the conversation around potential technology solutions more concrete.

We presented to participants two prototypes: single-use URLs and disappearing messages [1, 8, 9]. For each prototype, we asked participants:

1. Would you or your organization ever use something like this? What potential benefits, if any, do you see?
2. What would you change about this tool? Are there any new threats or concerns that it would raise for your clients or your organization?

### Closing

1. If you had a magic wand and could solve any issue in this space, what would you do first?
2. What do you want to tell the computer security and privacy community to focus on with regards to helping victim service providers?
3. What drew you to participate in this study?
4. Is there anything you'd like to add about technology use in your job that I didn't ask about?

# Clinical Computer Security for Victims of Intimate Partner Violence

Sam Havron<sup>\*,1</sup> Diana Freed<sup>\*,1</sup> Rahul Chatterjee<sup>1</sup> Damon McCoy<sup>2</sup>

## Abstract

Digital insecurity in the face of targeted, persistent attacks increasingly leaves victims in debilitating or even life-threatening situations. We propose an approach to helping victims, what we call *clinical computer security*, and explore it in the context of intimate partner violence (IPV). IPV is widespread and abusers exploit technology to track, harass, intimidate, and otherwise harm their victims. We report on the iterative design, refinement, and deployment of a consultation service that we created to help IPV victims obtain in-person security help from a trained technologist. To do so we created and tested a range of new technical and non-technical tools that systematize the discovery and investigation of the complicated, multimodal digital attacks seen in IPV. An initial field study with 44 IPV survivors showed how our procedures and tools help victims discover account compromise, exploitable misconfigurations, and potential spyware.

## 1 Introduction

As computers and other digital technologies take an increasingly central role in people's lives, computer insecurity has for some people become debilitating and even life-threatening. Activists and other dissidents are monitored [7, 23, 25, 26], journalists are harassed and doxed [10], gamers are subjected to bullying [9], and abusers are exploiting technology to surveil and harass their intimate partners [35]. Traditional security mechanisms most often fail in the face of such targeted, personalized, and persistent attacks.

A different approach for helping targeted individuals is what we call *clinical computer security*. The idea is to provide victims of dangerous attacks the opportunity to obtain personalized help from a trained technologist. Just like people visit doctors for health problems, seek out lawyers when suffering legal troubles, or hire accountants for complex tax situations, so too should victims of dangerous digital attacks have experts to assist them. But while these other examples of professional

services have a long history leading to today's best practices, for computer security we are essentially starting from scratch: existing technology support services are ill-suited for helping victims in dangerous situations. The research challenge is therefore to develop rigorous, evidence-based best practices for clinical approaches to computer security, as well as design the supporting tools needed to help victims.

In this paper we explore clinical computer security in the important context of intimate partner violence (IPV)<sup>1</sup>. IPV is widespread, affecting one out of three women and one out of six men over the course of their lives [32]. Prior work has shown how abusers exploit technology to harass, impersonate, threaten, monitor, intimidate, and otherwise harm their victims [8, 14, 19, 20, 27, 35, 43]. Prevalent attacks include account compromise, installation of spyware, and harassment on social media [20, 27]. In many cases digital attacks can lead to physical violence, including even murder [34]. Unfortunately, victims currently have little recourse, relying on social workers or other professionals who report having insufficient computer security knowledge to aid victims [19].

Working in collaboration with the New York City Mayor's Office to End Domestic and Gender-Based Violence (ENDGBV), we designed, prototyped, and deployed a clinical computer security service for IPV survivors.<sup>2</sup> Doing so required not only developing first-of-their-kind protocols for how to handle face-to-face consultations while ensuring safety for both clients (the term we use for IPV victims in this context) and technology consultants, but also the design and implementation of new technical and non-technical instruments that help to tease apart the complicated, multifaceted digital insecurities that clients often face.

We designed a first-of-its-kind consultation procedure via a careful, stakeholder-advised process that made client safety paramount. Initial designs were refined over two months via 14 focus groups with a total of 56 IPV professionals, including

<sup>1</sup>A full version of this paper and materials is available at: <https://www.ipvtechresearch.org>

<sup>2</sup>Our initial and refined research protocols were approved by our institution's IRB and the ENDGBV leadership.

<sup>\*</sup>These authors contributed equally to the paper.

social workers, police, lawyers, mental health professionals, and more. This led to substantive feedback and refinements, culminating in a consultation design that appropriately takes into account the socio-technical complexity of IPV and the unique risks that clients face.

Our consultation procedure starts with a referral from an IPV professional, and then proceeds through a face-to-face discussion where we seek to *understand* the client's technology issues, *investigate* their digital assets via programmatic and manual inspections, and *advise* them and the referring professional on potential steps forward. This last step, importantly, involves procedures for clearly communicating new found information about technology abuse so that professionals can help clients with safety planning. Supporting this understand-investigate-advise framework are a number of tools that we created, including: a standardized technology assessment questionnaire (the TAQ); a diagrammatic method for summarizing a client's digital assets called a technograph; succinct guides for helping consultants and clients manually check important security configurations; and a new spyware scanning tool, called ISDi, that programmatically detects whether apps dangerous in IPV contexts are installed on a client's mobile devices.

After completing our design process, we received permission to meet with clients in order to both help them and field test our consultation procedures and tools. Thus far, we have met with 44 clients and our consultations have discovered potential spyware, account compromise, or exploitable misconfigurations for 23 of these clients. The tools we developed proved critical to these discoveries, and without them our consultations would have been significantly less effective. For clients with discovered issues, we provided advice about improving security, in parallel with appropriate safety planning guided by case managers knowledgeable about their abuse history and current situation. Many other clients expressed relief that our consultations did not discover any problems.

Professionals at the FJCs have uniformly responded positively to our field study, and reported that the consultations are helpful to their clients. Demand for consultations has increased and we are performing them on an ongoing basis. More broadly, our tools, including ISDi, will be made open-source and publicly available, providing a suite of resources for testing the replicability of our clinical approach in other locations. Whether our approaches and methods can be useful for other targeted attack contexts beyond IPV is an interesting open question raised by our work. We discuss this question, and others, at the end of the paper.

## 2 Towards Clinical Computer Security

This paper considers targeted attacks in the context of intimate partner violence (IPV). Prior work indicates that IPV victims are frequently subject to technology abuse [8, 14, 19, 20, 27, 35, 43], and a taxonomy by Freed et al. [20] includes four

broad categories: (1) ownership-based attacks in which the abuser owns the victim's digital accounts or devices, giving them access and control; (2) account or device compromise; (3) harmful messages or posts (e.g., on social media); and (4) exposure of private information online. Abusers use access to victim devices or accounts to setup dangerous configurations, such as adding their fingerprints to be accepted for device login, configuring devices to synchronize data with an abuser-controlled cloud account, or setting up tools such as Find My Phone to send location updates to an abuser's email address. Another avenue is installation of spyware apps that provide powerful features for monitoring devices [8].

Technology abuse in IPV is certainly complex in the aggregate, but even specific individuals suffer from complex, multifaceted threats. To concretize this, we give an example. For privacy reasons it is not any particular person's story. However, it is representative of many of the actual client situations we have encountered in our work.

**Example scenario, Carol's experience:** *Carol's now ex-husband subjected her to several years of increasing physical, emotional, and technology abuse before she obtained an order of protection, physically moved out, and filed for divorce. They are in a custody battle over their two children, ages four and ten, who live with the ex-husband part of the time.*

*Carol knows that he installed spyware on at least one of her devices, because she found the purchase of mSpy on their joint credit card statement. Additionally, he had access to her private photos that he then posted on Facebook. He would also routinely, over the period of a year, "hack" into her online accounts, posing as her in efforts to further alienate her from her friends and family. He even locked her out of her Gmail account by changing the recovery emails and phone number to his, which was devastating to her career in sales because it contained her business contacts.*

*Carol currently has five devices: a new Apple iPhone that is her primary device, two Android phones used by her children, an Apple iPad tablet bought for her children by her ex-husband, and a several-year-old Apple iPhone originally bought for her by her ex-husband. She routinely uses Facebook, a new Gmail account (since her old one was stolen by her ex-husband), and a variety of other social media apps that are important for her work in sales.*

This representative example highlights the complexities faced by IPV victims. Carol has a complicated *digital footprint* that includes a wide variety of devices and online accounts, some of which may be linked (e.g., different devices may have stored authentication credentials for different online accounts). She has complicating *entanglements*, meaning digital or personal relationships that may enable or complicate tech abuse, or render its mitigation more difficult. In Carol's case, the abuser has access to the children's devices, owns some of the devices in her digital footprint, and her need to use social media for her career limits options for preventing

harassment via it. The complex timeline of events, such as when she physically moved out and when the children visit the abuser, may be directly relevant to the tech problems she is facing. Finally, there is also the risk that blocking digital attacks causes an *escalation* of abuse, such as triggering physical violence as the abuser seeks to regain his control.

One avenue for improving on the status quo is pursuit of new technology designs that better resist such targeted attacks. While doing so is very important, future designs will not help IPV victims in the near term. More pessimistically, it may in fact *never* be possible to rule out damaging attacks by highly resourced, determined adversaries against lower-resource victims. We therefore need complementary socio-technical approaches to helping victims.

Unfortunately, existing victim support services struggle to help with complicated tech abuse situations [19,27]. The case workers, lawyers, police, and other professionals that work with victims report having insufficient tech expertise to help victims with digital threats [19]. There currently are no best practices for how to discover, assess, and mitigate tech issues [19]. Existing tools for programmatically detecting spyware are ineffective [8], and the state-of-the-art in practice is that professionals assume spyware on phones if a victim reports that the phone is acting strangely [20].

Commercial tech support services (e.g., Geek Squad [36] or phone stores) are unfortunately not a ready solution for addressing tech abuse. Prior work reports that victims occasionally use these services [19,27], but that even when used they often fail to effectively diagnose problems [20]. We believe this is because commercial IT support professionals do not have context-specific training needed to identify and handle complex tech abuse situations prevalent in IPV. In the worst case, they put victims into more danger due to a lack of appropriate safety planning. Finally, victims with lower socio-economic status may find such services hard to access.

**Clinical computer security.** We target new approaches for victims to obtain personalized and appropriately contextualized support from a trained technologist. There are a handful of existing efforts from which we drew some inspiration. The Citizen Lab [13] and related Citizen Clinic [1] have been working for several years with targets of government persecution, a recent Technology-Enabled Coercive Control (TECC) clinic was established for IPV victims in Seattle [2], and individual computer security experts have long informally volunteered to aid those suffering attacks [24]. However, there has been little research into how such personalized security services should be systematically designed and deployed.

We propose an approach that we call *clinical computer security*. The goal is to develop, in a rigorous, evidence-based way, a set of best practices for how a technology *consultant* can assist a victim — called the *client* in such a service context — with digital insecurity. Best practices will need to encompass a range of issues, including how to setup and run

clinics, recruit and train volunteers or paid professionals to staff them, deal with the many legal issues that will inevitably arise, and how consultations with clients should proceed. In this initial work we focus on designing and prototyping consultations, the fundamental element of any clinical approach. We discuss other aspects of running a clinic in Section 8.

**The challenges faced in client consultations.** As seen in Carol’s example, individual IPV victims often experience a wide range of tech problems. They have a complex digital footprint, including multiple devices and online accounts, each of which can be a vector for abuse. They often have many nuanced entanglements. Existing tools for detecting spyware have a high false negative rate [8]. To improve outcomes for IPV victims, we need to design a protocol for face-to-face consultations that can integrate into existing victim support infrastructure, help us understand the client’s problems from their point of view, discover tech risks they may not be aware of, and safely advise them about what steps they could take to improve their computer security.

Of course, we can look to other disciplines that use clinical interventions for guidance, including medicine, social work, mental health counseling, and even legal practice. These areas have long histories leading to today’s best practices, including common interview procedures such as standards for psychiatric assessments [28] or client-centered advocacy [31]. However, none of these disciplines speak to procedures for computer security, so while we incorporate ideas from them when useful, overall, we need new approaches.

### 3 Methods, Client Safety, and Ethics

We designed a client consultation protocol and associated instruments to improve computer security outcomes for IPV victims via face-to-face discussions and both programmatic and manual investigations of their digital assets (i.e., their computing devices and online accounts). Here we discuss our iterative design methods that optimized for client safety.

IPV victims can be in dangerous and even life-threatening situations, and we made client safety and well-being central to our methodological approach. No consultation process will ever be perfect, in the sense that one could guarantee that all of the client’s technology problems will be discovered, accurately assessed, and successfully mitigated. Indeed, the current status quo is reportedly missing many issues, accurately assessing few of them, and only sometimes properly mitigating them [19]. To make progress, we must develop research protocols that respect client well-being, are cognizant of safety risks, weigh the relative benefits of research to those risks, and, overall, minimize the potential for harm.

We therefore put into place a multifaceted strategy for performing this research responsibly. We partnered with the New York City Mayor’s Office to End Domestic and Gender-Based Violence (ENDGBV) [16], which runs Family Justice

Centers (FJCs) [17] in each borough of New York City (NYC). The FJCs provide a diverse array of resources for IPV victims, including police, legal, mental health, housing assistance, and more. All research protocols were approved not only by our institutional IRB but also by the ENDGBV leadership.

Our consultation protocols went through a thorough, iterative design process that: (1) started with initial designs grounded in findings from prior work [19, 20, 27]; (2) a two-month process of iterative and incremental refinements driven by focus groups with relevant IPV professionals; (3) a review and approval process with the ENDGBV leadership of our refined protocols and instruments for client consultations; and (4) an ongoing refinement process that was responsive to needs that arose during client consultations.

This process maximized the amount of meaningful research we could do *before* interacting with clients. In step (2) we conducted 14 rounds of iterative design with a total of 56 IPV professionals. Each round involved a 60–90 minute focus group held at one of the FJCs, in which we summarized the current consultation design, demonstrated our methods, and gave participants copies of our questionnaires and materials. They were encouraged to edit, rewrite, and redesign them. We took detailed notes. Data analysis was performed immediately after each focus group, consisting of a detailed assessment of our notes with a specific focus on suggestions for improvements or changes. In subsequent sections, we give examples of quotes emanating from focus groups that help explain, or led to changes in, our consultation protocol. These quotes are illustrative and not intended to represent a comprehensive thematic analysis of the focus groups.

After nine rounds of changes based on participant feedback, we had several consecutive focus groups that did not elicit any new suggestions. We therefore determined our procedure and methods were ready for a review and approval process with the ENDGBV. This involved presentations to, and discussions with, ENDGBV leadership about our protocol. Ultimately, we and the ENDGBV concluded that it was ready for use with clients due to (i) the sufficiency of safety procedures we put in place to minimize potential harm to clients, and (ii) the fact that the ENDGBV leadership concluded that our research would benefit their clients. We discuss our safety procedures for consultations in detail in Section 6.

Finally, we note that safety issues extend also to the well-being of the participating researchers. In addition to the potential for vicarious trauma or other emotional strain, spyware could in theory leak recordings of consultations to abusers. We discuss self-care and researcher safety in Section 6.

## 4 A Consultation Protocol for IPV Victims

We created and refined a first-of-its-kind protocol for conducting a tech consultation in which a trained volunteer with expertise in technology meets face-to-face with an IPV victim. We refer to the volunteer as the tech consultant, or simply

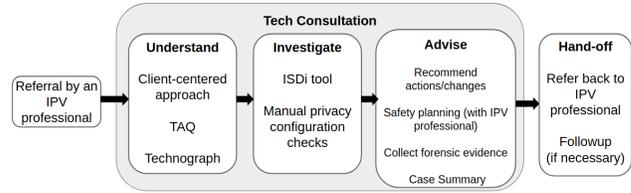

Figure 1: Summary of how a client participates in a tech consultation, beginning with a referral from an IPV professional.

consultant, and the victim as the client. A diagrammatic overview of our consultation procedure appears in Figure 1. We give a high level walk-through, and provide more details about various aspects of the procedure starting in Section 4.1. Throughout we give examples of how the iterative design process with stakeholders impacted our design.

We use a referral model that ensures safe integration of our consultations into NYC’s existing survivor support services. Upon setting an appointment and meeting with a client, we use a procedure that we refer to as *understand-investigate-advise* (UIA). This emphasizes three important aspects of the consultation: understanding tech risks in the client’s digital footprint, investigating their root causes, and providing advice about how they might improve their digital security.

To maximize the efficacy of the UIA procedure, we developed a number of non-technical and technical instruments to aid consultants, including: a technology assessment questionnaire, a diagrammatic approach called a technograph for mapping a client’s digital footprint, guides for reminding consultants how to check security settings for common services and devices, and a software tool called ISDi (**IPV Spyware Discovery**) that can safely detect the kinds of spyware reported as used in IPV settings by prior work [8]. We also developed a number of training materials, checklists, and associated protocols to help prepare consultants for meeting with clients. These instruments were refined via focus groups with professionals as well as in an ongoing manner as we gained experience working with clients.

### 4.1 Integration into Client Support Services

One of the first questions we faced is how to make tech consultations fit into the broader landscape of victim support services, such as legal, financial, and social services. Although consultants will be qualified to provide assistance with technology security and privacy, they will not necessarily be qualified to help with overall safety planning, legal advice, mental health, or other aspects of a client’s case. It is therefore essential that other IPV professionals are able to assist the client before, during, and after a consultation.

To ensure all clients have appropriate support from an IPV professional, we use a **referral model** in which consultants only see clients that are referred to them by other IPV professionals for potential tech problems. Using a referral model

has significant safety and procedural benefits over alternative models. In particular, the referring professional will know the client's background and abuse history and be qualified to help them safety plan around the results of the consultation (e.g., if it is safe to change their privacy settings, remove apps, etc.). If possible, and if the client is comfortable, we encourage the referring professional (or client case manager) to be present during the consultation so that they can also discuss their questions or concerns with the consultant.

Referral models have other benefits as well. They allow us to balance client anonymity with continuity of care, since the professional can serve as a safe communication channel between the consultant and client. This specifically enables consultants to perform **followups** for issues that cannot be fully investigated during a consultation. For example, we saw clients asking about esoteric or non-English apps, having browser extensions that are not on the extension market, and describing seemingly inexplicable tech situations. In such cases, we perform further research on the topic after the consultation, and communicate any discoveries back via the referring professional. If appropriate, the client may elect to participate in a second consultation, which happened a couple times so far in our work.

Regardless of followup requirements, when a consultation is complete (and with client permission) the consultant performs a **hand-off** procedure that communicates relevant findings to the referring professional. If the professional is in the room, this may happen at the end of the consultation. Otherwise, it happens via email or phone call. This hand-off is vitally important. First because it facilitates proper safety planning, as we discuss later in the section. In addition, it provides some reassurance to clients potentially frightened by a consultation's discoveries. As one professional described, our hand-off procedure:

*"...might help the client feel a little bit more comfortable. 'Oh my gosh, I'm being tracked. At least I know there's an officer that can help me with this situation.' You're also aware of what's going on as a screener, as well as a case manager. I have three different backups. I think it was very well done."* (P36, Case Manager)

## 4.2 Understand-Investigate-Advise Procedure

When the client arrives for a consultation, we follow standard IPV advocacy practices and take a **client-centered approach** [31], which assumes the client knows best regarding their own situation and will be the one to make decisions. One professional described client-centered practice as:

*"having a conversation with the client and ... letting the client formulate their decisions, their answers. [Professionals] cannot provide them with*

*[answers] because they're the only ones who know what risks are being posed."* (P36, Case Manager)

Therefore, taking a client-centered approach, the consultant begins by asking the client what their main concerns are and/or what caused them to seek out a consultation. We refer to these as their chief concerns<sup>3</sup> and a primary goal of the consultant is to try to accurately identify them. For example, we heard clients express fear that spyware was installed on their devices, that their "phones were tapped", or that their abuser had access to information they should not have (e.g., a client's photos). In some cases the chief concerns are not very clear and take some gentle questioning to ascertain.

From this starting point, the tech consultant will utilize a wide range of instruments and tools that we have created to (1) **understand** the client's digital footprint and entanglements to identify potential avenues for harm; (2) **investigate** their devices, apps, and services to look for, and assess the root cause(s) of, their tech problems; and (3) **advise** clients on how they might move forward. See Figure 1.

**Understanding footprint and entanglements.** Prior work on tech and IPV [14, 19, 27, 34, 43] indicates that there are no best practices or standard procedures for asking about tech risks or understanding the root cause(s) of client concerns. The lack of standardized procedures may contribute to serious, on-going tech abuse being overlooked. We therefore created several instruments that help systematize the discovery and assessment of tech problems in IPV.

To systematize problem discovery, we created and refined a Technology Assessment Questionnaire, or **TAQ** (Figure 5 in the Appendix). We started with questions that aimed to uncover common problems surfaced in prior work [20], such as risk of device/account compromise if the abuser knows or can guess the client's passwords (e.g., their password is their child's birthday), or ownership-based risks, when the abuser is the legal owner of the client's devices or accounts. Feedback from focus groups helped us refine question wording, and include additional questions that professionals thought would be helpful. As one example, we received many suggestions on the importance of asking about children's devices. As one professional told us,

*"[For parents] with younger kids, I think another question that might be important is asking if your children go on visits and if they take their electronics with them on visits."* (P40, Social Worker)

We added five questions about risks with children's devices. This feedback was particularly helpful, as we saw several cases in our field study of children's devices being the likely avenue by which the abuser had access to client data.

To support a client-centered approach, the TAQ is designed to be used as a reference to ensure consultants cover important

<sup>3</sup>In medicine, this would be called a chief complaint, but we feel that 'concern' is more client-centered.

topics, rather than as a prescribed interview format. The consultant lets the client lead the conversation and discuss topics they find important, which often touches on a subset of the TAQ. The consultant uses the TAQ to remember to raise remaining topics that the client may not have thought about. We arrived at this approach after early feedback from professionals that it is more empowering to let clients drive conversations, rather than peppering them with questions.

A challenge that came up in early consultations is building a mental map of the client's digital footprint and entanglements. Carol's example in Section 2 illustrates the potential complexity of client technology use. In the field, clients often came with half a dozen devices, many accounts, an involved abuse timeline, and various pieces of (often circumstantial) evidence of account or device compromise (e.g., the abuser keeps tracking or calling them despite changing phones). It is easy for consultants to lose track of relevant details.

We therefore created the **technograph**, a visual map loosely inspired by genograms, a technique used by clinicians in medicine and behavioral health to map family relationships and histories [22]. The technograph uses shapes and symbols to visually document relationships between (1) devices, (2) accounts, and (3) people (usually the client's family). Drawing connections between entities gives the consultant a clearer picture of potential sources of compromise. An example that may have been created discussing Carol's situation appears in the full version of this paper.

The technograph is particularly helpful to identify when abusers may have indirect access to a client's digital assets. For example, two-factor authentication for iCloud accounts can be bypassed if a child's device is a contact for the account. Another example is when family plans synchronize data across devices and accounts. The technograph allows tracing these potential indirect access routes more easily.

**Investigating devices, accounts, and services.** After using the TAQ and technograph to construct a clearer picture of the client's situation, the next phase of the consultation is to thoroughly investigate devices, accounts, or services that may be compromised by the abuser. We created tools that investigate in two ways: (1) by scanning the client's mobile devices for spyware or other unwanted surveillance apps using a new IPV Spyware Discovery (ISDi) tool that we built, and (2) by manually checking the privacy configurations of the client's devices, apps, and accounts. We discuss each in turn.

As we detail later, most clients have hundreds of apps on their devices. In addition to the threat of spyware-capable apps being installed surreptitiously, many otherwise legitimate apps may be configured by the abuser to act as spyware. For example, Google maps can be configured to update an abuser about the client's location, and while it provides various notifications that tracking is ongoing, their effectiveness is uncertain. We therefore have a dichotomy between unwanted and wanted apps, with the mere presence of the former being

sufficient for a safety discussion whereas the latter require investigation into their configuration.

Detecting unwanted apps manually via the user interface (UI) will not work: many IPV spyware apps can effectively hide their presence from the UI [8]. Indeed, current state-of-the-art practice by non-technologist professionals is to use circumstantial evidence to conclude spyware is installed, e.g., if a phone acts "glitchy" it most likely has spyware and should be reset if not discarded [20]. We therefore constructed an IPV Spyware Discovery (**ISDi**) tool for detecting unwanted apps on a client's iOS or Android devices. It also checks if the device has been jailbroken (for iOS) or rooted (for Android), which may indicate that dangerous spyware is installed. With the client's permission, the consultant uses ISDi to programmatically obtain via USB connection the apps installed on their devices, highlighting ones that are known to be risky in IPV. Should the device be detected as rooted/jailbroken or any risky apps found, the consultant can discuss whether the client rooted the phone, recognizes the app, etc.

Our focus groups with professionals helped us iterate on the user flow and understand how best to integrate the tool into client consultations. We learned that clients and professionals want to view and understand the steps required to use the tool as well as visually examine the scan results. Professionals expressed concern about communicating to clients appropriately about privacy issues. One professional suggested that, during a consultation, we say that:

*"We will see and go through every application on your phone, we will not see any information in your social media, texts, photos. We will only see the names of all the applications but not see anything inside any of the apps and give an example, such as, if you have WhatsApp, we will not see any conversation inside."* (P41, Case Manager)

Focus groups also led us to realize that both clients and consultants are consumers of the ISDi UI (see Figure 2). We therefore avoided language that would be too confusing or scary to a client. Finally, while we have not yet done a thorough user study of the tool, we have begun some initial user studies with IPV support organizations (e.g., TECC [2]) interested in integrating ISDi into their own procedures. We discuss this further in Section 8.

That leaves checking configurations of common apps that are often wanted but potentially dangerous, as well as checking built-in system services (e.g., "find my phone" features), account backup mechanisms, and authentication lists (e.g., registered fingerprints), all of which may be sources of vulnerability. The same holds for online accounts deemed important by the client (e.g., email and social media accounts). Unfortunately, checking the privacy of these accounts cannot be easily automated, not only due to lack of device or web interfaces to support querying this kind of data, but also because one needs to understand the context and have the client help identify

dangerous configurations. For example, in several cases we saw that the client's Facebook or Gmail accounts had been accessed by devices the client could confirm as the abuser's.

To assist the consultant with these **manual investigations**, we constructed simple-to-follow guides for popular apps, device settings, and online service settings. For instance, our Google privacy configuration guide lists steps to check a device's login history, location sharing, photo sharing, and Google Drive backup settings. On iCloud we check family sharing, backups to iCloud, and if the abuser still has access to the account. We continue to expand the list of apps and services for which we have guides in response to ongoing work with clients, and currently cover Android (including Google maps and Gmail), Apple (including iCloud and location sharing), Facebook, Instagram, and Snapchat. Unfortunately such guides may become out-of-date if software updates change configuration features. Future work on how to sustainably keep guides up-to-date will be needed (see Section 8).

Another benefit of performing manual investigations during consultations is that they serve as impromptu computer security training for clients, which prior work indicated is sorely needed [19]. In fact, many clients we met with did not know about security configuration features, and we were able to show them for the first time that, for example, they could tell what devices were logged into their Gmail or Apple accounts. Clients often asked followup questions about security best practices during this part of the consultation, leading into an open-ended discussion about computer security.

**Advising clients on potential next steps.** In the final phase of the consultation, the consultant combines information gleaned from the understanding and investigation phases to assess the client's situation and, based on this assessment, discuss with the client (and professional, if present) what might be causing tech problems the client is experiencing. If the investigation phase yields any spyware, risky software, or privacy problems with the client's accounts and devices, these are discussed calmly with the client, including how the breach may have happened and potential actions that might remedy the situation. In these cases, the consultant can offer the client a printout that explains what was found and how it may be causing problems (see examples in the full version).

Before taking actions or changing any settings, it is essential that the client discuss their consultation results with a professional to perform **safety planning**. Ideally the professional should be familiar with the client's situation and abuse history, since this is necessary to highlight potential safety issues related to tech abuse. One professional said:

*"Safety planning is such an individualized thing. I can think of some cases where it would be advantageous to leave the spyware on. I can think of some where we would want it gone immediately. If you can, just find a way to integrate it into the normal safety planning protocol." (P37, Paralegal)*

If the client's case manager is not present, the consultant asks the client if they would like to contact their case manager and/or receive immediate assistance from another on-site professional. Thus, even if the consultation has identified tech problems that are the likely causes of the client's concerns, in many cases, the client may leave the consultation with their devices and accounts unchanged. For a few clients we met with who had complicated scenarios, we encouraged them to schedule a follow-up consultation via their professional, so we could help them further after safety planning.

Consultations also provide new opportunities for collecting **forensic digital evidence**. The need for clients to document evidence of tech abuse is an issue that legal professionals discussed at length in our focus groups. If properly collected, such evidence may help a client secure an order of protection or aid a criminal investigation. Although clients may want to delete suspicious apps or reconfigure settings, our protocol has the consultant discuss with clients the potential benefits of documenting any discoveries before taking action. We asked professionals about how to handle forensic evidence, and they suggested various approaches, such as:

*"I would definitely take photos. Because ultimately [a detective] will be investigating that report, but I will definitely take photos, write down the name of the app on my report." (P39, Police Officer)*

We therefore settled on the expedient approach of having the client (or a lawyer acting on their behalf) take a photo or screenshot of any discovered spyware, evidence of compromises, etc. As suggested in the quote above, this is actually the standard of evidence currently, at least in family court, and several clients we met with have ongoing court cases in which they plan to use evidence discovered via our consultations.

In many cases the consultation will not yield any tech problems or causes for concern, in which case the consultant may reassure the client that, at least, our approaches did not find any problems. We are careful to not dismiss any problems that remain unaddressed or unexplained by our consultation. If additional investigation is warranted, the consultant explains to the client that they will do more work and follow-up via the referring professional (as explained in Section 4.1).

Finally, at the end of a consultation, the consultant completes a **case summary** that documents (1) the client's chief concerns (in their own words), (2) the consultant's assessment of problems, (3) the results of the ISDi scan and manual configuration check-ups, and (4) advice or recommendations discussed with the client. This case summary is for internal use only<sup>4</sup> and provides useful documentation for the consultant (or other consultants) that can be used should the client request another consultation or need followup.

<sup>4</sup>In some contexts such written documentation may be ill-advised due to the potential threat of hostile subpoena by lawyers working for the abuser. In our work, FJC professionals felt this threat was remote since our consultations take place within a research study that maintains client anonymity.

### 4.3 Replicability

An important question for our consultation protocol is how to ensure a standard of care that can be maintained across different locations and by different consultants. Many of the tools we created help by systematizing the assessment and investigation of tech problems. To complement these, prior work in disease diagnosis [15], surgery [42], and aviation [11] suggests that simple checklists are a valuable tool for systematizing procedures. Checklists help consultants follow a systematic procedure despite the complexity of many client cases, from both an emotional and technological standpoint. We created three checklists: one each for before, during (see Appendix of full version), and after the consultation.

We also developed a process for training researchers involved in consultations. We wrote a 13-page training manual that includes a detailed description of our protocol with example situations. It also discusses consultant emotional well-being and safety considerations (e.g., that consultants not give their full names until after spyware scans are complete). Training included reading and understanding this manual, along with guided introductions to our instruments, including ISDi.

To gain experience in face-to-face consultations before interacting with clients, we performed mock consultations in which researchers role-play as clients (including setting up, beforehand, a realistic scenario possibly involving spyware or other misconfigurations) and others role-play as consultants (that do not a priori know the scenario). After each mock consultation, the group analyzes how it went, revealing the scenario and constructively discussing how to improve. These are valuable for consultants to gain confidence in their ability to handle consultations as well as for the research team to gather feedback on the usability of various instruments.

Although clearly more research can be done to further refine our instruments, our field evaluation, discussed in Section 6, indicates their immediate practical value. We have publicly released all training materials, instruments, and open-source tools as resources that other advocacy organizations might find useful in their work supporting survivors<sup>5</sup>. We have already been collaborating with the TECC group in Seattle [2], sharing materials and getting feedback. They have adopted some TAQ questions for use in their clinical settings, and we are working towards prototyping ISDi at their clinic.

## 5 The IPV Spyware Discovery (ISDi) Tool

We now discuss the technical design and testing of ISDi, our IPV Spyware Discovery tool designed for IPV contexts. While technologically ISDi currently only uses, relative to modern anti-virus tools, simpler techniques such as blacklists and other heuristics, the innovation is in tailoring it to IPV: (1) flagging apps that in other contexts are not necessarily

<sup>5</sup><https://www.ipvtechresearch.org/resources>

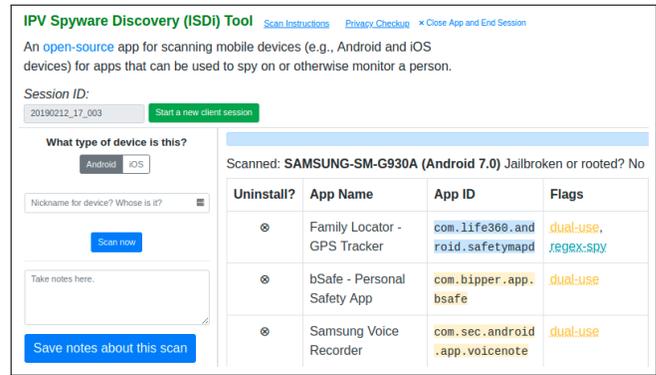

Figure 2: Screen capture of the ISDi tool’s main interface after scanning an Android testing device.

dangerous and, importantly, (2) mitigating potential discoverability by existing IPV spyware. Both issues necessitated a new tool, as existing ones fail on both accounts.

Regarding (1), in IPV harmful apps may include both spyware and what are called dual-use apps: otherwise legitimate apps that may be repurposed to act as spyware. We use the term ‘IPV spyware’ for both types of apps. Prior work showed how existing tools do not detect dual-use apps [8], whereas ISDi was designed to flag all spyware apps, including dual-use apps. Regarding (2), installing an existing anti-virus app is detected by current spyware, potentially endangering victims, while ISDi was designed to be more covert.

ISDi is a Python application with a browser-based user interface (Figure 2) that is used by the consultant to scan a client’s devices and identify potentially harmful apps. The tool shows the scan results and serves as a starting point for discussion with the client about any discovered apps. During the investigation phase of a consultation, the consultant, with the client’s permission, helps connect the client’s device via USB to a laptop running ISDi. A benefit of this design architecture is that it does not require an app to be installed on the device, making it minimally invasive and leaving little to no trace of its execution. We discuss the safety of connecting to client devices below. Further details about how ISDi works are provided in Appendix A.

**Detectability of ISDi.** A key design consideration is that ISDi does not endanger victims due to being detectable by abusers. As discussed above, we chose to not make ISDi a downloadable app since we know some spyware reports any new apps that are installed. Instead we use the USB interface to connect the device to a laptop running ISDi.

In theory a sophisticated spyware tool might be able to detect ISDi’s use of USB interfaces on iOS or Android. Therefore, we conducted additional risk assessments. We installed six highly capable, overt spyware apps found by Chatterjee et al. [8] on an iPhone 6 (running iOS 11.4) and also on a rooted Moto G4 Play phone (running Android 6.0.1). The six

apps are: mSpy, Cerberus, FlexiSpy, SpyToApp, SpyZie, and Trackview. We inspected the features and descriptions of the less sophisticated apps reported on in [8], and decided they were unlikely to support detection of USB connections.

For each of the six considered spyware apps, we created an account (simulating the role of an abuser) and manually investigated capabilities that might allow the app to detect the scanning process (including those tailored to rooted Android devices). We then simulated normal use of the device for several minutes (e.g., opening apps, scrolling) and ran ISDi while network connectivity was enabled. We repeated this process with network connectivity disabled for the scan (and then re-enabled), the intuition being that spyware apps exfiltrate device activities and data to an external cloud-based account configured by the abuser, only some of which may be monitored in real time. We examined the information that the abuser obtains in both cases, and found that for five of the apps there was no way to infer that ISDi was used.

The remaining app, Cerberus, allows exfiltrating system logs on Android, although this capability must be manually invoked by the abuser. These system logs include entries about USB connections to the device and that the device connected to a power source, but nothing beyond that. A technically sophisticated abuser aware of our tool and who carefully analyzed these logs might suspect, but would not have conclusive evidence, that the device was scanned.

Finally, spyware might reveal that the client came to an FJC, and there have been reports of abusers physically confronting victims at FJCs or shelters [20]. However, our consultations and ISDi do not exacerbate this risk given that our clients already visit FJCs for other reasons.

**Data collection.** Although it is possible to use ISDi without collecting any data, for research and safety reasons we choose to store some information, including the list of apps on a device. Importantly, we do not collect any personally identifiable information or content, such as phone number, emails, photos, etc. See Appendix A for more details.

## 6 Field Study

After developing and refining our consultation protocol and instruments, we performed a six-month field evaluation with IPV survivors. The study was conducted in collaboration with the ENDGBV, who helped recruit participants, provided safe space for consultations, and ensured the availability of IPV professionals to help with safety planning. Before beginning our study we obtained ethics approval for all procedures from our university's IRB and from the ENDGBV.

**Recruitment.** We distributed fliers to all five FJC locations (one in each borough of NYC). These fliers advertised the study as a way for clients to obtain a tech safety and privacy consultation, making both clients and professionals aware of the opportunity. Interested clients were asked to speak

with their case manager who, after consulting with the client, created a referral and an appointment with our team. Consultations were typically scheduled for days when our team arranged to be at the FJC, with a minimum of one and a maximum of four consultations on a single day. At the suggestion of ENDGBV staff, we gave participants \$10 compensation to cover the cost of transportation to/from the FJCs.

**Procedure.** Consultations took place in a private room at one of the FJCs. Each consultation was done by a team of two or three researchers: one person focused on communication with the client, another on the technical parts of the consultation (ISDi scan, manual privacy checks), and a third (when available) to take notes. Consultations were done individually.

Clients scheduled for a consultation were advised to bring any digital devices that they used or that they wished to have checked. However, two participants did not bring all their devices to their first consultation and therefore made an appointment to return so as to have additional devices checked. Thus, two clients participated in two consultations.

Consultations lasted between 30 minutes and two hours. We began by introducing the team members to the client, explaining the purpose of the study, outlining the activities that would be performed, and discussing the data that would be collected about them and from their devices. We then obtained the client's verbal consent to participate. We also asked participants for permission to audio record the consultation for data collection purposes and received permission to record 36 out of 46 consultations. If the participant did not want to be audio recorded, we instead took detailed notes.

After receiving the client's consent to participate, we followed the consultation procedure detailed in Section 4, including questions from the TAQ, constructing a technograph, scanning the client's devices with ISDi, and performing manual privacy configuration checks. Whenever possible, we suggested it may be advantageous for the client to have their case manager or another IPV professional present during the consultation so they could assist with safety planning and/or documenting relevant findings. In total, 16 out of 44 clients had a professional present during their consultation. After performing all procedures and discussing relevant findings with the client (and professional, if present) we thanked the client for their time. For clients requiring followup, we discussed what that followup would be and confirmed the relevant professional to contact when the followup was complete.

**Data collection and analysis.** We collected detailed handwritten notes and audio recordings (when permitted) that document each consultation, including client answers to TAQ questions, discussion of their digital footprint, details of manual privacy checks, results from ISDi device scans, the advice or recommendations discussed with the client, and any followups that were done. All audio recordings were professionally transcribed and collated by consultation with the relevant handwritten notes, completed technograph, and ISDi data.

We manually went through all this data multiple times to carefully summarize each consultation and produce the descriptive and aggregate statistics presented in Section 7. The data was stored securely with controls limiting access to only the subset of the research team that performed analysis.

**Safety protocols.** As discussed in Section 3, IPV presents a sensitive landscape within which to conduct research and survivors are a vulnerable, at-risk population. Our research procedures were carefully designed to protect clients' privacy and safety. For example, we did not ask participants to sign a consent form since we did not want to know or collect any identifying information (e.g., names), and all communication with clients took place through the referring professional, including scheduling and any post-consultation followups.

Although we offered participants a variety of printed handouts to help them understand their digital safety and privacy, we explained there may be risks with taking such materials home, especially if they still lived with their abuser, since someone may discover they had received a consultation. In addition, since changing privacy settings or uninstalling surveillance apps could lead to potentially dangerous escalation of abuse, whenever possible we encouraged participants to have a trusted IPV professional present during their consultation. When this was not possible, we made sure that another experienced case worker was available to help develop safety plans that accounted for any detected tech abuse and/or discuss new protection strategies that participants may want to adopt.

We also considered safety and well-being for our research team. Part of our training included ways to balance the need to properly inform participants about who we were and our affiliation, while avoiding giving out detailed identifying information about the individual researchers. For example, we introduced ourselves by first name only. This was because of the risk that spyware on devices was recording conversations.<sup>6</sup> In addition, working with IPV survivors and hearing their stories may be mentally and emotionally challenging. We regularly met as a team after consultations to debrief and encouraged team members to discuss their feelings, experiences, or anything they were struggling with. Moreover, an experienced IPV case worker was available at all times to speak with researchers and help them process any upsetting experiences that occurred during the consultations.

## 7 Results of the Field Study

The main goal of our study was to evaluate the utility of our consultation protocol for IPV victims. Our tools and instruments uncovered important, potentially dangerous security problems that we discussed with clients and professionals. This preliminary data suggests our consultation protocol pro-

<sup>6</sup>We explored other ways to protect researchers, such as leaving client devices outside or placing them in sound-insulated containers or Faraday bags, but these proved impractical.

vides benefits. Given the small sample size taken from a single city, we warn that our results should not be interpreted as statistically representative of problems faced by IPV survivors. We discuss limitations of our results more in Section 8.

For the sake of client anonymity, we necessarily cannot report on the full details of our consultations. Instead, we give aggregate results, or when we discuss a particular situation we only do so in a way that makes it coincide with widely reported IPV technology abuse situations, as per prior work [8, 14, 19, 20, 27, 35, 43] and our experiences.

**Participants and devices.** We conducted a total of 46 consultations with 44 IPV survivors (43 female, 1 male) who were all clients at the FJCs. Two clients received second consultations (at their request) to scan additional devices. All participants were adults and one still lived with their abuser.

As shown in Figure 3 (left table), clients brought a total of 105 devices to the consultations. Of these 82 were Android or iOS and we scanned 75 of these with ISDi. Two unscanned devices were iPhone Xs, which initially caused an error in ISDi when Apple changed the format of device IDs (updates to ISDi fixed this for subsequent scans). In two cases, ISDi could not scan a very old iPhone, potentially due to an error in the libimobiledevice tool we use to communicate with devices. One iPhone was not scanned due to a client leaving early and two other phones were not scanned either because the client was locked out of the device or stated they were not concerned about scanning it. All devices that were not scanned with ISDi were checked manually, except two where clients were locked out of the device (a phone and laptop).

We performed manual checks on 97 out of 105 devices brought in by clients. Clients brought a number of devices for which we did not have a protocol for manual privacy check up, including Internet-of-Things devices such as Amazon Echos, gaming systems, a Blackberry phone, and a flip phone. We performed a best-effort inspection in such cases, except the flip phone for which the client had no privacy concerns.

**Participants' chief concerns.** Clients expressed a range of chief concerns, as shown in Figure 3 (middle table). The descriptions here, such as "abuser hacked accounts" reflect terminology used by clients. A relatively large number of clients (20) described experiences that suggest abusers had access to clients' online accounts (often described as "hacking") or reported evidence indicative of such access (e.g., abuser knows information only stored in an account). The second most prevalent chief concern (18 clients) were general concerns about their abuser tracking them or installing spyware, but without specific reasons for suspecting it. Other clients were concerned that their location was being tracked, their phone was acting suspiciously, and more. Finally, a few clients wanted to learn more about tech privacy and had no specific concerns about tech abuse directed towards them.

Chief concerns were often connected to the security issues we detected, discussed more below. For example, chief

Clients & Devices	Chief Concerns	Detected Issues
Clients seen	Worried about tech abuse/tracking/spyware	Clients w/ vulnerabilities
Consultations performed	Abuser hacked accounts or knows secrets	Clients w/ unsolved problems
Devices seen	Worried abuser was tracking their location	Clients w/ no problems detected
Devices manually inspected	Phone is glitchy	Potential spyware detected
Devices scanned w/ ISDi	Abuser calls from unknown numbers	Potential password compromise
Median devices per client	Unrecognized app on child's phone	Presence of unknown "trusted" devices
Max devices per client	Money missing from bank account	Shared family/phone plan
Median apps per scanned device	Curious and want to learn about privacy	Rooted device

Figure 3: Summary of field study results. **Left:** Breakdown of the number of clients seen, consultations performed, and devices encountered. **Middle:** The chief concerns, as described by the clients (some had multiple chief concerns). **Right:** The problems detected during consultations, including vulnerabilities, security risks, and spyware (some clients had multiple problems).

concerns involving illicit access to accounts were often best explained by poor password practices, family sharing, or confirmation of account access by abuser devices. In one case the chief concern was entirely unrelated to the discovered security issue, however. All this confirms the importance of both identifying the chief concerns, but also using instruments and procedures that may surface unexpected problems.

**Security vulnerabilities discovered.** For 23 of 44 clients (52%), our consultations identified important security risks, vulnerabilities, or plausible vectors for tech abuse. Before describing our findings, it is important to note that, in most cases, we do not have definitive proof that the vulnerabilities discovered are the root causes of clients' problems. For example, if a client's password is the name of a child they share with the abuser, or if their phone is part of a shared family plan, these provide plausible theories for, but not hard evidence of, how compromises may be occurring.

**Results from ISDi:** ISDi flagged a total of 79 apps as problematic across all device scans. The majority of these (61) were dual-use apps, with "find my phone" and child monitoring apps the most prevalent categories. For all but one of these dual-use apps, discussions with clients confirmed that they recognized the apps and were aware of their presence. For one dual use app, the client said that they did not install or recognize the app, which was a controller for remote home surveillance systems with WiFi, camera, and motion detection capabilities. We treated this case as a true positive result. The other 18 apps detected by ISDi were false positives (i.e., clearly not relevant to IPV) that the consultant easily dismissed as such. The number of false positives in any individual consultation was low, the maximum number of flagged apps on a client's device was five. This meant that, thus far, we have not had any issues with consultants being overwhelmed by large numbers of apps flagged by ISDi.

The relatively low rate of actual spyware detection may be because, as discussed below, many abusers are seemingly able to surveil clients via compromised accounts, and so may not need to install spyware. In addition, almost all clients no longer lived with the abuser, had changed or reset their devices since leaving (which would remove spyware in most cases),

and for many devices the abuser no longer had physical access needed to (re-)install spyware. Finally, ISDi detected that one client's Android tablet was rooted. Subsequent discussion revealed that the abuser bought this tablet for the client, had physical access to it during the relationship, and had insisted the client log into her accounts with it. As a result of our conversation, the client decided to stop using the tablet.

**Results from TAQ and technograph:** For many clients, we discovered security vulnerabilities through combined use of the TAQ, technograph, and/or manual privacy checks. In some cases, the TAQ and technograph were the primary (or only) way to uncover a potential problem. For example, four clients reported that they were still part of a shared family plan or that their abuser pays for their phone plan, vulnerabilities that could give the abuser access to, for example, the location of the client's device and call and text history. Another common problem that the TAQ and technograph revealed for 14 clients was the use of passwords that the client said were known, or could be guessed, by their abuser. In several of these cases, a compromised password provided a plausible explanation for how the abuser may be gaining access to the client's accounts.

**Results from manual checks:** Combining TAQ and technograph information with subsequent manual privacy checks often yielded evidence of malicious account access. For example, during manual checks of iCloud account settings for four clients, we discovered that their iCloud accounts listed "trusted" devices that the client either did not know or recognized as belonging to the abuser. Similarly, manual checks of client email and social media accounts showed unknown or abuser device logins for another eight clients.

iCloud and email account access, whether by password compromise or via unauthorized "trusted" device access, also yielded plausible explanations for a range of other problems. For example, three clients reported that they kept written records of passwords for all their accounts in files that were then synced with their compromised iCloud, potentially resulting in the abuser obtaining all these passwords. Similarly, several clients emailed copies of their new passwords to themselves via potentially compromised email accounts. Another prevalent avenue for compromise that we saw happened when

clients used a compromised account as the backup account for other services (e.g., social media), with clients unaware of how this might result in abuser access to these services.

For two clients, manual checks of laptops revealed browser extensions that the clients did not install or know about. In one case, the extension was “off store” (not available via the official Chrome Web Store), may have been sideloaded (installed via developer mode), and had permission to read and write all browser data. We regarded this as possible spyware. For the other case, the extension is available via the Chrome Store and is used to monitor access to web content. This extension provides a plausible explanation for the client’s chief concern, which was that her abuser knew about her online activities, and we regarded it as probable spyware.

**No problems detected.** For 21 out of 44 clients, our instruments did not surface any evidence of potential tech issues. For 19 of these, the lack of discovered problems was reassuring and many left the consultation visibly relieved and more at ease. However, in two cases, the consultation’s inability to address their chief concerns left the client unsatisfied. In these cases we performed follow-up research, including reaching out to other tech experts for second opinions about their concerns (in an anonymized fashion) but unfortunately still have no plausible explanation for what they were experiencing.

**Hand-off and followup.** For the 23 clients with discovered problems and two clients with unresolved issues, we conducted a hand-off in which we discussed our results with the referring professional. For 12 of these, the professional was onsite and hand-off occurred immediately. For the other 13, we followed up with the professional via email and/or a phone call. Although many clients did not resolve discovered problems immediately because of the need to safety plan, they said that it was helpful and empowering to at least know how the abuser was plausibly obtaining information about them.

Eleven cases required further research after the consultation. Six of these were client requests for information about specific apps we were unfamiliar with (e.g., can app X track my location?). For the remaining five we found something during the consultation that needed further analysis to assess its danger. In 10 cases, the consultant researched the issue at length and provided a comprehensive answer to the referring professional within a few days of the consultation. In the remaining case, we could not provide a satisfactory explanation for what the client was describing even after significant research, which we explained to the referring professional.

## 8 Discussion

Although the results from our field study are preliminary, they suggest that our consultation protocol is already valuable to clients in dangerous situations. Encouragingly, the ENDGBV have asked our team to schedule more consultations with clients at the FJCs. This in turn raises new open questions

about how to sustain and scale our clinical computer security approach. In this section we discuss: (1) limitations of our current study; (2) open questions that it raises about how to realize the vision of clinical computer security for IPV victims more generally; and (3) open questions that our work raises about clinical approaches to computer security beyond IPV.

**Limitations.** This first study on clinical computer security interventions has several limitations that we acknowledge. First, our study was restricted to a single municipality and our participants were not representative of all people who suffer IPV. Although New York City has a large and diverse population, and our sample does include socioeconomic and cultural diversity, all but one of our participants were women, all but one were no longer living with their abuser, and the majority had been in heterosexual relationships. As a result, our study may fail to capture some of the nuances associated with abusive relationships for LGBTQIA+ people or those who may still live with their abuser.

Another limitation is our sample size. Although 44 clients may be sufficient to verify the utility of our consultations, it certainly does not yield statistically significant estimates of, for example, likelihood of spyware or other harms being seen in practice. Further, our study context purposefully biases our sample towards victims that are specifically worried about tech problems. Still, our results provide guidance on what a tech clinic is likely to see, and our experiences are consistent with prior work on tech attacks in IPV [20, 27].

Our consultations may not catch all issues, either due to consultant error (e.g., forgetting to ask a TAQ question) or technical error (e.g., ISDi mislabeling an app). Indeed, one of the fundamental challenges faced in this area is dealing with complex, multifaceted attacks, and it is not possible to be perfect. That said, our new approach vastly improves over the current status quo in practice, which is essentially nothing. Moving forward, future research will need to assess if, and how, our protocol and instruments impact client lives in the longer term, determining, for example, whether our interventions measurably decrease illicit account accesses.

Should a client change their behavior as a result of our consultations, abusers may change behavior, retaliate against the victim, or otherwise escalate abuse. We designed our protocols to try to minimize the potential for this, but no procedures can eliminate such risks entirely. That said, we are in active communication with FJC leadership and have not received any indication that a client has faced retribution as a consequence of participating in a consultation.

**Clinical computer security for IPV.** Our work focused on client consultations, which are a fundamental component of realizing our vision of clinical computer security. Given the success of our initial field study, we are faced with a range of open questions. The most obvious is that our design and evaluation so far did not perform in-depth investigation of issues related to scalability and sustainability.

A sustainable computer security clinic will likely need a supporting organization, outside the scope of a research study, to handle recruitment, screening, and training of sufficiently many volunteer consultants (or paid professionals, should there be funding to pay them). Although the assessments and materials we developed in this work will help with training future tech consultants, they do not yet speak to challenges that are outside the context of the consultation. In a referral model like the one we used, just scheduling consultations took many hours per week and, more broadly, how best to organize delivery of clinical computer security for IPV victims raises a host of questions for future research.

As a financially sustainable recruitment strategy, we might draw on existing models like pro-bono legal services [30], and initial conversations with tech professionals and companies suggest that some may be willing to offer their time free of charge. (This model is used by the TECC clinic [2].) Another approach is student-run clinics, similar to law school legal clinics [12] or medical school free clinics [37]. In any such model, it will be essential to develop strong protocols for screening consultant applicants, particularly to ensure that abusers are prevented from enrolling as consultants. Advocacy groups have protocols for screening applicants, and one could start by adopting these. In parallel, future research will be needed to localize clinical techniques to geographic locations with different support organizations and laws.

Another pressing issue is maintenance of instruments. ISDi's coverage currently relies on labor-intensive updating of blacklists, based on web crawling and manual analysis. Like malware detection in other contexts, maintaining accuracy over time and staying ahead of emerging threats is an immense challenge [40]. It is also important to consider the longer-term implications of making ISDi's existence and methods public. While current spyware does not infer ISDi was used, if it becomes widespread enough to become a target, spyware developers might turn to more sophisticated methods that monitor USB-related system processes. Similarly, spyware vendors may start attempting to avoid detection. As such, we keep ISDi's blacklist private, allowing access via legitimate requests from those working to help victims.

Our other instruments will also require updating at various time intervals. By design, the TAQ should maintain relevance for quite a while to come, requiring updating only when technology changes suggest new, broad classes of threats we must consider. But our manual investigation guides for checking security or privacy settings may need to be updated more frequently as companies change their products. Future work might evaluate the right balance between generalizability and actionability of such guides (c.f., [19]), or infrastructure for maintaining them (e.g., expert crowdsourcing [29]).

**Clinical computer security beyond IPV.** IPV is not the only context in which victims suffer targeted, persistent, and personalized attacks. Some examples include the dissidents,

activists, and NGO employees targeted by nation-state hacking campaigns [7, 23, 25, 26], or the gamers [9], journalists [10], politicians [6], and researchers [21] who are at high-risk of being harassed online [18, 33]. As in IPV, in all these cases the attacker wants to harm their particular target. There is also an asymmetry between the victim and attacker, with the latter having more resources, time, and/or technological sophistication. Indeed, in some cases the adversary in these other contexts has significant technical prowess.

Clinical approaches to computer security may be of utility in these other contexts. In the near term, adapting our techniques to other communities of victims similar to IPV — such as victims of elder, parental, or child abuse, or victims of sex trafficking (which are also served by FJCs) — could constitute important research directions. Despite the similarities, research will be needed to understand how the nuances emanating from particular circumstances or demographics change best practices for clinical interventions.

Further afield are contexts that are less similar to IPV. For example, those targeted by government agencies as mentioned above might benefit from systematized clinical approaches. One could perhaps start with the work done by the Citizen-Lab [13] and Citizen Clinic [1], and determine to what extent, if any, our methodologies for stakeholder-driven design could help improve clinical interventions.

## 9 Conclusion

This paper lays out a vision for clinical computer security and explores it in the context of IPV. Through an iterative, stakeholder-driven process, we designed a protocol for conducting face-to-face tech consultations with victims of IPV to understand their tech issues, investigate their digital assets programmatically and by hand to discover vulnerabilities, and advise on how they might proceed. Our preliminary study with 44 IPV victims surfaced vulnerabilities for roughly half our participants, including account compromise, potential spyware, and misconfiguration of family sharing plans. Our consultations also provided advice and information to victims and professionals on ways to document such discoveries and improve computer security moving forward. Our clinical approach provides immediate value, while also laying a foundation for future research on evidence-based refinements to clinical tech interventions in IPV and, potentially, beyond.

## Acknowledgments

We would like to sincerely thank all our study participants, the Family Justice Centers, and the NYC ENDGBV. This work was funded by the NSF through grants CNS-1717062 and CNS-1558500, and by gifts from Comcast and Google.

## A More Details about ISDi

**How ISDi works.** ISDi uses the `libimobiledevice` tool [4] for iOS or Android Debug Bridge (`adb`) [5] for Android to programmatically access the connected device. On Android, the device must be configured to allow USB debugging, which is done by enabling developer mode for the scan and revoking it again after the scan is complete. When a scan is initiated, ISDi pairs with the connected device and queries it for a list of all installed apps, including those that are hidden from the app drawer on Android (c.f., [8]). ISDi then runs additional queries on the device to obtain the OS version, hardware model, and manufacturer. It also performs heuristic checks to infer if the device is jailbroken (iOS) or rooted (Android). ISDi displays information about the outcome of these checks via the tool's UI, along with a list of all installed apps with potentially dangerous apps listed first. We compute each app's threat score by combining several heuristics.

First, we created a blacklist of potential IPV spyware and dual-use apps using techniques from Chatterjee et al. [8]. To ensure the list was not stale, we re-ran their measurements several times and added the results to the blacklist. We applied the machine learning classifier used in [8] to remove the obviously irrelevant apps. However, we did not manually prune the list further to reduce the falsely flagged apps, as during consultation a consultant can check those apps and ignore if not relevant for IPV. The most recent update was shortly before we initiated meetings with clients. Our current blacklist contains over 500 iOS and 5,000 Android apps. A second heuristic is a set of regular expressions that app names are checked for, including substrings such as “spy” or “track”. Lastly, on Android, ISDi checks whether any apps were installed outside of the Play Store. A threat score is then computed for each app so that the apps can be listed in decreasing order of potential risk.

Clicking on an app name in ISDi's UI displays more information about that app, including installation date, developer description of the app, requested permissions, and when permissions were last invoked (on Android). ISDi is also capable of uninstalling apps (after appropriate safety planning) via its interface, which is especially useful for hidden apps on Android that cannot be located using the device's UI.

ISDi is not perfect and may have both false positives and false negatives. The former are less dangerous, and in our experience were easily dealt with by the consultant in the field. False negatives are of course potentially dangerous, and so we purposefully designed ISDi to have a low false negative rate by allowing for more false positives.

ISDi collects the following information of each app: the app ID, permissions, installation date (Android only), and package files (Android only). ISDi also generates and stores a keyed cryptographic hash of the device's serial number. The latter is useful to ensure we can determine if we scan the same device twice, since clients may have multiple consultations,

without explicitly storing the device identifier. Collected data is linked to a random client identifier. Storing a list of apps is helpful not only for our research, but also because it allows us to further examine, via followup if necessary, any suspicious apps discovered during a consultation. In addition, whenever we update the blacklist, we retroactively scan the apps from past consultations to ensure that no newly found IPV spyware apps were on a previously scanned devices. (Fortunately, we have not yet detected any spyware retroactively.) All data is stored securely and accessible only to our team.

**Detecting potential IPV spyware.** A core feature of ISDi is its detection of IPV spyware apps (either overt or dual-use) on iOS or Android devices. To do so, ISDi integrates various heuristics into a rank-ordered list of apps by an internal threat score. After querying the device for a list of installed apps, ISDi assigns a threat score to each app, that score derived from summing the weights of heuristics.

The main heuristic is two blacklists of app IDs, one for overt spyware apps and one for dual-use apps. The blacklists deployed with ISDi was seeded with the list of apps discovered in [8], but then updated by using their snowball searching techniques on the Google Play store and iTunes store. Note that Google Play occasionally bans apps and reportedly banned some in response to the results of [8]. We do not remove apps from a blacklist should they be removed from the play store — they could have been downloaded and installed by an abuser before removal. We additionally included any apps we discovered via manual searches or that we discovered in any other way. Following [8], we aggressively added apps to a blacklist, at risk of creating false positives. This favors having a low false negative rate, and we built into our protocol the ability for consultants to handle false positives when they arose. To help with ordering, we kept a separate blacklist of overt spyware, with other apps appearing on the dual-use blacklist.

In addition to blacklists, ISDi uses a few other heuristics. First are regular expressions applied to application names, as described in Section 5. Second was that we marked any off-store app as potentially dangerous. Third was whether the device is a system app, meaning it was pre-installed on the device by the cellular provider or OS vendor.

We then gave a weighted score to each app according to the values shown in Figure 4. The score of an app is equal to the sum of the weights for the set of heuristics that apply to the app. A higher score denotes being potentially more dangerous. The weights are admittedly somewhat arbitrary, but roughly correspond to our perception of the danger each heuristic indicates. In practice, the number of apps on a device that were assigned risk signals by ISDi were sufficiently small that our choice of weights and rank-ordering did not make much of a difference during consultations.

**App detection accuracy.** While ISDi lists all apps on the device, and the consultant is encouraged to visually inspect

Heuristic	Weight	Description
Overt spyware blacklist	1.0	Known, overt spyware
Dual-use blacklist	0.8	Legitimate uses, but possibly harmful in certain situations
Offstore app	0.8	Not installed through an official app marketplace
Regex match	0.3	App name or ID contains 'spy', 'track', etc.
System app	-0.1	Pre-installed by device vendor

Figure 4: The ISDi heuristics for ordering apps. Each app is assigned a score that is the sum of the weights for each heuristic that applies to it.

the entire list, we would still consider it a false negative if a dangerous app was not flagged by one of the four heuristics (excluding the system app heuristic).

As discussed in Section 5, ISDi’s accuracy depends in part on labor intensive web crawling and manual pruning. Our blacklist of dual-use apps included all 2,474 seed apps from Chatterjee et al. [8], as well as 3,263 new apps from our own periodic crawls since May 2018 and filtering using the ML classifier given in [8]. Unlike in [8], we do not manually prune the 3,263 apps we added to the blacklist to further remove apps falsely flagged by the machine learning classifier. During consultation, the consultant ignores apps that are not relevant, which was not a problem during our consultations.

Most overt spyware apps we have encountered (and certainly all dual-use apps we have inspected) do not try to hide their presence from a programmatic scan. However, for a few of the overt spyware apps we have observed that they chose innocuous-looking app IDs (such as “com.android.system”). This reiterates the need for programmatic scans, which are not fooled by this. However, if apps change their app IDs frequently to avoid detection, our blacklists may not cover the full set of app IDs associated with a spyware. We have observed that one overt offstore spyware app, mSpy, has published versions of its Android APK with different app IDs: sys.framework and core.framework, while others such as SpyToApp, FlexiSpy, and SpyZie have not changed their app IDs to our knowledge (we re-downloaded them in September 2018 and in February 2019). We have found no evidence that onstore dual-use apps change their app IDs, though Trackview has published their app twice on the Google Play Store, as both net.cybrook.trackview and app.cybrook.trackview under different developer IDs. We have added all of the changed app IDs to our blacklist as we have discovered them.

Finally we note that ISDi is not designed to detect more sophisticated malware, such as that used by national intelligence agencies. We believe such malware is unlikely to arise in IPV

settings, since it requires special access to obtain it. For a client for which it is plausible that her abuser might have access to such capabilities (e.g., the abuser works as a computer security expert), a discussion about potential remediations, such as obtaining new devices, would be appropriate.

**App reports.** Upon clicking on an app, ISDi gives a number of details about the app. This includes a developer description (if available), when the app was installed (Android only), the permissions the app has requested, and the time of all the permissions recently used by the app (Android only), including dangerous permissions such as microphone, camera, or GPS. It also provides a link to a Google search on the app ID, which allows the consultant to quickly attempt to look up more information about the app should it be unfamiliar.

**Detecting jailbroken or rooted phones.** ISDi attempts to determine if the scanned device is jailbroken (iOS) or rooted (Android), since such devices are at much greater risk for installation of powerful spyware. For example, most spyware vendors enable for sophisticated features if the device is jailbroken/rooted. Moreover, it is unlikely that a client purposefully jailbreaks or roots their phone.

Thus ISDi uses a set of heuristics to determine whether a device is jailbroken/rooted. If any heuristic comes back positive, ISDi considers the device to be jailbroken or rooted and indicates this along with the results of the scan. Detecting jailbroken/rooted devices is under active discussion for both Android and iOS because app developer communities want to prevent their apps from being illegitimately being used on a jailbroken/rooted device. We therefore collected different heuristics from such community forums. For both iOS and Android, ISDi checks whether common jailbreak/rooting applications are installed on the device [3]. On Android devices, ISDi checks whether or not the su tool is installed on the system “shell” application [38]. On iOS devices, ISDi attempts to mount the filesystem at the root directory.

To the best of our understanding, ISDi will detect any jailbroken or rooted device. However, it is possible that a device could evade detection by ISDi using techniques that are not publicly known. We regularly look into app developer forums for new heuristics and update ISDi accordingly.

**Possible attack vectors on ISDi.** We have considered that spyware installed by an abuser on a client’s phone may attempt to use its USB connection to ISDi as a possible attack vector [39, 41]. We are not aware of any overt spyware apps that try to misuse USB connections to a host computer. We ensured that all commands used by ISDi to communicate with iOS and Android devices, over libimobiledevice and adb, respectively, were run over least privilege (i.e., without sudo).

## Technology Assessment Questionnaire (TAQ)

*Start with the most pressing concern widely expressed by clients thus far*

- Do you worry that your device(s) is being used to track you?
  - Does the abuser show up unexpectedly or know things they shouldn't know?

*Probe for risks of device compromise*

- What devices do you use in your home or carry with you?  
(e.g., smartphone, iPad, tablet, desktop, laptop, kindle, echo, etc.)
- Do you currently (or have you in the past) share(d) your devices with your abuser?
- Is there any chance that your abuser has (or had) physical access to your devices?
  - Does (Did) your abuser ask or demand physical access to your devices?
- Who set up the screen locks or passwords on your devices?
  - Do you use fingerprint or facial recognition to unlock your devices?

*Probe for risks from ownership-based attacks*

- Do have a shared family plan?
- Do you or does someone else pay for your phone plan or Internet access plan?

*Probe for risks of account compromise*

- Who set up your email account or other online accounts?
- Have you ever shared any passwords with your abuser (or anyone)?
  - When did you last update your passwords for your email or other online accounts?
  - How do you remember your passwords?
  - Do you ever take photos of your passwords?
  - Is there a chance your abuser knows (or could guess) the answers to your password reset questions?
- Do you think your abuser has access to your accounts online?
  - Do you have an iCloud or Google account?
  - Do you think the abuser knows the password or has access to your bank account?
  - Do you think the abuser knows the password or has access to your email accounts?
  - Do you think the abuser knows the password or has access to your social media accounts? (Facebook, Instagram, WhatsApp, etc.)

*Probe for risks from children's devices*

- Do you have any children?
  - Do you share devices with your children?
  - Do you or does someone else pay for your children's devices?
  - Who gave your child their device?
  - Does the abuser have access to the child's device?
  - Does your child bring their device to visitation with the other parent?

Figure 5: The current version of the Technology Assessment Questionnaire (TAQ).

# Evaluating the Contextual Integrity of Privacy Regulation: Parents’ IoT Toy Privacy Norms Versus COPPA

## Abstract

Increased concern about data privacy has prompted new and updated data protection regulations worldwide. However, there has been no rigorous way to test whether the practices mandated by these regulations actually align with the privacy norms of affected populations. Here, we demonstrate that surveys based on the theory of contextual integrity provide a quantifiable and scalable method for measuring the conformity of specific regulatory provisions to privacy norms. We apply this method to the U.S. Children’s Online Privacy Protection Act (COPPA), surveying 195 parents and providing the first data that COPPA’s mandates generally align with parents’ privacy expectations for Internet-connected “smart” children’s toys. Nevertheless, variations in the acceptability of data collection across specific smart toys, information types, parent ages, and other conditions emphasize the importance of detailed contextual factors to privacy norms, which may not be adequately captured by COPPA.

## 1 Introduction

Data privacy protections in the United States are enforced through a combination of state and federal legislation and regulatory action. In Europe, the General Data Protection Regulation (GDPR) is currently the best example of strong, centralized privacy legislation. The GDPR has inspired similar laws in other countries, such as the Brazilian General Data Privacy Law. According to the United Nations Conference on Trade and Development [51], 57% of countries have data protection and privacy legislation as of 2018.

Although data privacy protections vary across countries in terms of details and implementation, many share a common provenance: public pressure to protect sensitive personal data from unauthorized use or release. Surveys report that consumers worldwide were more concerned about online privacy in 2016 than 2014 [7] and that over 60% of U.S. survey respondents in 2018 are concerned about data privacy in general [34]. However, there has been no rigorous, quan-

tifiable, and scalable way to measure whether existing legal privacy protections actually match the privacy expectations of affected individuals. Without such data, it is difficult to know which aspects of privacy regulation effectively align company behaviors with social and cultural privacy norms and which necessitate further revision.

In this paper, we demonstrate that an existing survey technique [3] based on the formal privacy theory of contextual integrity (CI) [32] can be directly adapted to test the conformity of specific regulatory requirements to privacy norms, providing much-needed data to policymakers and the privacy research community. The survey technique can be applied to any privacy regulation that defines guidelines for data collection and transfer practices. Importantly, the survey technique involves questions describing privacy scenarios that are concrete and understandable to respondents from all backgrounds. It also allows straightforward longitudinal and cross-sector measurements to track the effectiveness of regulatory updates over time.

We present a rigorous case study of this technique evaluating the U.S. Children’s Online Privacy Protection Act (COPPA), which provides a federal legal framework to protect the online privacy of children under the age of 13. Specifically, we investigate whether parents’ opinions about the acceptability of data collection practices by Internet-connected “smart” children’s toys match COPPA mandates. Since the Federal Trade Commission (FTC) only updated its guidance on COPPA to explicitly include “connected toys or other Internet of Things devices” in June 2017 [16], our results provide the first indication as to whether COPPA aligns with parents’ privacy expectations.

This question is particularly relevant given the recent high-profile security breaches of smart toys, ranging from the theft of personal information of over 6 million children from toy manufacturer VTech to vulnerabilities in Mattel’s Hello Barbie [13]. More recently, Germany banned children’s smart watches and Genesis Toys’ My Friend Cayla doll, citing security risks and “spying concerns” [17, 31].

We survey a panel of 195 U.S. parents of children from

ages 3 to 13, the largest sample size for a study of parent opinions of smart toy data collection in the literature to date. We find that parents generally view information collection predicated on requirements specified by COPPA (e.g., “if the information is used to protect a child’s safety”) as acceptable, while viewing equivalent information collection without COPPA-specified conditions as unacceptable. This indicates that the existing conditions COPPA places on information collection by smart toys are generally in line with parents’ privacy norms, although there may be additional data collection requirements which could be added to regulation that were not tested in our study.

Additionally, we find that COPPA requirements for notification and consent result in more acceptable data collection practices than requirements related to confidentiality and security. This corroborates previous work indicating the primary importance of consent to user privacy norms [3]. We also find variations in the acceptability of COPPA-permitted data collection practices across specific smart toys, types of information, certain information use cases, parent ages, parent familiarity with COPPA, and whether parents own smart devices. These variations emphasize the importance of detailed contextual factors to parents’ privacy norms and motivate additional studies of populations with privacy norms that may be poorly represented by COPPA.

We conclude by noting that COPPA’s information collection criteria are broad enough to allow smart toy implementations that compromise children’s privacy while still adhering to the letter of the law. Continuing reports of smart toys violating COPPA [6] also suggest that many non-compliant toys remain available for purchase. Further improvements to both data privacy regulation and enforcement are still needed to keep pace with corporate practices, technological advancements, and privacy norms.

In summary, this paper makes the following contributions:

- Demonstrates that an existing survey method [3] based on contextual integrity [32] can be applied to test whether privacy regulations effectively match the norms of affected populations.
- Provides the first quantitative evidence that COPPA’s restrictions on smart toy data collection generally align with parents’ privacy expectations.
- Serves as a template for future work using contextual integrity surveys to analyze current or proposed privacy regulation for policy or systems design insights.

## 2 Background & Related Work

In this section, we place our work in the context of related research on contextual integrity, COPPA, and smart toys.

### 2.1 Contextual Integrity

The theory of contextual integrity (CI) provides a well-established framework for studying privacy norms and expectations [32]. Contextual integrity defines privacy as the appropriateness of information flows based on social or cultural norms in specific contexts. CI describes information flows using five parameters: (1) the subject of the information being transferred, (2) the sender of this information, (3) the attribute or type of information, (4) the recipient of the information, and (5) the transmission principle or condition imposed on the transfer of information from the sender to the recipient. For example, one might be comfortable with a search engine (*recipient*) collecting their (*subject & sender*) Internet browsing history (*attribute*) in order to improve search results (*transmission principle*), but not in order to improve advertisement targeting, which is a different transmission principle that places the information in a different context governed by different norms. Privacy norms can therefore be inferred from the reported appropriateness and acceptability of information flows with varying combinations of these five parameters.

Previous research has used CI to discover and analyze privacy norms in various contexts. In 2012, Winter used CI to design an interview study investigating Internet of things (IoT) device practices that could be viewed as privacy violations [54].

In 2016, Martin and Nissenbaum conducted a survey with vignette questions based on CI to understand discrepancies between people’s stated privacy values and their actions in online spaces [27]. Rather than straightforward contradictions, they find that these discrepancies are due to nuanced effects of contextual information informing real-world actions. This result motivates the use of CI in our study and others to investigate privacy norms in realistic situations.

In 2016, Shvartzshnaider et al. used the language of CI to survey crowdworkers’ privacy expectations regarding information flow in the education domain [46]. Survey respondents indicated whether information flows situated in clearly defined contexts violated acceptability norms. The results were converted into a logic specification language which could be used to verify privacy norm consistency and identify additional acceptable information flows.

In 2018, we designed a scalable survey method for discovering privacy norms using questions based on CI [3]. We applied the survey method to measure the acceptability of 3,840 information flows involving common connected devices for consumer homes. Results from 1,731 Amazon Mechanical Turk respondents informed recommendations for IoT device manufacturers, policymakers, and regulators.

This paper adapts the survey method from our previous work [3] for a specific application: comparing privacy norms to privacy regulation. Our use of language from regulation in CI survey questions, direct comparison of discov-

ered privacy norms to policy compliance plans, and survey panel of special interest individuals (parents of children under age 13) distinguishes our work from previous uses of the survey method and previous CI studies in general.

## 2.2 COPPA & Smart Toys

Previous research has investigated Internet-connected toys and COPPA from various perspectives. Several studies have focused on identifying privacy and/or security vulnerabilities of specific smart toys [45, 48, 53], some of which are expressly noted as COPPA violations [6]. Our work uses these examples to inform the information flow descriptions included on our survey.

Researchers have also developed methods to automate the detection of COPPA violations. In 2017, Zimmeck et al. automatically analyzed 9,050 mobile application privacy policies and found that only 36% contained statements on user access, editing, and deletion rights required by COPPA [59]. In 2018, Reyes et al. automatically analyzed 5,855 Android applications designed for children and found that a majority potentially violated COPPA [43]. Most violations were due to collection of personally identifiable information or other identifiers via third-party software development kits (SDKs) used by the applications, often in violation of SDK terms of service. These widespread violations indicate that COPPA remains insufficiently enforced. Nevertheless, COPPA remains the primary legal foundation for state [30] and federal [12] action against IoT toy manufacturers and other technology companies for children’s privacy breaches.

Additional work has investigated parents’ and children’s relationships with Internet-connected toys. In 2015, Manches et al. conducted observational fieldwork of children playing with Internet-connect toys and held in-school workshops to investigate parents’ and children’s cognizance of how IoT toys work [26]. They found that most children and caregivers were unaware of IoT toys’ data collection potential, but quickly learned fundamental concepts of connected toy design when instructed.

In 2017, McReynolds et al. conducted interviews with parents and children to understand their mental models of and experience with Internet-connected toys [28]. Parents in this study were more aware of and concerned about IoT toy privacy than in [26], likely due to the intervening two years of negative publicity about connected toy privacy issues. The parents interviewed by McReynolds et al. provided feedback about desired privacy properties for connected toys, such as improved parental controls and recording indicators. The researchers urge ongoing enforcement of COPPA, but do not evaluate the parents’ responses in light of the law.

Our work builds on past research by obtaining opinions about smart toy information collection and transfer practices from a much larger pool of parents (195 subjects). We use these data to evaluate whether privacy protections mandated by COPPA align with parents’ privacy norms.

## 3 CI Survey Method

This study adapts a CI-based survey method first presented in our previous work [3] to evaluate whether specific requirements in privacy regulations align with user privacy norms. We chose this particular survey method because it is previously tested, scalable to large respondent populations, and easily adaptable to specific domains. The survey method works as follows, with our modifications for regulation analysis marked in italics:

1. Information transfers (“flows”) are defined according to CI as sets of five parameters: subject, sender, attribute, recipient, and transmission principle (described in Section 2.1).
2. We select lists of values for each of these parameters *drawn from or directly relevant to a particular piece of privacy regulation*. Using these values, we generate a combinatorial number of information flow descriptions *allowed or disallowed by the regulation*.
3. Survey respondents rate the acceptability of these information flows, each of which describe a concrete data collection scenario in an understandable context.
4. Comparing the average acceptability of flows *allowed or disallowed by the regulation* indicates how well they align with respondents’ privacy norms.
5. Variations in acceptability contingent upon specific information flow parameters or respondent demographics can reveal nuances in privacy norms *that may or may not be well served by the regulation*.

The following sections provide detailed descriptions of our survey design (Sections 3.1–3.2), deployment (Section 3.3), and results analysis (Section 3.4) for comparing parents’ privacy norms about smart toy data collection against COPPA regulation. Many of these steps mirror those in our previous work [3], but we include them here with specific details from this study for the sake of replicability.

### 3.1 Generating Smart Toy Information Flows

We first selected CI information flow parameters (Table 1) involving smart toys and specific data collection requirements from COPPA. We then programmatically generated information flow descriptions from all possible combinations of the selected CI parameters.

We next discarded certain information flow descriptions with unrealistic sender/attribute pairs, such as a toy speaker (sender) recording a child’s heart rate (attribute). Unrealistic sender/attribute pairs were identified at the authors’ discretion based on whether each toy could reasonably be expected to have access to each type of data during normal use. This decision was informed by smart toy products currently available on the market. The use of exclusions to remove

unrealistic information flows is a core part of the CI survey method [3] for reducing the total number of questions and the corresponding cost of running the survey. This process resulted in 1056 total information flow descriptions for use in CI survey questions (Section 3.2).

The degree to which these flows are rated as acceptable or unacceptable by survey respondents indicate agreement or disagreement between COPPA and parents' privacy norms. This rest of this section describes how we selected values for each information flow parameter in detail.

**Transmission Principles from COPPA.** We used the Federal Trade Commission's Six Step Compliance Plan for COPPA [10] to identify transmission principles. Some of these transmission principles match those in our previous work [3], facilitating results comparison.

We converted steps 2–4 of the Compliance Plan into four transmission principles regarding consent, notification, and privacy policy compliance (Table 1). COPPA dictates that parents must receive direct notice and provide verifiable consent before information about children is collected. Operators covered by COPPA must also post a privacy policy that describes what information will be collected and how it will be used. Our corresponding transmission principles allow us to test whether these requirements actually increase the acceptability of data collection from and about children.

The fifth step of the Compliance Plan concerns "parents' ongoing rights with respect to personal information collected from their kids" [10]. Operators must allow parents to review collected information, revoke their consent, or delete collected information. We translated this requirement into the transmission principle "if its owner can at any time revoke their consent, review or delete the information collected."

The sixth step of the Compliance Plan concerns operators' responsibility to implement "reasonable procedures to protect the security of kids' personal information" [10] and to only release children's information to third party service providers who can do likewise. We translated this step into five transmission principles involving confidentiality, security, storage and deletion practices (Table 1).

The Compliance Plan also lists a set of exclusions to COPPA. We converted the exclusions that were most applicable to Internet-connected children's devices into four transmission principles (Table 1). We also added the transmission principle "if it complies with the Children's Online Privacy Protection Rule" to test parents' trust and awareness of COPPA itself.

Importantly, we also included the *null* transmission principle to create control information flows with no COPPA-based criteria. Comparing the acceptability of flows with the *null* transmission principle against equivalent flows with COPPA-based transmission principles allows us to determine whether the COPPA conditions are relevant to parents' privacy norms.

**Smart Toy Senders.** The senders included in our survey represent five categories of children's IoT devices: a smart speaker/baby monitor, a smart watch, a toy walkie-talkie, a smart doll, and a toy robot. We chose these senders by searching for children's Internet-connected devices mentioned in recent press articles [13, 17, 20, 29, 31, 35], academic papers [5, 25], blogs [9, 19, 37], IoT-specific websites [21, 23, 38], and merchants such as Toys "R" Us and Amazon. All of the selected senders are devices that are reasonably "directed towards children" [10, 11] in order to ensure that they are covered by COPPA. We excluded devices such as smart thermometers or other smart home devices that might collect information about children but are not directly targeted at children.

It is important to note that the selected devices do not represent the full breadth of smart toy products. However, information flow descriptions involving specific devices or device categories evoke more richly varied privacy norms from survey respondents than flows describing a generic "smart toy." This is supported by existing interview data [58] noting that IoT device owners often have very different privacy opinions of specific entities than of their generic exemplars (e.g., the "Seattle government" versus "government").

**Information Attributes.** We reviewed academic research [25], online privacy websites [38], toy descriptions [15], and privacy policies [18, 36] to compile a list of information attributes collected by the toys in our sender list. The final selected attributes include heart rate, frequently asked questions, the times the subject is home, frequently traveled routes, the times the device is used, location, sleeping habits, call history, audio of the subject, emergency contacts, video of the subject, and birthday. These attributes cover a variety of personally identifiable or otherwise sensitive information with specific handling practices mandated by COPPA.

**First- and Third-party Recipients.** We included device manufacturers and third-party service providers as recipient parameters. This allowed us to examine variations in privacy between first and third parties while limiting the total number of information flows and the corresponding cost of running the survey.

**Children as Information Subjects.** The only subject parameter included in the survey is "its owner's child." This wording emphasizes that the child is not the owner of the device and acknowledges the parental role in ensuring children's privacy. It also accounts for devices that may not be used directly or exclusively by the child (e.g., a baby monitor). We indicated in the survey overview that respondents should think about their own children's information when interpreting this subject.

Sender	Transmission Principle
a smart speaker/baby monitor a smart watch a toy walkie-talkie a smart doll a toy robot	<i>COPPA Compliance Plan Steps 2-3</i> if its privacy policy permits it if its owner is directly notified before the information was collected
<b>Recipient</b> its manufacturer a third-party service provider	<i>COPPA Compliance Plan Step 4</i> if its owner has given verifiable consent if its owner has given verifiable consent before the information was collected
<b>Subject &amp; Attribute</b> its owner's child's heart rate its owner's child's frequently asked questions the times its owner's child is home its owner's child's frequently traveled routes the times it is used its owner's child's location its owner's child's sleeping habits its owner's child's call history audio of its owner's child its owner's child's emergency contacts video of its owner's child its owner's child's birthday	<i>COPPA Compliance Plan Step 5</i> if its owner can at any time revoke their consent, review or delete the information collected
	<i>COPPA Compliance Plan Step 6</i> if it implements reasonable procedures to protect the information collected if the information is kept confidential if the information is kept secure if the information is stored for as long as is reasonably necessary for the purpose for which it was collected if the information is deleted
	<i>COPPA Exclusions</i> if the information is used to protect a child's safety if the information is used to provide support for internal operations of the device if the information is used to maintain or analyze the function of the device if the information is used to serve contextual ads
	<i>Other</i> if it complies with the Children's Online Privacy Protection Rule <i>null</i>

Table 1: Contextual integrity parameter values selected for information flow generation. The *null* transmission principle is an important control included to generate information flows with no explicit conditions. The transmission principles were derived from the FTC's Six Step Compliance Plan for COPPA [10].

### 3.2 Survey Design

We created and hosted the survey on the Qualtrics platform [39]. The survey was split into six sections: consent, demographic questions I, overview, contextual integrity questions, awareness questions, and demographic questions II. This section provides details about each section. The survey did not mention COPPA, privacy, security, nor any potential negative effects of smart toy information flows prior to the contextual integrity questions to prevent priming and framing effects.

**Consent.** Respondents were initially presented with a consent form approved by our university's Institutional Review Board. Respondents who did not consent to the form were not allowed to proceed with the study.

**Demographic Questions I.** The first set of demographic questions asked respondents for the ages of their children under 13. We chose this age limit because COPPA only applies to data collection from children under 13. We randomly

selected one of the ages for each respondent,  $n$ , which was piped to the survey overview.

**Overview.** Respondents were then presented with a survey overview containing a brief description of Internet-connected devices and instructions for the contextual integrity questions (Appendix A). This overview also explained how respondents should interpret the recurring phrase "its owner's child," and instructed them to keep their  $n$ -year-old child in mind while taking the survey (where  $n$  was selected for each respondent from their responses to the demographics questions I).

**Contextual Integrity Questions.** The core of the survey consisted of 32 blocks of questions querying the acceptability of our generated information flows (Section 3.1). Each question block contained 33 information flows with the same sender, same attribute, varying recipients, and varying transmission principles. For example, one block contained all information flows with the sender "a smart doll" and the at-

tribute “the times it is used.” Each question block also included one attention check question.

Each respondent was randomly assigned to a single question block. Answering questions about flows with the same sender and attribute reduced cognitive fatigue and ensured independence across recipients and transmission principles.

The information flows in each block were divided into matrices of individual Likert scale multiple choice questions. The first matrix in each block contained questions about information flows to different recipients with the *null* transmission principle (Figure 1). The remaining matrices each contained questions about information flows to a specific recipient with varying transmission principles (Figure 2). The order of the information flows in each block was randomized for each respondent.

Each individual multiple choice question in the matrices asked respondents to rate the acceptability of a single information flow on a scale of five Likert items: Completely Acceptable (2), Somewhat Acceptable (1), Neutral (0), Somewhat Unacceptable (-1), Completely Unacceptable (-2). We also included the option “Doesn’t Make Sense” to allow respondents to indicate if they didn’t understand the information flow.

**Awareness Questions.** Respondents then answered questions about their general technological familiarity and Internet use, ownership of Internet-connected devices, ownership of children’s Internet-connected devices, and previous knowledge of COPPA.

**Demographic Questions II.** Finally, respondents answered standard demographic questions from the United States Census. This allowed us to check the representativeness of our sample (Appendix B, Section 5.2) and account for demographic variables in our analysis.

### 3.3 Survey Deployment

We tested the survey on UserBob [52] once during the survey design process and again immediately prior to deployment. UserBob is a usability testing service for obtaining video screen capture of users interacting with a website while recording audio feedback. Each survey test involved creating a UserBob task with a link to the survey, brief instructions for users,<sup>1</sup> and settings to recruit 4 users to take the survey for 7 minutes each. UserBob automatically recruited users through Amazon Mechanical Turk at a cost of \$1 per user per minute. The resulting video and audio recordings of users interacting with the survey informed changes to our survey design. In particular, we reduced the number of questions per block and increased the number of pages over which the questions were presented. This reduced the amount of

<sup>1</sup>UserBob task instructions: “This is a survey that will be given to a group of parents with children younger than 13. Take the survey, pretending you have one or more children younger than 13. Record your thoughts on the user interface and whether the questions do/don’t make sense.”

scrolling necessary to complete the survey and improved engagement. This practice of using pre-deployment “cognitive interviews” to test and debug survey design is common in survey research [49]. UserBob responses were not included in the final results.

We used Cint [8], an insights exchange platform, to deploy our survey to a panel of 296 adult parents of children under the age of 13 in the United States. We selected respondents with children younger than 13 because COPPA applies to “operators of websites or online services directed to children under 13” [11]. Our surveyed population therefore consisted entirely of individuals affected by COPPA. We chose not to set a minimum age for respondents’ children, because there is a lack of readily available information on the minimum age of use of Internet-connected children’s devices. While certain manufacturers list recommended minimum ages for their connected toys and devices, this was not the case for the majority of the devices we considered. Additionally, many devices such as wearable trackers, water bottles, baby monitors, are targeted towards very young children. Lastly, not restricting the minimum age allowed us to relax the demographic requirements for survey deployment.

Respondents were paid \$3 for valid responses where the attention check question was answered correctly. Each respondent was only allowed to answer the survey once. The survey responses were collected over an 18 hour time frame. We chose Cint to deploy our survey instead of Amazon Mechanical Turk, because Cint allowed us to directly target a specific panel of respondents (as in Zyskowski et al. [60]) without requiring a preliminary screening questionnaire to identify parents [44].

### 3.4 Response Analysis

We began with 296 responses. We removed the responses from 8 respondents who did not consent to the survey (none of their information was recorded) as well as those from 85 respondents who did not correctly answer the attention check question. We removed 2 responses in which over 50% of the information flows were characterized as “Doesn’t make sense.” We also removed 2 responses where not all information flow questions were answered. Finally, we removed 1 response where the respondent self-reported over 10 children and 3 responses that were completed in less than 2 minutes. This resulted in a final set of 195 responses with an average of 6 responses per information flow (standard deviation 1.4).

The responses to all contextual integrity questions (Section 3.2) were on a Likert scale with the following Likert items: “Completely acceptable” (2), “Somewhat acceptable” (1), “Neutral” (0), “Somewhat unacceptable” (-1), and “Completely unacceptable” (-2). We call this value the “acceptability score” of each information flow for each respondent.

In order to generalize privacy norms beyond individual respondents and information flows, we averaged the accept-

A toy walkie-talkie records the times it is used. How acceptable is it for the toy walkie-talkie to send this information to the following recipients?						
	Completely unacceptable	Somewhat unacceptable	Neutral	Somewhat acceptable	Completely acceptable	Doesn't make sense
its manufacturer	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
a third-party service provider	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>

Figure 1: Example CI question matrix with information flows to different recipients and the *null* control transmission principle.

A toy walkie-talkie records the times it is used. How acceptable is it for the toy walkie-talkie to send this information to its manufacturer under the following conditions?						
	Completely unacceptable	Somewhat unacceptable	Neutral	Somewhat acceptable	Completely acceptable	Doesn't make sense
if the information is stored for as long as is reasonably necessary for the purpose for which it was collected	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
if the information is deleted	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
if it implements reasonable procedures to protect the information collected	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
if the information is kept confidential	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>
if the information is kept secure	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>

Figure 2: Example CI question matrix with information flows to a fixed recipient and varying transmission principles.

ability scores of flows grouped by CI parameters or respondent demographics. For example, we averaged the acceptability scores of all information flows with the recipient “its manufacturer” and the transmission principle “if the information is deleted” in order to quantify the pairwise effects of these two parameters on privacy norms. We then plotted these pairwise average acceptability scores as heatmaps to visualize how individual CI parameters or respondent demographic factors affect the overall alignment of information flows with privacy norms (Figures 3 & 4).

We statistically compared the effects of different COPPA provisions (Sections 4.1–4.4) by averaging the acceptability scores of all information flows grouped by transmission principles. For example, one group contained the average score given by each of the 195 respondents to information flows with non-*null* transmission principles, while a second group contained the average score given by each respondent to information flows with the *null* transmission principle. We then applied the Wilcoxon signed-rank test to find the likelihood that these two groups of scores come from the same

distribution. We performed three such tests with different transmission principle groups and set the threshold for significance to  $p = 0.05/3 = 0.016$  to account for the Bonferroni multiple-testing correction.

We statistically compared the effects of smart device awareness, COPPA familiarity, and demographic factors (Sections 4.5–4.8) by averaging the acceptability scores of all information flows grouped by respondent category of interest. For example, one group contained the average score given by each respondent who owned a smart device across all answered CI questions, while the second set contained the average score given by each respondent who did not own a smart device. We then applied the Wilcoxon signed-rank test to find the likelihood that these two groups of scores come from the same distribution. We performed five such tests with groupings based on COPPA familiarity, age, smart device ownership, education, and income and set the threshold for significance to  $p = 0.05/5 = 0.01$  to account for the Bonferroni multiple-testing correction.

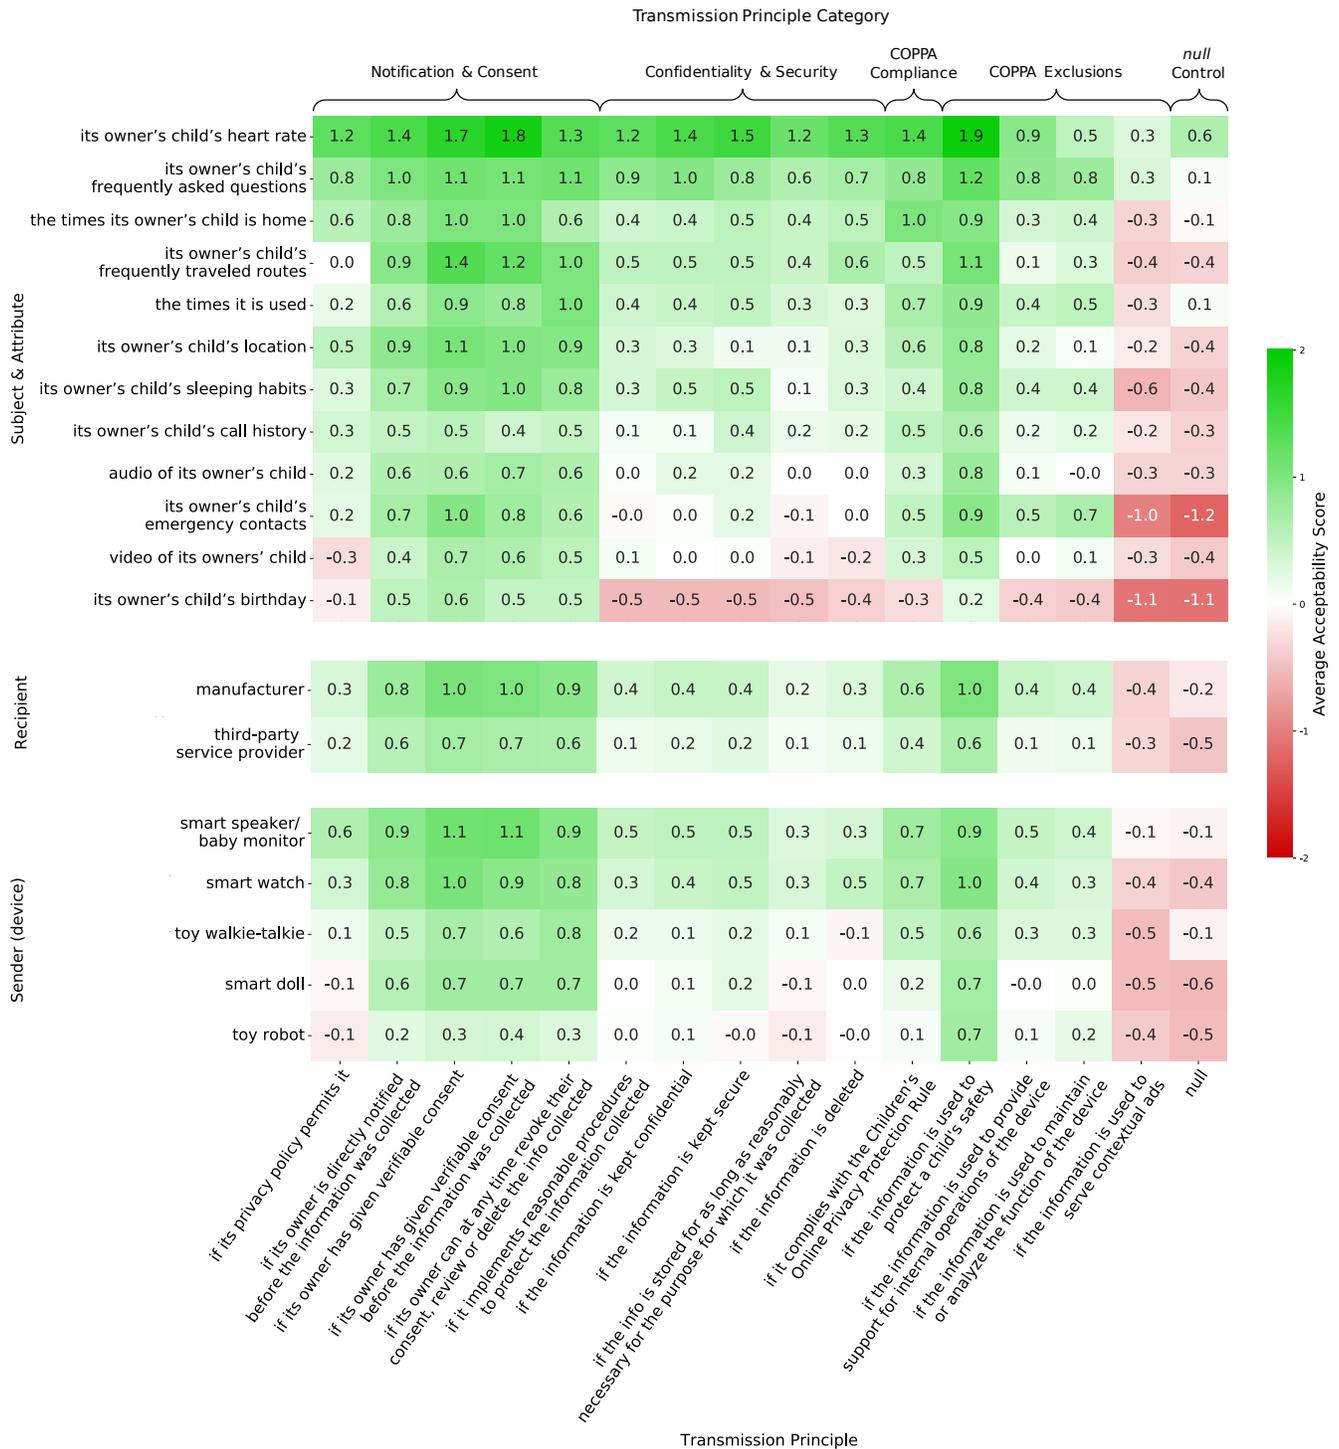

Figure 3: Average acceptability scores of information flows grouped by COPPA-derived transmission principles and attributes, recipients, or senders. Scores range from -2 (completely unacceptable) to 2 (completely acceptable).

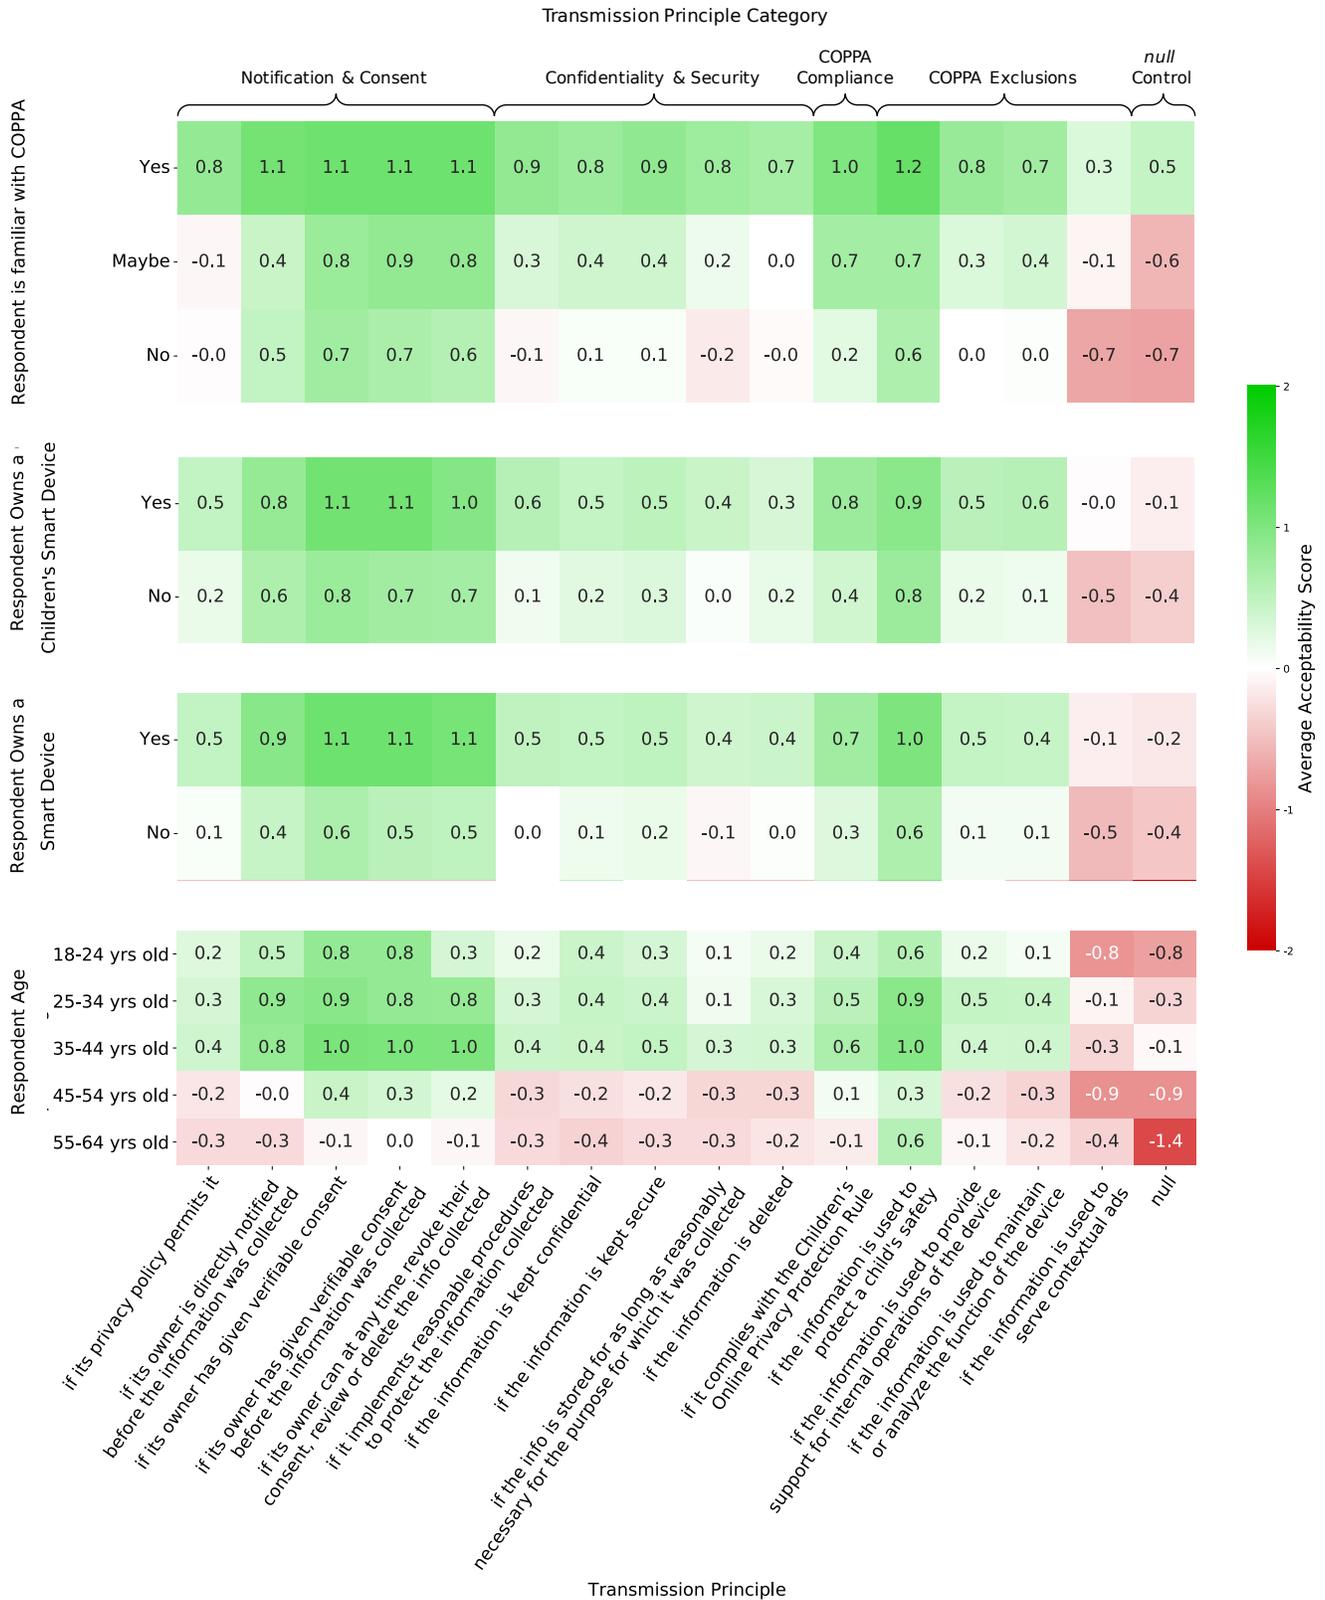

Figure 4: Average acceptability scores of information flows grouped by COPPA-derived transmission principles and respondent ages, familiarity with COPPA, or ownership of smart devices. Scores range from  $-2$  (completely unacceptable) to  $2$  (completely acceptable)

## 4 Results

Overall, surveyed parents view information flows meeting COPPA data collection guidelines as acceptable while viewing equivalent information flows without COPPA criteria as unacceptable (Figures 3 & 4). This supports the conclusion that COPPA-mandated information handling practices generally align with parents' privacy norms. In this section, we elaborate on this finding and explore additional trends in our survey responses to further compare COPPA to parents' privacy norms regarding children's smart toys.

### 4.1 COPPA Data Collection Requirements Align with Parents' Privacy Norms

COPPA requirements were incorporated in the survey as information flow transmission principles derived from the FTC's Six-Step Compliance Plan for COPPA [10] (Section 3.1). The average acceptability scores of information flows explicitly obeying these requirements are mostly non-negative (Figures 3 & 4). This indicates that most surveyed parents consider these flows as "completely acceptable" or "somewhat acceptable." In comparison, the average acceptability scores of information flows with the control *null* transmission principle are mostly negative (Figures 3 & 4), indicating that most surveyed parents consider these flows without COPPA criteria as "completely unacceptable" or "somewhat unacceptable."

This difference between information flows with no explicit conditions versus flows with COPPA requirements holds regardless of information sender, recipient, attribute, or parents' demographics (apart from a few specific exceptions which we discuss below). On average, information flows with COPPA-derived transmission principles are 0.73 Likert-scale points more acceptable than their *null* transmission principle counterparts ( $p < 0.001$ ).

Our research provides the first quantitative evidence that COPPA guidelines generally match parents' privacy norms for Internet-connected toys. This indicates that regulation can mandate meaningful transmission principles for information flows and supports further creation and fine-tuning of regulation to keep Internet data collection within the bounds of consumer privacy preferences.

### 4.2 Parents View Data Collection for Contextual Advertising as Unacceptable

Information flows with the transmission principle "if the information is used to serve contextual ads" have negative average acceptability scores across almost all senders, recipients, and attributes (Figure 3). Unlike all other information flows on our survey with non-*null* transmission principles, these flows are actually prohibited by COPPA. The "contextual ads" transmission principle is a "limited exception to COPPA's verifiable parental consent requirement" as

listed in the COPPA Compliance Plan [10]. This exception only applies to the collection of persistent identifiers (such as cookies, usernames, or user IDs) and not to any of the attributes included on our survey. Our respondents generally agree that collecting the attributes on our survey for contextual (targeted) advertising would be unacceptable, providing further support for COPPA's alignment with parents' norms.

This result indicates that the CI survey technique can detect regulatory provisions that reduce alignment with privacy norms, essential for future applications of the method (Section 6.2). It also provides evidence that the mere presence of a transmission principle doesn't necessarily improve the acceptability of information flows.

This result relates to existing work about opinions of data collection for advertising. Zheng et al. [58] interviewed owners of non-toy Internet-connected home devices and found mixed opinions of targeted advertising with data from these devices depending on the perceived benefit to the user. Combined with our results, this suggests that parents do not believe that relaxing COPPA to allow contextual advertising from more types of children's toy data would have enough benefit to outweigh privacy concerns.

### 4.3 Parents View Children's Birthdays as Especially Private

Information flows including the subject and attribute "its owner's child's birthday" are an exception to the trend described in Section 4.1. The average acceptability scores of information flows with this attribute and 10 of the 15 COPPA-derived transmission principles are negative (Figure 3). This discrepancy could be attributed to the relatively small number of parents (11 parents or 5.6% of total respondents) who were asked to score flows with this attribute. Parents may also view their children's birthdays as more personal than the other surveyed attributes or as less necessary for some of the surveyed transmission principles (such as "to maintain or analyze the function of the device"). Follow-up qualitative studies could focus on specific attributes, such as children's birthdays, to understand parents' rationales behind corresponding privacy norms.

### 4.4 Notification & Consent Versus Confidentiality & Security

Our results also provide insights into the relative importance of different sections within COPPA to parents' privacy norms. This could help regulators prioritize certain forms of non-compliant information collection for legal action.

Our COPPA-derived transmission principles can be divided into categories based on their topic and the section of the COPPA Compliance Plan [10] from which they were drawn (Section 3.1). One category consists of transmission principles from the Compliance Plan steps 2–5 regarding notification and consent (Table 1). These transmission princi-

ples involve device privacy policies, the collection of verified consent, and the ability to revoke consent or review collected information. Another category consists of transmission principles from the Compliance Plan step 6 regarding information confidentiality and security (Table 1). These transmission principles involve reasonable data protection, confidential and secure storage, and limited information lifetime.

Across all senders, attributes, and recipients, information flows with transmission principles in the notification/consent category have significantly higher acceptability scores than flows with transmission principles in the confidentiality/security category by an average of 0.43 Likert scale points ( $p < 0.001$ ) (Figure 3). One notable exception to this trend is the transmission principle “if its privacy policy permits it.” The acceptability scores for this transmission principle are an average of 0.53 Likert points lower than for others in the notification/consent category ( $p < 0.001$ ). We suspect this reflects the general distrust of privacy policies evidenced in previous research [50]. Privacy policies are typically dense, lengthy, and difficult to interpret even for experts [42]. It therefore makes sense that parents would not view the disclosure of information collection in privacy policies as acceptable as other notification methods.

The greater acceptability of information flows with notification or consent criteria versus flows with confidentiality or security criteria corroborates previous research using the CI survey method to discover privacy norms of non-toy consumer IoT devices [3]. This provides longitudinal data indicating that users of Internet-connected products continue to prioritize consent over built-in security when reasoning about the appropriateness of information collection practices. This motivates continued work to improve the state of notification and consent mechanisms for Internet data collection. The most prevalent mechanisms, privacy policies and mobile application permissions, are widely understood to be ineffective for informing users or providing meaningful privacy control options [47]. As policies change to nuance the definitions of informed consent to include ideas of intelligibility, transparency and active opt-in, among others, it is important to continue to study and evaluate consumer’s privacy expectations regarding consent.

#### **4.5 COPPA Compliance and Familiarity Increase Data Collection Acceptability**

Information flows with the transmission principle “if it complies with the Children’s Online Privacy Protection Rule” received a positive average acceptability score of 0.49 across all senders, recipients, and attributes. As expected, flows with this transmission principle were rated as more acceptable by the 67% of respondents familiar with COPPA than by the 33% of respondents unfamiliar with the rule.

Furthermore, respondents who indicated that they were familiar with COPPA rated all information flows 0.75 Lik-

ert points more acceptable on average than respondents who were not familiar with the rule ( $p < 0.001$ ) (Figure 4).

In both cases, stated compliance and/or familiarity with COPPA may increase parents’ acceptance of smart toy data collection by reassuring them that their children’s privacy is protected by regulation. However, this may be a false sense of security, as COPPA guidelines are relatively broad and COPPA violations are likely widespread in practice (Section 6.1) [6,43].

#### **4.6 Younger Parents are More Accepting of Smart Toy Data Collection**

Parents younger than 45 gave an average acceptability score of 0.48 to all rated flows, following the trend discussed in Section 4.1 (Figure 4). In comparison, parents 45 years and older gave an average acceptability score of  $-0.17$  to all rated flows. This difference in the acceptability scores of these two groups is significant ( $p < 0.01$ ). Nevertheless, context still matters, as information flows specifically “to protect a child’s safety” are viewed as generally acceptable to all surveyed parents regardless of age.

Previous work indicates that young American adults are more aware of online privacy risks and more likely to take steps to protect their privacy online than older adults [40]. Future studies could investigate why this awareness of online privacy risks makes younger parents more accepting of smart toy data collection.

#### **4.7 Parents Who Own Smart Devices are More Accepting of Data Collection**

Parents who own generic smart devices or children’s smart devices were more accepting of information flows than respondents who do not own these devices on average, but the difference in scores (0.34 Likert scale points) between these two groups is not significant ( $p = 0.12$ ).

Nevertheless, this difference corroborates previous work using the CI survey method, in which owners of non-toy consumer IoT devices were found to be more accepting of information flows from these devices than non-owners [3]. This difference likely reflects a self-selection bias, in which those more uncomfortable with Internet data collection are less likely to purchase Internet-connected toys or other devices. However, the small effect size in both this study and the previous work may be due to parents purchasing smart toys unaware of their data collection potential [26] or willing to trade-off privacy concerns for other benefits provided by the products [58].

#### **4.8 Education & Income have Little Effect on Parents’ Smart Toy Privacy Norms**

Parents’ education and income did not have significant effects on acceptability scores. Parents earning more than

\$100,000 per year gave an average acceptability score of 0.46 to all rated flows, not significantly different from the average score of 0.37 from parents earning less ( $p = 0.77$ ). Similarly, parents with at least some college education gave an average acceptability score of 0.37, not significantly different from the 0.33 average score of parents with a high school diploma or less ( $p = 0.58$ ). This is perhaps unexpected given previous work indicating that parents with more resources are more likely to engage with children on privacy issues [41] and is a topic for follow-up research.

## 5 Limitations

Our results must be considered in the context of the following limitations.

### 5.1 Privacy Attitudes Versus Behaviors

Individuals often self-report greater privacy awareness and concerns than reflected in actual privacy-related behaviors [1, 22]. This “privacy paradox” is well-documented and poses a challenge for researchers. The CI survey method is vulnerable to privacy paradox effects. However, there is a reasonable argument that privacy regulation should prioritize the expressed norms of users (measured by the survey instrument) over norms evidenced through behaviors, which are influenced by external factors (such as confusing user interfaces) that could be affected by the regulation. For example, it is often difficult for consumers to determine the data collection practices of IoT devices, including Internet-connected children’s toys, due to poor company disclosure practices [42] and limited auditing by third parties. Just because many parents purchase smart toys does not mean that they approve of the toys’ data collection practices and wouldn’t support new regulation to improve privacy.

### 5.2 Respondent Representativeness

The self-reported demographics of our respondents (Appendix B) indicate that the sample, while diverse, is non-representative in ways that may influence measured privacy norms.

Females and high-income individuals are notably overrepresented in our sample compared to the United States population. The literature on gender differences in online privacy concerns suggests that women may generally perceive more privacy risks online than men [4, 14, 56], but some studies contradict this conclusion, reporting no significant gender effect [55]. The effect of income on online privacy concerns is similarly unsettled, with some reporting that high-income individuals are less concerned about privacy [24, 33], others reporting that high-income individuals are more likely to engage in privacy-preserving behaviors [41], and still others finding no significant income effect [57].

Limiting our survey to parents also ignores the opin-

ions of other parties, including school and daycare teachers and extended family members, who also purchase Internet-connected toys for children but may have different privacy norms. These individuals are also affected by COPPA and have legitimate justification for their opinions and interests to be reflected in children’s privacy regulation. Likewise, we did not ask whether our respondents were members of communities that may have less common privacy norms, but our respondent panel, drawn from across the United States, certainly missed smaller demographics.

Finally, our respondent panel consisted entirely of parents living in the United States, as COPPA only applies to products sold in the U.S. These respondents are therefore influenced by American attitudes toward privacy, which may vary from those of parents in other countries. We hope that future work will apply the CI survey method used in this paper to evaluate the alignment between privacy norms and privacy regulation in non-U.S. contexts.

### 5.3 Goals of Privacy Regulation

Our use of CI surveys to evaluate privacy regulation assumes that the underlying value of such regulation is to better align data collection practices with privacy norms. This makes an implicit normative argument about the purpose of privacy regulation, which does not necessarily hold, especially for the norms of majority populations. For example, privacy regulation may seek to protect minority or otherwise vulnerable populations. In these cases, surveys of all individuals affected by the regulation may reflect a majority view that does not value the norms or appreciate the situation of the target population. CI surveys could still be applied in these contexts, but care would need to be taken to identify and recruit respondents from populations differentially affected by the regulation in order to uncover discrepancies between the regulation and the norms of these groups.

Additionally, some regulation may be created with the goal of changing existing norms. In these cases, the CI survey method will indicate that the regulation does not match current privacy expectations upon enactment. However, CI surveys would still be useful for conducting longitudinal measurements to track whether the regulation has the desired effect on privacy norms over time.

## 6 Discussion & Future Work

We would like this study to serve as a template for future work using contextual integrity to analyze current or pending privacy regulation for policy or systems design insights. This section discusses our COPPA findings and presents suggestions for future applications of our method by policymakers, device manufacturers, and researchers.

## 6.1 COPPA Insights & Concerns

Previous research indicates that parents actively manage the information about their children on social media platforms to avoid oversharing [2], and that owners of IoT home appliances view most data collection by these devices as inherently unacceptable [3]. We expected that these domains would overlap, resulting in skepticism of smart toy data collection that even the restrictions in COPPA could not ameliorate. Surprisingly, it seems that the COPPA criteria assuaged parents' privacy concerns on average.

While we are encouraged that COPPA generally aligns with parents' privacy expectations, we are also concerned that the existence of COPPA may give parents an unreasonable expectation that their children's data is protected, especially since parents familiar with COPPA were less critical of smart toy information flows. In fact, several online services and Internet-connected toys have been found to violate COPPA [6,43], and many more non-compliant toys are likely available for purchase. Additionally, the information collection guidelines in COPPA are relatively broad, leaving room for technical implementations that adhere to the letter of the law but still compromise children's privacy. This motivates continued work by regulators and researchers to identify toys that place children's privacy at risk, as well as healthy skepticism by parents before purchasing any particular toy.

As an additional policy insight, variations in information flow acceptability across recipients<sup>2</sup> corroborate previous work [58] indicating that privacy norms are deeply contingent on the perception of entities that collect online data. COPPA distinguishes between first- and third-parties, but does not further categorize data recipients. This increases the flexibility of the law, but raises the potential that some recipients, which may be viewed as completely unacceptable by privacy norms, could still legally get access to children's data. This suggests that incorporating a more contextual framing of entities could improve the ability of future regulation to prevent unwanted data collection practices.

## 6.2 Further Policy Analysis Applications

The CI survey method is not limited to COPPA. We would like to see the results of follow-up studies focusing on different regulation, such as the Health Insurance Portability and Accountability Act (HIPAA), the Family Educational Rights and Privacy Act (FERPA), the National Cybersecurity Protection Advancement Act, the European General Data Protection Regulation (GDPR), and others from the local to international level, to see if their requirements result in similarly acceptable information flows for members of their target populations. As most privacy regulation encompasses information transfer or exchange, the theory of contextual integrity is an appropriate framework for this research. Further

<sup>2</sup>Information flows to first-party manufacturers have higher average acceptability scores than flows to third-party service providers (Figure 3).

studies would also allow cross-regulatory analysis to find common factors that affect alignment with privacy norms.

The CI survey method could also be incorporated into the policymaking process. Policy formulation and resource allocation could be guided by surveying a wide-variety of information flows allowed under current regulation and identifying egregious or unexpected norm violations that require attention. Policymakers could test whether previous regulatory approaches will be applicable to new innovations by conducting surveys with CI parameters describing new technologies and existing regulation (e.g., smart toys and COPPA prior to the 2017 inclusion of IoT devices [16]). Policymakers could also perform A/B tests of policy drafts with different stipulations and/or language by conducting multiple parallel surveys with varying CI parameters. These and other use cases would improve quantitative rigor in data-driven policy development and facilitate the design of regulation responsive to the privacy norms of affected populations.

## 6.3 Systems Design Applications

The application of CI surveys to guide systems and product design is covered in detail in our previous work [3]. To summarize, device manufacturers can conduct CI surveys to determine whether information collection practices of devices or new features under development will violate consumer privacy norms. This allows modifications during the design process to prevent consumer backlash and public relations debacles.

Applying CI surveys to evaluate privacy regulation can also yield valuable insights for systems research and development. For example, learning that parents value the ability to revoke consent or delete information (Figure 3) motivates research into verifiable deletion of cloud data from IoT platforms. Such insights are especially relevant as neither privacy norms nor regulations are necessarily tied to technical systems feasibility. Discovering that a particular CI parameter value is crucial to privacy norm adherence could launch several research projects developing efficient implementations or correctness proofs. We expect future applications of the CI survey method will generate many such results.

## 7 Conclusion

Increased interest in data privacy has spurred new and updated regulation around the world. However, there are no widely accepted methods to determine whether this regulation actually aligns with the privacy preferences of those it seeks to protect. Here, we demonstrate that a previously developed survey technique [3] based on the formal theory of contextual integrity (CI) can be adapted to effectively measure whether data privacy regulation matches the norms of affected populations. We apply this methodology to test whether the Children's Online Privacy Protection Act's re-

restrictions on data collection by Internet-connected “smart” toys align with parents’ norms. We survey 195 parents of children younger than 13 about the acceptability of 1056 smart toy information flows that describe concrete data collection scenarios with and without COPPA restrictions.

We find that information flows conditionally allowed by COPPA are generally viewed as acceptable by the surveyed parents, in contrast to identical flows without COPPA-mandated restrictions. These are the first data indicating the general alignment of COPPA to parents’ privacy norms for smart toys. However, variations in information flow acceptability across smart toys, information types, and respondent demographics emphasize the importance of detailed contextual factors to privacy norms and motivate further study.

COPPA is just one of many U.S. and international data privacy regulations. We hope that this work will serve as a template for others to adopt and repeat the CI survey method to study other legislation, allowing for a cross-sectional and longitudinal picture of the ongoing relationship between regulation and social privacy norms.

## Acknowledgments

We thank Yan Shvartzshnaider and our survey respondents. This work was supported by the Accenture Fund of the School of Engineering and Applied Science at Princeton University.

## Appendix A: Survey Overview

### **Survey Overview**

"Smart" Internet-connected household devices are becoming increasingly popular. Such devices often have sensors that collect information about the people who own and use them. This information may be sent to a variety of recipients for a variety of reasons.

This survey contains questions about information flows from devices used directly or indirectly by children. You will be asked whether you think each information flow is acceptable.

The information flows include the phrase "its owner's child." Here, "it" refers to the device, "owner" refers to the child's parent or legal guardian who purchased the device, and "child" refers to the child who is using the device or about whom the device collects information.

**Please keep your 9 year old child in mind while answering the questions.**

Please answer each question as honestly as possible.

Survey overview shown to participants before contextual integrity information flow questions. Participants are asked to keep one child in mind when answering the survey questions. The age of this child (9 in above example) is selected randomly for each participant from the self-reported ages of each of their children younger than 13.

## Appendix B: Self-Reported Demographics and Technical Background of Survey Respondents

Metric	Sample	Metric	Sample
Female	61%	18-24 years old	3%
Male	39%	25-34 years old	31%
Other/Prefer not to disclose	-	35-44 years old	48%
9th, 10th, 11th, 12th - no diploma	1%	45-54 years old	13%
High school graduate	14%	55-64 years old	4%
Some college but no degree	22%	65 years or older	<1%
Associate degree in college - Vocational	6%	Has 1 child	33%
Associate degree in college - Academic	4%	Has 2 children	45%
Bachelor's degree	30%	Has 3 children	15%
Master's degree	16%	Has 4 or more children	7%
Professional school degree	2%	answers based on 0-3 yr old child	14%
Doctorate degree	5%	answers based on 4-7 yr old child	36%
Less than \$25,000	13%	answers based on 8-12 yr old child	50%
Between \$25,000 and \$50,000	22%	0-3 hours of internet use per day	15%
Between \$50,000 and \$75,000	21%	4-7 hours of internet use per day	45%
Between \$75,000 and \$100,000	21%	8-12 hours of internet use per day	25%
Between \$100,000 and \$200,000	17%	>12 hours of internet use per day	14%
More than \$200,000	4%	Uses a personal computer	97%
Prefer not to disclose	2%	Uses a smartphone	94%
Asian	7%	Uses a tablet device	78%
Black or African American	11%	Owens a smart device*	49%
Native Hawaiian or Other Pacific Islander	1%	Does not own a smart device	50%
White	76%	Unsure	<1%
White, American Indian or Alaska Native	<1%	Owens a children's smart device**	33%
White, Asian	<1%	Does not own a children's smart device	66%
White, Black or African American	1%	Unsure	1%
Other	3%	Familiar with COPPA	63%
Hispanic	14%	Not familiar with COPPA	33%
Not Hispanic	85%	Maybe familiar with COPPA	4%
Prefer not to disclose	<1%

## Abstract

Augmented reality (AR), which overlays virtual content on top of the user’s perception of the real world, has now begun to enter the consumer market. Besides smartphone platforms, early-stage head-mounted displays such as the Microsoft HoloLens are under active development. Many compelling uses of these technologies are multi-user: e.g., in-person collaborative tools, multiplayer gaming, and telepresence. While prior work on AR security and privacy has studied potential risks from AR applications, new risks will also arise among multiple human users. In this work, we explore the challenges that arise in designing secure and private content sharing for multi-user AR. We analyze representative application case studies and systematize design goals for security and functionality that a multi-user AR platform should support. We design an AR content sharing control module that achieves these goals and build a prototype implementation (ShareAR) for the HoloLens. This work builds foundations for secure and private multi-user AR interactions.

## 1 Introduction

Augmented reality (AR) technologies, which overlay digitally generated content on a user’s view of the physical world, are now becoming commercially available. AR smartphone applications like Pokemon Go and Snapchat, as well as smartphone-based AR platforms from Apple [5], Facebook [6], and Google [4], are already available to billions of consumers. More sophisticated AR headsets are also available in developer or beta editions from companies like Magic Leap [37], Meta [41], and Microsoft [24]. The AR market is growing rapidly, with a market value projected to reach \$90 billion by 2022 [15].

The power that AR technologies have to shape users’ perceptions of reality—and integrate virtual objects with the physical world—also brings security and privacy risks and challenges. It is important to address these risks early, while AR is still under active development, to achieve more robust security and privacy than would be possible once systemic issues have become entrenched in mainstream technologies.

The computer security and privacy community has already taken steps towards identifying and mitigating potential risks from malicious or buggy AR apps. These efforts—e.g., limiting untrusted apps’ access to sensor data [28, 49, 54] or restricting the virtual content apps can display [32, 34]—are reminiscent of recent work on access control for untrusted apps on other platforms, such as smartphones [16, 53]. Despite this valuable initial progress, we observe a critical gap in prior work on security and privacy for AR: though past efforts are valuable for protecting *individual* users from untrusted *applications*, prior work has not considered how to address potentially undesirable interactions between *multiple human users* of an AR app or ecosystem.

**The need to consider security for multi-user AR.** Despite this gap in prior work, we observe that many compelling use cases for AR will involve multiple users, each with their own AR device, who may be physically co-located or collaborating remotely and who may be interacting with shared virtual objects: for instance, in-person collaborative tools [63], multi-player gaming [3], and telepresence [18]. As one concrete example already available to AR users, Ubiquity6 has released a beta version of its smartphone platform in which all users can view and interact with all AR content within the app [67], as shown in Figure 1.

In these contexts, the potential security, privacy, and safety risks for AR users come not only from the apps on their own devices but also from *other users*. For example, one user of a shared AR app might accidentally or intentionally spam other users with annoying or even disturbing virtual objects, or manipulate another person’s virtual object (e.g., artwork) without permission. Indeed, even though multi-user AR technologies are not yet ubiquitous in the consumer market, precursors of such issues have already begun to emerge in the wild and in research settings today. In AR specifically, for example, there have been reports of “vandalism” of AR art in Snapchat [38], and a recent study found that pairs of AR users often positioned virtual objects in each other’s personal space [35]. Similar findings have been made in virtual reality (VR), where users have blocked each other’s vision

Figure 1: Sample screenshots from Ubiquity6 multi-user application (taken from [67]). Users can, for instance feed a virtual cat (left) or tend a virtual garden (right).

with virtual objects [66] and invaded each other’s personal space [1]. In earlier work on digital tabletop displays, researchers observed conflicts between users closing or stealing each others’ documents [44]. As a final example, Apple’s AirDrop scheme for sharing files between physically co-located Apple devices has been misused to send inappropriate content to strangers in public spaces [11].

Thus, we can and should expect conflicts and tensions to arise between multiple AR users, which raises the critical question: how should AR platform and app designers handle these issues? Existing AR platforms provide limited or no support to app developers on this front. For example, though HoloLens supports running an app shared between multiple device users, it surfaces only basic cross-device messaging features, providing no framework for developers to reason about or support complex multi-user interactions.

**This work: Sharing control for multi-user AR.** In this work, we thus address the challenge of *providing secure and private content sharing capabilities for multi-user augmented reality applications*. Unlike prior AR security work that focused on protecting users from untrusted apps, we aim to limit undesirable interactions between mutually distrusting human users — similar to how traditional file system permissions attempt to separate mutually distrusting human users from each other. By addressing this issue before multi-user AR becomes widespread, we aim to inform the design of future AR systems, thereby preventing such multi-user concerns from manifesting broadly.

In our exploration of this space, however, we find that controlled sharing for AR content raises unique challenges not present in traditional settings such as file systems or shared online documents. The root cause of this complexity is AR’s integration with the physical world. Because people share the same physical world, they may have certain expectations about how AR content is shared. Indeed, prior work has found that users often expect co-located users to see the

same virtual content [35]. For example, a user might want to have control of their personal physical space, not allowing another user to place too many virtual objects near them. Fulfilling this request requires that either the second user is restricted in augmenting his or her own view of the world, or that the two users see different things. Diverging views of the world can violate expectations, however: consider watching or interacting with an AR object that only you can see while another AR user unknowingly steps into the space between you and your object.

AR’s integration with the physical world further complicates many access control design decisions. Consider the seemingly simple notion of Alice sharing an AR object with Bob: for instance, giving him read access to a piece of virtual artwork. When this object is shared, does Bob see the artwork in the same place as Alice (e.g., on a particular wall), or does Bob see his own instance of the object in a different place? The answer may depend on the semantics of the app and whether Alice and Bob are physically co-located, and the answer interacts with many other design choices.

In our work, we thus explore a set of multi-user AR case study apps that represent different points in the possible design space (co-located and remote users, opt-in versus opt-out sharing) to surface functionality and security goals for an AR sharing control module. We then present the design of such a module, which we envision as an app-level library or OS interface that can be leveraged by AR application developers. This module supports app developers in (1) allowing users to *share* AR content with other (co-located or remote) users, (2) allowing users to *control* both inbound and outbound AR content, while (3) addressing fundamental challenges raised by AR’s integration with the physical world.

One key challenge is to define and manage different ways that AR content might be mapped into the physical world — we do so by supporting both location-coupled objects (which all users see in the same physical place) and location-decoupled objects (for which users see their own copies in separate locations), and by managing the resulting impact of these types of objects on sharing and access control functionality. Another key challenge is to address potential discontinuities in user expectations around private content in a shared physical world — we do so by introducing “ghost” objects that allow users to share with other AR users *that* they are interacting with a virtual object without sharing sensitive details about that object. Finally, a third key challenge is to respect users’ possible sense of ownership of physical space (e.g., personal space) — to that end, our design supports policies for how to handle AR objects that are within a protected region (e.g., making objects closer to a user more transparent to that user). Through our exploration, we find that no single sharing control model will work for all apps, but that our proposed module can provide key features to support app developers in creating multi-user AR apps that meet users’ expectations.

**Contributions.** In summary, our contributions include:

1. We are the first to rigorously explore the design space for secure and private AR content sharing between users. Through an exploration of multi-user AR case study apps, we identify (in Section 2) key design goals, challenges, and features that app developers require to support secure and private multi-user AR experiences.
2. Building on our design space exploration (Section 2), we present the design (in Section 4) of a multi-user AR sharing control module. Our design addresses key challenges and enables app developers to meet our design goals: supporting users in controlling how they share AR content with others and how AR content is shared with them, while taking into account the ways in which AR content might integrate with the physical world.
3. We provide a concrete prototype implementation (ShareAR, in Section 5) and evaluation (in Section 6), iteratively refining our design and demonstrating its feasibility in practice. Our source code will be made available at the project website.<sup>1</sup>

This work lays a foundation for future secure and private multi-user AR apps. Mitigating undesirable interactions between users can facilitate user adoption of AR and help the technology reach its full potential.

## 2 Problem Formulation and Design Goals

We begin by formulating, for the first time, the problem space and goals for secure and private multi-user AR content sharing. To do so systematically, we consider four case study apps (Section 2.1) that we selected to explore unique points in the multi-user AR design space and that we envisioned might exercise a broad range of functionality and security needs. From these case studies, we then derive our security and functionality goals (Sections 2.2 and 2.3).

In exploring possible apps, we observe that the key aspect of AR that differentiates it from previous technologies is its tight *physical-world integration*: virtual content appears to the user to be situated in 3D space among physical objects (e.g., the examples in Figure 1). Thus, one key axis is (1) co-location: are the users sharing virtual content co-located or not? A second key axis is (2) opt-in versus opt-out sharing: is sharing a deliberate opt-in action between specific people (as the HoloLens developer guidelines prioritize [43]) or are virtual objects public by default, requiring a deliberate opt-out (as the Meta developer guidelines advocate [40])? The example case studies we highlight explore these dimensions.

### 2.1 Case Study Applications

**Paintball: Co-located, opt-in.** In this app, users in the same physical space can play a game of paintball with virtual paint. All users can see the game objects (weapons, paint, etc.). Users may also have a dashboard where they can see

the game status. This type of AR multiplayer gaming is already emerging in smartphone apps [20].

**Multi-Team Whiteboards: Not (necessarily) co-located, opt-in.** We envision a collaborative AR whiteboard app in which a user, possibly in a co-located group, may choose to share a whiteboard with other users who may be in the same or different physical locations. Although each co-located group of users sees the same whiteboard in the same location, different groups may see the whiteboard instantiated in different locations; furthermore, a user in a group may split off an individual copy of the whiteboard in order to leave the room and still collaborate from another remote space. The contents of all users' copies are synchronized in real-time. Since different whiteboards may have different levels of sensitivity, access control must be at least at whiteboard-level granularity. Unlike in *Paintball*, where a shared game state is core to app function, users of this app may encounter users with whom they don't want to share a sensitive whiteboard. This case study, also, is grounded in existing work: a pending patent application by Apple [29] describes a GUI for AR document editing, though it does not mention access control.

**Community Art: Co-located, opt-out.** We now consider an example in which co-located users automatically see each other's objects by default. We consider a virtual art app, where users can create and view sculptures, free-drawn markup, and other artistic artifacts made by other, potentially unknown AR users in the same physical (and virtual) space. Variants of *Community Art* might be used to decorate for a celebration so that guests or passersby will see the content, or to place advertisements outside one's shop. Though we consider *Community Art* as an example of a public-by-default app, some use cases may necessitate more fine-grained access control. For instance, artists may choose to keep their art private while constructing it or allow the public to view but not edit their sculptures. This case study is similar to Ubiquity6's smartphone app [67], in which all content is public.

**Soccer Arena: Not co-located, opt-out.** Finally, we consider an app that lets the user watch a virtual replica—e.g., on the user's living room table—of the soccer game that it is currently broadcasting. By default, all users of this app see all aspects of the playing field, commentator annotations, and ads. Some users may watch the game together in the same physical space, while others may be in separate physical spaces. While using the app, a user may wish to block a distracting ad or turn off annotations. The ability to form AR reconstructions of soccer games from monocular video footage, demonstrated in [51], shows that this app is within reach of today's technology. We find that *Soccer Arena* does not surface new security, privacy, or functionality requirements not covered by the other case studies. In particular, it raises the same spam-related concerns as *Community Art* does and the same non-colocation challenges as *Multi-Team Whiteboards* does. However, we include it for completeness.

## 2.2 Functionality Goals

From the above case studies, we now derive a set of functionality design goals for multi-user AR apps and platforms. Any sharing control solution must coexist with these functionality goals — while one could trivially meet the security and privacy goals outlined in the next section by allowing *no* shared content, supporting sharing functionality is critical to the success of emerging multi-user apps.

- **Support physically-situated sharing.** For both *Paintball* and *Community Art*, physically co-located users will want to see the same virtual objects. The multi-user AR platform must support a way of sharing virtual state, and a mapping between virtual objects and the physical world, among the collaborating users.
- **Support physically-decoupled sharing.** *Multi-Team Whiteboards* requires that AR content be synchronized for each person’s copy, regardless of the users’ relative location — when they’re in the same room, or adjacent rooms, or halfway across the world. Thus, the platform must support sharing virtual content decoupled from the physical world as well.
- **Support real-time sharing.** Users of *Paintball* will expect for their interactions with other players to occur in real time. Real-time state changes are also desirable for the other case studies. Thus, the platform must support low latency updates of shared state among multiple users, and any sharing control solution should not impose an undue performance burden. (Note that real-time performance also confers a security benefit, since access control changes can propagate quickly.)

## 2.3 Security Goals

A trivial solution that provides all of the above functionality would make all AR content public by default. However, interaction between multiple users may not always be positive. For example, a malicious or careless user may attempt to:

1. *Share unwanted or undesirable AR content* with another user. For example, in *Multi-Team Whiteboards*, a user may plaster a wall with offensive messages, or in *Community Art*, violate another user’s personal space by attaching virtual objects to them as a practical joke. Such behavior has already manifested in shared VR settings [1, 66].
2. *See private AR content* belonging to another user. For example, in *Multi-Team Whiteboards*, a user may attempt to read another user’s private whiteboard.
3. *Perform unwanted manipulations on AR content* created by or belonging to another user. For example, in *Community Art* or *Multi-Team Whiteboards*, a user may delete or vandalize another user’s virtual creations. Such behavior has already appeared in the wild, with vandalism of AR art in Snapchat [38].

In response to such multi-user threats, we develop the following security and privacy goals for an AR sharing module.

**Control of outbound content.** Sharing of AR content involves two parties: the originator of the content and the recipient. We decompose our security goals along this dimension, beginning with control of outbound content, i.e., managing the permissions of other users to access shared content.

Three canonical access control rights are “read,” “write,” and “execute.” Extending “read” and “write” to the AR domain (and deferring “execute” to Section 7):

- **Support granting/revoking per-user permissions.** The multi-user AR platform should support setting edit and view permissions for different users. A user of *Paintball* may wish to share a game session only among a specified friend group instead of allowing any nearby user to join, and may wish to retain full control of game administration even among the set of players.
- **Support granting/revoking per-object permissions.** A user of *Community Art* may wish to leave one piece of art publicly visible while working privately on another. Thus, regulating permissions at the granularity of the app is not sufficient to cover all use cases; object-level permissions must be supported as well.

The consequence of the above goals is that users in the same physical space may not share the same view of the virtual space. This is in sharp contrast to current technologies, where the physical presence of a device — e.g., a smartphone or a television set — enables the user of that device both (1) to signal to others that they are busy with that device, and (2) to establish a dedicated spatial region upon which their use of the device depends. The physicality of the device, then, serves as a scaffold around which interpersonal norms have developed. For instance, a person might avoid standing in front of a television set when a user is watching it, and might refrain from blocking the line of sight from a user to the smartphone they are holding.

AR content has no such physicality. Consider, for instance, *Multi-Team Whiteboards*: as thus far stated, a user looking at or interacting with a private whiteboard will appear to a nearby user as staring into or manipulating empty space. There is no mechanism by which the user can exercise agency over their working space in the presence of other users, and no mechanism by which other users passing by can determine whether the object is five feet away from its owner or up against a more distant wall. As a result, one user may inadvertently stand in front of content that a second user is interacting with. Further adding to this issue, prior work has also shown that people can be uncomfortable with the presence of AR users due to not knowing what the AR user is doing [14,35], and private content causes this rift even between users of the same AR platform. The Meta developer guidelines [40] thus recommend that developers build public-by-default content in accordance with human intuition about a shared physical world. Indeed, novice users in the same *physical* space may expect to also see the same *virtual* content [35]. It is possible that social behaviors

will adapt to this physicality disconnect over time, particularly around the current social discomfort of bystanders. But although social norms may change, and although mitigating these issues for bystanders — non-AR users, or AR users of a different and non-compatible platform — is difficult and beyond the scope of this work, we still seek to address this physical-world disconnect at least in the near term for multiple AR users of compatible platforms. Specifically, we wish to achieve the above content privacy goals while at least partially supporting a shared-world physical intuition:

- **Support physically intuitive access control.** An app may wish to signal to a nearby user that another user is (for example) drawing on a whiteboard, without revealing the content being drawn.

**Control of inbound content.** We next consider security properties from the perspective of the recipients of shared content. Since shared content can have serious implications for the receiver, such as spam that obscures important real-world information [34], we derive the following goals:

- **Support user control of incoming virtual content.** For instance, users of *Community Art* may wish to filter content to only that which is age-appropriate or that does not contain foul language.
- **Support user control of owned physical space.** In the case of *Community Art*, a user may not want arbitrary other users to attach content to their heads without consent, a homeowner may wish to prevent house guests from placing virtual content inside private rooms, and the keepers of a public monument may not want the monument to be vandalized with virtual graffiti. We note that users may want control over their physical space even when they cannot see the object in question: for instance, an app may wish to prevent a virtual “kick me” sign from being attached to a user’s back such that the user cannot see and cannot control the sign. We consider the question of determining who controls a particular physical space to be out of scope for the design we present in Section 4 (see Section 4.4 for further discussion), and instead focus on enforcing owned physical space; however, we urge future work to also address this complementary issue.

## 2.4 Supporting Flexibility

Stepping back, in defining the above functionality and security goals, we observe that not all multi-user AR apps will have the same needs. For example, AR content that is shared with all users by default is suitable for some apps (e.g., *Community Art*) but not others (e.g., *Multi-Team Whiteboards*). Likewise, not all security and privacy goals are relevant in all cases: for instance, enforcing personal space for shared AR content may conflict with the functionality needs of *Paintball*, which requires that virtual paint stick to players upon a hit. Even in an app that is otherwise simple from a sharing control perspective, user needs may warrant a degree of

added sharing control complexity: for instance, an AR assistive technology object that transcribes spoken words for deaf users may be exempt from the app’s general rules for the enforcement of owned physical space so that it always remains visible to the deaf user who needs it.

Because the right sharing control model is app-specific, AR app developers will need the ability to implement multi-user features with their chosen model. To that end, we identify the need for a flexible AR sharing control module that can be leveraged by app developers. We envision this module as either an app-level library or an OS interface (i.e., set of APIs) that provides sharing control features. The advantage of an app-level library is that it does not require explicit changes to the platform. That is, an app developer could create an app that runs on different AR platforms and, by including the platform-appropriate version of a library, support interactions among users with different types of AR devices. For example, although we prototype our design as an app-level library for HoloLens, in principle it could be adapted for compatibility with Meta or Magic Leap apps.

## 3 Threat Model and Non-Goals

We aim to design a flexible module that helps app developers create multi-user AR apps that incorporate shared AR content while mitigating the risk of undesirable interactions between multiple users. We focus on the case of a developer building a single app and mediating the interactions of its multiple users, deferring to future work the problem of cross-app communication. We now present the threat model under which we develop our design in Section 4, as well as specify non-goals of this work.

**Threat Model.** Our primary focus in this work is on *untrustworthy users*. That is, we aim to help app developers create multi-user AR apps that are resilient to security and privacy threats between multiple users of the *same* app. In that context, we assume that two or more users are using the same AR app, written by the same developer and incorporating our sharing module. We thus assume that users trust both the developers of the apps that they install as well as their AR operating system, but that users may *not* trust each other. This trust dynamic is akin to traditional desktop environments — e.g., where two users of a Unix operating system might both trust the underlying system and installed apps, but might not trust each other and hence might not make their home directories world readable or world writable. A key difference, as noted earlier, is that in our model we only consider sharing of content between users of the same app.

Under this threat model, we do not consider malicious apps that omit or misuse our sharing module. We explicitly trust app developers to incorporate our module (e.g., as an app-level library) into their apps; a malicious app developer might choose to simply not use our sharing module, implementing their own adversarially-motivated sharing functionality, or use our module but violate security or pri-

vacy properties through out-of-band means. Though a user may install malicious apps alongside legitimate ones that use our module, these malicious apps cannot interfere via our module: we consider (and our module supports) AR content sharing only among multiple users of the *same* app, rather than also considering sharing *across* apps. This is consistent with the capabilities of current AR technologies, which are either single-app or do not allow multiple concurrently running apps to communicate [33]. We also assume that all users are running legitimate, uncompromised versions of the app; strategies for verifying [36,75] or enforcing [73,74] this assumption are significant research challenges of their own.

Finally, we assume that communication between devices is secured with today’s best practices, e.g., end-to-end encrypted. Thus, we rule content eavesdropping and content modification attacks as out of scope. Current network best practices still suffer from denial-of-service attacks and traffic analysis attacks, but we do not aim to protect against such attacks in this work, focusing instead on the app-level security and privacy issues.

**Non-Goals.** We consider the following design questions to be non-goals of our present effort:

- **Non-goal: UI/UX design.** Although we propose underlying mechanisms for the sharing control needs of app logic, and although those mechanisms in some instances have implications for what developers are empowered to surface at the UI level, we do not aim to define exactly how those mechanisms should manifest to users in the specific interaction modality or look-and-feel of an app. Thus, we leave the design of specific interfaces — including how much of our module’s control should be surfaced directly to users versus shouldered by the app — to future efforts by researchers and app developers. Our work is similar in spirit to work on user interface toolkits (e.g., [25, 27]) in that our goal is to enable app developers to easily create and innovate on a range of user interfaces and experiences, rather than to design and iterate on these interfaces directly.
- **Non-goal: Network architecture design.** It remains an open question whether multi-user AR will ultimately be enabled by client-server, peer-to-peer, or other network architectures; we thus design our platform to be agnostic to network architecture. Additionally, we do not consider how two AR devices initially bootstrap communication; prior, complementary work considers how to securely pair two HoloLens devices [60].
- **Non-goal: App-specific choices about sharing control properties.** We do not aim to recommend to apps which sharing control properties and functionalities might make sense in the context of the app, instead enabling app developers to choose the appropriate subset of properties for their specific use cases.

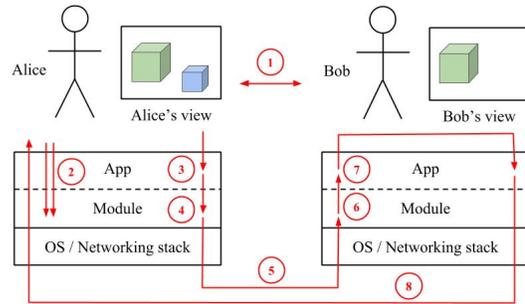

Figure 2: Basic object sharing flow: Alice creates the blue and green boxes and then chooses to share the green box with Bob. See Section 4.1 for details.

- **Non-goal: Accurate spatial localization of AR users and content.** We do not aim to design a system by which the location of an AR user can be accurately and securely determined. Prior work has studied how to localize devices accurately [23, 31], how to verify location claims [10, 69], and how to verify co-location claims [21, 55]. We note that even without further sharing controls, future location-based AR apps will benefit from secure location and co-location verification methods. Thus, we consider this topic to be orthogonal and of independent in.

## 4 Design

We now present the design of a module that AR developers can use to support secure and private sharing of AR content among multiple users. Compatible with our threat model of untrusted users but trusted developers, we envision this module as an app-level library or an OS interface.

### 4.1 Module Design Overview

To illustrate the relationships between the OS, the sharing control module, the app, and multiple users, we begin by walking through a simple case of Alice creating two objects and sharing one with Bob (Figure 2).

1. *Precondition:* Alice and Bob are both running an app that incorporates the sharing module and, as such, already have an open communications channel between their devices.
2. *Object creation:* Alice creates two AR objects, a small blue box and a large green box. Her app calls the sharing module’s `InstantiateShared()` API for both objects, allowing the module to track permissions at the granularity of those objects (in this case, beginning with view and edit permissions for only Alice).
3. *Outbound sharing (app-level):* Through some user interface provided by the app, Alice chooses to share the green box with Bob.
4. *Outbound sharing (module-level):* On Alice’s device, the app calls the sharing module’s `SetPermission()`

API. As a result, the module updates its internal permission map, adding Bob to the list of users with view permissions for the green box.

5. *Communication*: The sharing module sends a message (via the device’s OS and networking stack) containing object content and metadata to Bob’s device, whose OS and networking stack dispatch it to the sharing module in Bob’s instance of the app.
6. *Inbound sharing (module-level)*: The sharing module surfaces a `SetPermission` event to Bob’s app.
7. *Inbound sharing (app-level)*: On Bob’s device, the app shows some user interface to allow Bob to accept or deny the shared object. (Other apps may skip this step and show the object to Bob automatically, and/or respect Bob’s previously-set preferences for shared objects from Alice.) Bob chooses to accept the shared object from Alice; the app updates his view of the world to include the green box.
8. *State update and communication*: The app calls the sharing module’s `AcceptObject()` API, which in turn transmits that message back to Alice’s device.

Following this transaction, Bob can now see a shared copy of Alice’s green box and, depending on the sharing settings, can manipulate that box in ways that are also visible to Alice.

This sharing flow might seem simple: the sharing control module provides APIs that help an app keep track of which users can access which AR objects — i.e., view and edit permissions — and syncs this information across the devices of all users of the app. However, as surfaced in Section 2, sharing in the AR context requires thoughtful consideration — particularly in the face of users’ expectations of and interactions within the physical world.

**Key design challenges.** While striving to achieve the functionality and security goals identified in Section 2, our design space exploration surfaced several key questions which do not arise for sharing and access control in traditional systems (e.g., file systems). These challenges are deeply connected with AR’s integration with the physical world, and although they do not on the surface appear to be security-centered questions, they affect the security and privacy mechanisms we design, and so we must address them:

- *Integration of shared AR objects with the physical world (Section 4.2)*: How is a shared object integrated into the physical world? In the above example, do Alice and Bob see the green box in the same physical location or in different physical locations? Are Alice and Bob themselves in the same physical location, and what happens when their co-location status changes?
- *Private content in a shared physical world (Section 4.3)*: How should the sharing module handle or help shape users’ expectations of private AR content, such as Alice’s blue box, when they interact in a shared physical world?

	Outbound sharing controls	Inbound sharing controls
What and with whom	Permission management	Two-party sharing consent
Where	Location coupling (§4.2)	Personal space (§4.4)
How much	Ghosting (§4.3)	Clutter management

Table 1: Summary of the components of our design for controlling the outbound and inbound sharing of AR content.

- *Ownership of physical-world spaces (Section 4.4)*: How can a sharing module help apps respect people’s existing ownership of physical spaces? For example, users may wish to control AR content that they or others see in front of their homes or on their own bodies.

Effective solutions to these challenges must integrate with the system design components that have more direct analogues in current technologies. In particular, we incorporate the following established control structures into our design:

- *Permission management*. We leverage classic access control work [30] to track and enforce per-object and per-user permissions. Although we aim to be compatible with whichever access control model a particular app chooses to layer atop our module — e.g., a model akin to Google Docs for the *Multi-Team Whiteboards* case study — we note that this alone is not enough to support the 3D experience of AR, and that the above key design challenges must also be addressed.
- *Two-party sharing consent*. Some existing sharing models require that both the sharer and the receiver of digital content authorize a sharing event before its completion (e.g., Google Drive, Apple AirDrop). We use this principle in our design, with one twist: to help developers avoid decision fatigue in apps with high-volume content sharing, we allow the app to authorize a sharing event without the user in the loop. For instance, an app might automatically authorize content under some contexts but not others [70], use a notification UI that minimally disrupts the user’s workflow, or allow users to always trust content from a specific other user. We advise developers to be conscious of habituation and interruption in their app designs.
- *Clutter management*. Our design supports temporarily or permanently removing an object from the user’s field of view, as we discuss further in Section 4.2.

We summarize these aspects of sharing control, both new and precedented, in Table 1. We categorize the design points along two axes: (1) where in the above sharing flow the control occurs (*outbound* on the sharer’s end, or *inbound* on the receiver’s end), and (2) what type of control is enforced (*what* object is shared and *with whom*, *where* a shared object can be, or *how much* information from that object is shared).

## 4.2 Physical World Integration

The sharing flow in Section 4.1 demonstrates the basic building blocks of a sharing module, with view and edit permis-

sions for users at the granularity of AR objects (e.g., a virtual cat or virtual browser window). We now explore how these notions become significantly more complicated when shared AR objects are integrated into the physical world.

**Location-coupled and -decoupled sharing.** Recall from Section 2 that we aim to support both physically co-located sharing (i.e., two users in the same physical place and seeing the same AR objects in the same physical locations) and remote sharing (i.e., two users physically separated but seeing the same AR objects in their own physical spaces).

Accordingly, our design supports two notions for how an AR object can be shared with respect to the physical world: (1) *Location-coupled* objects, which all users see in the same physical location, and (2) *Location-decoupled* objects, where all users see the same object but in different physical locations. In the coupled case, if one user moves the object, other users also see the object’s location update; in the decoupled case, the two instantiations of the object can be moved independently.

We intend for these notions not to be mutually exclusive for an object but rather to apply between sets of users. For example, an AR object (say, a virtual whiteboard) may be shared (1) in a location-coupled way between Alice and Bob co-located in New York, and (2) in a location-coupled way between Guanyou and Huijia in Beijing, and simultaneously (3) in a location-decoupled way between the two groups.

**Handling people moving around the physical world.** A challenge for location coupling and decoupling of shared objects arises when we consider that users’ co-location can change as they move around the physical world.

For example, suppose that Alice and Bob share a location-coupled AR object — say, a whiteboard — both seeing it in the same physical location. Alice may *also* share it in a location-decoupled way with collaborator Carol working in another room — i.e., Carol will see an instantiation of the whiteboard in her own physical space. Initially, this appears to meet our goals: all users see the whiteboard in their own physical space in the same location as other co-located users.

What happens, however, when Carol moves into the same physical space as Alice and Bob? Since the whiteboard is shared among all of them, they will likely assume that all three of them can now see the same AR whiteboard object on the same wall [35]. This is not the case, however: Alice and Bob see one instantiation of the whiteboard, and Carol sees a separate instantiation in a slightly different location.

To resolve this potential inconsistency, our design keeps track of all copies of a shared object, allowing the app to show *all* of these copies to all users. Thus, when Carol joins Alice and Bob in the same room, all users see *both* versions of the whiteboard. All users then share the same view of the augmented physical world. Note that this location information may have privacy implications, though none in scope for this work; we discuss this point further in Section 7.

Moreover, since users’ co-location may change over time, their desired location-(de)coupling of objects may change over time too. For example, in the above scenario, Alice and Bob may wish to merge their whiteboard object with Carol’s instantiation, so that all three indeed see the same, single whiteboard object in the same place. Conversely, users may wish to collaborate on a location-coupled object while they are physically co-located but to both take their work with them when they physically separate. Thus, we also provide mechanisms to *merge* two location-decoupled instances into a location-coupled object and to *separate* a location-coupled object into two location-decoupled instances.

Another way to think about shared AR objects, then, is that there is one conceptual object and potentially multiple views of it. Each user sees a view in the same location as do all other users, and users in different physical spaces will see different views. If a user is in the same space as multiple views, that user will see all present views. The object’s views may be manipulated separately in space; a single view may be split into two, or two may be merged into one, but the underlying object that all views represent remains the same.

**Implications of location coupling for object deletion.** A shared object’s location coupling or decoupling has design implications for other features as well. For example, our design lets users delete AR content that they have created; it is not clear, however, that this decision should propagate to other users with whom the object has been shared, and location coupling or decoupling affects how deletion is handled.

We design the module to support three cases, which can be chosen by the app developer as appropriate:

1. *Case 1: Local Deletion: Affect user’s local view of object only.* This option allows Alice to delete her object without affecting other users. If, in *Multi-Team Whiteboards*, Alice and Bob share a whiteboard in a location-coupled manner, Alice can delete her instance of the object while Bob keeps working.
2. *Case 2: Global Location-Coupled Deletion: Affect all users’ views of location-coupled object.* Here, a deleted object is also deleted for all other users with whom that object was shared in a location-coupled way. That is, when Alice deletes her document, Bob also sees that document disappear. However, if Alice has also shared the document in a location-decoupled way with remote collaborator Carol, this option allows Alice to delete her and Bob’s location-coupled instantiation without affecting Carol’s remote, location-decoupled instantiation.
3. *Case 3: Global, Location-Independent Deletion: Affect all users’ view of object, independent of location coupling.* In this case, *all* instantiations of the object for all users are deleted. Continuing the previous example, Alice, Bob, *and* Carol will all see the object deleted.

Which of these cases is most appropriate depends on the semantics of an app and each use case within that app.

Location coupling and decoupling have other design and implementation implications as well. For instance, hiding content with which the user does not currently wish to interact requires considering the same set of options as deletion.

### 4.3 Private Content in Shared Physical World

As raised in the *Multi-Team Whiteboards* case study in Section 2 and in prior work [35], the fact that AR supports per-user private content can have benefits, but it can also fail to provide a signal about the use of physical space (e.g., leading to one user inadvertently standing in front of another’s virtual content, or causing social tension due to one user not knowing what another user is doing).

Thus, in this section we propose a design that allows users to socially signal to other AR users that they are busy interacting with private content without sharing the details of their activities. Further, we aim for this design to align with users’ intuitions about a shared physical world.

**Strawman designs.** Consider two incomplete solutions:

*Status quo.* A solution with no further intervention would cause private content to be completely invisible to other AR users. A user interacting with private content thus appears to others as if the user were staring off into and manipulating an undefined region of empty space, giving no cue to other users about how far away the object is if they want to walk around it as well as no sense for what the user might be doing.

*Occlusion by virtual barrier.* Meta’s developer guidelines recommend that sensitive content be shared publicly but occluded by a virtual barrier such as a curtain [40]. Although this does provide a shared-world physical intuition and social cue, it is not a robust privacy-preserving mechanism. Consider a user who places a virtual curtain around sensitive content so that the content is visible only from the user’s point of view. A curious other user can surreptitiously look over the user’s shoulder and observe the sensitive content, similar to shoulder-surfing with current mobile devices [56, 64].

**Our approach: “Ghosts”.** We propose an alternate design that achieves our goal while avoiding the above drawbacks. The key idea is to allow users to share *that* they are interacting with an AR object, without sharing the *details* of that object. This idea is analogous to how a user interacting with a smartphone implicitly signals to bystanders that they are engaged in another activity located in the palm of their hand, without the contents of that activity being directly revealed, or to how users may share free/busy information about specific time blocks on their calendar to avoid double-booking without sharing the details of their calendar events.

To support this interaction, we introduce a new partial-visibility state for shared AR objects that we call *ghosting*. Ghost objects show only their location in space, not the sensitive content they contain, no matter at which angle they are viewed. As such, unlike the above smartphone analogy, they are not susceptible to shoulder-surfing. Furthermore, a user with whom a ghost object is shared receives from the sharer

only the data needed to instantiate the ghost, rather than the full object data; this further insulates the private content.

**Ghost shape granularity.** For non-planar objects, we encounter the following question: How does the sharing module determine the appropriate level of granularity to expose in the ghosted object, given that object shapes may contain app-specific information content?

For instance, in *Community Art*, the ghost of a sculpture that is private during its development should not mimic the original sculpture’s shape too closely. However, a shape with too coarse of a granularity—e.g., a large fixed-size cube regardless of the sculpture—no longer gives meaningful physical-world information to nearby users: e.g., by marking an unreasonably large physical space as occupied.

To balance this dilemma, we allow app developers to specify what the ghosted view of an object should look like. This approach allows for non-planar objects to assume an obscured shape appropriate for the app-specific information they carry. For instance, in the *Community Art* case study, a sculpture that is private during its development might be displayed to others as an appropriately sized cylinder.

### 4.4 Respecting Ownership of Physical Spaces

Finally, we turn to the question of how the sharing control module can help apps respect people’s existing ownership of physical-world space. We refer to both personal space (near one’s body) and static owned space (e.g., one’s home) as *owned physical space* in this section.

Helping users protect their owned physical spaces requires several components: (1) Determining who owns a region in space, (2) Determining what the boundaries of that region are, and (3) Enforcing some kind of policy on shared AR objects in that region.

We defer to future work (1), how to determine *who owns* a region in space. This in itself is complex; for instance, Google has analyzed abuse of location ownership in its Maps app [26], and prior work has considered physical world ownership for restricting continuous sensing apps (including AR) [54]. Accounting for different types of space ownership is also nontrivial: in particular, we identify (a) fixed-location physical spaces (e.g., a house, a room, a storefront, or a public park), (b) person-relative spaces (e.g., within 5 feet of a user), and (c) object-relative spaces (e.g., within 35 feet of a virtual art object). A complete solution to this issue should also consider non-AR users, and we offer the following suggestion as a starting point for future work: locally on the AR user’s device, employ computer vision techniques to identify the spatial positions of bystanders visible by the AR user, estimate the rough pose for each bystander, and use that information to mark bystanders’ forms as protected regions of space (e.g., using techniques from [2, 39]). However, we do not pursue this topic further in this work, since it is a complex area of investigation in its own right; instead, we assume a prior definition of owned physical space, and we focus on

the challenges of enforcing that space.

For (2), we observe that defining the boundaries of a protected region of physical space—e.g., around a person or house—is not a simple binary determination. A user might perceive an object two feet away to be too close, for instance, but may consider an object nine inches away to be even more so; this definition may also vary across different users [22]. Building on this observation, our solution is to model owned physical space as a *continuum*, where violations become more severe—and thus policies could become stricter—as virtual content approaches the protected region.

The key question, then, is (3): what should an app do when one user’s shared AR content overlaps another user’s personal physical space, or a physical region (e.g., a house) that another user owns?

**Policies for AR content violating owned spaces.** To answer this question, we propose that the sharing control module can provide a variety of policies that an app’s developer could choose to apply in such a case. These policies can be enforced either such that the result of enforcement is only visible to the user whose personal space is in question, or such that *all* users with access to the shared object see the result of enforcement. App developers may choose which policies to enable based on the needs of the app.

A simple, binary policy might make objects *invisible inside a fixed radius*: for instance, define a three-foot radius around a person within which AR content should not be visible (at least to that user). Such a policy can be exploited by surrounding the person with AR content just outside the boundary; thus, there is a tension between a large radius to minimize the effects of such an attack and a small radius to enable legitimate functionality.

To help balance this tension, and to take advantage of the continuum in the boundary described above, our design provides a *transparency gradient* policy, by which the module makes shared objects more transparent the closer the objects are to the boundary of any protected region (e.g., around a person). Under this policy, objects would start becoming transparent much farther than three feet away, avoiding blocking the person’s vision but still being useful.

By having owned-space policies be enforced by apps themselves (via the sharing module), rather than by users, they can be applied without changing the underlying permissions on the shared object. This avoids two pitfalls. First, it prevents malicious users from exploiting the policy, e.g., by gaining control of an object simply by walking up to it. Second, it enables policy enforcement even on objects that the physical space owner cannot see (protecting even non-AR user bystanders from the “kick me” sign from Section 2).

## 5 Implementation

We now describe our prototype, which we implement as an app-level library for the Microsoft HoloLens, demonstrating the feasibility of our design for a currently available head-

mounted AR platform. Our prototype, called ShareAR, is implemented in C# and uses the HoloLens Unity development kit. We implemented the concept of an AR object using the Unity `GameObject` primitive, which is a virtual entity comprising shape, texture, location, physics properties, script-controlled behavior, etc. Our implementation consists of a core module (1888 lines of code), a network shim layer (1137 lines of code), and a short supplementary script to accompany any object shared using the toolkit (45 lines of code), totalling 3070 lines of code.<sup>2</sup>

The ShareAR core comprises:

- Data and meta-data, including an access control matrix [30] and options for how objects are shared (e.g., location coupled or decoupled).
- Methods to instantiate objects, manually or automatically accept shared objects, change permissions on objects, and sync data between users. Table 2 summarizes sample corresponding message types in our prototype.
- Simple fixed-radius personal space controls in the form of Unity’s *plane clipping*, where the portion of an object closer to the user than the fixed plane-clipping distance is not rendered. We did not implement more nuanced controls, like our proposed transparency gradient.

Though network architecture is out of scope of our design, in practice we must choose some way to connect between HoloLens devices. In our prototype, we used the MixedRealityToolkit Sharing toolkit, an open-source library from Microsoft.<sup>3</sup> MixedRealityToolkit does not provide any sharing control or access control functionality; we use it only as a basic tunnel to send messages between HoloLens devices.

We build a network shim layer that serializes and deserializes ShareAR messages and uses MixedRealityToolkit Sharing to send them between devices. A developer who wishes to use a different networking solution—e.g., one relying further on a central server for data storage, or one implementing a more rigorous consensus protocol—may write a replacement network shim layer satisfying the same interface with the ShareAR core.

Users may join, leave, and re-join the network. To be robust to access control changes occurring while a user is offline, we include in our implementation a means for a newly reconnected user to receive a “digest” version of an object containing only the information needed for consistency with the other online users. Since consensus is best done with network architecture in mind, we provide a means to create this object “digest” as a higher-level functionality but relegate consensus operations to the networking shim layer.

<sup>2</sup>To calculate lines of code, we use the CLoC tool version 1.80 available at <https://github.com/AlDanial/cloc/releases/tag/v1.80>. We omit lines of code solely related to our performance evaluation.

<sup>3</sup><https://github.com/Microsoft/MixedRealityToolkit-Unity>

Message name	Sent when	Bytes
InstantiateShared	A new shared object is created	104
AcceptObj	A newly-shared object is accepted	22
SetPermissionNew	A newly-instantated public object is accepted and there are more than 2 users present	38
SetPermissionObject	A permission change is made or offered on an existing object	92
SetPermission	A permission change on an existing object is accepted and there are more than 2 users present	54
UpdateLocation	A shared object's location in space is updated	62
DeleteShared	A shared object is deleted	22

Table 2: Example message types and sizes in our prototype. Messages are relatively small because they do not include full AR object meshes but rather an ID corresponding to the type of object in question and a string of object data that fully specifies the particular object of that type. Sizes are for basic objects with no additional object data.

## 6 Evaluation

We now evaluate our prototype's functionality (Section 6.1), security (Section 6.2), and performance (Section 6.3).

### 6.1 Functionality Evaluation

We evaluate the functionality of our prototype by implementing case study apps and by comparing against existing AR design guidelines. We find that our prototype is flexible enough to support a range of app sharing control needs and is compatible with all considered existing design guidelines.

**Case study applications.** To evaluate the flexibility of our design to support our functionality goals, and the associated developer effort, we built bare-bones prototype versions of our case studies from Section 2.1: Paintball, Doc Edit (a variant of *Multi-Team Whiteboards*), and Cubist Art. (We did not implement *Soccer Arena*, since it does not surface new security, privacy, or functionality requirements not covered by the other case studies. Section 2 provides further analysis.) Our prototypes are intended to cover a broad spectrum of sharing control functionalities; see Appendix A for detailed descriptions of the apps. Screenshots of the apps are in Figure 3, the range of sharing control features each exercises is in Table 3, and the sharing-related lines of code for each is in Table 4.

We use lines of code as a proxy measure for developer effort (see Table 4). For each app, we count the total lines of code in the app and the lines of code specific to sharing functionality. The low number of sharing-related lines of code suggests that the burden on app developers to use our

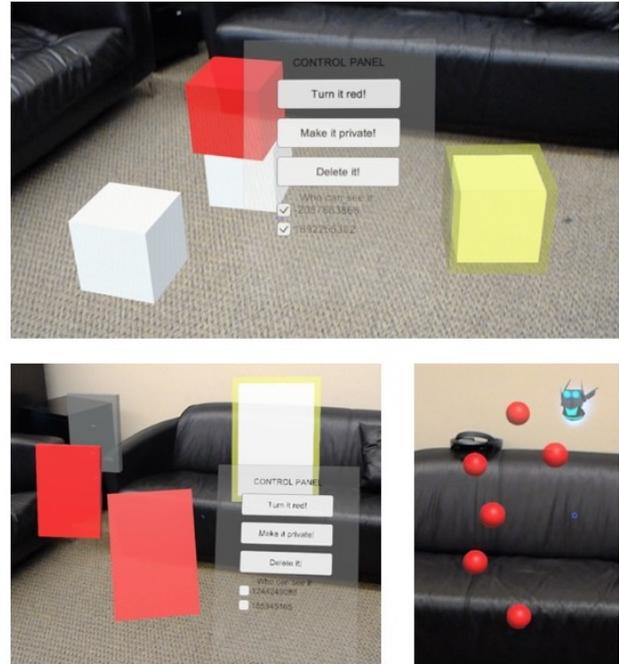

Figure 3: Screenshots of prototype apps: Cubist Art (top), Doc Edit (bottom left), and Paintball (bottom right). In the Doc Edit app, the semitransparent gray box in front of the file cabinet in the upper left is a ghost view of another user's document, and the two red boxes are two users' separate instantiations of the same shared document.

toolkit in practice is reasonable. Furthermore, we conjecture that fully fledged apps are likely to contain many more lines of code unrelated to sharing, further reducing the comparative proportion of sharing-related lines of code in the app. We note also that the repetition of some prototyped features across multiple apps (such as location-coupled sharing in both the Paintball and Shared Blocks apps) suggests that ShareAR's features are composable, and that developers can choose an app-appropriate subset of functionality.

**Compatibility with existing guidelines.** We also consider the compatibility of ShareAR with existing design guidelines from AR headset manufacturers. We focus on guidelines related to multi-user interactions, asking: Does ShareAR allow an app developer to meet these guidelines? We in-

App	Sharing LoC	Total LoC
Paintball	13	240
Doc Edit	173	1236
Cubist Art	153	1131

Table 4: Lines-of-code counts for the three prototype applications. We report both the total lines of code for the application and the lines of code dedicated to interfacing with the ShareAR toolkit.

investigate the Microsoft HoloLens guidelines [43] and Meta guidelines [40]; we find that ShareAR is compatible with all of them. The results are summarized in Table 5; see Appendix B for additional information.

## 6.2 Security Evaluation

We examine the security and privacy of our ShareAR-enabled apps under our threat model of untrusted users (but trusted OS and apps). As described in Section 3, we rely on app developers to use the ShareAR APIs that are appropriate for their use case. For the sake of exposition, we focus on the Doc Edit app since it invokes all of the restrictions our ShareAR prototype supports; our observations also extend to Paintball and Cubist Art where applicable.

We find that ShareAR’s security and privacy restrictions function as intended and meet the security goals in Section 2.3. Considering first the outbound security goals:

- *Support granting/revoking per-user permissions:* The Doc Edit app includes a menu that allows a user to grant and revoke per-user permissions. A user who never received or no longer has view permissions on a document cannot see it.
- *Support granting/revoking per-object permissions:* The aforementioned menu controls permissions on a per-document basis: only the currently selected document is affected by a permission change.
- *Support physically intuitive access control restrictions:* Doc Edit provides a ghost version of a document object (as a flat gray box). A user with permission only to view the ghost cannot tell if the original document is red or not; but the user sees the ghost in the same location as the document’s owner sees the original document, and this location remains synchronized when the document’s owner moves the document in physical space.

Considering the inbound security goals from Section 2.3:

- *Support user control of incoming virtual content:* The Doc Edit app surfaces an incoming permission-granting message to the user via a small menu, through which the user can choose to accept or decline. If the user accepts, a new (location-decoupled) instantiation of the document appears in front of the user, and the user can also see the sharer’s instantiation of the document in its full (rather than ghost) form. If the user declines the document, no such change occurs.
- *Support user control of owned physical space:* As described in Section 5, our prototype leverages a Unity

plane-clipping feature to implement simple owned physical space enforcement. We clip parts of any object closer to the user than 0.85 m (with the distance chosen to match a HoloLens recommended setting [42]).

## 6.3 Performance Evaluation

We now evaluate ShareAR’s performance, measuring its operations (and comparing them to baseline operations where possible) and studying how it scales with numbers of virtual objects and users. We find that ShareAR imposes only a modest overhead on interdevice communication even as the number of objects and users increases.

**Experimental setup.** We build an app (1506 lines of C# code) to exercise ShareAR’s components and measure its performance. In our test app, a test device creates objects that are location-coupled or location-decoupled, sharing them publicly, as ghosts, or keeping them private. One or more other test devices auto-accept or manually accept objects. The first device changes the objects’ permissions, updates the objects’ location, and finally deletes the objects.

Our experimental setup consists of five HoloLens devices communicating on the same local network, in two experimental scenarios: (1) for each  $n \in \{1, 2, 3, 4, 5\}$ , we select  $n$  devices and fix  $h = 1$  shared AR object; (2) for each  $h \in \{2^0, 2^1, 2^2, 2^3, 2^4, 2^5\}$ , we set  $h$  to be the number of objects present and fix  $n = 2$  devices. All devices run our evaluation app with the same  $n$  and  $h$  parameters; all devices join the network sequentially, and then the last device to join the network triggers the evaluation app.

The operations we measure are Create, Accept Create, Change Permission, Accept Change, Update Location, and Delete. Each operation involves work done on User A’s device to initiate the operation, a message sent across the network from User A to User B, and work done on User B’s device to process the operation. Note that in some cases (for Create and Change Permission) User B’s device reacts by initiating an operation that we also measure (Accept Create and Accept Change).

In addition to measuring the within-module time for A’s initiating action and B’s receiving action, we measure and report on *operation completion time*, i.e., the time it takes from A’s initiating action until B has finished processing. To correct for clock skew between the two devices, we add into the evaluation script a message from B to A containing B’s timestamps (note that this is not part of our module’s protocol, but exists solely for the purposes of the evaluation). Device A then combines this information with its own timestamps to compute the final timing numbers.

Finally, for the sharing module operations that clearly correspond to a primitive Unity operation (Create, Update Location, and Delete), we also measure as a baseline the timing of the Unity operation.

We repeat each evaluation point—defined by operation, configuration (e.g., location coupled or decoupled), number

of users, and number of objects — for 2 warm-up trials and 5 measured trials, reporting the mean and standard deviation.

**Basic profile of operations.** We begin by considering ShareAR's operations with a single pair of users ( $n = 2$ ) sharing a single object ( $h = 1$ ).

The overall operation completion time is between approximately 70 ms and 250 ms, depending on the operation and configuration. This overall time is significantly dominated by factors external to the ShareAR module, and that *any* multi-user sharing solution would encounter: i.e., the network latency and the HoloToolkit Sharing library on either end of it. The overhead specific to ShareAR is minimal: we find that `Create` and `Change Permissions` operations are most expensive on average, still taking less than 5 ms in the worst case for the computation on each device; all other operations take less than 1 ms on each device. For the operations that we can compare directly with Unity baselines, we also find that ShareAR's overhead is minimal: the operations stay within 2.5 ms of the baseline in the worst case.

**Scaling with the number of users.** Next, we consider how ShareAR scales as the number of users increases.

In terms of network traffic, a user sharing an object needs to send object create and update messages to  $n - 1$  others; additionally, once a user accepts a sharing offer, their device sends an acceptance message back to the sharer and an informational message to all other  $n - 2$  users to stay in sync. The total number of messages in the interaction thus scales quadratically. For updates to already-shared objects (location change, deletion), the sharing user sends one message per other user, and no replies or additional messages are sent (overall scaling linearly with users).

In terms of timing, all operations under all test conditions took less than 5 ms. For all but `Create` and `Change Permission`, the operations on average remained under 1 ms. These overheads are reasonable, especially given their small additional overhead beyond to the corresponding base-

line operations where present (shown with a dashed line for `Create`, `Update Location`, `Delete`). More detailed performance data is in Appendix C.

In terms of scaling, `Create` and `Change Permission` scale approximately linearly with the number of users; all other operations remain approximately constant. Different configurations for an operation (e.g., location coupled versus decoupled sharing, or different object deletion modes) may slightly affect performance (as reflected in the differently colored lines in the graphs), typically taking longer for location-decoupled objects due to the overhead of processing multiple instantiations of the same object.

**Scaling with the number of objects.** Finally, we measure ShareAR with increasing numbers of AR objects.

In terms of network traffic, we observe that it scales linearly with the number of objects, as each operation and associated message is independent per object.

In terms of timing, all operations took less than 3 ms (and often less than 1 ms). These overheads are reasonable, especially given their relation to the corresponding baseline operations where present. (For the module operations for which a baseline Unity operation is plotted — `Create`, `Update Location` and `Delete` — the relevant module operation timing is very close to that of the baseline Unity operation.) Additional details are in Appendix C.

In terms of scaling, for all operations, the time taken is approximately constant per object as the number of objects scales: in other words, an operation on one object registered with the module is independent of how many other objects are also registered with the module. Some operations exhibit a slight slope downward, suggesting caching benefits.

**Performance evaluation summary.** From our measurements, we see that object creation and permission changes are the most computationally expensive operations. However, we anticipate that in practice these operations will only occur during a small fraction of the frame updates in an app.

Even so, the greatest observed time taken for an operation was under 5 ms, and most measurements remained under 1 ms. Furthermore, since these measurements were of our unoptimized research prototype, continued code optimization may bring the performance overhead down even further.

## 7 Discussion

This work presents the first systematic investigation of multi-user sharing control for AR apps. We propose a module that is flexible enough to support many different decisions by app developers. Below we discuss several examples of future directions enabled by our work.

**Execute permissions.** Although multi-user AR systems are still primitive, we envision that future systems will support not only read and write but also execute permissions. One possible manifestation may be to allow a user to execute *predefined actions* on another user's object without having full edit control. For instance, an app may allow other users to make a virtual dog wag its tail without allowing them to make the dog arbitrarily large. Our module can be extended to include additional permissions, including this one.

**Asynchronous sharing.** Our design exploration assumes that both users are online when a sharing action occurs; extensions of our work could explore removing this assumption. For example, consider a user who places publicly visible virtual decorations outside their home. We may want (1) the objects to still be visible to a passerby when the user is not home, but (2) the passerby's device to only become notified of the objects' existence and public visibility when the passerby is physically proximate to the home. Such a design may require an alternate network architecture than peer-to-peer; our module's network agnosticism would support this.

**Minimizing developer errors.** We emphasize that one consequence of our module's flexibility is that developers must be cautious to use it in a way that supports their app use case. Some potential user-to-user threats may be subtle: for example, if app developers chose to share ghost objects automatically with no way to refuse or delete them, one user might intentionally or accidentally clutter another user's view with ghost objects (an example of a denial-of-service attack). Or, if an app developer implements a personal space policy that makes AR objects invisible to all users but does not provide a way to interact with or retrieve an invisible object, then a malicious user could walk up to others' objects to force them to become invisible and non-interactable. Still other pitfalls may depend on app semantics: for instance, if the developer of an app such as *Community Art* does not put limits on users, a user could monopolize a common space and prevent other users from placing objects there. Future work, then, may explore ways to support app developers in using the features from our system that are most suitable for their overall goals.

**Analysis in the wild.** More broadly, our work lays a foundation for future empirical studies on how developers use our

module's components in practice and how users respond to concrete usage of these components. Such an evaluation is nontrivial since evaluating the usability of a single app does not generalize well to the usability of others [45], for the same reason described in Section 2 that a sharing control module cannot be one-size-fits-all. However, we note the importance of follow-up studies considering user perceptions when making specific design decisions, and we encourage future work to leverage our technical foundation to examine under which circumstances certain sharing mechanisms are appropriate.

**Location privacy.** Much multi-user app functionality, including our design, requires that users share their location with the app: sharing at least where one is within a physical space is necessary for location-synchronized virtual content. Some users may not anticipate or agree with such location sharing, even for trustworthy apps, though such sharing may be fundamental to the design of location-based AR apps. Additional location privacy concerns could be introduced by app developers, if app developers mishandle and accidentally or intentionally expose a user's location to *other users*. This threat, however, is dependent upon app-level semantics, and is neither unique to nor preventable by the underlying sharing framework. We encourage future work to explore this point further.

**Inherently conflicting goals.** Finally, we conjecture that there may be fundamental tensions in some aspects of secure and private content sharing between users. For example, consider the case of a shared space in which one user owns a publicly visible ball object and another user owns a private wall object. When the public ball is thrown at the private wall, it is not obvious which user(s) should see the ball rebound. If the ball rebounds for both users, then the ball owner gains information about the presence of the wall; if the ball does not rebound for either user, then the wall owner sees the ball go through the wall, defying physics; if only the wall owner sees the ball rebound, then the two users no longer have a synchronized view of the shared space. Determining how physics-obeying virtual objects should interact to minimize information leakage via this side channel while maximizing physical intuition is a subtle area for future work, and we conjecture that *no* content sharing solution can simultaneously achieve both goals perfectly.

## 8 Related Work

Although AR has a long history (e.g., [61]), the computer security community has only recently begun examining the space [13, 52]. Prior efforts on AR security and privacy include filtering raw real-world input [12, 28, 49, 54, 65] and regulating untrusted AR output [32, 34]. These efforts focus on the case of a single user interacting with an AR device.

Literature on multi-user AR security and privacy is just beginning to emerge. Some prior work has proposed methods

for secure device pairing via out-of-band channels [19, 60]; our work is complementary. Other prior work has proposed specific multi-user interaction modalities, such as location-based interfaces for making virtual content private and auditing content visibility [8, 9], mediating shared experiences with remote collaborators [50], and using personal tablets in shared spaces to separate private and public content [62, 72]. While these works present specific multi-user AR systems, our work is the first to systematically and broadly consider the design space for AR sharing control and our module could be leveraged when implementing these prior ideas.

There is a rich literature on access control (see, e.g., [7] for an overview). Our work does not assume what access control model is best for a particular app. Our implementation leverages an access control matrix [30] as a simple and flexible model for per-user and per-object permissions; we intend for other established access control models in specific app contexts (e.g., [17, 68]) to be layered on top of our toolkit, and we instead focus on the challenges of managing the implications of access control in the 3D physical AR setting.

Work in AR user experience has surfaced security- and privacy-relevant themes for multi-user contexts. Lebeck et al. [35] surface multi-user concerns such as physiological attacks, virtual clutter, and the obscurity of other users' actions. Poretski et al. [48] examine normative tensions in AR, emphasizing enforcing personal space and designing for user control. Olsson et al. [46, 47] identify user needs such as control over privacy, socially appropriate ways to interact with devices, and solutions for abuse of public content by other users. These studies shed light on desired system properties and user concerns but do not directly address system design; our work builds concretely on these findings.

Multi-user digital interactions that take place in a physical space have also been studied in the context of tabletop interfaces and large computerized displays [44, 57–59, 71]. Our work addresses similar needs for and tensions around public versus private content arising in the AR setting, where immersive 3D content can be situated anywhere in the physical world rather than constrained to a shared display.

## 9 Conclusion

Multi-user AR technologies hold much promise, but also raise security and privacy risks in the potentially undesirable interactions between human users. These risks should be addressed while AR ecosystems are being actively developed rather than after sub-optimal ad hoc conventions have taken root. To that end, we are the first to systematically develop a set of security and functionality goals for multi-user AR. We present the design of a sharing control module for AR content, which we envision as an app-level library or OS interface that can be leveraged by app developers. Our work identifies and addresses key challenges that stem from AR's tight integration into the physical world. Our proto-

type, ShareAR,<sup>4</sup> for the Microsoft HoloLens demonstrates the feasibility of our design, and our evaluation suggests that it meets our design goals and imposes minimal performance overhead. By addressing multi-user AR sharing control systematically now, we are taking steps toward securing the fully fledged multi-user AR applications of the future.

## Acknowledgments

We thank Ivan Evtimov, Earlene Fernandes, Kiron Lebeck, Lucy Simko, and Anna Kornfeld Simpson for valuable discussions and feedback on previous drafts; we thank James Fogarty for his advice on tabletop interface related work. ## A Prototype Application Descriptions

In Section 6.1, we describe our assessment of our design’s functionality by its ability to flexibly support our representative case study apps. Here, we provide further details on our implemented prototype case study apps.

**Paintball.** This is a minimalist implementation of the *Paintball* case study. Players can launch red spheres that, upon contact with another player, attach to that other player. All users in the game session can see all of the red spheres. For the purposes of the prototype, we leave out scorekeeping and more advanced game features.

**Doc Edit.** This is a basic version of *Multi-Team Whiteboards* in which each user accessing content has a personal instantiation of it. Users, by interacting with a simple control panel, create flat rectangular boxes as documents. Documents are location-decoupled, and though they are private and ghosted by default, users can choose to share individual documents with individual users. A user can also turn a document red, modifying the document’s contents in a way that ghost documents do not display (for the prototype, this emulates arbitrary content entry, which we do not implement); the user can also delete the document in a group-extended way (i.e., all other users’ instances of the document are also deleted).

**Cubist Art.** This is a simplified version of the *Community Art* case study. Rather than making and manipulating arbitrary objects, users create and control cubes and can choose to share them or not. Although many of the user’s possible actions via the control panel are similar to those of Doc Edit, there are several key differences: (1) Cubes are public by default rather than private. (2) Cubes are shared in a location-coupled way rather than location-decoupled. (3) Cubes obey real-world physics instead of being entirely script-controlled. (4) Object deletion is global location-coupled rather than

global location-independent (note, though, that the semantics of location-coupled sharing make these two cases visually equivalent for solely location-coupled objects).

We did not implement the *Soccer Arena* case study, since it does not surface new security, privacy, or functionality requirements not covered by the other case studies. Section 2 provides further analysis.

## B Interaction with Existing Design Recommendations

Below we include a further analysis of our module’s compatibility with existing design recommendations.

**How are they sharing?** The HoloLens guidelines list possible sharing scenarios as consisting of presentation, collaboration, or guidance. Our design supports all of these: for instance, a developer can use ShareAR to set appropriate controls such as view-only permissions when a presenter shares content with an audience. Besides the opt-in scenarios that the HoloLens guidelines describe, our design also supports opt-out public content sharing, which we argue should be treated as another important use case for AR.

**What is the group size?** The HoloLens guidelines remind developers to design for as many users as needed. Our design can support an arbitrary number of users. (In practice, our implementation stores both object IDs and user IDs as 32-bit integers, providing a generous upper bound on its capacity. We examine performance questions in Section 6.3.)

**When are they sharing?** The HoloLens guidelines ask whether sharing is asynchronous or synchronous. Although we explicitly design ShareAR to support real-time sharing, we do not preclude the possibility of asynchronous sharing. A developer could, for instance, write a replacement network shim layer that relies on a central server for data storage and periodically queries the server for updates.

**What devices are they using?** In particular, the HoloLens guidelines ask whether AR users might share content with VR users. Although this is outside the scope of this work, we note that there is nothing in principle that fundamentally prevents developers from extending our work into VR as well. More broadly, we note that in principle, the ShareAR design is compatible across any AR HMD platforms that satisfy basic assumptions such as a shared notion of 3D space. (Our implementation is built for the HoloLens and has not been ported to other platforms as of this writing.)

**Clip planes near user.** HoloLens recommends setting a “plane clipping” distance of 0.85 m so that a user does not see any portions of AR objects that are closer than that in the user’s field of view [42]. Plane clipping may conceptually be considered a partial way of enforcing personal space; however, it only affects the view of the user whose space is invaded, and other users still see the object as being close to the user. ShareAR’s treatment of owned physical space

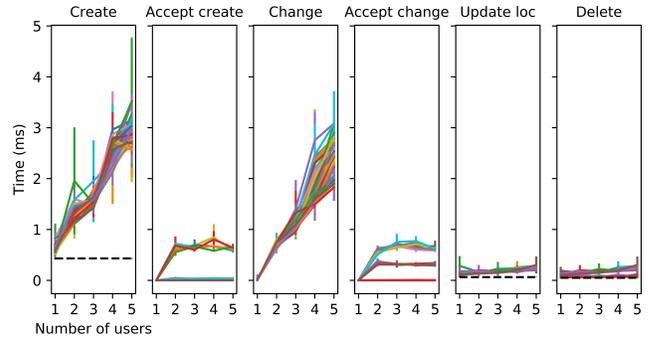

Figure 4: Timing measurements for all steps in the evaluation protocol, each from the perspective of the device initiating the step, as the number of present users scales. Acceptance times are measured on the receiver’s device; all other times are measured on the sharer’s device. Black dashed lines denote a corresponding baseline Unity operation where one exists.

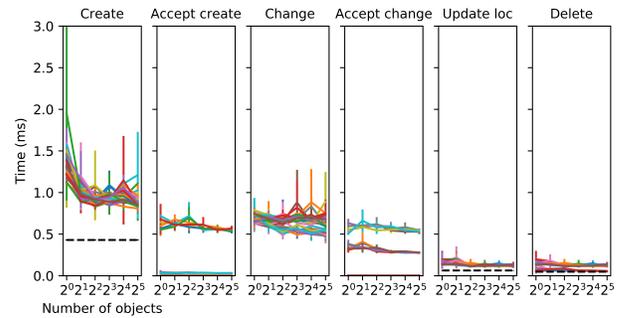

Figure 5: Timing measurements for all steps in the evaluation protocol, each from the perspective of the device initiating the step, on a per-object basis as the number of objects scales. Acceptance times are measured on the receiver’s device; all other times are measured on the sharer’s device. Black dashed lines denote a corresponding baseline Unity operation where one exists.

encompasses this recommendation and is a more complete solution. (Our implementation does not yet include personal space; however, it does include basic plane clipping.)

**Do not disturb.** Meta cautions against showing the user incessant notifications. Our design does not specify the user interface: notifications from other devices are passed as an event to the app but not displayed to the user. Thus, ShareAR is flexible enough to support this design choice.

**Public by default.** This recommendation is similar in spirit to our goal of supporting shared physical-world intuition. Although our design does support a purely public virtual world, we do not recommend it for all circumstances; our ghosting mechanism maintains a basic shared-world intuition while preserving a degree of privacy.

## C Detailed Performance Data

Results as the number of users scales are shown in Figure 4; results as the number of objects scales are shown in Figure 5.

# Understanding and Improving Security and Privacy in Multi-User Smart Homes: A Design Exploration and In-Home User Study

Eric Zeng

University of Washington*

## Abstract

Smart homes face unique security, privacy, and usability challenges because they are multi-user, multi-device systems that affect the physical environment of all inhabitants of the home. Current smart home technology is often not well designed for multiple users, sometimes lacking basic access control and other affordances for making the system intelligible and accessible for all users. While prior work has shed light on the problems and needs of smart home users, it is not obvious how to design and build solutions. Such questions have certainly not been answered for challenging adversarial situations (e.g., domestic abuse), but we observe that they have not even been answered for tensions in otherwise functional, non-adversarial households. In this work, we explore user behaviors, needs, and possible solutions to multi-user security and privacy issues in generally non-adversarial smart homes. Based on design principles grounded in prior work, we built a prototype smart home app that includes concrete features such as location-based access controls, supervisory access controls, and activity notifications, and we tested our prototype through a month-long in-home user study with seven households. From the results of the user study, we re-evaluate our initial design principles, we surface user feedback on security and privacy features, and we identify challenges and recommendations for smart home designers and researchers.

## 1 Introduction

Smart devices and smart home platforms, such as Samsung SmartThings, Philips Hue lights, Google Home, the Amazon Echo, and Nest thermostats and cameras, are being increasingly adopted and deployed in the homes of end users. These devices and platforms allow users to remotely control and monitor their devices as well as to create automations (e.g., automatically locking the door when the user leaves home).

**Security and Privacy in Multi-User Smart Homes.** Smart homes are fundamentally multi-user platforms. Multiple people living in or accessing a home—including partners,

roommates, parents and children, guests, and household employees—may want or need the ability to use and configure the smart devices within the home. As prior work (e.g., [14, 36, 41]) has begun to show, conflicts and tensions may arise between these multiple stakeholders—even in generally non-adversarial (e.g., non-abusive) households. For example, the more tech-savvy users who install smart devices in their homes may intentionally or unintentionally restrict other users from accessing home functions (like thermostats) that were previously physically accessible [14, 41]; privacy concerns and violations may arise between co-occupants [3, 41]; and remote control of devices can be used for harassment [3].

Unfortunately, current smart homes are not yet thoughtfully designed for interactions between and use by multiple people. Though prior work has surfaced the need for additional access control options [16], transparency, and privacy features [41], many commercial smart home platforms present only simple security and privacy controls, or even none at all [22]. For example, Samsung SmartThings, a popular smart home platforms, forces home administrators to choose between provisioning additional accounts with administrator privileges or not provisioning additional accounts at all [33].

**Designing to Address These Challenges.** Providing multi-user smart home security, privacy, and usability is not a straightforward matter of simply building it, but rather requires careful consideration of a complex design space. We take a step back to ask: What security, privacy, and other goals *should* a multi-user smart home design aim to achieve? How might it achieve those goals? And do those goals and their implementation meet the needs of end users in practice?

In this work, we focus specifically on answering these questions for generally functional households without explicitly adversarial relationships. That is, we consider “typical” tensions that may arise between roommates, partners, and parents and children as they interact with and through a smart home; we do not consider explicitly adversarial relationships, such as domestic abuse. Addressing such challenging situations is of course also critically important, but we observe that even the seemingly “easy” case has not yet been sufficiently addressed

in prior work or today’s commercial platforms.

To begin answering these questions, we thus systematized prior work to develop an initial set of design principles for smart homes in generally non-adversarial multi-user households: *access control flexibility, user agency, respect among users, and transparency of smart home behaviors*. Based on these initial principles, we designed and prototyped a mobile app for smart home control, which includes concrete features such as location-based access controls, supervisory access controls, and activity notifications.

**In-Home User Study and Design Recommendations.** To evaluate how well our proposed design principles and our prototype’s specific design choices meet the use cases of real (non-adversarial) households — and to gain a deeper understanding of the multi-user smart home access control needs and use cases of this class of users — we conducted a month-long *in situ* user study. We deployed our prototype with seven households in the Seattle metropolitan area.

The empirical findings from our user study allow us to evaluate and refine our proposed principles for security and privacy in multi-user smart homes, and we surface technical directions and open questions for platform designers and researchers, which were not apparent in prior work that did not conduct *in situ* design evaluations.

Among our multiple findings, we found that for some of our participants, positive household social norms and relationship dynamics obviated the need for technical access controls. This finding suggests directions and questions for future work, including: How can a smart home platform design leverage or scaffold these social norms rather than simply existing alongside them? And how can the platform simultaneously support use cases and user groups where these social norms and relationship dynamics are not as positive [3] or (as in the case of our participant families with teenagers) in tension?

Another finding surfaced through our user study was that participants’ varied access control desires required our prototype to support complex combinations of access control options. Unfortunately, when we increased complexity, it decreased usability, potentially discouraging less motivated or savvy users from using access controls. This finding raises the question: how can smart home designers increase the flexibility of smart home access control systems while making the complexity manageable for all users?

**Contributions.** Our work makes the following contributions:

1. *Design Principles and Prototype:* We systematize from prior work a set of possible design principles for security and privacy in multi-user smart homes, and we develop a prototype based on these principles targeting generally cooperative households.
2. *In-Home User Study:* We use our prototype to conduct a month-long in-home user study with seven (non-adversarial) households, including couples, roommates, and families with children of various ages. Our study

serves to both test our proposed design principles in practice and to more generally enrich the literature on people’s security and privacy needs, concerns, and priorities in a multi-user smart home.

3. *Lessons and Recommendations:* Based on our design experience and in-home study, we reflect on our proposed design goals for multi-user smart homes and surface future technical directions as well as open questions for designers and researchers.

## 2 Background and Motivation

Smart homes raise significant potential security and privacy challenges. These challenges include, for instance, vulnerabilities in the devices themselves (e.g., [29]) and privacy concerns due to ubiquitous recording in the home [6, 21, 42].

In this work, we focus primarily on multi-user security and privacy: how peoples’ behavior and usage of the smart home can impact each others’ security and privacy. We begin by systematizing the multi-user security and privacy issues prior work has identified for smart homes, as well as the shortcomings of existing approaches in addressing these issues.

### 2.1 Multi-User Challenges in Smart Homes

Prior work suggests that smart homes can cause or intensify conflicts or tensions between people living in the home — even when relationships between people are not explicitly adversarial (e.g., abusive).

**Power and Access Imbalances.** One negative dynamic that emerges from smart homes is a power imbalance between the person(s) who install(s) and configure(s) the home, and the other users who are more passively involved. In the worst-case — in the context of intimate partner violence — abusers may have total control over the smart home, enabling harassment and abuse [3]. However, power imbalances also arise in more benign relationships. For example, Geeng et al. observed how more tech-savvy users have more agency in the home, including more access to device functionality, more information about what devices and people in the home are doing, and the power to restrict others from using devices [14].

**Privacy Violations.** Smart homes can also intentionally or unintentionally be used to expose privacy sensitive information about one user to another. Zeng et al. found examples of such situations, like users being unaware of automated notifications sent by cameras to their landlord, and users feeling a loss of privacy because others could view their behavior through smart home logs [41]. Choe et al. studied how devices that capture video, audio, and other behavioral traces could cause tensions between household members, or between guests and household members, who would object to being recorded [6].

**Direct Conflict.** Lastly, smart homes can be focal points of conflict between people in the home, both due to explicit

malice (e.g., abuse) and due to ordinary conflicts between household members. For example, prior work has documented conflicts arising due to differences in opinion on thermostat setting [14, 41], due to conflicting goals between parents and teens in the context of entryway surveillance [36], or due to the potential use of recorded evidence in household disputes [6].

## 2.2 Additional Actors: Apps and Automations

The above multi-user issues are compounded by the presence of additional “actors” in smart home systems: third-party apps and integrations that users may install (such as SmartApps or IFTTT), as well as end-user programmed automations. These apps and automations can range from simple rules (such as automatically locking the door or turning off lights when leaving home) to more complex “smart” features that integrate with other cloud services, e.g. weather data and calendars.

These applications and automations can expose users to physical security risks and privacy violations. Third-party applications and automations may be expressly malicious, or buggy and exploitable (e.g., [11]). Moreover, end users themselves may make mistakes programming automations, leading to unexpected behavior, bugs, and potential security and privacy risks [27, 34, 39]. In a multi-user smart home, this combination of actors means that when something unexpected happens in the home, it may be challenging or impossible for a user to determine whether it was the result of another user actuating the smart home remotely, a buggy application or automation, a legitimate application or automation that another user installed, or explicitly malicious activity.

## 2.3 Shortcomings of Existing Approaches

Though many commercial smart home platforms exist, and a growing body of research literature supports the need to address the above challenges, we are not aware of existing approaches that succeed at addressing them and/or have been rigorously evaluated with end user — neither for explicitly adversarial settings nor in generally cooperative households.

There are many types of access control policies that could be used in smart homes, including time-based policies, location-based policies, per-user policies, and per-device policies. However, Mare et al. found that adoption of these techniques in smart home platforms is uneven and limited [22]. Some platforms support a subset of these policies, e.g., Apple Homekit has location-based access controls, and Vera has multiple privilege tiers for admins and guests. However, some popular platforms have minimal or no access control at all: Samsung SmartThings has only a single privilege level for all users and no access control policies, while Google Home and Amazon Echo do not authenticate voice commands. He et al. [16] and Ur et al. [35] found similar fragmentation of access control and authentication policies between individual devices: some devices like door locks had many access

controls, while others like smart thermostats had none.

While having no access controls or user roles at all is clearly insufficient for user needs (e.g., [33]), the jury is still out on what are the *right* access control designs for multi-user smart homes. To that end, He et al. [16] surveyed hundreds of participants to understand their smart home access control preferences, such as which device capabilities people felt need restrictions (like “deleting door lock logs”) and which types of device capabilities and people could use special contextual controls (e.g., allowing children to control devices only when parents are around). These survey results provide a valuable basis for future smart home access control designs, but they still only represent a theoretical view of people’s preferences. To the best of our knowledge, there have been no direct, *in situ* evaluations of multi-user smart home access controls designs with end users. We aim to close that gap in this work.

## 3 Scope and Research Questions

Prior work has surfaced many multi-user security and privacy challenges in current smart home systems. However, this body of research lacks concrete design proposals that have been evaluated with end users. We aim to advance our understanding of this space.

We focus in this work on generally functional multi-user households, rather than on explicitly adversarial situations (e.g., domestic abuse) or cases where users do not belong to a household together (e.g., Airbnb-style rentals). Understanding and designing for these cases is also critical, but different (and significant) challenges exist in designing systems that are resilient to motivated adversaries with malicious intent, elevated privileges, and physical device access [23]. We discuss the ways in which our work may address — but also falls short of addressing these challenges, in Section 7.4.

Yet prior work has not answered the question of how to design multi-user smart homes for “typical” households; thus, in this work, we seek to answer two research questions:

**RQ1: How should a smart home be designed to address multi-user security and privacy challenges (in generally functional households)?** What design principles and concrete features may help mitigate tensions and disagreements among otherwise cooperative (e.g., non-abusive) co-habitants that stem from multi-user security and privacy issues?

**RQ2: What security and privacy behaviors and needs do these smart home users exhibit in practice?** Prior work has provided some understanding of users’ security and privacy preferences in the smart home, like preferences for access controls [16], or examples of undesirable situations [14, 41]. However, these preferences could conflict with other priorities, such as utility and convenience. We ask: when presented with a smart home with more advanced security and privacy features, how do people (in non-adversarial households) use them in practice? Do users’ security and privacy related be-

aviors differ from their stated preferences? Do our initial design principles match their needs?

To answer these research questions, we take a two-part approach. First, we design and implement a multi-user smart home interface, based on design principles (Section 4.1) that we distill from prior work. Second, we conduct an in-home user study using our prototype, to evaluate whether these design principles meet user needs in practice, and to improve our understanding of users' behaviors given improved multi-user security and privacy features in a smart home.

## 4 Prototype Design and Implementation

To support the investigation of our research questions, we prototyped a mobile application for controlling smart homes that provides multi-user security and privacy features such as access controls, designed for households in which members are generally motivated to cooperate. We now describe the guiding design principles for our prototype.

### 4.1 Initial Design Principles

We developed our prototype based on lessons from prior work, which suggested that the following design principles may be important for multi-user smart homes:

**Access Control Flexibility.** Prior work [16] has suggested that smart home access control and authentication systems should be flexible enough to support a wide variety of use cases, people, and types of relationships that exist in homes. We aimed to support a variety of relationships, like couples, roommates, children, guests, and domestic workers, and also different contextual factors, like location. These factors can be combined to create the policy that suits the user.

**User Agency.** Prior work [14] found power imbalances among smart home users that reduce the agency of users with less (technical or interpersonal) power. We aimed to support a feeling of agency for all users in the smart home, by making the smart home more accessible and discoverable. For example, for access controls, our prototype allows people to “ask for permission”, rather than to be locked out entirely. We aim to make smart home functionality more discoverable, by showing users which devices are nearby and accessible. We also aimed to simplify the process of on-boarding new users.

**Respect Among Users.** Prior work has surfaced significant potential for tensions and conflicts among users of a smart home (e.g., [14, 41]). We aimed to encourage respectful usage of the smart home by minimizing conflict points: for example, making it harder for one user to remotely control or automate devices in a way that would surprise or disturb another.

**Transparency of Smart Home Behaviors.** Prior work suggests that smart home automations and apps may malfunction or act maliciously (e.g., [11, 34]), violate the privacy of

unaware users (e.g., [41]), or confuse users who did not configure them. When smart homes are used for domestic abuse, abusers have harassed victims with remote control, masking it as automatic behavior [3]. We aimed for the smart home to transparently surface its behavior to all people in the home (realizing that there may be privacy implications, as we discuss below), especially when people are remotely controlling it, or when an automation/third-party app is acting on its own.

### 4.2 General Design Description

We designed a mobile application that allows multiple users to control their smart home devices. In terms of threat model, we assume that the control application and the underlying smart home (SmartThings, in our study) are trustworthy and uncompromised. We assume that third-party smart home automations or applications may be buggy or compromised, but our design does not aim to prevent such issues. We assume that users may use or configure the smart home in ways that are undesirable to others in the home, though we focus on cases in which this behavior is accidental or mildly malicious (e.g., “trolling”); we do not attempt to defend against a determined, malicious adversary (e.g., an abuser).

The basic interface of our app is similar to other mobile apps for controlling smart homes (e.g., Samsung SmartThings). The main view of the app displays a list of devices and their current status (Figure 1a). Devices can be organized by room for convenience. The state of a device can be adjusted by tapping its status, and tapping its name reveals options for access controls and notifications (described below).

We aimed to simplify the process of onboarding additional users, towards meeting the “user agency” principle. The first user must create an account with a username and password, but they can add other users by scanning a QR code on the new user's phone. These additional users do not need a login, instead using public key authentication tied to their device.

### 4.3 Access Controls

Towards meeting the “access control flexibility” and “respect among users” principles, we designed access controls for accessing device capabilities, based on access control preferences and use cases surfaced in prior work (e.g., [10, 16]).

**Role-Based Access Control.** Each household member has a separate user account. Users can be restricted from using a device via the ‘Allowed Users’ setting (Figure 1b). Users are also assigned to roles (admin, child, guest). Only admins have the ability to make configuration changes: changing access control policies, adding new users, organizing the devices.

**Location-Based Access Control.** Users can also be restricted from controlling device capabilities if they are not physically near the device, or not at home, using the “Remote Control” permission (Figure 1c). This access control can be

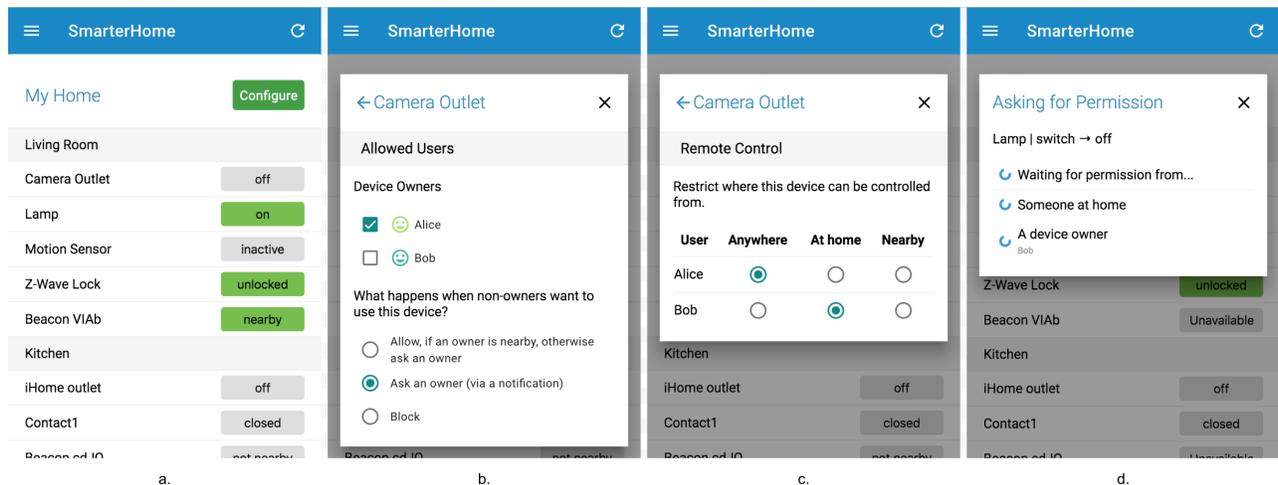

Figure 1: **Access Control UI.** From left to right: (a) The main interface for controlling devices. (b) Interface for setting access controls on devices, by role, and options for reactive/supervisory access control. (c) Interface for setting location-based access controls on a device, for each user. (d) Reactive access control prompt: what users see while waiting for approval.

set per-user, to accommodate use cases like only allowing guests and domestic workers to access smart home devices while in the house. It could also be used to promote respect among users by preventing them from remotely controlling devices like lights when other people are in the room.

**Supervisory Access Control.** Access controls are in some ways antithetical to user agency. For example, parents may want to use parental controls to keep children from causing trouble, but may not want to block children from using the smart home at all times, like when the parents are at home and are able to supervise. To serve this potential use case, we implemented supervisory access control (first proposed by He et al. [16]): if a user is restricted from controlling a device, they can still be permitted to control it if another (authorized) user is nearby (Figure 1b).

**Reactive Access Control.** Access control policies based on role and location could be too rigid for every situation. There may be occasional edge-cases where it does not make sense to enforce a policy. Towards the principles of increasing flexibility and supporting user agency for restricted users, we implemented reactive access control [10, 24]. If a user attempts to access a capability they do not have permission to use (Figure 1d), the app will ask a more privileged user for permission in real-time, by sending a notification to asking them to approve or deny the request (Figure 2c).

#### 4.4 Activity Notifications

Towards meeting the “transparency of smart home behaviors” principle, i.e., to make it more transparent when the smart home is being remotely controlled, or controlled by automations and apps, we designed notifications that alert users when the states of home devices change. Each notification displays

the name of the device, the change in state, and the user or process responsible for causing the change (Figure 2).

We chose to use notifications over other designs that focused on visualizing automations and events in-app [5, 26], to explore a different point in the design space. Rather than having users navigate to a particular interface when motivated to investigate activity in their smart home, we hypothesized that real-time notifications could provide information in a more timely and relevant manner.

Because the number of notifications from the smart home could be overwhelming, we allowed users to disable notifications on a per-device basis, or to only receive notifications from physically nearby devices.

#### 4.5 Discovery Notifications

Prior work (e.g., [14, 41]) suggests that one challenge with multi-user smart homes is that less technically savvy or engaged users may struggle with accessing smart devices. Thus, towards meeting the “user agency” principle, we wanted to make it clear which smart devices were nearby and could be actuated, especially for novice users. We designed a persistent notification which displays the status of nearby devices, and includes action buttons to toggle those devices (Figure 2b). This design makes devices that are nearby (and potentially relevant) accessible without needing to open the app. We designed it to be minimally intrusive—the notification is silent and is minimized at the bottom of the notification tray.

#### 4.6 Implementation

We implemented a prototype mobile app with these features for Android, iOS, and web, using the Cordova framework. Rather than implement our own smart home controller that

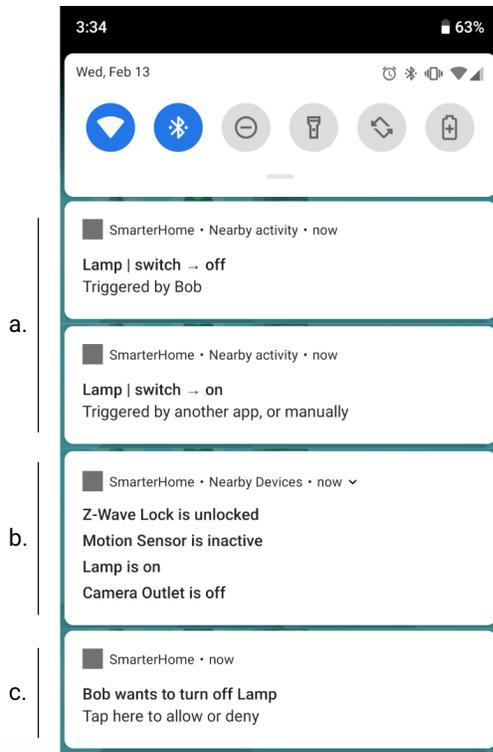

Figure 2: **Overview of Notification Types.**

(a) *Activity Notifications.* When an event occurs in the home, this notification shows the name of device, capability being changed, and who or what caused the change.

(b) *Discovery Notifications.* Persistent, low priority notification that shows nearby devices and their current state; can be expanded to reveal action buttons for controlling devices.

(c) *Reactive Access Control prompt.* Appears when another user asks for permission to use a restricted device capability.

interfaced with hardware devices directly, our prototype connected to devices via the Samsung SmartThings API. Participants set up their smart home devices using SmartThings, and then used our app to control the system. Our prototype did not support automations and third party apps — users accessed this functionality through the SmartThings app. Our prototype consisted of 10257 lines of JavaScript, CSS, and HTML.<sup>1</sup>

**Proximity Sensing.** To enable room-scale proximity-based features (location-based access controls, proximity-scoped notifications), we incorporated Bluetooth Low Energy beacons into our system. Beacons broadcast an ID that can be scanned by modern smartphones that support Bluetooth 4.0+. Users register physical beacons in our app using an ID printed on the device, and then assign it to a room in the app. When a user’s phone detects the beacon, the app infers that the user is near the devices in that room. We chose beacons as our proximity sensing solution out of convenience: they are supported by all

<sup>1</sup>The source code and a demo of the prototype are available at <https://github.com/UWCSecurityLab/smarter-home>

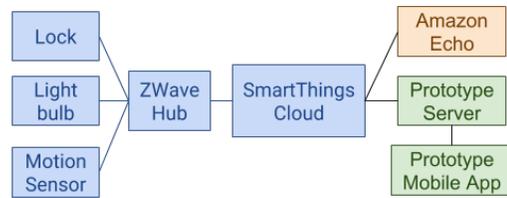

Figure 3: **Prototype Architecture Diagram.** We use the SmartThings API to communicate with smart home devices.

modern Android and iOS devices. However, our design does not require a specific proximity sensing technology; others such as WiFi or ultrasonic sensing would work as well.

**SmartThings and iOS Limitations.** Due to the limitations of the SmartThings API, activity notifications cannot attribute changes in home state to particular third-party apps, automations, or manual actuation of devices. For state changes in these categories, our implementation only displays “Triggered by an automation or manually”. Discovery notifications were only implemented on Android, as the iOS notification center does not support persistent, low priority notifications.

## 5 User Study: Goals and Methodology

Our prototype allows us to study the research questions we set out in Section 3. To do so, we recruited seven households in the Seattle metropolitan area to use our prototype to interact with their smart homes for a month-long period. We conducted studies between October 2018 and January 2019.

**User Study Goals.** Our goals in conducting the user study were two-fold, corresponding to our two research questions. First, we aimed to evaluate how participants used and reacted to the specific multi-user smart home features (and corresponding design principles) we implemented in our prototype. Second and more generally, we aimed to understand the multi-user access control and other needs and behaviors of end users, grounded in the use of a specific prototype in real homes.

Our specific evaluation questions, paired with the design principles our prototype intended to embody, included:

1. *Access Control Use Cases:* Is our current combination of access controls sufficient for users’ desired access control use cases? If not, what use cases are we missing?
2. *User Agency and Respect:* We envisioned that location-based and reactive access controls could be used to mitigate conflicts and tensions over controlling the home. Can we observe this in practice?
3. *Transparency of Smart Home Behaviors:* We envisioned that notifications could improve users’ mental models of smart homes, which would help with understanding privacy implications; and also improve security by creating a simple mechanism for auditing automations and apps. Do notifications provide these benefits to users in

practice? Conversely, do notifications harm privacy by revealing one person’s activity to other people?

**Study Overview.** We conducted a month-long *in situ* user study in the homes of participants. We recruited households in the Seattle metropolitan area. We provided a Samsung SmartThings smart home to households that did not already own smart home devices, or integrated SmartThings with the smart homes of households that owned an existing system. We collected qualitative data about participants’ previous experiences with smart homes and feedback on our prototype through interviews, experience sampling, and log data.

**Recruitment.** We recruited seven households, containing 19 participants who actively participated. Participating households were recruited via Facebook ads, targeted at people interested in smart homes and home DIY projects. People who clicked on the ads filled out a short survey including information about their household composition and interest in smart homes. We did not require participants to own any smart home devices prior to the study. We conducted a screening call with participants that met our criteria to collect additional information. We selected participants who lived within a 45 minute radius from our homes (so that it was feasible to make an in-home visit), and we aimed for a variety of multi-person household compositions, including roommates, families, and couples. Participating households are summarized in Table 1.

A limitation of our recruitment strategy and study design is that it introduces self-selection bias: our participants were likely to be living in generally cooperative households, with one or more technology early adopters. We discuss this, and other limitations, further in Section 7.5.

**Initial Interview.** We made an initial visit to participants’ homes to conduct a semi-structured interview about their existing experiences and attitudes towards multi-user smart home security, privacy, and usability issues (see Appendix A).

Following the interview, we assisted with the setup of any devices if needed, and then we set up our prototype app. We guided them through app installation because it required using the developer mode in SmartThings, which was cumbersome and not representative of a typical install experience for commercial apps. We also assisted participants in adding other household members, to ensure that we could study multi-user interactions (rather evaluating the onboarding barrier).

We also walked through the access control and notification features of the app, and collected their initial impressions of the features. To counteract participant response bias [8] we stressed that we were testing an imperfect prototype, and that we wanted honest, negative feedback on things that were not useful or usable. We used some participant feedback from this stage to iterate on our implementation and push updated features to participants throughout the duration of the study.

**Daily Usage.** Participants then used the app for 3-4 weeks during their daily lives. During this period, the integrated experience sampling interface in our app prompted participants

to provide feedback or to share anecdotes about multi-user interactions in the home. We also collected log data about how users set up access controls, permissions, and notifications.

**Exit Interview.** At the end of the usage period, we conducted a phone interview with each household. In this semi-structured interview we collected specific feedback about their experience using (or not using) the access control and notification features in our prototype. We also followed up on any interesting data from experience sampling or logs. A list of interview questions is available in Appendix B.

**Compensation.** Participating households were compensated \$250 over the course of the study, in installments. Participants could keep the provided smart home devices after the study, or return them for the equivalent cash value.

**Ethics.** The study was approved by the University of Washington’s human subjects review board. Participants had to be age 18+ to consent to participating; household members under 18 could participate with verbal assent and approval from their parents and guardians. We had approval to collect incidental data via the smart home on children who declined to participate or were too young to actively participate.

During the study, we experienced a security breach due to a firewall and database misconfiguration, resulting in the possible exposure of hashed passwords, log data, and temporary access tokens. Based on access patterns, we believe the data was accessed by port scanners, and not by targeted attackers. We remediated the issue within 24 hours of discovery. We notified our institution’s human subjects board, and contacted participants with a description of the issue, protective steps like changing matching passwords on other sites, and the option to opt out of the study. No participants opted out.

**Analysis.** We transcribed and analyzed 633 minutes of content from the 14 initial and exit interviews. We analyzed the interviews using a collaborative qualitative coding technique. First, two researchers read over all of the data and developed a codebook, using descriptive codes like “access control: use cases”, “relationship: guests”, “notifications: too noisy”, and “access control: trust/respect” (see Appendix C for a full list). Two researchers independently coded two interviews, and then met to resolve differences and clarify ambiguities in the codebook. Then, one researcher coded the remaining interviews based on our revised understanding of the codes. We used a custom code aggregation tool to help identify patterns and extract higher level themes across interviews.

## 6 User Study: Results

We now present the findings from our user study, including direct feedback on the features implemented in our prototype, and general findings about participants’ desired features and use cases, surfaced by their concrete experiences with our prototype and the smart devices in their homes.

Participants	Gender	Age	Devices	Household Info	
H1	H1A H1B	25-34 35-44	F M	Lock*, motion sensors*, contact sensors, thermostat*, security camera*, lights*, Amazon Echo*	Family with two non-participating children (0-6), living in house
H2	H2A H2B	25-34 25-34	M F	Lights*, Amazon Echo*, contact sensor, door lock (not connected)*	Couple, living in house
H3	H3A H3B H3C	25-34 25-34 25-34	F F F	Lights, contact sensor, motion sensor, power outlet	Roommates, living in apartment
H4	H4A H3B	25-34 25-34	F M	Lights, contact sensor, power outlet, Amazon Echo*	Couple, living in apartment
H6	H6A H6B H6C	35-44 45-54 13-17	F F M	Lights, contact sensor, door lock, Amazon Echo*	Family with 2 children (one aged 7-12), living in house
H7	H7A H7B H7C	18-24 18-24 18-24	F F F	Lights, contact sensor, motion sensor, power outlet, Ring video doorbell, Amazon Echo*	Roommates, living in house
H8	H8A H8B H8C H8D	45-54 45-54 18-24 13-17	F M F M	Lights, contact sensors, security cameras*, Amazon Echo*	Family with 2 participating children, one non-participating child (7-12), one non-participating relative (13-17), living in house

Table 1: **Summary of Participating Households.** Some children were too young to actively participate in the study. Asterisks (\*) indicate devices households owned prior to the study.

## 6.1 Desired Access Control Use Cases

We begin by exploring the situations where participants *wanted* multi-user access controls, and what form of access control mechanisms participants wanted. In some cases, our prototype was able to fulfill participants’ goals, and in others, the ability to explore concrete access control features in the context of their own home evoked hypothetical policies that they felt would better suit their needs.

**Location Restrictions for Visitors.** H1A wanted an access control setting that would allow visitors like guests and domestic workers to be able to access and control the devices in her home, but only while they were physically present.

I don’t want the nanny, who’s here all day — I trust her, obviously, or she wouldn’t be with my kids — but at the same time, like I don’t necessarily need her to be at her house, being able to control the lights at my house. ...if I have guests coming into my house, I’d like them to control automations, but... I certainly don’t want them having admin control. I’d prefer to have them to have geofenced control. (H1A-Initial)

At the time, our prototype’s location-based access controls did not quite meet her requirements, because it could only be applied as a blanket policy for all users of a given device. Based on this feedback, we updated the prototype to support location-based access controls both per-user and per-device.

**Preventing Configuration Changes.** Some participants were concerned about other family members accidentally

making changes to access control policies, automations, or device configuration. H1A recalled when they set up their smart home, H1B (her spouse) caused confusion by accidentally pairing some devices multiple times. As a result, H1A set H1B at the child privilege level in our prototype, which prevented him from configuring access controls and rooms.

H8A did not want her children to either change or override the existing automation for the porch light, which turned the lights on automatically at night for security purposes, nor did she want them to be able to change access control policies. As a result H8C/D were set at the child privilege level in our app (and were also not added to the native SmartThings app, from which the automations were created).

**Parental Controls for Device Usage.** Parents in our participant sample expressed interest in placing restrictions on children to prevent mischief or other undesired uses of devices. For example, H1A and H8A wanted to restrict their children from turning on/off security cameras. However, participants did not use our prototype’s features for restricting access to any devices in practice, for reasons we discuss below.

A parental control goal that we did not anticipate was that H1A and H8A were more interested in using the smart home to regulate screen time, e.g. blocking internet access at certain times, and using a smart power outlet to turn off the TV.

**Devices in Private Rooms.** The roommates of H3 placed smart light bulbs each of their bedrooms, and set an access control policy so that only the room’s owner could control the lights. They reported that it was “comforting” and a “good

feature to have” (H3C), but that in practice, they never encountered the access controls because they were respectful of each other and did not ever attempt to control another person’s lights. (We discuss similar cases of social norms obviating the use of technical access controls below.)

**Preventing Remote Access for Media Devices.** H4A/B expressed interest in location-based access controls for their Amazon Echo, based on past experiences where one of them accidentally changed the audio that was playing from outside of the room or house, due to confusion over whose Bluetooth device or Spotify account was playing. We did not see similar interest in location-based access controls for other device types — perhaps because unlike lights or locks, which are useful to remotely control for security and energy saving purposes, media devices are only useful to the people physically in the room.

**Access Controls for Voice-Controlled Devices.** H8A became aware that their Amazon Echo could be used to bypass the access controls and authentication of our prototype (see Section 7.3 for more detail). In one instance, she used this to allow her mother-in-law to access the smart home without installing our prototype. However, she also wanted the Echo to authenticate users by voice, so that they could use access control policies for to their youngest son, who was too young to have a phone but could control devices via the Echo.

## 6.2 Reasons for Not Using Access Controls

Based on findings about multi-user smart home tensions in prior works, we expected that households would use our access controls, for at least some of the potential use cases outlined in our design principles (Section 4.1). However, in general, we found that the access controls we implemented did not fit with the participants needs and use cases.

We analyzed participants’ usage logs, and found that while most households experimented with using access control policies in the first few days after the initial interview, most of them quickly settled on the least restrictive access control setting, not continuing to use location-based, role-based, or supervisory access controls to restrict access to devices. The only household that kept any access controls enabled was H3, a household of roommates who enabled per-device role-based access controls on the lights in their private bedrooms. However, none of the roommates ever attempted to violate these access controls (i.e., tried to turn on or off each others’ lights).

Given this limited long-term use of access control features in practice, we thus focus on our qualitative interview data, to dig into the reasons *why* participants did not use the access controls more than they did. Our findings surface several reasons that are more fundamental than simply reactions to our specific implementation — i.e., reasons that participants may not have used *any* access controls, regardless of design.

**Social Norms, Trust, and Respect.** The most common rea-

son participants cited for not setting access controls was trusting each other enough that they were not concerned about device misuse, relying instead on established household and interpersonal norms. We observed such trust and norms among relatively equal relationships, like partners and spouses:

No, we didn’t turn [remote control restrictions] on either... We both wanted full permissions to do anything whenever, we weren’t worried about the other. I had no concern that H2B, from not nearby, would turn off the lights. (H2A-Exit)

We also observed trust and norms among roommates:

I think we’re all pretty respectful and we wouldn’t turn on and off each others’ lights. (H7A-Exit)

And even with children:

If [H6C] were a different kid, I would probably leave [remote control] turned off for him. But for him, it would be useful, I would turn it on for him. ...I think it’s going to be very specific to who is using it, and having the option is important, but he’s just very responsible, so it could’ve been handy for him to be able to do something from school, like turn on and off lights. (H6A-Initial)

Participants mentioned similar social norms about multi-user privacy. For example, H1A and H8A/B were aware that it was possible to eavesdrop using devices like the Amazon Echo or security cameras, but chose not to do so.

**Interference with Other Functionality.** Particularly with location-based access controls, participants often felt that the available access controls were too restrictive and prevented them from accomplishing other goals. In our initial design, we expected that location-based access controls could serve a number of goals, like access control for guests, or preventing mischief or inconsiderate use of remote controls. However, multiple participants wanted unfettered remote control access, particularly for lights, because it was convenient.

I think a big thing for us was in case we forgot to turn off the lights or something, that was like the appeal, to turn it off remotely. (H7A-Exit)

Like the times when we would both need access to turn off the light we forgot to turn on, were more frequent than any need to restrict us from being able to remotely control it. (H4B-Exit)

In other words, at least for the smart devices our participants had, the convenience for all members of the household to be able to exercise remote control outweighed any concerns about intentional or accidental remote misuse.

**Lack of Concern About Devices.** Participants did not feel concerned enough to use access controls for certain types of devices, or for devices in certain locations. For example, participants did not feel that smart lights were sensitive enough for access control (but did want restrictions on more sensitive devices, such as cameras, for guests and children).

We cannot say whether participants would have used more access controls for more sensitive devices — since we allowed our participants to select their own devices, their *a priori* threat models likely influenced their devices selection (i.e., selecting devices they were comfortable having in their home). We discuss this issue further in Section 7. Moreover, we note that these limited multi-user concerns were consistent with participants’ overall smart home related threat models (likely due to self-selection bias). Though some participants were aware of potential risks such as password compromise, vulnerabilities in wireless protocols, data collection by companies, or lost phones, they did not consider these risks to overwhelm the utility of the smart home.

Some participants also did not find it necessary to control access to devices located in household common spaces, like locks and lights — again showing physical-world household social norms reflected in the configuration of the smart home.

### 6.3 Limited Utility from Activity Notifications

We found varied use of activity notifications among our participants. From our log data, we observe that 14 participants had activity notifications on at all times for all devices, while 4 participants used a combination of settings: on, off, and proximity scoped for various devices. This data suggests that proximity scoping provided utility for some participants. (One child participant did not have the app installed.)

But having notifications enabled does not necessarily mean that participants found them useful; we now dig further into our qualitative interview data to understand whether and how the notifications were useful to participants. Our participants found notifications useful for a few specific use cases, like home security and sanity checking their smart home automations. However, we did not find much evidence that our notifications provided benefits for transparency and agency.

**Monitoring and Home Security.** Participants found notifications to be most useful for home security and monitoring purposes. H1, H6, H7, and H8 used our prototype’s notifications in conjunction with sensors on their exterior doors and windows, to passively monitor their home’s security. H3C used notifications to monitor devices in their bedroom, to check if others were entering the room.

**Proximity Scoping for Activity Notifications.** While participant H8D found proximity scoping useful, as she did not want to be notified about devices while away from home, other participants said that the feature would be more useful if they could be notified only when *not* at home — either as a home security measure (H8A), or because they could already tell when their devices changed while at home (H4B).

**Confirmation of Home Behaviors.** Some participants found the notifications to be comforting because they confirmed that both people and automations were behaving as expected.

It was nice to know it was at that point in the day,

and really what I had it set on were essentially the lights to come on and go off at appropriate times, and so it was a notice that, yes, today is progressing as it should. (H6A-Exit)

**Desire for Contextual Notifications.** Our activity notifications prompted participants to propose more advanced, context-dependent notifications that would be more useful to them. For example, H3C suggested notifications which would suggest turning off the lights to save energy. H6A wanted more intrusive notifications when something incorrect happens (e.g., a window is open when it should not be).

We were not able to test whether notifications would be helpful for identifying actions caused by specific automations, because limitations of the SmartThings API did not let us see *which* automation caused an event to happen. None of our participants mentioned encountering a situation in which they wanted more specific information about provenance.

**Quick Access via Discovery Notifications.** Most participants did not notice or see discovery notifications. (Unfortunately, persistent notifications of this sort are not supported on iOS, and few of our participants were Android users.) One participant, H8D, was interested in these notifications, but for convenience, not device discoverability, as it allowed him to toggle the state of the device without opening the app.

**Limited Concern about Privacy.** No participants reported that the notifications affected their sense of privacy, nor that they changed their behavior as a result of knowing that notifications would be shown to others. Participants also did not report learning new information about others via notifications.

**Notifications Were Overwhelming or Not Useful.** For some participants, the notifications were annoying and overwhelming. H1A said she just did not care when other people, like her husband and nanny, used devices. H7A complained about redundant notification: each time someone walked through the front door, their doorbell and contact sensor would both trigger notifications, resulting in four notifications.

Other participants said that the notifications were not useful when at home, because it was information that was already apparent. Participants in H3 and H4 lived in small apartments, and could naturally observe all of the information from the notifications (e.g., the sound of others walking around and the glow of lights in other rooms). And H7A said that their dogs already notified them when people were at the front door.

### 6.4 Usability and Configuration Complexity

Hands-on experience with our app revealed that the complexity of access controls and other smart home features were adversely affecting the usability of the system. The complexity came from both the granularity of the settings, and the number of different devices managed by the home.

**Complexity as a Barrier to Access Control Use.** While we

aimed to make our prototype's access controls as easy to understand as possible, the inherent complexity in the matrix of options may have still been too much of a barrier for novice users to configure them. For example, usability may have been an issue for H8A/B, where both expressed interest in setting various access controls during the feature walkthrough in the initial interview, but did they did not ending up using them. When we asked about other goals they might have for access controls and the smart home in general, H8A said:

It interests me, but you have to think it through, what you want to do, how it would benefit you... part of the Smart Things is you're taking on a bit of a responsibility, getting it set up, getting it working, it's kind of like getting a new computer, but there's a bit of the downside, you have more options but it's complicated. (H8A-Exit)

**Design Complexity from Combinations of Settings.** During the study, participants requested more fine-grained options for the access control and notification features. Based on this feedback, we iterated on the implementation of our prototype and released updates. However, we struggled with adding these features, as each additional access control dimension compounded the complexity of the interface.

One example was for location-based access controls. Initially, these access controls were set per-device. However, H1A and H8B wanted to set these access controls per-user in addition to per-device, so that they could restrict their nanny and kids (respectively), but not themselves. To fulfill this request, we had to surface more options ( $3n$  options per device, where  $n$  is the number of users, instead of 3 options per device). As another example, if we wanted to add toggles for supervisory and reactive access controls to location-based access control when users are not nearby and try to use the device, there would not be enough space to display these options without an additional submenu, making it more laborious to set policies for each user and device (see Figure 1c).

Usability is fundamentally in tension with the desire to support access control flexibility and surface all of these options to users - we discuss this issue further in Section 7.

**Displaying Access Control Policies.** Participants remarked that it would have been helpful if the main device control page (Figure 1a) surfaced each device's access control policies. Living in a home with 14 devices, H1B struggled with identifying and remembering which devices had access controls:

Seeing the list of all of the devices in the room, and knowing which ones he could click, and which ones he couldn't, and which ones had to ask for permission... (H1A-Exit)

H1 suggested an interface for favorite devices (a feature supported by Vera), while H3 suggested that devices that you did not have access to would simply be hidden.

**Install Barrier.** We attempted to make the install process as painless as possible for our app, implementing a QR-code

passwordless public key authentication system for additional users. However, even this barrier was too much for some users — H1A did not want to go to the effort for adding their nanny (despite stating the desire to set access controls for her), and H8A did not feel confident in being able to add her mother-in-law without our guidance. As a result, these household members were either shut out of the smart home, or accessed it via other means (i.e. Amazon Echo), bypassing our prototype's access controls and losing access to notifications.

## 7 Discussion

### 7.1 Lessons on Smart Home User Behaviors

Based on our *in situ* prototype evaluation, we surface lessons about users' security and privacy behaviors in smart homes, including how they interact with concrete security and privacy features in practice, and how our observations of actual behavior align with user preferences identified in prior work.

**Limited Usage of Access Controls.** Though our participants mentioned multiple use cases for access controls in our initial interviews, such as restrictions on guests, domestic workers, and children, in practice, few of them made use of the access controls we implemented. There are several possible reasons for this. In two cases, usability was a barrier; one household was discouraged by the complexity of the access control interface, and the other by the difficulty of onboarding guests. More commonly, participants did not have a strong need to use access controls, either because they were unconcerned about restricting access to mundane devices, or that existing social norms and trust in their household checked against bad behavior. Lastly, some participants chose not to use access controls because it would interfere with other desired functionality, like occasionally allowing children remote access.

These findings suggest that while at first glance there are many user goals that could be achieved with access controls, there are only a few specific use cases that access controls are well suited for in practice, like limiting access for domestic workers. But for other use cases where users have weak or subtle preferences, access controls can be too rigid, complex, or simply not useful, even with reactive and contextual mechanisms, such as parental controls.

**Importance of Social Norms.** Among our study population, we observed that in circumstances where prior work has shown the potential for multi-user conflicts and privacy issues, our participants often did not experience these problems due to the norms of interpersonal behavior in their home. For example, children were trusted to follow rules, roommates respected each others' spaces, and people were not concerned about information revealed by the smart home when it matched their household's privacy norms. This finding suggests that in generally cooperative households, multi-user security and privacy issues may be able to be addressed in

part by cultivating good norms around usage of the smart home. We discuss this topic further below.

**Acceptance of Security and Privacy Tradeoffs.** As we expected from prior work [41], participants were willing to accept (multi-user) security and privacy risks posed by usage of the smart home because of the convenience and utility it provided. Participants often explicitly mentioned the tradeoff between convenience and privacy, when asked about their concerns about data privacy. H8 decided against setting up access controls (for parental controls) because the smart home would be less convenient for the household, and H1 decided against using access controls for their nanny because the setup process would be inconvenient. While this finding is not new, it re-emphasizes that when designing security and privacy features for smart homes, these features must work with, and not limit, users' primary use cases for the smart home.

## 7.2 Revisiting our Design Principles

In Section 4, we proposed a set of design principles which we hypothesized could help address multi-user security and privacy issues. Based on the insights provided by our evaluation and user study, we revisit these principles:

### **Access Control Flexibility: Important But Not a Panacea.**

Our results suggest that while access controls might not be suitable for satisfying all user preferences, the flexible access control mechanisms we implemented, such as location-based access controls and per-device ownership, can help users in clear-cut use cases, like guest access. However, we also found that increasing flexibility also increases the complexity of the interface, and as we discuss below, a challenging open question remains how to support such a complex array of options in a usable and useful way.

### **User Agency and Respect: Dominated by Social Norms.**

Contrary to our initial hypotheses, we found that our participants relied more heavily on household social norms to support user agency and minimize conflicts than the access control, notification, and device discovery features we designed in our prototype. While such norms would not exist in abusive or adversarial households, for generally cooperative households, we propose a new research and design question that we discuss further below: how can a multi-user smart home be designed to *support and leverage* positive social norms, rather than existing alongside or supplanting them?

### **Transparency of Smart Home Behaviors: Inconclusive.**

Our results suggest that smart home transparency features did not provide significant benefits for our participants, in terms of our design principles (user agency and respect among users). Participants were generally indifferent to the information provided by the activity and discovery notifications, though some participants found them to be useful for other reasons: home security and verifying that their automations were working. However, our investigation is not sufficient to conclude that

transparency might not be valuable in other contexts, e.g., with cameras or voice assistants, or among people with more adversarial relationships. It is also possible that our implementation of transparency via notifications was not effective, and that another design, like calendar [26] or dashboard [5] interfaces, would provide different reactions.

## 7.3 Design Recommendations and Challenges

Based on our findings and revised design principles, we surface several design recommendations for multi-user smart home systems, particularly for platforms that can orchestrate access controls and features across all devices of the home.

### **Support Smart Home-Specific Access Control Needs.**

Our study highlights a number of use cases for access controls that appear to be common in smart home settings, including restrictions on visitors, and different policies for different rooms. To support these use cases, we recommend that smart home platforms support the following primitives: (1) Location/proximity-based access control, for handling guests and domestic workers, as well as restricting access to media devices, (2) Time-based access control, also for guests, (3) per-device roles for private rooms, (4) and per-user roles, for limiting access to device and access control configuration.

**Simplify Access Control Configuration.** A system with all of the above access control mechanisms will run into serious usability challenges if it simply surfaces a large matrix of multi-dimensional per-user, per-device options. In fact, such complexity risks increasing the access gap between the smart home's primary user and others with less technical or interpersonal power. It could also put the use of access control out of reach for novice users. Moreover, complex policies could introduce errors or conflicts between access control rules.

A good first step towards simplifying smart home access control could be to use sensible defaults based on data on people's access control preferences, as suggested by He et al. [16]. However, our results suggest that individual factors, social norms, and conflicting use cases may cause household needs to diverge from these broad preferences, so it is still important to have a usable configuration interface. However, it is not clear what kind of interface would be effective in this context. In Section 7.4, we recommend that future work investigate systems for simplifying access control configuration in smart homes, such as natural language-based policy creation.

### **Incorporate Voice Assistants into Access Control Systems.**

A major limitation of our prototype was that our access control system could be (intentionally or unintentionally) bypassed by sending a command through a voice assistant, such as the Amazon Echo. This is likewise a challenge for current smart home platforms: in platforms like SmartThings, voice assistants and other third party apps like IFTTT are given unrestricted access to smart home devices via OAuth integrations. Additionally, current voice assistants do not explicitly

perform voice recognition, so a smart home would not be able to identify who is issuing a command. In order for access controls to be consistently applied, voice assistants should support voice-based authentication, and voice assistant manufacturers should work with smart home platforms to develop a federated access control system. This is particularly important as adoption of voice assistants increases and they become a popular way to interact with smart homes.

**Reduce User Onboarding Barrier.** The smart home control interface still needs to be made more accessible to users. Even by our best efforts, a mobile app was too much to ask for some participants to install without our direct assistance and urging. If a smart home control system provides perfect security and privacy features that are locked up in an app that not all household members install, the benefits of these features will be limited. And in worst-case scenarios, if a household members cannot gain access to the smart home, it can enable domestic abuse by those with control. We suggest several potential approaches to address this issue:

One approach is to lower the installation barrier by making a mobile web version of control interfaces. In our experience, Web APIs were sufficient for all functionality, except for Bluetooth beacon scanning for proximity sensing — though browsers intend to implement this feature in the future [7].

Another approach is to further simplify user authentication. Our prototype required only a QR code rather than a username/password for subsequent users. We suggest exploring even more radical approaches, such as not requiring *any* traditional authentication to use the smart home, and instead granting basic smart device control functions to anyone in physical proximity (just as someone with physical access to a manual light switch can toggle it).

## 7.4 Directions for Future Research

Our work also suggests research questions that we encourage future work to investigate:

**Study and Design for Positive Household Norms.** We observed in our study that in cooperative households, social norms were effective at mitigating multi-user security and privacy issues, sometimes more so than the features we implemented in our prototype. Rather than trying to provide features that play the same role as these social norms, like location-based access controls for preventing inconsiderate use of remote access, we suggest (1) studying households that exhibit positive social norms around smart home usage and (2) designing and evaluating smart home systems that encourage the development of these norms in generally cooperative households. Based on the results of our study, we propose a few design “nudges” that could potentially instill better behaviors in smart home users.

First, rather than asking users to design access control policies around considerate usage, smart home platforms could

automatically detect commands that are potential norm violations, and then ask the user “Are you sure?”, including a reason for why the command might violate a norm. For example, this prompt could be triggered when attempting to control devices in another user’s private bedroom, or when remotely controlling devices that would impact other people physically present. Such a prompt could encourage users to think twice about disturbing others, while still allowing for seamless access if necessary.

Another type of nudge could promote user agency: during the setup of a smart home, the app could encourage the person installing the smart home to involve other occupants in the setup process, including encouraging and even guiding the setup of additional accounts and conversations about the different devices, automations, and policies that should be part of the new smart home. How to best design such a conversational guide is an interesting question for future work.

Nudges could also be designed to “scold” users for excessive trolling or other playful behavior, like rapidly flicking lights on and off. While it might be good to allow playful experimentation when the smart home is set up initially, eventually the app could rate limit these behaviors, or display a dialogue box encouraging the user to stop.

While norm-based nudges would of course not protect against users with malicious intent, our study results suggest that promoting positive norms could help reduce friction in the case of generally cooperative households, where conflicts and tension may arise from unfamiliarity with how one’s actions affect others in the smart home. Next, we discuss the challenge of designing smart homes for adversarial settings.

**Investigate Designs for Adversarial Situations.** Smart homes can enable or amplify harms in adversarial living situations, like in households where domestic abuse is occurring, or in homes with Airbnb-style rentals. While some of the design principles we proposed could mitigate some of these harms, such as using notifications to provide more transparency about how surveillance cameras are being used, our prototype would not provide adequate protections against other harmful actions, such as a malicious admin abusing their privileges to deny victims control of the home, or overriding protections against remote harassment that location or role-based access controls could provide. This is a very challenging problem, because some of these security and privacy features are inherently dual use: for example, admin roles and access controls may be desirable for parents to prevent children from doing harmful things, but could be used by abusers to exercise power over their victims. A critical but challenging design question for future work is how to design smart home access controls and monitoring that both protects users from abuse, but still enables benign use cases.

**Study Transparency Features for Privacy-Sensitive Devices.** As discussed above, a limitation of our prototype was that we could not provide activity notifications for privacy

sensitive smart home devices like voice assistants and security cameras, because of the limitations of the SmartThings API. We suspect that surfacing information about when audio and video is being recorded or viewed could change users' perceptions of the privacy risks of these devices, and could help people identify when their privacy is being violated. We propose an *in situ* evaluation of user reactions to a smart home system that notifies people if they are being recorded, or if another user views or listens to a log that they are present in.

Audio/video recording notifications could also be surfaced not just in the smart home, but at a global level with cooperation from mobile operating systems and device manufacturers. Cameras and microphones could emit Bluetooth beacon signals when they are active, so that users could receive notifications whenever they are nearby an active recording device.

**Study Natural Language-based Access Control Policy Creation for Smart Homes.** During our interviews, we observed that our participants were able to clearly convey their access control preferences and hypothetical policies verbally. Given that these policies are easily comprehensible in natural language, a possible way to simplify configuration is to allow users to craft policies using a natural language interface, rather than menus with drop-down lists and checkboxes. While prior work has found that direct conversion from natural language to policy is possible but imprecise [20, 31, 32], controlled natural language policy creation could be used to constrain the space of usable words and sentence structures. Using a controlled natural language approach, a possible interface could be an autocomplete-style input, which guides users through picking access control mechanisms, possible devices, users, roles, and other conditions. While this approach was found to be relatively usable in a systems administration context [17, 30], future work should evaluate whether it is usable for typical end users in a smart home setting.

**Further Study of Automations and Attributions.** We were not able to fully study whether notifications could help users with debugging automations, or attributing issues caused by automations and third-party apps, because of technical limitations of our prototype (specifically, that SmartThings does not surface to third-party applications the provenance of programmatic smart device actuations). Other researchers have proposed ways of preventing buggy or malicious behavior by third-party smart home integrations, such as detecting provenance [37] or contextual permission prompts for third-party apps [19]. These research contributions are technically valuable but their usability and utility have not been tested with real end users; we suggest that future work do so.

## 7.5 Limitations

Though an in-home user study allowed us to study how people used our prototype under realistic circumstances, this study design nevertheless comes with several limitations.

Most importantly, as discussed already, our prototype and user study focused on generally cooperative households, rather than households with adversarial relationships. Since we required consent from all participating household members, our sample is skewed towards households with sufficiently functional interpersonal relationships to agree to participate together in the study. Thus, we were unable to evaluate how our prototype would perform in an adversarial setting, nor did we gain insight into how to design for those settings.

Moreover, our protocol design involved conducting interviews with participants in a group setting, with the entire household. It is possible that participants were unwilling to reveal multi-user conflicts and privacy issues, because it would also reveal these problems to other household members.

Additionally, the devices our participants chose were generally not among the most invasive. This was due both to technical limitations (e.g., our prototype could not integrate with most security cameras using the SmartThings API), and because we gave participants the freedom to choose devices they were comfortable with. While our prototype did not interface with these more privacy sensitive devices, we still learned from participants via hypotheticals about access control grounded in their concrete experiences with our prototype and their past experiences with those devices. Future work should further consider multi-user smart home design in the face of more invasive devices.

Finally, the complexity and cost of an in-home study limited the feasible number of participating households, preventing us from drawing any quantitative conclusions from our results.

Despite these limitations, we believe our study provides valuable insights into how to design multi-user smart home security/privacy features for many (though not all) households.

## 8 Additional Related Work

Methodologically, our paper drew on a number of other in-home studies of smart homes, from HCI and ubiquitous computing. Most closely related to our work were the design and evaluation of a calendar-based interface for smart home control [26], and of a smart home data visualization dashboard [5]. Other in-home studies in HCI have studied how users interact with commercial smart homes in practice, like general usage patterns and usability [4, 18, 25], setup and configuration [9], and end user programming [39]. Researchers have also studied how users perceive and use privacy sensitive devices like cameras and voice assistants, both in-situ [28, 40], and in interviews or surveys with broader populations [21, 42].

In terms of the security and privacy of smart home devices and platforms, researchers have discovered vulnerabilities in the underlying protocols and technologies (e.g., [2, 15, 29, 38]) and studied the spread and behavior of the Mirai botnet that targeted IoT devices [1]. Other work has analyzed security and privacy weaknesses in smart home platforms that support third-party apps like SmartThings [11]. To address the

risks posed by apps, researchers have proposed and evaluated various defenses, including modifications to trigger-action programming platforms to limit misuse of access tokens [13], restricting apps using flow control [12], using provenance detection to identify anomalies [37], and a contextual access control system to protect against malicious third-party apps [19].

## 9 Conclusion

Multi-user smart homes face unique security and privacy challenges, such as supporting a wide range of access control preferences, and managing tensions and conflicts between users. Finding the design of current smart home systems to be insufficient for addressing these challenges, and recognizing the gap in knowledge around what designs can meaningfully improve end user experiences, we conducted an in-home user study to investigate possible approaches and solutions. Focusing on generally cooperative (rather than explicitly adversarial) households, we designed a smart home control interface based on design principles of access control flexibility, user agency, respect among users, and transparency of smart home behaviors. We deployed our prototype in seven households in a month-long study to evaluate our proposed design principles, and to improve our understanding of how users interact with security and privacy features in practice. Based on the findings of our user study, we provide design recommendations and identify open challenges for future research. Among our recommendations, we suggest that researchers improve the usability of smart home access controls by developing more usable configuration interfaces (such as natural language policy creation), and design smart home platforms that reduce tensions and conflicts by leveraging and scaffolding positive household norms.

## Acknowledgements

We are extremely grateful to our user study participants for making this research possible, as well as our pilot study participant, Greg Akselrod. We would like to thank Christine Geeng, Ivan Evtimov, Kiron Lebeck, and Shrirang Mare for reviewing an earlier draft of this paper. We would also like to thank Tadayoshi Kohno for his feedback in the early stages of this research. We thank Sarah Mennicken for her advice on conducting in-home user studies. Lastly, we thank our anonymous reviewers and our shepherd, Sascha Fahl, for providing us valuable feedback for improving our paper. This research was supported in part by the National Science Foundation under Award CNS-1513584.

## Appendices

### A Initial Interview Script

#### Control and Agency

- Who found out about the study? Who wanted to be a part of it?
- Did you set up your smart home together, or did one person take the lead?
- Do all of you have access to all smart home devices right now? If not, why?
- What are you hoping that your smart home will do for you?

#### Multi-user Privacy

- Have you ever unexpectedly learned anything about someone else, through the smart home?
- Can you think of ways you could “spy” on people using your smart home? Would you do it?
- Do you think it’s a good or bad thing that you can find out those things?

#### Transparency

- Are you having any trouble figuring out how to control your devices? Or figuring out which devices are smart?
- Has there been any confusing moments where you weren’t sure what was causing something to happen in your home? How did you figure it out?

#### Access Control Preferences

- Can you think of any situations where you want to restrict where people could remotely control devices from?
- Can you think of any situations where you want to restrict certain people from controlling certain devices?

#### General Security and Privacy Questions

- Do you have any security and privacy concerns about smart homes?
- Are there any potential security and privacy issues that you are aware of, but aren’t worried about?

### B Exit Interview Script

#### General Usage and Control

- How did you end up using your new devices?
- Did you set up any automations?
- How involved were each of you in configuring the home? Like setting up rooms and permissions?

#### Notifications and Transparency

- Let’s talk about the activity notifications feature - the notifications you can get when someone turns something on or off, or trips one of your sensors. Did you have this feature on? (Why not?)
- How did you set your preferences for notifications? Why? Which devices? Proximity based or not?
- In what situations did you normally see notifications?
- Did seeing notifications provide any useful or interesting information?
- Did any notifications help you understand what your smart home was doing?
- Did you learn something about other people’s behavior that you wouldn’t have found out about without notifications?
- Did you change your behavior in your home because of the notifications?
- Were the notifications overwhelming, or not useful?
- What changes would you like made to make to this feature?
- Leaving aside the particular capabilities of our app, can you think of any situation where it would be useful to get notifications, maybe just for particular devices?

#### Supervisory, Reactive, and Role-based Access Control

- Let’s move onto the allowed users feature. This is the feature that lets you designate owners for each device, and have everyone else ask for permission to use it. Did you use this feature?
- If so, who was restricted? What devices and policies did you set? (block, ask, ask if not nearby)
- If not, why?
- How did you all decide on who to set restrictions on?
- In what situations did <restricted user> have to ask for permission to use a device?
- Did anyone try to circumvent restrictions on them? How?
- To blocked user: was it clear to you which devices you needed permission to use? How did you find out?
- To blocked user: How comfortable did you feel pushing the button to ask for permission?
- To blocked user: Did you change your behavior as a result of having to ask for permission?
- To admin users: How did you feel when you got notifications when someone asked for permissions?
- To blocked user: when you asked for permission, did the other person usually respond in time?

- To admin user: did you receive notifications in a timely manner? Were you able to fulfill requests?
- What changes would you like made to make to this feature?

### Location-based Access Control

- Now let's talk about permissions for remote control. This is the setting where you can make people ask for permission to use a device if they aren't nearby. Were any devices restricted to remote control in a particular location? If not, why?
- How did you all decide on which devices to set restrictions on?
- In what situations did you have to ask for permission to use a device?
- Did anyone try to circumvent the restrictions on a device? How?
- When you had to ask for permission, did someone respond in time?
- When you got a permission request, did you receive a notification in a timely manner? Were you able to fulfill the request?
- Did the beacons usually accurate put you in the correct room?
- Was it clear which devices were location restricted? How did you know?
- To blocked user: How comfortable did you feel pushing the button to ask for permission?
- To blocked user: Did you change your behavior as a result of having to ask for permission?
- To admin users: How did you feel when you got notifications when someone asked for permissions?
- Did you ever use this feature to check who was home?
- What changes would you like made to make to this feature?
- Hypothetically, imagine we built an app that had every access control scheme and level of granularity you wanted - custom permission tiers, time-based access controls, proximity-based access controls, and device-level granularity. How would you set these for the different people who visit your home? (Spouse, children, guests, domestic workers?)

### C Codes Used for Qualitative Analysis

- Access control - ask for permission
- Access control - complexity/discoverability
- Access control - conflicts with other goal

- Access control - desired use cases
- Access control - location-based
- Access control - not useful
- Access control - role-based
- Access control - side channel
- Access control - trust/respect each other
- Access control - unconcerned about device
- Access control - useful
- Multi-user - conflicts
- Multi-user - pranks
- Multi-user - privacy
- Multi-user - unexpected home behavior
- Notifications - checking/debugging automations
- Notifications - desired use cases
- Notifications - not noisy
- Notifications - not useful
- Notifications - privacy
- Notifications - proximity scoping
- Notifications - too noisy
- Notifications - useful
- Relationship - children
- Relationship - couples
- Relationship - domestic workers
- Relationship - guests
- Relationship - roommates
- SecPriv - Accepts risk
- SecPriv - Concern about location/proximity
- SecPriv - Concern about others
- SecPriv - Non concern
- SecPriv - Privacy concerns
- Usability - automation confusion
- Usability - complexity
- Usability - discoverability/naming
- Usability - install barrier
- Usability - need phone
- Usability - setup difficulty
- Utility - automation
- Utility - general convenience
- Utility - provides security
- Utility - remote control
- Utility - time cost

# PAC it up: Towards Pointer Integrity using ARM Pointer Authentication\*

## Abstract

Run-time attacks against programs written in memory-unsafe programming languages (e.g., C and C++) remain a prominent threat against computer systems. The prevalence of techniques like return-oriented programming (ROP) in attacking real-world systems has prompted major processor manufacturers to design hardware-based countermeasures against specific classes of run-time attacks. An example is the recently added support for *pointer authentication* (PA) in the ARMv8-A processor architecture, commonly used in devices like smartphones. PA is a low-cost technique to authenticate pointers so as to resist memory vulnerabilities. It has been shown to enable practical protection against memory vulnerabilities that corrupt return addresses or function pointers. However, so far, PA has received very little attention as a general purpose protection mechanism to harden software against various classes of memory attacks.

In this paper, we use PA to build novel defenses against various classes of run-time attacks, including the first PA-based mechanism for data pointer integrity. We present PARTS, an instrumentation framework that integrates our PA-based defenses into the LLVM compiler and the GNU/Linux operating system and show, via systematic evaluation, that PARTS provides better protection than current solutions at a reasonable performance overhead.

## 1 Introduction

Memory corruption vulnerabilities, such as buffer overflows, continue to be a prominent threat against modern software applications written in memory-unsafe programming languages, like C and C++. These vulnerabilities can be exploited to overwrite data in program memory. By overwriting control data, such as code pointers and return addresses, attackers can redirect execution to attacker-chosen locations. *Return-oriented programming* (ROP) [35] is a well known technique that allows the attacker to leverage

corrupted control-data and pre-existing code sequences to construct powerful (Turing-complete) attacks without the need to inject code into the victim program. By overwriting non-control data, such as variables used for decision making, attackers can also influence program behavior without breaking the program's *control-flow integrity* (CFI) [1]. Such attacks can cause the program to leak sensitive data or escalate attacker privileges. Recent work has shown that non-control-data attacks can also be generalized to achieve Turing-completeness. Such *data-oriented programming* (DOP) attacks [16] are difficult to defend against, and are an appealing attack technique for future run-time exploitation.

Software defenses against run-time attacks can offer strong security guarantees, but their usefulness is limited by high performance overhead, or requiring significant changes to system software architecture. Consequently, deployed solutions (e.g., Microsoft EMET [26]) trade off security for performance. Various hardware-assisted defenses in the research literature [15, 42, 41, 14, 38, 40, 28, 32] can drastically improve the efficiency of attack detection, but the majority of such defenses are unlikely to ever be deployed as they require invasive changes to the underlying processor architecture. However, the prevalence of advanced attack techniques (e.g, ROP) in modern run-time exploitation has prompted major processor vendors to integrate security primitives into their processor designs to thwart specific attacks efficiently [17, 29, 31]. Recent additions to the ARMv8-A architecture [3] include new instructions for *pointer authentication* (PA). PA uses cryptographic message authentication codes (MACs), referred to as *pointer authentication codes* (PACs), to protect the integrity of pointers. However, PA is vulnerable to *pointer reuse* attacks where an authenticated pointer is substituted with another [31]. Practical PA-based defenses must minimize the scope of such substitution.

**Goals and Contributions** In this work, we further the security analysis of ARMv8-A PA by categorizing pointer

Extended version of this article is available as a technical report [24].

reuse attacks, and show that PA enables practical defenses against several classes of run-time attacks. We propose an enhanced scheme for *pointer signing* that enforces *pointer integrity* for all code and data pointers. We also propose *run-time type safety* which constrains pointer substitution attacks by ensuring the pointer is of the correct type. Pointer signing and run-time type safety are effective against both control-flow and data-oriented attacks. Finally, we design and implement *Pointer Authentication Run-Time Safety* (PARTS), a compiler instrumentation framework that leverages PA to realize our proposed defenses. We evaluate the security and practicality of PARTS to demonstrate its effectiveness against memory corruption attacks. Our main contributions are:

- *Analysis*: A categorization and analysis of pointer reuse and other attacks against ARMv8-A pointer authentication (Section 3).
- *Design*: A scheme for using *pointer integrity* to systematically defend against control-flow and data-oriented attacks, and *run-time type safety*, a scheme for guaranteeing safety for data and code pointers at run-time (Section 5).
- *Implementation*: PARTS, a compiler instrumentation framework that uses PA to realize data pointer, code pointer, and return address signing (Section 6).
- *Evaluation*: Systematic analysis of PARTS showing that it has a reasonable performance overhead (< 0.5% average overhead for code-pointer and return address signing, 19.5% average overhead for data-pointer signing in nbench-byte (Section 7)) and provides better security guarantees than fully-precise static CFI (9).

We make the source code of PARTS publicly available at <https://github.com/pointer-authentication>.

## 2 Background

### 2.1 Run-time attacks

Programs written in memory-unsafe languages are prone to memory errors like buffer-overflows, use-after-free errors and format string vulnerabilities [39]. Traditional approaches for exploiting such errors by corrupting program code have been rendered largely ineffective by the widespread deployment of measures like data execution prevention (DEP). This has given rise to two new attack classes: *control-flow attacks* and *data-oriented attacks* [11].

#### 2.1.1 Control-flow attacks (on ARM)

Control-flow attacks exploit memory errors to hijack program execution by overwriting code pointers (function return addresses or function pointers). Corrupting a code pointer can cause a control-flow transfer to anywhere in executable memory. Corrupting the return address of a function can be

used for ROP attacks, which are feasible on several architectures, including ARM [19].

ARM processors, similar to other RISC processor designs, have a dedicated Link Register (LR) that stores the return address. LR is typically set during a function call by the Branch with Link (b1) instruction. An attacker cannot directly influence the value of LR, as it is unlikely for a program to contain instructions for directly modifying it. However, nested function calls require the return address of a function to be stored on the stack before the next function call replaces the LR value. While the return address is stored on the stack, an attacker can use a memory error to modify it to subsequently redirect the control flow on function return. On both x86 and ARM, it is possible to perform ROP attacks without the use of return instructions. Such attacks are collectively referred to as *jump-oriented programming* (JOP) [9].

Control-flow integrity (CFI) [1] is a prominent defense technique against control-flow attacks. The goal of CFI is to allow all the control flows present in a program’s control-flow graph (CFG), while rejecting other flows. Widely deployed CFI solutions are less precise than state-of-the-art solutions presented in scientific literature.

#### 2.1.2 Data-oriented attacks

In contrast to control-flow attacks, *data-oriented attacks* can influence program behavior without the need to modify code pointers. Instead, they corrupt variables that influence the program’s decision making, or leak sensitive information from program memory. Such attacks are called *non-control-data attacks*. Chen et al [11] demonstrated a variety of non-control-data attacks for forging user credentials, changing security critical configuration parameters, bypassing security checks, and escalating privileges. Recent work on DOP [16] showed that non-control-data corruption can also enable expressive attacks without compromising control-flow integrity. DOP may compromise the input of individual program operations and chain together a chosen sequence of operations to achieve the intended functionality.

A data-oriented attack can in principle corrupt arbitrary program objects, but corrupting data pointers is often the preferred attack vector [12]. In Chen et al.’s attack against the GHTTPD web server [11], a stack buffer overflow is used to corrupt a data pointer used in input string validation in order to bypass security checks on the input under the attacker’s control. Data pointers are also routinely corrupted in heap exploitation. For instance, the “*House of Spirit*” attack on Glibc<sup>1</sup>, involves corrupting a pointer returned by `malloc()` to trick subsequent `malloc()` calls into returning attacker controlled memory chunks. The DOP attacks in [16] also involve the corruption of pointers as a means to control which data is processed by vulnerable code.

<sup>1</sup>Team Shellphish repository of educational heap exploitation techniques: <https://github.com/shellphish/how2heap>

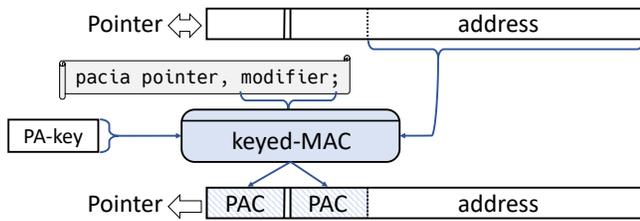

Figure 1: The PAC is created using key-specific PA instructions (*pacia*) and is a keyed MAC calculated over the pointer address and a modifier.

## 2.2 ARM Pointer Authentication

ARMv8.3-A includes a new feature called *pointer authentication* (PA). PA is intended for checking the integrity of pointers with minimal size and performance impact. It is available when the processor executes in 64-bit ARM state (AArch64). PA adds instructions for creating and authenticating *pointer authentication codes* (PACs). The PAC is a tweakable message authentication code (MAC) calculated over the pointer value and a 64-bit *modifier* as the tweak (Figure 1). Different combinations of key and modifier pairs allow domain separation among different classes of authenticated pointers. This prevents authenticated pointer values from being arbitrarily interchangeable with one another.

The idea of using of MACs to protect pointers at run-time is not new. *Cryptographic CFI* (CCFI) [25] uses MACs to protect control-flow data such as return addresses, function pointers, and vtable pointers. Unlike ARMv8-A PA, CCFI uses hardware-accelerated AES for speeding up MAC calculation. Run-time software checks are needed to compare the calculated MAC to a reference value. PA, on the other hand, uses either QARMA [5] or a manufacturer-specific MAC, and performs the MAC comparison in hardware.

64-bit ARM processors only use part of the 64-bit address space for virtual addresses (Figure 2). The PAC is stored in the remaining unused bits of the pointer. On a default AArch64 Linux kernel configuration with 39 bit addresses and without address tagging [3, D4.1.4], the PAC size is 24 bits. However, depending on the memory addressing scheme and whether address tagging is used, the size of the PAC is between 3 and 31 bits [31]. Security implications of the PAC size are discussed in Section 9.

PA provides five different keys for PAC generation: two for code pointers, two for data pointers, and one for generic use. The keys are stored in hardware registers configured to be accessible only from a higher privilege level: e.g., the kernel maintains the keys for a user space process, generating keys for each process at process exec. The keys remain constant throughout the process lifetime, whereas the modifier is given in an instruction-specific register operand on each PAC creation and authentication (i.e., MAC verification). Thus it can be used to describe the run-time context in

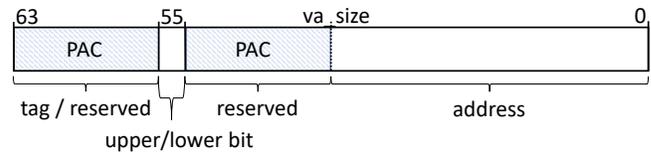

Figure 2: Pointer layout on 64-bit ARM. The PAC is stored in the reserved bits, and its size depends on the used virtual address range. If pointer tagging is disabled, then the PAC can also extend to the tag bits.

which the pointer is created and used. The modifier value is not necessarily confidential (see Section 4) but ideally such that it 1) precisely describes the context of use in which the pointer is valid, and 2) cannot be influenced by the attacker.

PA is used by instrumenting code with PAC creation and authentication instructions. PA instruction mnemonics are generally prefixed either with *pac* or *aut* for creation and authentication, respectively, followed by two characters that select one of the data or code keys. For instance, the *pacia* instruction in Figure 1 will generate an authenticated pointer (*pac*) based on the instruction (i) A-key (a). Table 5 in Appendix C provides a list of PA instructions referred to in this paper. An authenticated pointer cannot be used directly, as the PAC embedded in the pointer value intentionally interferes with address translation. The corresponding PA authentication instruction (in this case, *autia*) removes the PAC from the pointer if authentication is successful, i.e., if the current pointer value, key and modifier for *autia* yields a PAC that matches the PAC embedded in the pointer. If authentication fails, the pointer is invalidated such that a dereference or call using the pointer will cause a memory translation fault. Dedicated PA instructions are encoded in NOP space; older processors without PA support will ignore them.

**Return address signing.** Qualcomm’s return address signing scheme [31] is the first to make use of ARMv8-A PA. It was first introduced in Linaro’s GCC toolchain, but has been supported by mainline GCC since version 7.0<sup>2</sup>. It thwarts attacks that manipulate function return addresses through stack corruption (see Section 2.1.1) by ensuring that the return address in LR always contains a PAC when written to or retrieved from memory. Listing 1 shows an example.

The instrumentation adds *paciasp* (①) at beginning of the function prologue, before the LR value is stored on the stack. *paciasp* adds a PAC tag using the current Stack Pointer (SP) value as the modifier. Before function return, *autiasp* (②) authenticates the pointer and either removes the PAC or invalidates the pointer. An alternative is to use the combined *autiasp+ret* instruction, *retaa*, but it is not backwards-compatible with older processors.

<sup>2</sup>GCC return address signing and PA support is based on patches provided by ARM, <https://github.com/gcc-mirror/gcc/commit/06f29de13f48f7da8a8c616108f4e14a1d19b2c8>

```

function :
  paciasp          ; ① create PAC
  stp FP, LR, [SP, #0] ; store LR
  ; ...
  ldp FP, LR, [SP, #0] ; load LR
  autiasp         ; ② authenticate
  ret             ; return

```

Listing 1: Return address signing using PA. At function entry, `paciasp` is used to create a PAC in LR (①). The value is then authenticated with `autiasp` before return (②).

The PAC cryptographically binds the return address to the current SP value. It is valid only when authenticated using the same SP value as on PAC creation. The goal is to limit the validity of the PAC to the function invocation that created it, thus preventing reuse of authenticated return addresses.

### 3 Attacks on Pointer Authentication

PA prevents an attacker from injecting or forging pointer values. This effectively prevents any attack that relies on corrupting pointers, resisting even attackers with *arbitrary access to program memory*.

The modifier value used in computing a PAC can depend on both static (e.g., a hard-coded value) and dynamic (e.g., the SP) information. We assume that the program code itself is not confidential and that the attacker can learn how dynamic modifiers are generated and may infer their values.

PA also relies on the security of the underlying cryptographic primitives. In particular, an attacker may attempt to brute-force either the PA keys themselves, or individual PAC values. Sophisticated adversaries may even attempt cryptanalysis attacks based on known PAC values, or side-channels attacks against the hardware circuitry for computing PACs. The security of the QARMA block cipher has already been analyzed [43, 23]. We leave the scrutiny of the cryptographic building blocks outside the scope of this paper. Nevertheless, the limited PAC size means that guessing attacks are a potential concern. We discuss the feasibility of brute-forcing PACs in Section 7.2.4. Assuming proper precautions for the lifetime of PA keys (see Section 2.2), we do not consider guessing attacks the primary attack vector against PA. However, the following concerns for the security of PA-based defenses remain: 1) an attacker controlling the creation of PAC values, or 2) an attacker *reusing* previously authenticated pointers.

**Malicious PAC generation.** Attackers can potentially control PAC values in three ways, by controlling:

1. *the unauthenticated pointer value before PAC creation:* get an arbitrary authenticated pointer for any context with the same modifier and PA key.
2. *control the PA modifier value:* get an authenticated pointer for a context with the same PA key, but with an attacker-chosen modifier.
3. *both:* get arbitrary authenticated pointers for a context with attacker-chosen modifier, and the same PA key.

To prevent the attacker from generating arbitrary authenticated pointers, the program must not contain PA creation instructions with attacker controlled inputs. Also, a control-flow attack could be mounted by chaining together instruction sequences to prepare the PA operand registers with attacker controlled input and then jump to a PA instruction at another part of the program. This suggests that PA-based defenses *must provide, or be combined with, CFI guarantees* that prevent the use of individual authentication instructions as attacker-controlled gadgets.

**Reuse attacks.** The attacker can read authenticated pointers (including PAC values), and later reuse them to either:

- *rollback* an authenticated pointer to a previous value, or
- *substitute* an authenticated pointer with another using the same PA modifier.

For instance, in GCC’s return address signing scheme (Section 2.2), the return address is bound to the location of the stack frame by using the current SP value as the PA modifier. However, the SP value is not necessarily unique to a specific function invocation. Consequently, an attacker can reuse the authenticated return addresses value from one function when a different vulnerable function executes with a matching SP value. Given that typical programs offer no guarantees on the uniqueness of SP values between different function invocations, this approach exposes a large attack surface for pointer reuse attacks. Therefore, a concern for any PA-based defense is partitioning authenticated pointers into distinct classes based on different <PA key, modifier> pairs.

Attackers can reuse only those pointers they can observe (as opposed all possible values a function pointer can take). Even with full read access to memory (and hence the ability to observe any pointer value that has been generated so far), attackers are still limited to authenticated pointer values the program has already generated.

## 4 Adversary Model and Requirements

### 4.1 Pointer Integrity

Kuznetsov et al. [21] introduced the idea of *code pointer integrity*: ensuring precise memory safety for all code pointers in a program. Since control-flow attacks depend on the

manipulation of code pointers, guaranteeing code pointer integrity will render *all* control-flow attacks impossible [21].

The notion of *pointer integrity* is generalizable to both code and data pointers. In Section 9.1, we provide a more rigorous definition of pointer integrity. Intuitively, pointer integrity aims to prevent unintentional changes to pointers while they remain in program memory so that the value of a pointer at the time it is “used” (e.g., dereferenced or loaded from memory) is the same as when it was created or stored on memory. In particular, integrity-protected pointers reference the intended target objects. As explained in Section 2.1, all control-flow attacks, all known DOP attacks and many other data-oriented attacks rely on the manipulation of vulnerable pointers. Consequently, ensuring pointer integrity will prevent these attacks.

## 4.2 Attacker Capabilities

To reason about how effectively PA defends against state-of-the-art attacks we assume attacker capabilities consistent with prior work on run-time attacks (Section 2.1). Our adversary model assumes a powerful attacker with arbitrary memory read and write capabilities restricted only by DEP. The attacker can thus read any program memory and write to non-code segments. We further assume that the attacker has no control of higher privilege levels, i.e., an attacker targeting a user space process cannot access the kernel or higher privilege levels. Specifically, we assume that the attacker cannot infer the PA keys, as they are in registers not directly readable from user space (Section 2.2). We discuss protection of kernel code using PA in Section 10. The attacker’s ability to read arbitrary memory precludes the use of randomization-based defenses that cannot withstand information disclosure (e.g., address space layout randomization [36] or software shadow-stacks [1]). PA was specifically designed to remain effective even when the entire memory layout of the victim process is known.

## 4.3 Goal and Requirements

Our goal is to thwart control-flow and data-oriented attacks by preventing the attacker from forging pointers used by a vulnerable program. We identify the following requirements that our solution should satisfy:

- R1** *Pointer Integrity*: Detect/prevent the use of corrupted code and data pointers.
- R2** *PA-attack resistance*: Resist attempts to control PAC generation, and pointer reuse attacks.
- R3** *Compatibility*: Allow protection of existing programs without interfering with their normal operation.

- R4** *Performance*: Minimize run-time and memory overhead and gracefully scale in relation to the number of protected pointers and dereferences/calls.

## 5 Design

To meet our requirements (Section 4.3) we must solve a number of challenges which we elaborate below.

### 5.1 Instrument program with PA instructions

To meet requirement **R1**, the program executable must be instrumented with PA instructions to create and authenticate PACs when needed. For this, we designed and implemented *Pointer Authentication Run-Time Safety* (PARTS), a compiler enhancement that emits PA instructions to sign pointers in memory as required. Specifically, it protects:

- return addresses;
- local, global and static pointers; and
- pointers in C structures.

Figure 3 shows the overall architecture of the PARTS-enhanced compiler. PARTS analyzes the compiler’s intermediate representation (IR) to identify any pointers used by the program and then emits PA instructions at points in the program where pointers are (a) created or stored in memory, and (b) loaded from memory or used.

### 5.2 Create PACs in statically allocated data

Programs may contain pointers which are initialized by the compiler, e.g., defined global variables. However, PAC values for authenticated pointers cannot be calculated before program execution, as PA keys are set only at program launch. Consequently, initialized pointers in the program’s data segment pose a challenge, as their values are normally initialized by the linker and loaded into memory separately. PARTS solves this problem by generating a custom initializer function for pointers requiring PACs. At run-time, the PARTS runtime library, PARTSlib, processes the relocated variables and invokes the generated initializer function to ensure that any defined pointers are furnished with a PAC.

### 5.3 Pointer compartmentalization

As described in Section 3 the attacker may attempt to reuse previously signed pointers. To meet requirement **R2** PARTS therefore limits the scope of such reuse attacks by compartmentalizing pointers in three different ways, as shown in Table 1.

*Code / Data Pointer Compartmentalization*: Recall from Section 2.2, that PA provides separate key sets for data and code pointers making it possible to limit reuse attacks.

Table 1: For code and data pointers PARTS uses a static PA modifier based on the pointer’s *ElementType* as defined by LLVM. Return address signing uses a 48-bit `function-id` and the 16 most-significant bits of the SP value.

		key	Modifier type	Modifier construction
①	Data pointer signing	Data A	static	<code>type-id = SHA3(ElementType)</code>
②	Code pointer signing	Instr A	static	<code>type-id = SHA3(ElementType)</code>
③	Return address signing	Instr B	dynamic + static	<code>SP   function-id = compile-time nonce</code>

*Run-time type safety:* Pointer compartmentalization, while effective, is coarse-grained. To address this, PARTS adds run-time type safety for data and code pointers. Run-time type safety records the pointer’s type by encoding it in the PA modifier. Then, it checks that pointer dereferences or indirect calls take place using a pointer with a recorded type that matches the type expected at the use site. PARTS assigns pointers a unique id, `type-id`, based on the pointer’s LLVM *ElementType* which depends on the pointed-to data, structure, or function signature. Two pointers are *compatible* (have the same `type-id`) if their *ElementType* is the same. PARTS uses a deterministic scheme, detailed in Section 6.1 and shown in Table 1, to calculate `type-ids` during compilation. This ensures that separate compilation units generate equivalent `type-ids` for compatible objects, and different `type-ids` for non-compatible ones.

*Improved Return Address Signing:* While run-time type safety could also be applied for return addresses, it would result in an over-permissive policy for backward edges. As described in Section 3, binding the authenticated return address to the current stack pointer value alone is insufficient because the stack pointer may not be unique to a specific function invocation. Instead, PARTS uses a combination of the current stack pointer value, and a compile-time nonce (`function-id`) ensuring that the authenticated return address cannot be reused across invocations of *different functions*, while the stack pointer values effectively compartmentalizes return addresses to callers with different stack layouts.

## 5.4 On-load data pointer authentication

Pointers with PACs can be authenticated either as they are loaded from memory, or immediately before they are used. We refer to these as *on-load* and *on-use* authentication, respectively. Data pointers are often dereferenced frequently without intervening function calls, i.e., they will not be cleared after use. This allows the compiler to optimize memory accesses such that, for instance, temporary values might never be written to memory. PARTS accommodates this behavior by only using on-load authentication for data pointers. The combined PA instructions can be used for on-use authentication of code pointers, which are typically loaded to a register, used once, and cleared. On-load authentication always uses the standalone authentication instructions. An

attacker could attempt to exploit either the standalone authentication or the separate pointer dereference by diverting control flow to either. However, as mentioned in Section 3, PA solutions must be combined with CFI guarantees, which prevent this type of attacks.

## 5.5 Handling pointer conversions

A data pointer to an object of a specific type may be converted to a pointer to a different object type. When run-time type safety is applied to authenticated pointers, special care must be taken to not interfere with legitimate pointer conversions to meet requirement [R3](#). For instance, if a struct pointer is cast to a pointer to its first field, it will change the `type-id` and hence the expected PAC.

If the source and destination object types are compatible, no special consideration is needed. If not, PARTS must convert the authenticated pointer to the correct `type-id`. Because data pointer PAC creation and authentication is done at store/load, PARTS handles conversions by; (a) if loading the pointer from memory, validating and stripping the PAC using the `type-id` of the original object, and (b) on store, creating a new PAC using the destination object `type-id`.

A pointer to a function of one type may be converted to a pointer to a function of another type. However, the behavior when calling a function pointer cast to a non-compatible type is undefined [\[18\]\[6.3.2.3§8\]](#). Hence, PARTS does not need to convert the pointer’s PAC to match the destination function’s `type-id`. If the converted pointer is converted back, the result is expected to be the same as the original pointer [\[18\]\[6.3.2.3§8\]](#). PARTS satisfies this as it does not modify the pointer’s PAC.

## 6 Implementation

The PARTS compiler is based on LLVM 6.0 but modifies and adds new passes to the optimizer and the AArch64 backend (Figure 3). The optimization passes (❶) generate necessary metadata for PA modifiers, inserts wrappers for compatibility with legacy code, and prepares initializers for statically allocated pointers. The AArch64 Frame Lowering emits function prologues and epilogues and is modified to include instructions for authenticating the LR value (❷). The

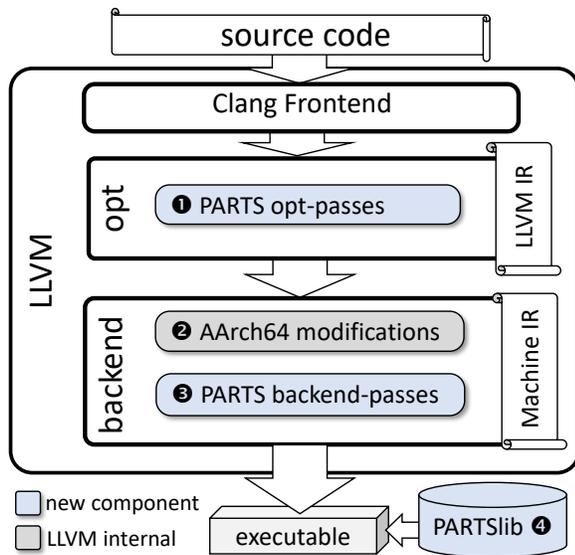

Figure 3: PARTS architecture.

PARTS backend passes (③) retrieve the PA modifiers and instruments appropriate low-level instructions. The resulting binary is linked with PARTSlib (④), which at run-time creates PACs for the initialized pointers.

## 6.1 LLVM Compiler Integration

While the LLVM 6.0 AArch64 backend recognizes PA instructions, they are not used by any pre-existing security feature. Our modifications consist of added optimizer and backend passes, minor modifications to the AArch64 backend, and new PARTS-specific intrinsics. Where applicable, we use optimizer passes that operate on the high-level LLVM *intermediate representation* (IR). Nonetheless, much of the needed functionality is PA-specific and thus implemented in the backend that uses low-level LLVM *machine IR* (MIR), and a register- and instruction set specific to 64-bit ARM.

**Determining pointer type-id.** The compiler backend views the program from a low-level perspective, and the MIR has lost much of the semantics present in C or the high-level IR. Therefore, PARTS must determine type-ids during its optimizer passes where this information is still available (Figure 3, ①). The type-id for data consists of a truncated 64-bit SHA-3 hash of the pointer’s LLVM *ElementType*. The *ElementType* represents the IR level data type and distinguishes between basic data types, but does not retain typedef or other information from the frontend (i.e., clang). Code pointers use the same scheme wherein the *ElementType* consists of the function signature at the same abstraction level. The type-ids are passed to the backend either via PARTS-specific compiler intrinsics, or by embedding them as metadata in the existing IR instructions. The

AArch64 instruction selection retrieves the information from the IR instructions and transfers it to the emitted MIR (Figure 3, ②). To facilitate the run-time bootstrap (Section 6.2) PARTS also includes a pass that prepares a custom initializer function that is called at run-time to generate PACs for defined global pointers (Figure 3, ①).

**Return addresses signing.** Return address signing is implemented in the AArch64 backend during frame lowering (Figure 3, ②). Frame lowering emits the function prologues and epilogues, and for non-leaf functions, emits instructions for storing and retrieving the LR value from the stack. PARTS authenticates the value of the LR only if it was retrieved from the stack. The PAC modifier is based on the 16 least-significant bits of the SP value and a 48-bit function-specific function-id. The function-id is guaranteed to be unique within the current compilation unit or, with link time optimization (LTO), the whole program. To avoid repetition across different compilation units, the function-id is generated using a pseudorandom, non-repetitive sequence.

**Code pointer signing.** PARTS uses the combined PA instructions for branches and converts branch instructions directly to their PA variants (Figure 3, ③). The PAC for any code pointer is created only once at the time of pointer creation, e.g., when the address of a function is taken. This is instrumented by adding a PAC-creation instruction immediately after the instruction that moves a code pointer to a register. Subsequent load and store operations do not authenticate the signed code pointers, instead they are authenticated only on use.

**Data pointer signing.** As discussed in Section 5.4, it is not feasible to perform on-use authentication for data pointers. Instead, we authenticate data pointers when they are loaded from memory and create PACs before storing them. In some cases, e.g., using globals, the IR will include explicit load and store operations that can be furnished with the type-id. Our modified Instruction Selection then forwards the type-id to the emitted MIR (Figure 3, ②). However, stack-based store and load operations, in particular, are often not present before the backend finalizes the stack-layout and register allocation. Thus, some load and store instructions must be instrumented solely in the backend.

While it would be possible to modify the AArch64 backend (e.g., register allocation), we have instead opted for a less invasive approach. The PARTS backend pass (Figure 3, ③) finds load and store instructions in the MIR, and uses the attached type-id for instrumentation. When the type-id is not present, e.g., because the load and store is a register spill, the type-id is fetched from surrounding code. For instance, when instrumenting the store due to register spilling

```

MACRO movFunctionId Mod
  movk Mod, #func_id16 , lsl #16
  movk Mod, #func_id32 , lsl #32
  movk Mod, #func_id48 , lsl #48
ENDM

function :
  mov Xd, SP ; ① get SP
  movFunctionId Xd ; ② get id
  pacib LR, Xd ; ③ PAC
  stp FP, LR, [SP, #0] ; store
  ; function body
  ldp FP, LR, [SP, #0] ; load LR
  mov Xd, SP ; ⑤ get SP
  movFunctionId Xd ; ④ get id
  autib LR, X ; ⑥ auth
  ret

```

Listing 2: The PARTS return address signing binds the PAC to the SP (①,⑤) and unique function id (②,④). The PA modifier is in register Xd during PAC creation (③) and authentication (⑥). The 48-bit func-id is split into three 16-bit parts, each moved individually to Xd by left-shifting.

a pointer variable, the correct type-id can be fetched from the original load.

## 6.2 Run-time Bootstrap

Programs may contain pointers in statically allocated data, i.e., pointers stored in global variables or static local variables. These are initialized by the compiler or linker, and therefore cannot include PACs. The PARTSlib runtime library instead invokes the compiler generated custom PAC initializer function at process startup. Our Proof-of-Concept implementation invokes the PARTSlib bootstrap using compiler instrumentation that explicitly calls the functionality when entering `main`.

## 6.3 Instrumentation

PARTS uses only in-line instrumentation and does not require storage of separate run-time metadata. With the exception of the bootstrap process the original code structure is thus largely unchanged. As discussed in Section 2.2, no explicit error handling is added by PARTS; instead, an authentication failure will set specific high-order bits in the pointer, thus triggering a memory translation fault on subsequent dereference or call using the pointer that failed authentication. The high-order bits ensure that the fault is distinguishable as one caused by authentication failure. Our code listings use two macros for setting up PA modifiers for

```

MACRO movTypeId Mod
  mov Mod, #type_id00
  movk Mod, #type_id16 , lsl #16
  movk Mod, #type_id32 , lsl #32
  movk Mod, #type_id48 , lsl #48
ENDM

mov cPtr, #instr_addr ; load cPtr
movTypeId Xd ; ① get id
pacia cPtr, Xd ; ② PAC
; no intermediate cPtr instrumentation
movTypeId Xd ; ③ get id
blraa cPtr, Xd ; ④ branch

```

Listing 3: The PARTS forward-edge code pointer signing uses the code pointer’s type-id as the PA modifier (①,③). The 64-bit type-id is split into four 16-bit parts. The PAC is created only once when initially creating the code pointer (②). Upon use, i.e., indirect call, the PAC is authenticated using the combined branch and authenticated instruction (④). PARTS does not instrument intermediate store/load operations.

return address signing and type-id based PACs, these are shown in Listing 2 and Listing 3.

**Return address signing.** The return address signing instrumentation is similar to GCC’s implementation [31] but includes an added modifier (Listing 2). The function prologue is instrumented such that it prepares the PA modifier by moving SP (①) value into a free register. The SP value is combined with the `function-id` (②) to form the PA modifier, which is then used with the instruction B key (③). The `function-id` is generated at compile-time using LLVM’s random number generator, and is guaranteed to be unique within the LLVM Module (i.e., the whole program, when using link time optimization). The function epilogues (i.e., any part that ends with a return or a tail-call) are similarly instrumented to generate the same PA modifier (④,⑤) and to verify the PAC in the restored LR (⑥).

**Code pointer signing.** PARTS instruments code pointers only on creation and use (Listing 3). Specifically, when a code pointer is initially created, PARTS will use the instruction A-key to create a PAC (②) based on the target type-id (①). The instrumentation will at no point remove the PAC from a code pointer. Instead, PARTS uses the combined authenticate and branch instructions — e.g., `blraa` — to perform the branch directly on an authenticated pointer (④), again using the same PA modifier (③).

```

ldr  dPtr, [SP, #0] ; load dPtr
movTypeId Xd, #type_id ; ① get id
autda dPtr, Xd ; ② authenticate
; dPtr is directly usable

```

Listing 4: PARTS immediately authenticates data pointers loaded from writeable memory. This is done by first loading the type-id (①) and then verifying the PAC (②).

**Data pointer signing.** All data pointer stores and loads are instrumented such that a PAC is created immediately before store and authenticated immediately after load (Listing 4). When a data-pointer is used the instrumentation first sets up the correct PA modifier, i.e., the type-id (①). The pointer is then immediately authenticated using the modifier and data A-key (②); this also strips the PAC from the pointer. As long as the data pointer resides in a register it can thus be used without any performance overhead. PARTS creates PACs for pointers immediately before store in the same manner, save for the pacda instruction.

## 7 Evaluation

We develop our Proof-of-Concept implementation of PARTS on the ARMv8-A Base Platform Fixed Virtual Platform (FVP), based on Fast Models 11.4, which supports version 8.0 to 8.4 of the ARMv8-A architecture [4]. At the time of writing, the only PA-capable hardware is the Apple A12 and S4 SoCs featuring ARMv8.3-A CPUs [2]. However, these proprietary SoCs are, to the best of our knowledge, not available in development versions outside Apple. The FVP provides a software simulation of an ARMv8.3-A processor in AArch64 mode, and is, to the best of our knowledge, the only publicly available environment with ARMv8-A PA support.

### 7.1 ARMv8.3 Emulation and Software Stack

We use GNU/Linux with a 4.14 kernel, modified to support PA. We modified the bootloader and kernel to activate ARMv8-A PA, and allow key configuration during kernel scheduling at Exception Level 1 (EL1 in Figure 4). Our kernel modifications are based on Mark Rutland’s 2018 PA patches<sup>3</sup>.

PA keys for each task are stored in a process-specific `mm_context_t` structure (in the process’ memory descriptor in the kernel) which contains architecture-specific data related to the process address space. Threads within the same process have a common memory descriptor, and thus share the same PA keys. The scheduler will configure the PA key registers using the keys in the process’ memory descriptor

<sup>3</sup><https://lwn.net/Articles/752116/>

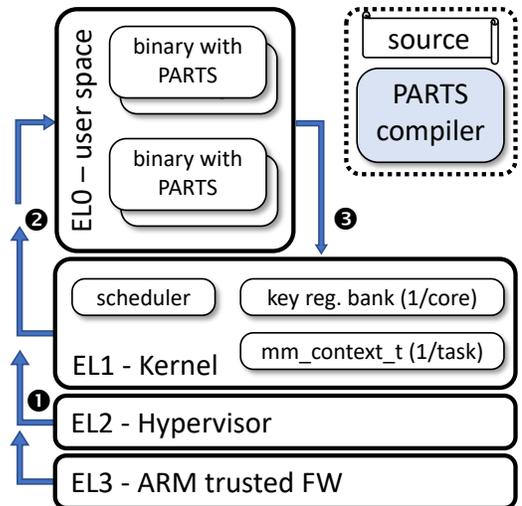

Figure 4: The trapping of PA configuration must be released ①, in order to allow the kernel to manage the PA keys on process creation and context switches ②. Faults generated by failed authentications will be trapped by the kernel ③.

whenever a task is scheduled to run. When a new child process is forked, the parent’s keys are duplicated to the child’s memory descriptor. However, when a new executable file is exec’d in the context of an existing process, the kernel initializes a new set of PA keys using `get_random_bytes()`. In other words, each new process receives a new set of PA keys which remain unchanged thereafter.

## 7.2 Security Evaluation

### 7.2.1 Return address signing

Return address signing in both GCC [31], and PARTS prevents an attacker from introducing forged return addresses to the program stack. Compared to GCC, PARTS augments the PA modifier used for return address signing by combining a function-specific identifier with the SP value (`R2`). As a result, PARTS return address signing precludes the possibility of reuse of the return address between different functions, irrespective of SP value collisions. It remains susceptible to pointer reuse between distinct invocations of the same function from call sites with same SP value (`R1`).

### 7.2.2 Forward-edge code pointer signing

As with PARTS return address signing, forward-edge code pointer signing prevents an attacker from using forged code pointers injected into program memory (`R1`). This prevents a large class of attacks (e.g., typical ROP/JOP gadgets) that rely on redirecting the control flow to code in the middle of functions, i.e., addresses that never were valid targets of benign control-flow transfers.

PARTS restricts forward-edge code pointer reuse by enforcing *run-time type safety* for signed pointers (R2). Under this scheme, pointers used in a pointer reuse attack must share the same `type-id` (i.e., have a matching type on the LLVM IR level). This prevents large classes of function-reuse attacks. The solution is compatible with common programming patterns involving function pointers (R3), such as callbacks, but allows reuse between code pointers to functions with identical type signatures.

### 7.2.3 Data pointer signing

PARTS data pointer signing protects all data pointers and prevents an attacker from loading a forged data pointer to program memory (R1). This prevents all non-control data attacks that rely on corrupting data pointers to unintended parts of memory. This class of attacks includes all currently known DOP attacks [16].

PARTS restricts data pointer reuse by enforcing run-time type safety also for data pointers (R2). Reuse attacks would be more useful to an attacker if they could substitute a vulnerable pointer with one referencing an object of different size or type. Therefore restricting pointer substitution based on the pointer's type restricts the attacker's capability to cause unintended data flows within the program. However, pointer conversions are a challenge for data pointer integrity. As discussed in Section 5.3, PARTS accommodates data pointers that are cast from type *A* to an incompatible type *B* by writing the converted pointer using the `type-id` of *B*. This may expand the effective set of reusable pointers under our threat model; the attacker can record pointers of type *A* and reuse them at PAC conversion site  $A \rightarrow B$ , thereby obtaining a pointer of type *B* to an object of type *A*. This converted pointer can then be used at de-reference sites that require pointers of type *B*. If the program also includes a conversion from *B* to *A* this makes both types interchangeable.

PARTS data pointer integrity does not guarantee spatial safety of pointer accesses to data objects, nor does it address the temporal safety (e.g., prevent use-after-free conditions). ARMv8-A PA does not provide facilities to directly address these challenges. We discuss orthogonal schemes that can be used in combination with PARTS to provide spatial and temporal safety guarantees in Section 8.

### 7.2.4 PAC entropy

As explained in Section 3, the PAC size *b* is a concern for any PA-based scheme. On typical AArch64 Linux systems, *b* is between 16 and 24. To succeed with probability *p*, a PAC guessing attack requires  $\frac{\log(1-p)}{\log(1-2^{-b})}$  guesses on the assumption that a PAC comparison failure leads to program termination. On our simulator setup where *b* = 16, achieving a 50%-likelihood for a correct guess requires 45425 attempts.

Note that ROP/DOP attacks require an environment where a set of jumps (gadgets) can be set up, each requiring a separate PAC to be broken. Consequently, success probability of a complete attack will decrease exponentially with the number of jumps necessary.

Pre-forked or multithreaded programs will share the same PA key between the parent and all sibling threads/processes. This could allow an attacker to brute force a PAC by targeting a sibling, if PAC failure on a sibling does not result in the termination (and hence PA key reset) of all threads/processes sharing the same PAC key. In this scenario,  $2^{b-1}$  guesses on average are enough to guess a *b*-bit PAC (32768 guesses for *b* = 16). Multithreaded / pre-forking applications could be hardened against guessing attacks by requiring a full application restart if the number of unexpected terminations of child threads/processes exceeds a pre-defined threshold.

## 7.3 Performance Evaluation

The FVP processor, peripheral models, and micro-architectural fabric is simplified. Consequently, timing on the FVP model differs from actual hardware. The ARM Fast Models documentation states that "*all instructions execute in one processor master clock cycle*". We confirm this behavior for PA instructions in the FVP by using microbenchmarks that allow PA instructions to be timed in isolation. As a result, we cannot use the FVP to estimate the expected run-time overhead of PARTS. Instead, we estimate the execution time of PA instructions and develop a PA-analogue that emulates the run-time cost of PA instructions (Section 7.3.1). We then run large-scale benchmarks on real (non-PA) hardware using our PA-analogue (Section 7.3.2).

### 7.3.1 PA-analogue

From [5, Table 8] we can deduce that on a (1.2GHz) mobile core, the PAC is computable with an approximate overhead of 4 cycles, without accounting for the potential speed benefits of opportunistic pipelining or the inclusion of several parallel PAC computing engines per core. For simplicity, we assume equal cycle counts for all PA instructions. Based on this assumption we construct a *PA-analogue* (Listing 5) as a proxy to measure overhead of PA instrumentation on non-PA CPUs: it consists of four exclusive-or (eor) operations to account for the 4 cycles. The final eor operates on the modifier and SP to enforce a memory read/write dependency, thus preventing the CPU pipeline from arbitrarily delaying the operations. We have confirmed that our PA-analogue exhibits the expected overhead using our microbenchmarks.

```

eor Xptr, Xptr, #0x2 ; spend cycles
eor Xptr, Xptr, #0x3 ; to approximate
eor Xptr, Xptr, #0x5 ; PA instruction
eor Xptr, Xptr, Xmod ; overhead

```

Listing 5: PA-analogue simulating PA instructions

### 7.3.2 nbench-byte benchmarks

For our performance evaluation we use the Linux nbench-byte 2.2.3 synthetic benchmark<sup>4</sup> designed to measure CPU and memory subsystem performance, providing a reasonable prediction of real-world system performance<sup>5</sup>. We follow work such as [6, 10, 22, 33, 37, 10] and use nbench rather than the SPEC CPU standardized applications benchmarks for our evaluation, as nbench allows us verify the functionality of PARTS instrumentation with manageable simulation times on the FVP. The current version of the SPEC CPU benchmark suite, SPEC CPU2017<sup>6</sup>, has replaced many tests in the previous, now retired SPEC CPU2006<sup>7</sup> with significantly larger and more complex workloads (up to ~10X higher dynamic instruction counts). As a result, the SPEC simulation times on the FVP proved to be unmanageable; for example, running individual SPEC benchmarks take hours to *days* to complete on the FVP. This is a challenge for both researchers and industry practitioners who rely on hardware simulation for evaluation [30]. We report our results for a subset of SPEC CPU2017 tests in Appendix B.

The nbench benchmarks include 10 different tests. We adopt the same methodology as Brasser et al. [6] and run each test a constant number of iterations for the following cases: a) uninstrumented baseline b) each PARTS scheme (return address signing, forward-edge code pointer integrity, and data pointer integrity) enabled individually, and c) all schemes enabled simultaneously. Compiler optimizations were disabled for all tests. The tests were performed on a 96boards Kirin 620 HiKey (LeMaker version) with a ARMv8-A Cortex A53 Octa-core CPU (1.2GHz) / 2GB LPDDR3 SDRAM (800MHz) / 8GB eMMC, running the Linux kernel v4.18.0 and BusyBox v1.29.2. Figure 5 shows the results, normalized to the baseline. A more detailed description can be found in Appendix A.

Return address signing incurs a negligible overhead of less than 0.5%. This is expected because the estimated per-function overhead of 12 to 16 cycles is typically small compared to the full execution time of the instrumented function. The same holds for indirect calls (6-8 cycle overhead at the call site), although indirect calls are underrepresented in nbench-byte. However, our microbenchmarks for the code

pointer integrity instrumentation indicate that a 6 to 8 cycle overhead per indirect function call is reasonable under the assumed QARMA performance.

Data pointer integrity depends largely on the memory profile of the instrumented program. For instance, the floating point emulation test extensively handles data pointers, resulting in a 39.5% overhead. In contrast, the Fourier and neural network benchmarks contain no data pointers and thus incur no discernible overhead. The geometric mean of the overhead of the combined instrumentation for all tests is 19.5%.

## 7.4 Compatibility Evaluation

Based on our evaluation, PARTS is compatible with standard C code (`R3`). Because return address signing only affects the instrumented function, it can be safely applied without interfering with the operation of other parts of programs, or uninstrumented code.

PARTS forward-edge code pointer integrity and data pointer integrity can be safely applied to complete code bases. However, if PARTS is applied only to a partial code base, the instrumented code interfacing with non-instrumented (legacy) libraries requires special consideration. In particular pointers used by both instrumented and uninstrumented code cannot be passed directly between them. We discuss solutions for backwards compatibility with legacy libraries in Section 10.

We encountered no compatibility issues with PARTS during our performance evaluation with nbench (Section 7.3).

## 8 Related Work

*Code-pointer integrity (CPI)* [21] protects access to code pointers — and data pointers that may point to code pointers — by storing them in a disjoint area of memory; the *SafeStack*<sup>8</sup>. The SafeStack itself must be protected from unauthorized access. Randomizing the location of the SafeStack is efficient [20], but easily defeated by an attacker who can read arbitrary memory. Stronger protection of the SafeStack using hardware-enforced isolation or software-isolation incurs an average performance overhead of 8.4% or 13.8% in SPEC CPU2006 benchmarks.

**Protecting pointers using cryptography.** Prior cryptographic defenses against run-time attacks generally assume the attacker cannot read memory. *PointGuard* [12] instruments a program to apply a secret XOR mask to all pointer values. This prevents an attacker from reliably forging pointer values without knowledge of the mask. *Data randomization* [7] extends data masking to cover all data in memory. It uses static points-to analysis and distinct masks to partition memory accesses in separate classes. Neither

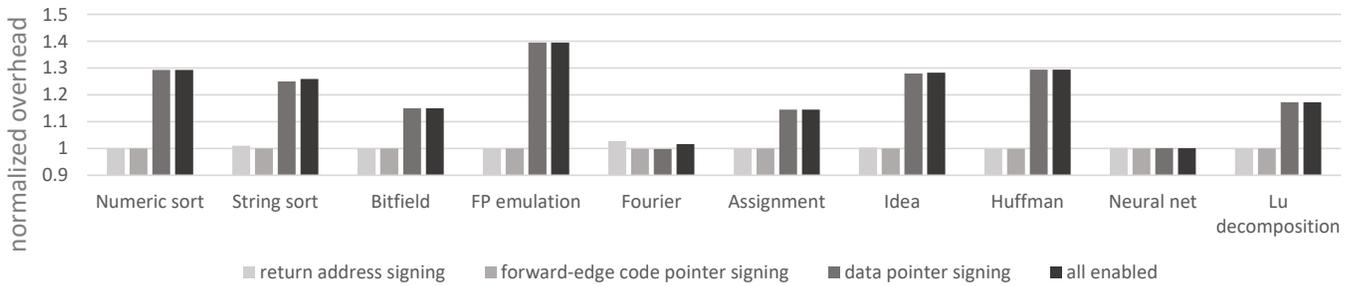

<sup>4</sup><http://www.math.utah.edu/~mayer/linux/bmark.html>

<sup>5</sup><http://www.math.utah.edu/~mayer/linux/byte/bdoc.pdf>

(a) Results of instrumented nbench-byte tests features, normalized to a non-instrumented baseline.

(b) Run-time count of executed locations instrumentable by PARTS. Because the program’s memory profile affects performance the benchmark results clearly correlate with observed memory use (e.g., FP emulation has a large data pointer integrity overhead because it uses many data pointers)

Figure 5: nbench benchmark results

PointGuard nor data randomization remain effective under our threat model.

Similarly to ARMv8-A PA, *Cryptographic CFI* (CCFI) [25] uses MACs to protect control-flow data, such as return addresses, function pointers, and vtable pointers. Like PARTS, CCFI uses a function’s type signature to separate function pointers to distinct protection domains, but does not protect function pointers embedded in C structures. Unlike PA, CCFI only benefits from hardware-accelerated AES for speeding up MAC, resulting in a high performance overhead (52% overhead on average in SPEC CPU2006 benchmarks). In contrast, PARTS also benefits from hardware-accelerated checks by using ARMv8-A PA instructions, protects both code and data pointers, including pointers embedded in C structures.

**Hardware-assisted mechanisms.** Various hardware-assisted defenses are described in research literature [15, 42, 41, 14, 38, 40, 28, 32]. The majority of such defenses have only been realized as soft microprocessor prototypes on FPGAs. Here we describe mechanisms available in commercial off-the-shelf processor architectures.

Only a few commercial processors, such as the SPARC M7<sup>9</sup>, support tagged memory, which can be used to realize variety of security models (including pointer integrity). ARM recently announced support for memory tagging in the

ARMv8.5-A architecture<sup>10</sup>. It enforces that all accesses to memory must be made via a pointer with the correct tag. Pointer tags use the existing address tagging feature in the ARM ISA that partly overlaps with the bits used to store PA PACs, meaning that enabling both features simultaneously reduces the available PAC size by eight bits.

Hardware-assisted memory tagging is designed primarily as a statistical debug aid against use-after-free and other temporal memory errors. *Hardware-Assisted AddressSanitizer* (HWASAN) [34] is an AArch64-specific compiler-based tool that builds upon *AddressSanitizer* (ASAN) — a memory-error detector popular for vetting memory safety bugs during software testing. ASAN can detect both spatial and temporal memory errors. HWASAN can leverage hardware tagged memory, such as SPARC ADI and the upcoming ARMv8.5-A to reduce the performance overhead associated with managing tagged memory checks in software. ASAN / HWASAN are complementary to PARTS, as they provide spatial and temporal safety for data accesses via pointers.

*Intel Memory Protection Extensions* (MPX) is a hardware feature for detecting spatial memory errors that debuted in the Intel Skylake microarchitecture. MPX is similar to the software based SoftBound [27] and its hardware-based predecessor [15]. Although Intel MPX is a hardware-assisted approach specifically designed to provide spatial memory safety guarantees, it is not faster than software-based approaches [29]. It can cause up to 4x slowdown in the worst

<sup>9</sup>[https://swisdev.oracle.com/\\_files/What-Is-ADI.html](https://swisdev.oracle.com/_files/What-Is-ADI.html)

<sup>10</sup><https://community.arm.com/processors/b/blog/posts/arm-a-profile-architecture-2018-developments-armv85a>

case with an average run-time overhead of 50%. It also suffers from other shortcomings, such as the lack of support for multithreading and several common C/C++ idioms. GCC has dropped support for MPX altogether<sup>11</sup>.

**Control-flow integrity.** Carlini et al. [8] define *fully-precise static CFI* as follows: “An indirect control-flow transfer along some edge is allowed only if there exists a non-malicious trace that follows that edge.” In other words, fully-precise static CFI enforces that execution follows a CFG that contains an edge if and only if that edge is exercised by intended program behavior. Fully-precise static CFI is thus the most restrictive *stateless* policy possible without breaking intended functionality. To date, there exist no implementation of fully-precise CFI; all practical implementations are limited by the precision of CFGs obtained through static *control analysis*.

Carlini et al. further show that all stateless CFI schemes, including fully-precise static CFI are vulnerable to *control-flow bending*; attacks where each control-flow transfer is within a valid CFG, but where the program execution trace conforms to no feasible benign execution trace. For instance, in a stateless policy such as fully-precise static CFI, the best possible policy for return instructions (i.e., backward edges in the CFG) is to allow return instructions within a function  $F$  to target any instruction that follows a call to  $F$ . In other words, fully-precise static CFI checks if a given control-flow transfer conforms to any of the known control-flow transfers from the current position in the CFG, and does not distinguish between different paths in the CFG that lead to a given control-flow transfer. For this reason CFI is typically augmented with a *shadow call stack* [1, 13] to enforce integrity of return addresses stored on the call stack. We compare PARTS to CFI solutions in Section 9.2.

## 9 Comparison with other integrity policies

### 9.1 Fully precise pointer integrity

As discussed in Section 4.1, Pointer Integrity can be loosely defined as a policy ensuring that the value of a pointer at the time of use (dereference or call) corresponds to the value of the pointer when it was created. In this section, we provide a more rigorous definition of Pointer Integrity.

We define *fully-precise pointer integrity* as follows: A pointer dereference is allowed if and only if the pointer is based on its target object. We adopt Kuznetsov et al.’s [21] definition of “*based on*” and say a pointer  $P$  is *based on* a target object  $X$  if, and only if,  $P$  is obtained at run-time by “(i) *allocating  $X$  on the heap*, (ii) *explicitly taking the address of  $X$ , if  $X$  is allocated statically, such as a local or global variable, or is a control-flow target (including return locations,*

*whose addresses are implicitly taken and stored on the stack when calling a function*), (iii) *taking the address of a sub-object  $y$  of  $X$  (e.g., a field in the struct  $X$ ), or (iv) computing a pointer expression (e.g., pointer arithmetic, array indexing, or simply copying a pointer) involving operands that are either themselves based on object  $X$  or are not pointers.*“

Kuznetsov et al.’s CPI [21] (Section 8) provides fully precise integrity guarantees for *code pointers* by ensuring that accesses to sensitive pointers are safe (sensitive pointers are code pointers and pointers that may later be used to access sensitive pointers). However, CPI requires dedicated, integrity-protected storage for sensitive pointers.

As discussed in Section 7.2, PARTS, and PA solutions in general, achieve an approximation of fully-precise pointer integrity. In particular, PARTS allows the substitution of a pointer  $P$  by another pointer  $P'$  *based on* object  $X$ , if  $P$  and  $P'$  share the PA modifier. In other words, when PA modifiers are unique to each protected pointer value, PA provides fully-precise pointer integrity. However, ensuring the uniqueness of PA modifiers is not possible in practice due to the following reasons: 1) program semantics may require a set of pointers to be substitutable with each other (e.g., pointers to callback functions) 2) the choice of allowed pointers may depend on run-time properties (e.g., which callback function was registered earlier). In these cases, a unique modifier must be determined at run-time. Fully-precise pointer integrity does *not* imply *memory safety*. In the case of PA, if the modifier is determined at run-time and stored in memory, the PA modifier itself may become a target for an attacker wishing to undermine the integrity policy. To avoid this, modifier values must be derived in a way which leaves the value outside the control of the attacker, e.g., stored in a dedicated hardware register, or read-only program memory.

### 9.2 Fully-precise static CFI

In contrast to stateless CFI, which allows control-flow transitions present in its CFG regardless of the origin of the code pointer value, PA-based solutions (including PARTS) can preclude forged pointer values from outside the process. The policy that prevents pointer reuse can suffer from limitations similar to those present stateless CFI.

PARTS return address signing provides strong guarantees even when subjected to pointer reuse. In contrast, a stateless CFI policy allows a function to return to any of its call sites. As such, static CFI cannot prevent injection of pointers that are within the expected CFG, i.e., control-flow bending attacks. PARTS additionally requires matching SP values, and that the reused return address originates from a prior function invocation of the same function within the same process for an attack to succeed.

PARTS forward-edge code pointer integrity provides similar guarantees (under reuse attacks) as LLVM’s type-based protection (when subjected to any forged pointer). In both

<sup>11</sup><https://gcc.gnu.org/viewcvs/gcc?view=revision&revision=261304>

cases, attacks are limited to using pointers of the correct dynamic type. PARTS in addition requires that the injected pointer originates from the victim process.

While shadow-stacks protected through randomization can be implemented with minimal performance overhead, our adversary model precludes this approach. Furthermore, software-isolated shadow stack solutions impose impractical performance overheads, and ARM processors do not currently provide direct hardware support for shadow stacks.

## 10 Conclusion and Future Work

We plan to extend PARTS protection architecture to other protection domains like the OS kernel, or hypervisor. The only significant change for PARTS architecture is to arrange for key configuration for both kernel and EL0 PARTS to be trapped (and managed) on a higher exception level (EL2,3). We are further looking at adding C++ support PARTS. While we do not expect any fundamental problems, some C++ specific features, such as inheritance, cannot be directly handled by our current instrumentation strategy.

Authenticated pointers with PACs cannot be used by legacy code (Section 2.2) while PARTS-instrumented code will trap if pointers without PACs are used. For legacy and PARTS code to interact, we can use wrappers that manipulate function arguments and return values by embedding/stripping PACs. For shared pointers or complex data structures, annotations can disable authentication of selected pointers, allowing programmers to manually adjust pointer conversion to and from legacy code.

Currently, the PARTS compiler assumes shared libraries to be uninstrumented. Instrumented shared libraries must deal with PACs for statically allocated pointers after linking, and thus require changes to the dynamic linker.

Pointer integrity does not imply full memory safety (Section 9.1). Although ARMv8-A PA does not support bounds checking for pointer accesses with authenticated pointers, it has a general-purpose instruction, `pacga`, for producing and validating PACs computed over the contents of two 64-bit registers. This can be used to build authenticated canaries to identify buffer overflow attacks, or to validate the integrity (freshness) of atomic data, such as integer or counter values. In principle, `pacga` instructions can even be chained to validate arbitrary-sized blocks of data.

Finally, effective ways of complementing PA with other emerging memory safety mechanisms like the forthcoming support for memory tagging in ARMv8.5-A is an important line of future work.

## A nbench experimental setup

The nbench benchmarks employs dynamic workload adjustment to allow the tests to expand or contract depending on the capabilities of the system under test. To achieve this, nbench employs timestamping to ensure that a test run exceeds a pre-determined minimum execution time. If a test run finishes before the minimum execution time has been reached, the test dynamically adjusts its workload, and tries again. For example, the Numeric Sort test will construct an array filled with random numbers, measure the time taken to sort the array. If the time is less than the pre-determined minimum time, the test will build two arrays, and try again. If sorting two arrays takes less time than the pre-determined minimum, the process repeats with more arrays.

Since we want to determine the relative overhead in execution time caused by our instrumentation, we employ the methodology described by Brassler et al. [6] and modify nbench to instead run each test a constant number of iterations. The number of iterations was determined individually for each test based on the iteration counts determined by a unmodified nbench run on the FVP. We then instrument the nbench benchmarks using our PA-analogue (Section 7.3.1) and measure the relative execution time between non-instrumented and instrumented nbench tests on the HiKey development platform using the BusyBox time utility.

Each individual benchmark test was run 200 times using the pre-determined number of iterations. Figure 5a, in Section 7.3.2 shows instrumentation overhead for individual tests in relation to the uninstrumented test run. Table 3 shows the numeric overhead ratio for each individual test. Because the nbench benchmarks are designed to measure performance in a manner which is operating system agnostic, they are written in ANSI C and only execute in a single thread. We therefore only consider user time when measuring the overhead of the instrumentation, and exclude context switches and system calls.

The run-time overhead of PARTS is dependent on specific run-time events, such as the number of function invocations in the case of return address signing. Figure 5b in

Table 2: Overhead as ratio and standard deviation ( $\sigma$ ) for return address signing and (forward-edge) code pointer signing for 505.mcf\_r and 519.lbm\_r SPEC benchmarks.

Benchmark	Uninstrumented		ret. addr. sign. + code ptr. integrity	
	ratio	$\sigma$	ratio	$\sigma$
505.mcf_r	1	0.004	1.005	0.004
519.lbm_r	1	0.000	1.000	0.000

Section 7.3.2 shows the order of magnitude of instrumented run-time events in the nbench tests. We also report the user mode run-time for uninstrumented nbench tests, the number of iterations of each individual test, and number of instrumented run-time events in Table 4.

## B SPEC CPU2017 experimental setup

Due to unmanageable simulation times in the FVP simulator we have verified the correctness of PARTS instrumentation only on a subset of SPEC CPU2017 benchmarks. Specifically, we chose the 505.mcf\_r and 519.lbm\_r benchmarks from the SPECrate 2017 integer and floating point suites, because these were the smallest C benchmarks in terms of lines of code. The benchmarks were compiled using SPEC runcpu, with a AArch64-specific configuration specifying whole-program-llvm<sup>12</sup>, with our PARTS-enabled LLVM, as the compiler. We then extracted the bitcode — created by whole-program-llvm during compilation — and used it to instrument and compile the binaries we used for evaluation: one uninstrumented, one instrumented with PA instructions, and one instrumented with our PA-analogue. We enabled both return address and forward-edge code pointer signing for the instrumented binaries.

We run the PARTS-instrumented binaries on the FVP simulator to confirm correct functionality. The simulation time for the tested benchmarks was between 12 and 48 hours. Performance benchmarks, for baseline and PA-enabled binaries, were run on the HiKey devices, using the same setup as our nbench evaluation. The results are shown in Table 2, and are based on five runs of each benchmark. In 505.mcf\_r we observed overheads consistent with our results from nbench. We observed no discernible overhead in 519.lbm\_r. We attributed this to the following properties of 519.lbm\_r: (a) it does not exhibit forward-edge code pointers, and (b) it has few non-leaf function calls in relation to the arithmetic computation performed part of the benchmark.

<sup>12</sup><https://github.com/travitch/whole-program-llvm>

Table 3: Overhead as ratio and standard deviation ( $\sigma$ ) for nbench tests reported separately for uninstrumented, return address signing, (forward-edge) code pointer signing, data pointer signing and all instrumentation enabled.

Test	Uninstrumented		PARTS							
	ratio	$\sigma$	ret. addr. sign ratio	$\sigma$	code ptr. signing ratio	$\sigma$	data ptr. signing ratio	$\sigma$	all enabled ratio	$\sigma$

## Abstract

CFI is an effective, generic defense against control-flow hijacking attacks, especially for C/C++ programs. However, most previous CFI systems have poor security as demonstrated by their large equivalence class (EC) sizes. An EC is a set of targets that are indistinguishable from each other in the CFI policy; i.e., an attacker can “bend” the control flow within an EC without being detected. As such, the large ECs denote the weakest link in a CFI system and should be broken down in order to improve security.

An approach to improve the security of CFI is to use contextual information, such as the last branches taken, to refine the CFI policy, the so-called context-sensitive CFI. However, contexts based on the recent execution history are often inadequate in breaking down large ECs due to the limited number of incoming execution paths to an indirect control transfer instruction (ICT).<sup>1</sup>

In this paper, we propose a new context for CFI, origin sensitivity, that can effectively break down large ECs and reduce the average and largest EC size. Origin-sensitive CFI (OS-CFI) takes the origin of the code pointer called by an ICT as the context and constrains the targets of the ICT with this context. It supports both C-style indirect calls and C++ virtual calls. Additionally, we leverage common hardware features in the commodity Intel processors (MPX and TSX) to improve both security and performance of OS-CFI. Our evaluation shows that OS-CFI can substantially reduce the largest and average EC sizes (by 98% in some cases) and has strong performance – 7.6% overhead on average for all C/C++ benchmarks of SPEC CPU2006 and NGINX.

## 1 Introduction

The foundation of our software stacks is built on top of the unsafe C/C++ programming languages. C/C++ provides strong

<sup>1</sup>We use ICT to denote forward indirect control transfers, *excluding* returns. An ICT can be either C-style indirect calls or virtual calls.

performance, direct access to resources, and rich legacy. However, they lack security and safety guarantees of more modern programming languages, such as Rust and Go. Vulnerabilities in C/C++ can lead to serious consequences, especially for low-level software. Many defenses have been proposed to retrofit security into C/C++ programs. Control-flow integrity (CFI) is a generic defense against most, if not all, control-flow hijacking attacks. It enforces the policy that run-time control flows must follow valid paths in the program’s control-flow graph (CFG). Since its introduction in the seminal work by Abadi et al. [2], there has been a long stream of research in CFI [1, 3, 6, 9, 11–14, 16, 17, 21, 25, 28, 29, 31, 38, 40, 41, 43, 44]. Many earlier systems aim at improving the performance by trading security for efficiency [25, 41, 43, 44], making them vulnerable to various attacks [6, 13, 15, 16]. Recent work focuses more on improving the precision and security of CFI [14, 17, 21, 38], which can roughly be quantified by the average and largest equivalence class (EC) sizes [21]. An EC is a set of targets indistinguishable from each other in the CFI policy; i.e., CFI cannot detect control flow hijacking within an EC. It has been demonstrated the control flow can be “bent” within the ECs without being detected, compromising the protection [6]. Therefore, there is a pressing need to further constrain the leeway of such attacks by reducing the average and largest EC sizes .

One way to improve the security of CFI is to refine the CFG with contextual information, the so-called context-sensitive CFI. Likewise, traditional CFI systems are context-insensitive because they do not collect and use the context information for validating the targets of an ICT. There are many choices of the contextual information. Existing context-sensitive CFI systems use the recent execution history as the context. For example, PathArmor uses the last few branches recorded by Intel processor’s Last Branch Record (LBR) [38]; while PittyPat uses the detailed execution paths recorded by Intel processor trace (PT) [14]. Both PathArmor and PittyPat are said to be path-sensitive since they use execution paths as the context. A path-sensitive CFI policy essentially specifies that if the execution comes from this specific path, the ICT can

only go to that set of targets. There are often multiple paths leading to an ICT. Consequently, the target set of the ICT can be divided into smaller sets by those paths. Another common choice of the context is the call stack [21]. Since the call stack can be represented by its return addresses, such a system is often called call-site sensitive. If the context consists of only one level of return address, it is denoted as 1-call-site sensitive. Similarly, 2-call-site sensitive CFI uses two levels of return addresses as the context.

Execution history based context can substantially reduce the average EC size, but is much less capable in reducing the largest EC size. Unfortunately, the largest EC gives the attacker most leeway in manipulating the control flow without risking detection. For example, PittyPat reports the largest EC size of 218 in SPEC CPU2006, even though it is equipped with the detailed execution history [14]. The fundamental weakness of such context is that most programs only have a small number of execution paths that reach an ICT; i.e., the in-degree of a node (representing an ICT) in the CFG is usually small. If an ICT has hundreds of possible targets, at least one of the ECs will be relatively large. Therefore, such context is more capable in handling small to medium-sized ECs but insufficient for large ones. To address that, we need a more *distributed* context that is not concentrated on the ICT.

In this paper, we propose a new type of context for CFI, origin sensitivity. Origin-sensitive CFI (OS-CFI) takes the origin of the code pointer called by an ICT as the context. It supports both C-style indirect calls and C++ virtual calls with slightly different definitions for them: the origin for the former is the *code* location where the called function pointer is most recently updated; that for the latter is the location where the receiving object (i.e., the object for which the virtual function is called) is created. As usual, returns are protected by the shadow stack, implemented either in software [10,23] or hardware [19]. Our measurement shows that origin sensitivity is particularly effective in breaking down large ECs. For example, it can reduce the largest EC size of a SPEC CPU2006 benchmark from 168 to 2, a reduction of 99% (see Table 1).

We have implemented a prototype of OS-CFI for C and C++ programs. The prototype enforces an adaptive CFI policy that automatically selects call-site or origin sensitivity to protect an ICT in order to improve the system performance without sacrificing security. Its CFG is built by piggybacking on the analysis of a demand-driven, context-, flow-, and field-sensitive static points-to analysis based on SVF (Static Value-Flow Graph) [36]. Its reference monitors are implemented securely and efficiently by leveraging the common hardware features in the commodity Intel processors (MPX and TSX). Our evaluation with SPEC CPU2006, NGINX, and a few real-world exploits shows that the prototype can significantly reduce the average and largest EC sizes, and incurs only a small performance overhead: 7.6% on average for the SPEC CPU2006 and NGINX benchmarks.

In summary, this paper makes the following contributions:

- We propose the concept of origin sensitivity that can substantially reduce both the average and largest EC sizes to improve the security of CFI. Origin sensitivity is applicable to both C-style ICTs and C++ virtual calls. Both types of ICTs are equally important to protect C++ programs.
- We have built a prototype of OS-CFI with the following design highlights: we re-purpose the bound table of MPX to securely store and retrieve origins, and use TSX to protect the integrity of reference monitors; we piggyback on the analysis of SUPA, a precise static points-to algorithm, to build the origin-sensitive CFGs.
- We thoroughly evaluated the security and performance of the prototype with SPEC CPU2006, NGINX, and a few real-world exploits. In particular, we carefully studied the CFGs generated from the points-to analysis and revealed a number of its issues. Detailed CFG generation and measurement are often overlooked in the evaluation of previous CFI systems.

## 2 Origin Sensitivity

In this section, we first introduce the initial definition of origin sensitivity that is simple, powerful, but potentially inefficient. We then derive a more viable but still effective definition.

### 2.1 A Simple Definition

OS-CFI takes the origin of the code pointer called by an ICT as the context. If the ICT is a virtual call, the origin is defined as the code location where the receiving object is created, i.e., where its constructor is called;<sup>2</sup> The context of a C-style ICT is similarly defined. A typical example of this type of ICT is an indirect call to a function pointer. The origin of the function pointer is defined as the instruction that initially takes the function address stored in the function pointer.

Next, we use a real-world example from `471.omnetpp` in SPEC CPU2006 to illustrate the concept of the origin (Fig. 1). `471.omnetpp` is a discrete event simulator for large Ethernet networks, written in the C++ programming language. It relies heavily on macros to initialize many objects of the simulated network. Line 1 - 10 shows how simulated networks are initialized: it creates an `ExecuteOnStartup` object for each network to call the network's initialization code; The constructor of `ExecuteOnStartup` sets the private member `code_to_exec` (a function pointer) and adds itself to a linked list (Line 18 - 23). When the program starts, it calls all the queued `code_to_exec` function pointers (`setup` → `executeAll` → `execute`).

The ICT at Line 25 has the largest EC of this program with 168 targets. Call-site sensitivity is not useful here because there is only one call stack to the ICT. Processor-trace-based path

<sup>2</sup>If the object is a global variable, its constructor is conceptually added to a compiler-synthesized function that is called before entering `main()`.

```

1  #define EXECUTE_ON_STARTUP(NAME, CODE) \
2      static void __##NAME##_code() {CODE;} \
3      static ExecuteOnStartup __##NAME##_reg(__##NAME##_code);
4
5  #define Define_Network(NAME) \
6      EXECUTE_ON_STARTUP(NAME##_net, \
7      (new NAME(#NAME))->setOwner(&networks);)
8
9  Define_Network(smallLAN);
10 Define_Network(largeLAN);
11
12 class ExecuteOnStartup{
13 private:
14     void (*code_to_exec)();
15     ExecuteOnStartup *next;
16     static ExecuteOnStartup *head;
17 public:
18     ExecuteOnStartup(void (*_code_to_exec)()){
19         code_to_exec = _code_to_exec;
20         // add to list
21         next = head;
22         head = this;
23     }
24     void execute(){
25         code_to_exec();
26     }
27     static void executeAll(){
28         ExecuteOnStartup *p = ExecuteOnStartup::head;
29         while (p){
30             p->execute();
31             p = p->next;
32         }
33     }
34 };
35 void cEnvir::setup(...){
36     try{
37         ExecuteOnStartup::executeAll();
38     }
39 }

```

Figure 1: Example to illustrate origin sensitivity

sensitivity can distinguish individual calls to `code_to_exec` (because it records each iteration of the while loop); but it is difficult to decide which target is valid because that depends on the unspecified order in which the constructors are called. Origin sensitivity can handle this case perfectly: the origin of `code_to_exec` is where the related function addresses are initially taken. For example, the macro at Line 9 creates a new function called `__smallLAN__net_code` and passes its address to the constructor of object `__smallLAN__net_reg`. Therefore, Line 9 becomes the origin of this function address. The origin is propagated through the program along with the function address when it is assigned to variables or passed as an argument, in a way similar to how the taint is propagated in taint analysis [33]. At the ICT, the origin is used to verify the target. Because only one function address can be taken at each origin, only one target is possible at the ICT. In other words, origin sensitivity *ideally* can reduce the EC size for this ICT from 168 to 1. The same security guarantee can be achieved for virtual calls because only one class of objects can be created at an origin (Section 2.2).

Execution history based context is limited by the in-degree of an ICT node in the CFG. Assuming the ICT node has  $n$  valid targets and  $m$  incoming edges, there exists at least one EC with more than  $\lceil \frac{n}{m} \rceil$  targets (the pigeonhole principle). For example, the in-degree of the ICT in Fig. 1 is only one for call-site sensitivity; Call-site sensitivity thus cannot reduce this EC at all. The in-degree of this ICT for PathArmor is only 16 because LBR can only record 16 most recent branches. In contrast, origins are associated with the data flow of the program. It traces how function addresses are propagated in the program. Because of this, origin sensitivity can uniquely identify and verify a single target for each ICT. Moreover, this example clearly demonstrates that CFI systems for C++ programs must fully support C-style ICTs because many C++ programs use them (they may even have the largest ECs). Protection of virtual calls alone provides only minimal security.

## 2.2 A Hybrid Definition

The previous definition of origin sensitivity is conceptually simple but powerful because it can identify a unique target at run-time for each ICT. However, we need to track origins as function addresses are propagated throughout the program in a way similar to how taint is propagated – the origin is the source of the taint, and the ICT is the sink. It is well-known that taint analysis has high overhead, even though the performance of origin tracking could be much better because function addresses are usually not as widespread as the regular data (e.g., a network packet) [23]. This problem is more severe for C-style ICTs because function pointers are frequently copied or passed as arguments. It will not affect virtual calls as much for the following reason: the origin of a virtual call is the location where the receiving object’s constructor is called. If an object is copied to another object, we essentially create a new object using its class’ copy constructor or copy assignment operator. This creates a new origin for that object. There is thus no need to propagate the origin for objects.

To address the challenge, we propose a hybrid definition of origin sensitivity that combines the origin with call-site sensitivity. More specifically, we relax the definition of the origin as the code location where the related code pointer is most recently updated. In Fig. 1, the only function pointer is `code_to_exec` in the `ExecuteOnStartup` class. It is last updated in the class’ constructor at Line 19; i.e., the origin of `code_to_exec` is just Line 19. Clearly, one origin cannot tell Line 9 and 10 (and other places not shown) apart. This can be solved by adding the call-site information to the origin. The origin can now be represented as a tuple of  $(CS, I_o)$ .  $I_o$  is the instruction that last updates the code pointer;  $CS$  is the immediate caller of the origin function (the function that contains  $I_o$ ). Under this new definition, the ICT at Line 25 has two origins: (Line 9, Line 19) and (Line 10, Line 19). Note how the two elements of the origin complement each other:  $I_o$  moves the context off the *current* execution path

Benchmarks	Language	Context-insensitive	1-call-site		2-call-site		Origin-sensitive	
		$EC_L$	$EC_L$	Reduce by	$EC_L$	Reduce by	$EC_L$	Reduce by
445.gobmk	C	427	427	0	427	0	427	0
400.perlbench	C	173	120	31%	113	35%	21	88%
403.gcc	C	54	54	0	54	0	42	22%
464.h264ref	C	10	2	80%	2	80%	1	90%
471.omnetpp	C++	168	168	0	168	0	2	99%
483.xalancbmk	C++	38	38	0	38	0	4	95%
453.povray	C++	11	11	0	11	0	10	10%

Table 1: Effectiveness of hybrid origin sensitivity in reducing the largest EC size ( $EC_L$ ) as compared to call-site sensitivity

(that reaches the ICT); while  $CS$  adds extra information to  $\mathcal{I}_o$  to separate different origins. We use call sites here because they can be directly fetched from the shadow stack in the user space. Other execution contexts such as last-branch record and processor trace can only be accessed in the kernel.

Interestingly, the addition of call sites does NOT make the context for virtual calls more powerful. The origin of a virtual call is where the constructor of the receiving object is called. C++’s constructors cannot be called virtually or indirectly.<sup>3</sup> As such, a call to the constructor can create an object of just one class. There is no ambiguity in the class created, hence no ambiguity in the virtual functions. As such, we keep using the object construction site alone as the origin for virtual calls.

Table 1 demonstrates the hybrid origin sensitivity’s capability in reducing the largest EC size as compared to call-site sensitivity [21]. Specifically, we run and recorded the complete execution history of all the C/C++ benchmarks in SPEC CPU2006. We then parsed the history to construct the CFGs for origin and call-site sensitivity. For example, 1-call-site sensitivity uses the most recent return address as the context. For each ICT, we grouped the recorded targets by the last return addresses. Each group was an EC. We report the largest EC sizes in Table 1 for all the benchmarks having the largest EC size greater than or equal to 10 (ten other benchmarks have less than 10 targets for every ICT). The table shows that origin sensitivity consistently out-perform call-site sensitivity. Particularly, we can reduce the largest EC size of 471. omnetpp by 99%, from 168 to 2. Neither call-site nor origin sensitivity is effective to 445. gobmk because it contains a loop over a large static array of function pointers (the owl\_defendpat array). 403. gcc similarly has a large array (operand\_data) used in a recursive function (expand\_complex\_abs). Common CFI policies cannot handle such cases because there is not sufficient information in the control flow to separate these targets apart. A similar case is shown in Fig. 4 of Section 4 with the code snippet.

<sup>3</sup>Bjarne Stroustrup’s C++ Style and Technique FAQ: “To create an object you need complete information. In particular, you need to know the exact type of what you want to create. Consequently, a ‘call to a constructor’ cannot be virtual.” [8].

### 3 System Design

In this section, we present the design of our LLVM-based prototype OS-CFI system in detail.

#### 3.1 Overview

Since its inception, many CFI systems have been proposed. To separate OS-CFI from the existing work, we have the following requirements for its design:

- **Precision:** OS-CFI must improve the security by reducing the average and largest EC sizes. Large ECs are the weakest link in a CFI system since they provide the most leeway in “bending” the control flow within the CFI policy
- **Security:** context-sensitive CFI systems, including OS-CFI, have more complex reference monitors to collect and maintain the contextual information. As such, we must protect both the contextual data and the (temporary) data used by reference monitors.
- **Performance:** high performance overhead can severely limit the application of any defense mechanism. OS-CFI must have strong performance relative to the native system.
- **Compatibility:** OS-CFI must support both C and C++ programs. As previously mentioned, any defense for C++ programs must protect both virtual calls and C-style ICTs.

A CFI system consists of three major components: the CFI policy, the CFG generation, and the enforcement mechanism. OS-CFI enforces an adaptive CFI policy that applies either origin or call-site sensitivity for each ICT and adopts the shadow stack to protect returns. OS-CFI’s CFG is generated with a precise context-, flow-, and field-sensitive static points-to analysis [36].<sup>4</sup> The enforcement mechanism of OS-CFI uses the hash-table based set-membership test with the hardware acceleration for metadata storage. Next, we describe each component in detail.

<sup>4</sup>Context sensitivity in the points-to analysis is, more precisely, call-site sensitivity. It is named as is for the historical reasons.

## 3.2 OS-CFI Policy

OS-CFI features an adaptive CFI policy [21] that applies either origin or call-site sensitivity to an ICT, decided by which one is more capable in reducing the EC size. If both have the same effectiveness, we prefer call-site sensitivity because it has lower overhead. If the EC size is already small without context, we just enforce the context-insensitive CFI for this ICT. In addition, call-site sensitivity can use multiple levels of call sites as the context. More levels generally improve the security but incur higher overhead. We limit call-site sensitivity in OS-CFI to at most three call sites. Note that origin sensitivity itself uses 1-call-site on its origins for C-style ICTs (Section 2.2).

We adopt this policy to improve the performance without sacrificing the security: origin sensitivity is a powerful context that can substantially break down large ECs, but it has to collect and maintain more metadata at the run-time. On the other hand, most ICTs in a program have a small number of possible targets. For example, the largest EC size for `400.perlbench` is 173, but its second largest one is only 18. For small ECs, call-site sensitivity is mostly sufficient. We select call-site sensitivity as the secondary policy because last-branch registers (LBR) and processor trace (PT) can only be accessed in the kernel mode, even though they provide more fine-grained execution records. Call-sites instead can be directly fetched from the shadow stack in the user space.

## 3.3 CFG Generation

A complete and precise CFG is the foundation of any CFI systems. A CFG must be complete to ensure that the resulting CFI system has no false positives (valid control flows reported as invalid). False positives are detrimental to the usability of a security system. Meanwhile, a precise CFG can reduce false negatives, making the system more secure. CFGs can have different levels of precision. For example, a CFG that assumes each ICT can target any address-taken functions is complete but utterly imprecise. Most CFI systems utilize static points-to analysis to construct CFGs because such analysis is (supposedly) conservative and the generated CFGs are complete. The precision of the points-to analysis directly decides the quality of the generated CFGs. A precise points-to analysis is often context- and flow-sensitive, such as SUPA [34].

OS-CFI enforces an adaptive CFI policy that combines call-site and origin sensitivity, which require call-site and origin-sensitive CFGs, respectively. We represent these CFGs as a set of tuples:

- **Call-site sensitive CFG:** each tuple of this CFG has the following form:  $(CS_{1/2/3}, I_i, \mathcal{T})$ .  $CS$  represents the callers of the current function on the call stack. OS-CFI may use up to three call sites.  $I_i$  is the address of the ICT instruction itself. It is either a C-style ICT or a virtual call.  $\mathcal{T}$  is the set of valid targets under this context.

```
1 typedef void (*Format)();
2 class Base {
3 protected:
4     Format fmt;
5 public:
6     Base(/* Base.o.vPtr, origin */) {
7         // store_metadata(Base.o.vPtr, Base::vTable,
8             //             origin);
9     }
10    ~Base() {}
11    virtual void set(Format fp) {
12        fmt = fp;
13        // store_metadata(fmt.addr, fp.value,
14            //             Base::set_loc1, Base::set_ctx);
15    }
16    void print() {
17        // ccall_ref_monitor(fmt.addr, fmt.value);
18        fmt();
19    }
20 };
21 class Child : public Base {
22 public:
23     Child(/* Child.o.vPtr, origin */) {
24         // Base(Child.o.vPtr, origin);
25         // store_metadata(Child.o.vPtr, Child::vTable,
26             //             origin);
27     }
28    ~Child() {}
29    void set(Format fp) {
30        fmt = fp;
31        // store_metadata(fmt.addr, fp.value,
32            //             Child::set_loc1, Child::set_ctx);
33    }
34    void print() {
35        // ccall_ref_monitor(fmt.addr, fmt.value);
36        fmt();
37    }
38 };
39 void exec () {
40     Base *bp = new Base(); // call constructor
41     // vcall_ref_monitor(Base.o.vPtr,
42         //             Base::vTable, Base::set())
43     bp->set(&targetA);
44     bp->print();
45
46     Child ci; // call constructor
47     ci.set(&targetB);
48     ci.print();
49
50     bp = &ci;
51     // vcall_ref_monitor(Child.o.vPtr,
52         //             Child::vTable, Child::set())
53     bp->set(&targetB);
54     bp->print();
55 }
```

Figure 2: An example featuring C-style ICT and virtual call.

- **Origin sensitive CFG for C-style ICTs:** each tuple of this CFG has the form of  $((CS_o, I_o), I_i, \mathcal{T})$ .  $(CS_o, I_o)$  is the hybrid origin of the function pointer. In particular,  $I_o$  is the

last store to the related function pointer; while  $\mathcal{I}_i$  is where the function pointer is actually called.

- **Origin sensitive CFG for virtual calls:** each tuple of this CFG has the form of  $(\mathcal{I}_o, \mathcal{I}_i, \mathcal{T})$ .  $\mathcal{I}_o$  is the location where the receiving object of a virtual call is constructed.

We use the C++ code in Fig. 2 to illustrate how the CFGs are generated (and later enforced). There are two classes, `Base` and `Child`. `Child` inherits `Base`. `Base` has a protected function pointer `fmt` that can only be set by virtual function `set`. `fmt` is called indirectly by the `print` function, which is overloaded in `Child`. As such, this example has both C-style ICTs (Line 18 and 36) and virtual calls (Line 43 and 53).

Our CFG construction algorithm is based on SVF, a static tool that “enables scalable and precise inter-procedural dependence analysis for C and C++ programs” [36]. SVF constructs a whole-program sparse value-flow graph (SVFG) that conservatively captures the program’s def-use chains. SVFG is imprecise because it overestimates the points-to sets when constructing the def-use chains. SUPA is a client of SVF. It is an on-demand context-, flow-, and field-sensitive points-to analysis based on the SVFG. It improves the precision by refining away imprecise value-flows in the SVFG with strong updates [34]. Our CFGs are constructed on top of the refined SVFG of SUPA.

SUPA is a demand-driven points-to analysis. It traverses the program’s SVFG reversely to compute the points-to sets. OS-CFI queries SUPA for every ICT in the program. In response, SUPA starts traversing the def-use chains to solve the request. OS-CFI piggybacks on SUPA during this traversal. Specifically, OS-CFI monitors the traversed nodes to identify the origin of the ICT. When SUPA stops the traversal, it has located the targets of the ICT, and OS-CFI has collected all the elements required to generate the tuples for the ICT. Next, we describe how OS-CFI generates the related tuples for the indirect calls in Fig. 2 since they are the more complex cases.

In Fig. 2, `Base` has a protected member function pointer `fmt`, which is called by `Base.print` and `Child.print`. Therefore, OS-CFI requests SUPA to resolve the points-to set for both uses of `fmt`. We describe the resolution of the first call to `fmt` by `Base.print` here. This indirect call to `fmt` is actually a use of the `fmt` field of the `this` object. SUPA can create a def-use chain from Line 18 to the assignment of the `fmt` field at Line 12 because it is field-sensitive. This def-use chain is linked by the `bp` pointer created at Line 40. When traversing this def-use chain, OS-CFI marks the first store to `fmt` as the origin for the ICT. The traversal continues until SUPA has reached the call to the `set` function at Line 43. OS-CFI then marks Line 43 as the call-site for the origin. Now, SUPA has located the target of `fmt` (`targetA`). Note that SUPA is precise enough to exclude `targetB` from the points-to set of `fmt` at Line 18. The CFG tuple for Line 18 is ((Line 43, Line 12), Line 18, `targetA`). Tuples for other CFGs can be similarly constructed.

## 3.4 Enforcement Mechanism

**Overview:** we use a hash-table based set membership test to enforce the OS-CFI policy. Specifically, we create a hash table for each CFG and instrument the program (at the LLVM IR level) to collect the run-time metadata at the origins. OS-CFI verifies the targets at each ICT site by searching the hash table for matches. As mentioned before, the CFGs are encoded as tuples. The hash function simply takes each element of the tuple and xor them together. It is extremely fast and leads to few conflicts in practice. The hash function can be easily replaced if necessary.

In this section, we will describe the instrumentation in detail. Note that OS-CFI adopts both call-site and origin sensitivity. The context for the former is the return addresses on the call stack, which can be fetched from the shadow stack at the ICT sites. As such, call-site sensitivity is enforced (instrumented) only at the ICT sites. However, we need to instrument both the origin and ICT sites for origin sensitivity.

### 3.4.1 Instrumentation at Origin Sites

OS-CFI has different origins for C-style ICTs and virtual calls. We describe them separately.

**C-style ICTs:** the origin for this type of ICTs is defined as  $(CS_o, \mathcal{I}_o)$ .  $\mathcal{I}_o$  is the address of the origin (i.e., the instruction that last writes to the function pointer), and  $CS_o$  is the most recent return address on the call stack. Since we are instrumenting the origin,  $\mathcal{I}_o$  is a known constant.  $CS_o$  can be retrieved directly from the shadow stack. To store the metadata, we use the address of the function pointer as the key and the context,  $(CS_o, \mathcal{I}_o)$ , as the value. At the ICT site, we can recover the context with the function pointer address. Fig. 2 has been annotated with the calls to store metadata at Line 13 and 31 for `Base.fmt` function pointer.

**Virtual calls:** the origin for virtual calls is the location where the object is created ( $\mathcal{I}_o$ ).  $\mathcal{I}_o$  is also a known constant at the origin site. To store this metadata, we use the object’s `vPtr` pointer address as the key and  $\mathcal{I}_o$  as the value. In C++, every object with virtual functions has a hidden member named `vPtr` that points to its `vTable`. `vTable` is used by the compiler for dynamic dispatching of virtual function calls. It is a table of virtual function pointers. Each virtual function of a class has a fixed offset in `vTable`. A virtual call is thus compiled as an indirect call to the corresponding entry in `vTable`. Initially, a sub-class inherits its base class’ `vTable`. If the sub-class overrides a virtual function, it sets the related function pointer in `vTable` to its own function’s address. Consequently, the virtual call can call either the base or sub-class’ virtual function, decided by the class of the receiving object. COOP attacks essentially compromise the binding of `vPtr` and `vTable` [32]. After an object is created, its `vTable` will not be changed.

The reason we use `vPtr`’s address as the key (instead of the base address of the object, even though they both can

uniquely identify the object) will be clarified as we discuss the metadata storage. The instrumentation is added to each class’ constructor so that we only need to insert the code once (instead of once at each location where the constructor is called). Line 7 and 25 of Fig. 2 show the added code. We simply pass the origin from the object allocation site to the constructor as a hidden parameter. Note that the constructor of a sub-class calls the constructor of its base classes first. We thus add the code near the end of the constructor so that the metadata will not be mistakenly overwritten.

**Metadata storage:** the storage of the contextual information (i.e., the metadata) is a key design component of OS-CFI. The metadata of OS-CFI is organized as (key, value) pairs. The key is the address of the function pointer or the receiving object’s `vPtr` pointer. The value is the origin associated with the key. We store the (key, value) pair at each origin site, and query the storage with the same key to retrieve the origin information at each ICT site. The performance and security of the storage is critical to OS-CFI. In our prototype, we uniquely (ab)use the hardware-based bound table of Intel MPX for metadata storage [18].

MPX is a hardware-based bound check system. With the support of the compiler, run-time, and kernel, MPX can check the bounds of memory access to prevent memory errors, such as buffer overflows and over-reads. However, whole program bound check is hard to implement correctly and efficiently, even with the hardware support [26]. In fact, the MPX support will be removed from GCC in version 9.0, after it was just integrated in 5.0 [27]. This leaves the whole MPX hardware free-to-use by OS-CFI and other (security) systems.

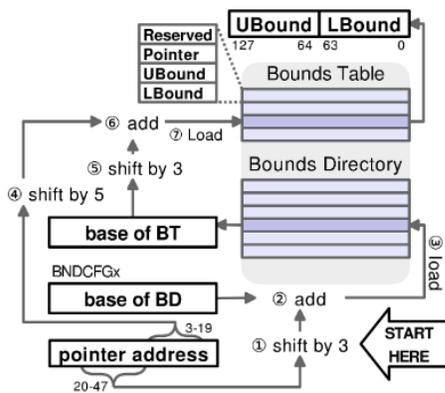

Figure 3: MPX operations, from Intel’s manual [30]

MPX’s bound table is indexed by the address of a pointer (i.e., the key). Each key has its own unique bound table entry, which consists of the content of the pointer, the upper bound, and the lower bound. The bound table is organized and operates like a two-level page table, as shown in Fig. 3: the bounds directory points to the second-level bounds tables; each bounds table contains a number of bound entries. The

pointer address is divided into two indexes. To locate a bound entry, MPX first indexes into the bounds directory to retrieve the base of the related bounds table, and then uses the second index to locate the related bound entry. If a bounds table does not exist, the kernel allocates a new one and links it to the bounds directory. The base of the bounds directory is stored in a special register, `BNDCFGx`, inaccessible to the user space.

We can store all the origins in the MPX bound table. Even though we are supposed to store the lower and upper bounds in this table, the hardware does not perform any validations on the bounds, as confirmed by both the official document and our experiments. Accordingly, we can store and retrieve arbitrary numbers in the bounds (after doing some simple calculations on these two numbers). This design not only significantly accelerates the access of the metadata but also improves the security: the MPX table stores the content of the key along with the bounds. When querying the table for a key, we need to provide the pointer’s address and its content. If the provided pointer content mismatches that in the table, MPX will return an error. Therefore, *we can detect any manipulation of these pointers, after they have been stored, without the extra performance penalty.*

For virtual calls, OS-CFI uses the address of the receiving object’s `vPtr` pointer, which points to the object’s `vTable`, as the *key*. As such, OS-CFI can readily detect any COOP attack, which compromises the object’s `vPtr` pointer [32], similar to how object-type integrity (OTI [4]) works. Note that OTI is not a complete protection for C++ virtual calls because the attacker can still call the “correct” virtual functions of an unintended object. In contrast, OS-CFI provides more comprehensive and complete protection for C++ programs because it not only enforces the precise CFI but also protects both virtual calls and C-style ICTs.

OS-CFI can use other keys for the virtual call. For example, it can use the address of the object itself as the key and a constant number as its content. We can retrieve the origin from the MPX table by this key and its “content”, and then enforce the CFI against the unique target decided by the origin. This is because the origin (i.e., the location where the receiving object is constructed) identifies the exact class of the object, hence the unique target of the virtual call (Section 2.2). Our prototype uses the address of the `vPtr` pointer as the key because it is more natural for MPX (i.e., the `vPtr` pointer address and its *real* content). This is not strictly necessary since OS-CFI nevertheless can detect these attacks.

### 3.4.2 Instrumentation at ICT Sites

The instrumentation at each ICT site is rather straightforward: it first queries the metadata storage with the key and its content to retrieve the origin. If the origin exists, it further checks the corresponding hash table whether the origin and the target are valid for the ICT site. Use the indirect call as an example, we need to reconstruct the tuple of  $((CS_o, I_o), I_i, T)$ .  $(CS_o, I_o)$

is the origin fetched from the metadata storage;  $I_i$  represents the address of indirect call instruction;  $\mathcal{T}$  is the target, i.e., the value of the function pointer. OS-CFI then queries the hash table whether this tuple is one of its items. If so, the indirect call is allowed. For call-site sensitivity, OS-CFI retrieves the return addresses from the shadow stack and uses a similar method to verify the target under this context.

### 3.4.3 Protection of Metadata

The MPX table is protected by ASLR. The 64-bit address space provides enough entropy to render brute force attacks difficult, if not impossible. Note that the access to the bounds directory and tables is implemented by the hardware, similar to the access to page tables. Particularly, the base of the bounds directory is stored in a kernel-mode register, inaccessible to the user space. Therefore, the address of the MPX table will not be leaked to the user space. This prevents the attacker from overwriting the metadata stored in the MPX table. We consider side-channel attacks out-of-scope. A number of defenses have been proposed to detect/mitigate them [7, 45]. If a stronger protection of the MPX table is necessary, we can use MPX’s bound check to protect it, with a small additional overhead [4, 22]. Note that this use of the bound check does not conflict with OS-CFI’s use of the MPX table since the bound check can be performed with just the bound registers.

The hash tables for CFGs are protected as the read-only memory and thus cannot be changed by the attacker. A subtle attack surface is the temporary data used by the reference monitors to search the hash tables. Context-sensitive CFI systems have more complex reference monitors, which have to use the memory (instead of all registers) to store the temporary data. This makes them vulnerable to race conditions in a brief time window. To address that, we utilize the transactional memory (Intel TSX) to protect the reference monitors [21]. Specifically, TSX keeps tracks of the memory accessed by a transaction and aborts the transaction if any of that memory is changed by others (e.g., attacks). We enclose each reference monitor in a transaction and repeat the transaction if it fails because, with a very low probability, transactions could fail without attacks (e.g., because of cache conflicts).

### 3.4.4 CFG Address Mapping

Our CFGs are generated using SUPA, a LLVM-based points-to analysis. The resulting CFGs are accordingly encoded as the LLVM IR locations. However, the instrumentation requires the run-time addresses of the CFG nodes. We need to map the IR locations to the run-time addresses. Previous systems often use the debug information for this purpose, which works for function addresses but not as well for call sites because they are not in the symbol table. To address that, heuristics such as the code structure are used to infer the locations of call sites. This approach works most of the time but may not be reliable

Benchmarks	Out of budget			Empty points-to sets	
	# of ICTs	SUPA	Type	# of ICTs	Type
400.perlbench	54	639	349	2	7
403.gcc	46	544	218	20	107
445.gobmk	22	1645	1637	1	4
447.dealIII	0	-	-	23	37
450.soplex	0	-	-	157	11
453.porvray	47	317	79	22	24
471.omnetpp	37	143	44	67	21
483.xalancbmk	0	-	-	349	29
NGINX	141	1066	102	4	34

Table 2: Failed cases of SUPA and the improvements of our type-based matching. Column 3, 4, and 6 show the largest EC sizes for SUPA and the type-based matching. SUPA works for all other benchmarks.

when the compiler optimization is turned on.

OS-CFI solves this problem without using any heuristics. Specifically, we insert a custom label after each call instruction. We then use the label-as-value extension of Clang to store the label addresses to an array and assign the array to a custom section. The compiler will automatically convert these labels to the addresses. Note that the array has to be marked as used so that the later stages of the compiler will not optimize it away. These extensions are supported by both GCC and Clang/LLVM. A benefit of this approach is that OS-CFI theoretically can support ASLR because the loader will automatically fix these addresses when the program is loaded. This resolves the run-time addresses of call sites. For the rest of the data in the CFGs, we encode the ICT and origin sites as IDs (specifically the hashes of their source code locations) since their concrete values are irrelevant. The target function addresses are obtained from the symbol table. With the address mapping information, we can encode the CFGs in the hash tables.

## 4 Evaluation

In this section, we evaluate how effectively OS-CFI can improve the security by reducing the largest and average EC sizes and what is the performance overhead for some standard benchmarks. We also experimented with real-world exploits to demonstrate how OS-CFI can block them.

### 4.1 Improvement in Security

The security of a CFI system can be measured by its CFGs, assuming the enforcement mechanism does not introduce imprecision. Particularly, the average and largest EC sizes reflect the overall quality of the CFGs [21]. OS-CFI’s CFGs are derived from SUPA, a static points-to analysis. Therefore, the quality of its CFGs are affected by SUPA.

**Advancements and issues of SUPA:** SUPA is a scalable and precise context-, flow-, and field-sensitive points-to analysis. Public availability of such algorithms is, to the best of our

knowledge, non-existent before the release of SUPA. Though, SUPA has its own issues. More specifically, SUPA is an on-demand points-to analysis. It allocates a specific amount of (configurable) budgets for each query. We found that, even with a generous budget on a relatively powerful machine (a 16-core Xeon server with 64GB of memory), SUPA can still run out of budgets for complex programs, such as `gcc` and `perlbench`. When that happens, SUPA may return wrong results in the points-to sets (e.g., functions with wrong signatures). In addition, SUPA may return empty results because of the language features it does not yet support (e.g., C++’s pointers to member functions).<sup>5</sup> When these issues were detected, we used a simple type-based matching to fix the points-to sets.

The results are listed in Table 2. Generally speaking, the type-based matching can substantially reduce the target sizes for the failed cases. For example, we can reduce the size of largest EC size of `NGINX` returned by SUPA from 1,066 to just 102. A noticeable exception is `gobmk`, which has more than 1,600 address-taken functions with the same signature (`(int, int, int, int)`). Our manual examination of the program shows that no ICTs in `gobmk` should have more than 500 targets.

It is no surprising that SUPA has some issues because scalable points-to analysis with multiple types of sensitivity is a hard problem. We suspect SUPA is still more scalable and/or precise than other publicly available points-to analysis algorithms, and expect these problems to be solved soon. However, these issues can put OS-CFI to a disadvantage currently – our CFGs are generated by piggybacking on the SUPA as it traverses the SVFG. For these failed cases, SUPA prematurely stops traversing the graph. Accordingly, we cannot generate call-site or origin sensitive edges for these failed ICTs. We instead have to fallback to the context-insensitive CFI for them. We would like to emphasize that *the issues of SUPA does not invalid the usefulness of origin sensitivity*. These are two orthogonal problems.

**Effectiveness of OS-CFI:** Table 3 shows how OS-CFI can significantly reduce both the average and largest EC sizes. This table focuses on measuring the effectiveness of origin sensitivity; the table thus does not take the ICTs that SUPA failed to resolve (Table 2) into consideration. We will present the overall results with all the ICTs in Table 4. Additionally, Table 3 compares OS-CFI against the context-insensitive CFG, which can be calculated directly from SUPA’s points-to sets. It is technically difficult to compare the origin-sensitive CFG against path-sensitive CFGs, such as these in PathArmor [38] or PittyPat [14]; they both use online points-to analysis to calculate the valid targets, with the help of run-time information; i.e., their CFGs are dynamically generated and are, most likely, incomplete for a fair comparison. In addition, the comparison to call-site sensitive CFG has been shown in

<sup>5</sup>SUPA may also returns empty results for ICTs in the dead code.

Benchmark	# ICTs	No Context		OS-CFI		Reduce by	
		Avg	Lg	Avg	Lg	Avg	Lg
400.perlbench	79	23.8	39	2.8	10	88%	74%

NGINX	248	9.4	43	1.1	19	88%	56%

Table 3: Improvement of precision by OS-CFI over context-insensitive CFI, shown by the significant reduction in the average (Avg) and largest (Lg) EC sizes.

Table 1. Nevertheless, the absolute average and largest EC sizes OS-CFI can achieve still clearly show its effectiveness. For example, OS-CFI can reduce the largest EC size of `omnetpp` from 109 to 2, a 98% reduction. It can also reduce the average EC size of `gcc` by 96% from 30.7 to 1.3. Overall, OS-CFI can reduce the average and largest EC sizes by 59.8% and 60.2% on average, respectively.

```

1  typedef int (*EVALFUNC)(int sq,int c);
2  static EVALFUNC evalRoutines[7] = {
3      ErrorIt,
4      Pawn,
5      Knight,
6      King,
7      Rook,
8      Queen,
9      Bishop };
10
11 int std_eval (int alpha, int beta) {
12     for (j = 1, a = 1; (a <= piece_count); j++) {
13         score += (*(evalRoutines[pienet(i)]))
14                 (i,pieceside(i));
15     }
16 }

```

Figure 4: An example in `sjeng` where the ICT at Line 15 has no context in SUPA.

**Overall statistics of OS-CFI:** Table 4 shows the overall statistics of OS-CFI when applied to all the C/C++ benchmarks in SPEC CPU2006 and `NGINX`. The second and third columns show the number of C-style ICTs and virtual calls, respectively. It is clear that C++ programs often use C-style ICTs. Any protection for C++ programs thus must support both types of ICTs. OS-CFI enforces an adaptive policy where an ICT can be protected by either origin or call-site sensitivity. However, it may fall back to the context-insensitive policy if SUPA fails to resolve the points-to set for the ICT or if SUPA

Benchmark	#ICTs		OS-CFI / Adaptiveness

Table 4: Overall distribution of ICTs among origin sensitive, call-site sensitive, and context-insensitive ICTs. The second column shows the total number of C-style indirect calls, while the third column shows the number of virtual calls. We omit the results of `mcf`, `libquantum`, and `sphinx3` from this table because they do not have ICTs in their main programs. Columns marked with Avg and Lg show the average and largest EC sizes, respectively.

fails to provide the context for the ICT. The latter could happen if the ICT uses global function pointers (e.g., Fig. 4). Specifically, the ICT in Line 13 calls global function pointers defined in the `evalRoutines` array. Because `evalRoutines` is initialized statically, SUPA will not generate any context for this ICT. Neither will origin or call-site sensitivity improve the precision of such cases because the target is decided by the index (`piecet(i)`). Even  $\mu$ CFI can only provide the same precision as context-insensitive CFI in this case because the constraint data (`piecet(i)`) can potentially be compromised before being captured by  $\mu$ CFI using processor trace [17].

In Table 4, most ICTs are protected by origin sensitivity. Interestingly, the number of origins (the 5<sup>th</sup> column) is often less than the number of ICTs (the 4<sup>th</sup> column) because some ICTs may share origins. Both origin and call-site sensitivity can reduce most of the average and largest EC sizes to less than 2 and 5, respectively<sup>6</sup>. Note that OS-CFI prefers call-site sensitivity over origin sensitivity. Origin sensitivity is used only if call-site sensitivity fails to provide sufficient security. Therefore, ICTs protected by origin sensitivity generally have larger ECs than those by call-site sensitivity. OS-CFI similarly prefers context insensitivity over call-site sensitivity. ICTs that SUPA failed to resolve are also context-insensitive. The majority of the largest ECs in the context-insensitive ICTs come from the problems in SUPA. We expect OS-CFI to substantially break down most of these ECs once the problems in SUPA are resolved.

Next, we present a few case studies to illustrate how OS-CFI can successfully break down largest ECs in some programs of SPEC CPU2006.

<sup>6</sup>Table 3 and 4 cannot be compared directly because Table 4 includes the ICTs SUPA failed to resolve while Table 3 does not.

#### 4.1.1 Case Studies

**Largest EC in 471. omnetpp:** Fig. 5 shows the virtual call in 471. omnetpp with the largest number of targets – 35 targets in context-insensitive CFG. The related ICT is located in Line 5, which calls the virtual destructor declared in Line 10. Unlike constructors, destructors in C++ can be called virtually. `cObject` is the root class in 471. omnetpp. It is inherited by many other classes, such as `CModuleType` (Line 12) and `cArray` (Line 17). Interestingly, `cArray` is a container of `cObject` even though itself is a sub-class of `cObject`. `cArray` has a clear function that calls `discard` on every contained object, which in turn calls the virtual destructor. Clearly, the ICT in Line 5 can target any virtual destructor of `cObject`'s sub-classes.

OS-CFI defines an origin for each location where an object of `cObject` or its sub-class is created. Because the constructor in C++ cannot be virtually called, each origin is associated with exactly one class. As such, OS-CFI can uniquely identify the specific destructor to be called; i.e., it can enforce a perfect CFI policy at Line 5 since the EC size is 1.

**Largest EC in 483. xalancbmk:** The ICT with the largest EC size in 483. xalancbmk is a C-style indirect call (Fig. 6, Line 11). The function pointer is defined in Line 4 as a private member of `XMLRegisterCleanup`. As such, it can only be set by function `registerCleanup` (Line 6). In Line 15 and 16, two objects of `XMLRegisterCleanup` are created. They register the cleanup function at Line 18 and 19, respectively.

The ICT at Line 11 have a EC size of 38. Since this is a C-style ICT, the origin is defined as  $(CS_o, I_o)$ .  $I_o$  is the location of the instruction that last writes to the function pointer (Line 7), while  $CS_o$  is the call sites of the store function (Line 18

```

Figure 7: The ICT with the largest EC in 456.hmmmer

Markov Models) file. This model file can have different versions and formats identified by its magic number. As such, the benchmark creates the HMMFILE structure with the parser function pointer (Line 9 and 10), and assigns the function pointer according to the model file's magic (Line 14-27). The function pointer is called at Line 31. In total, there are fifteen valid parsers.

Because HMMFileRead is called in the main function, call-site sensitivity is not useful for this case at all because there is just one call site. As such, OS-CFI applies the origin sensitivity for this ICT. It creates an origin for each assignment to parser (Line 15, 18, 21, 24...). Therefore, OS-CFI can enforce a perfect CFI policy for this ICT as well.

## 4.2 Security Experiments

We experimented with two real-world exploits and one synthesized exploit to show how OS-CFI can block them.

### 4.2.1 Real-world Exploits

We experimented with two vulnerabilities, CVE-2015-8668 in libtiff and CVE-2014-1912 in python. We used the existing PoC exploits to overwrite a function pointer in order to hijack the control flow. We first verified that the exploits work and then tested them again under the protection of OS-CFI.

**CVE-2015-8668:** This is a heap-based buffer overflow caused by an integer overflow. The program fails to sanitize the buffer size if the multiplication overflows (Fig. 8, Line 20). This causes the allocated buffer (`uncomprbuf`) to be too small, allowing the attacker to overflow the heap memory. A potential target of the attack is the TIFF object, which contains several function pointers. One of such function pointers is `tif_encoderow`, which is called by `TIFFWriteScanline` later in the program.

```
1 int TIFFWriteScanline(TIFF* tif, ...){
2     ...
3     status = (*tif->tif_encoderow)(tif, (uint8*) buf,
4         tif->tif_scanlinesize, sample); // <= exploit call-point
5 }
6 void _TIFFSetDefaultCompressionState(TIFF* tif){
7     tif->tif_encoderow = _TIFFNoRowEncode; // <= origin
8 }
9 TIFF* TIFFOpen(...){
10    ...
11    _TIFFSetDefaultCompressionState(tif);
12 }
13 int main(int argc, char* argv[]){
14     TIFF *out = NULL;
15     out = TIFFOpen(outfilename, "w"); // <= exploited object
16     ...
17     uint32 uncompr_size;
18     unsigned char *uncomprbuf;
19     ...
20     uncompr_size = width * length; // non-sanitized code and
21                                     // following memory allocation
22     uncomprbuf = (unsigned char *)_TIFFmalloc(uncompr_size);
23     ...
24     if (TIFFWriteScanline(out, ...) < 0) {}
25     ...
26 }
```

Figure 8: Sketch of the vulnerable code in libtiff v4.0.6.

The indirect call at Line 3 was protected in OS-CFI by origin sensitivity. OS-CFI identified twelve origins of `tif_encoderow` with twelve different targets. However, the only origin recorded during this exploit was the one in the `_TIFFSetDefaultCompressionState` function, and the corresponding valid target was `_TIFFNoRowEncode`. Although all twelve origins are possible for the ICT at Line 3, the run-time context allowed us to uniquely identify the only valid target. Our system successfully detected the exploit.

**CVE-2014-1912:** this buffer overflow in python-2.7.6 is caused by the missing check of buffer size (Fig. 9, Line

```
1 int PyType_Ready(PyTypeObject *type){
2     ...
3     bases = type->tp_bases;
4     PyObject *b = PyTuple_GET_ITEM(bases, i);
5     if(PyType_Check(b))
6         inherit_slots(type, (PyTypeObject *)b); // <= origin context
7 }
8 static void inherit_slots(PyTypeObject *t, PyTypeObject *b){
9     ...
10    type->tp_hash = base->tp_hash; // <= origin
11 }
12 long PyObject_Hash(PyObject *v){
13     PyTypeObject *tp = v->ob_type;
14     if (tp->tp_hash != NULL)
15         return (*tp->tp_hash)(v); // <= exploit call-point
16 }
17 static PyObject *sock_recvfrom_into(...){
18     Py_buffer buf;
19     ...
20
21     if (recvlen < 0) {
22         goto error;
23     }
24     if (recvlen == 0) {
25         recvlen = buflen;
26     }
27
28     // missing check if (buflen < recvlen) {}
29
30     // vulnerable code
31     readlen = sock_recvfrom_guts(s, buf.buf, recvlen, flags, &addr);
32 }
```

Figure 9: Sketch of the vulnerable code in Python-2.7.6

28) before receiving the data into a `Py_buffer` object. `Py_buffer` has a member of the type `PyTypeObject`, which contains a function pointer `tp_hash`. `tp_hash` is used by the `PyObject_Hash` function to hash objects. The buffer overflow at Line 31 can be used to overwrite this function pointer.

Our algorithm identified the origin of `tp_hash` as Line 10 plus its call-site at Line 6. As such, origin sensitivity is ineffective for the indirect call at Line 15 because there is only one origin. Instead, 3-call-site sensitivity was used for this ICT. We counted 40 immediate call sites to the `PyObject_Hash` function. With three call-sites, we were able to limit the valid targets to a single candidate for each valid call stack. Our system also successfully prevented this exploit.

In both cases, OS-CFI not only blocked the exploits but also constrained the vulnerable ICTs to a single target at run-time.

### 4.2.2 Synthesized Exploit: a COOP Attack

We used the example code in Fig. 10 to demonstrate how OS-CFI can detect both `vTable` hijacking and control-flow hijacking for C++ objects. The example was inspired by PittyPat [14]. There are two virtual calls (Line 44 and 48) and two vulnerable functions (`getPerson` and `isEmployee`). The `getPerson` function contains a heap-based overflow, which allows the attacker to compromise the returned object's `vPtr` pointer, for example, to overwrite `Employee`'s `vPtr` to `Employer`'s `vTable`. The buffer overflow in `isEmployee` can overwrite `res` to always return `true`.

OS-CFI prevented both exploits. The first exploit was de-

Benchmark	SUPA (s)	OS-CFI (s)	Overhead

Table 5: The analysis time of OS-CFI as compared to the vanilla SUPA algorithm. The unit of the analysis time in the table is seconds.

imprecision in both CFGs and enforcement mechanisms. For example, some of them enforce a coarse-grained CFG [37, 43], making them vulnerable to attacks [13, 16]. Even precise context-insensitive CFI systems may be vulnerable because of their large EC sizes [6]. Compared to these systems, OS-CFI is a context-sensitive CFI system. Its origin-based context can effectively break down large ECs, improving the security.

An effective method to improve the precision of CFI is to use the contextual information to differentiate sets of targets. However, the addition of context imposes stringent demands on the system design, leading to more trade-offs and opportunities: first of all, a context-sensitive CFI system requires context-sensitive CFGs. It is well-known that context-sensitive points-to analysis does not scale well. The situation has been substantially improved with the recent release of SUPA [35]. However, scalable path-sensitive points-to analysis, needed by systems like PathArmor and PittyPat, is still unavailable; The second challenge is how to securely collect, store, and use contextual information with minimal performance overhead. In the following, we compare OS-CFI to three representative context-sensitive CFI systems: PathArmor [38], PittyPat [14], and  $\mu$ CFI [17]. Table 6 shows their key differences.

PathArmor, PittyPat and  $\mu$ CFI all use the recent execution history recorded by Intel CPUs as the context, last branch record (LBR) for PathArmor and processor trace (PT) for the other two. LBR records only the last sixteen branches taken by the process; while PT provides more fine-grained

record of the past execution. Unlike MPX that can be accessed directly in the user space, LBR and PT are privileged and only accessible by the kernel. Transition into and out of the kernel is an expensive operation. It is thus impractical to check these records for each ICT. To address that, PathArmor enforces the CFI policy at the selected syscalls; i.e., only a small part of the program is protected. PittyPat and  $\mu$ CFI redirect the trace to a separate process and verify the control flow there. They can verify all the ICTs but only enforce the results at the selected syscalls. The drawback of this design is that the usable number of CPU cores is effectively reduced by half. Because all three systems cannot enforce the CFI policy at every ICT, their focus is to protect the other part of the system from attacks. OS-CFI instead collects the context by inline reference monitors protected by Intel TSX. It is a whole-program protection that enforces the CFI policy at every ICT. In addition, all these three systems require to change the kernel. OS-CFI uses the stock kernel, whose general MPX support is sufficient.

OS-CFI derives its CFGs from a context-, flow-, and field-sensitive static points-to analysis. However, PathArmor and PittyPat enforce path-sensitivity. To the best of our knowledge, there is no scalable path-sensitive points-to analysis available (at least publicly). Both systems, as well as  $\mu$ CFI, instead utilize on-line points-to analysis, based on the recorded context. The design of  $\mu$ CFI is interesting in that it turns the constraint data into indirect control transfers, which are recorded by PT. This securely conveys the constraint data to the monitoring process. Unfortunately, it seems that this usage puts too much pressure on PT, causing PT to lose packets. This renders  $\mu$ CFI unsuitable for large programs. Indeed, it cannot handle the most demanding benchmarks in SPEC CPU2006, such as gcc, omnetpp, and xalancbmk, and the benchmarks are tested with the smaller train data, not the regular reference data. OS-CFI focuses on reducing the EC sizes. PathArmor and PittyPat are unlikely to achieve the same effectiveness because they use the execution history as the context. The largest EC sizes will remain significant because of the limited incoming paths towards a ICT. For example, PittyPat reports one large EC size of 218. The goal of  $\mu$ CFI is to enforce unique target for each ICT. This is achieved by considering the constraint data during verification. However, the constraint data can potentially be compromised before being captured by  $\mu$ CFI, as mentioned in the paper [17]. This weakens its security guarantee.

CPI is another closely related system. It can guarantee the integrity of all code pointers in the program by separating them and related critical data pointers in a protected safe memory region [23]. As such, CPI can prevent all the control-flow hijacking attacks. Compared to CPI, OS-CFI achieves a similar but slightly relaxed protection in the CFI principle (because OS-CFI still allows some leeway to manipulate the control flow). OS-CFI uses the MPX table to store its metadata. This usage can be applied in CPI as well to further improve its performance, as suggested by the paper itself. Burow et al.

Categories	CFIXX	PathArmor	PittyPat	$\mu$ CFI	OS-CFI
Protected	Object type	Control flow	Control flow	Control flow	Control flow & Object type
Context	vPtr to vTable binding	last branches taken	Processor execution paths	Execution paths and constraint data	Origins of function pointers and objects
CFG	None	On-demand, constraint driven context-sensitive CFG	Abstract-interpretation based online points-to analysis	Run-time points-to analysis	CFGs based on context-, flow- and field-sensitive static points-to analysis
Coverage	Virtual calls	Selected syscalls	Whole program, enforced at selected syscalls	Whole program, enforced at selected syscalls	Whole program, enforced at every ICT
Required hardware	Intel MPX for metadata storage	Intel LBR for taken branches	Intel PT for execution history	Intel PT for execution history and control data	Intel MPX for metadata storage and Intel TSX to protect reference monitors
Kernel changes	No, built-in MPX support	Yes, enforce CFI on the syscall boundary	Yes, redirect traces and enforce CFI on syscall boundary	Yes, redirect traces and enforce CFI on syscall boundary	No, built-in MPX and TSX support
Runtime support	Library to track the type of each object	Per-thread control transfer monitoring	Additional threads to parse trace and verify control flow	Additional threads to parse trace and verify control flow	Hash based verification protected by TSX

Table 6: Comparison between OS-CFI and recent (context-sensitive) CFI systems

independently discovered the way to re-purpose the MPX table as a generic key-value store [5]. As a hardware accelerated data store, MPX can be used in a wide variety of security systems, especially considering that its bound registers can be used for high-performance SFI (software-fault isolation) [4, 22, 39].

Another closely related system is CFIXX [4], which enforces the object-type integrity (OTI). CFIXX prevents attacks such as COOP [32] from subverting an object’s vPtr pointer. OTI is a complementary policy to CFI [4]. It requires and strengthens CFI to provide more complete protection. OS-CFI’s protection of virtual calls uses the same key (but different metadata, i.e., the origin) as OTI as a by-product of using MPX to keep the metadata. As mentioned earlier, OS-CFI can use different keys in its design as long as it can retrieve the origin of the receiving object because the origin alone can uniquely identify the target. Overall, OS-CFI provides stronger security guarantee than CFIXX with its CFI for all ICTs. There are several other systems that focus on protecting virtual calls, such as VTrust [42] and SAFEDISPATCH [20]. OS-CFI supports both C-style ICTs and C++ virtual calls.

## 6 Summary

We have presented a new type of context for CFI systems – origin sensitivity. By considering the origins of function pointers and objects during the verification of control transfers, we can significantly improve the security of CFI by reducing the largest and average EC sizes. By leveraging the commodity hardware features such as MPX and TSX, our system incurs only a small overhead.

## 7 Availability

Our prototype is available as an open-source project at <https://github.com/mustaksecuet/OS-CFI>.

## 8 Acknowledgment

We would like to thank the anonymous reviewers and our shepherd, Dr. Nathan Dautenhahn, for their insightful comments that helped improve the presentation of this paper. This project was partially supported by National Science Foundation (NSF) under Grant 1453020. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of NSF.

## Abstract

Modern computer systems are becoming faster, more efficient, and increasingly interconnected with each generation. Thus, these platforms grow more complex, with new features continually introducing the possibility of new bugs. Although the semiconductor industry employs a combination of different verification techniques to ensure the security of System-on-Chip (SoC) designs, a growing number of increasingly sophisticated attacks are starting to leverage *cross-layer bugs*. These attacks leverage subtle interactions between hardware and software, as recently demonstrated through a series of real-world exploits that affected all major hardware vendors.

In this paper, we take a deep dive into microarchitectural security from a hardware designer’s perspective by reviewing state-of-the-art approaches used to detect hardware vulnerabilities at design time. We show that a protection gap currently exists, leaving chip designs vulnerable to software-based attacks that can exploit these hardware vulnerabilities. Inspired by real-world vulnerabilities and insights from our industry collaborator (a leading chip manufacturer), we construct the first representative testbed of real-world software-exploitable RTL bugs based on RISC-V SoCs. Patching these bugs may not always be possible and can potentially result in a product recall. Based on our testbed, we conduct two extensive case studies to analyze the effectiveness of state-of-the-art security verification approaches and identify specific classes of vulnerabilities, which we call *HardFails*, which these approaches fail to detect. Through our work, we focus the spotlight on specific limitations of these approaches to propel future research in these directions. We envision our RISC-V testbed of RTL bugs providing a rich exploratory ground for future research in hardware security verification and contributing to the open-source hardware landscape.

## 1 Introduction

The divide between hardware and software security research is starting to take its toll, as we witness increasingly sophis-

ticated attacks that combine software and hardware bugs to exploit computing platforms at runtime [20, 23, 36, 43, 45, 64, 69, 72, 74]. These cross-layer attacks disrupt traditional threat models, which assume either hardware-only or software-only adversaries. Such attacks may provoke physical effects to induce hardware faults or trigger unintended microarchitectural states. They can make these effects visible to software adversaries, enabling them to exploit these hardware vulnerabilities remotely. The affected targets range from low-end embedded devices to complex servers, that are hardened with advanced defenses, such as data-execution prevention, supervisor-mode execution prevention, and control-flow integrity.

**Hardware vulnerabilities.** Cross-layer attacks circumvent many existing security mechanisms [20, 23, 43, 45, 64, 69, 72, 74], that focus on mitigating attacks exploiting software vulnerabilities. Moreover, hardware-security extensions are not designed to tackle hardware vulnerabilities. Their implementation remains vulnerable to potentially undetected hardware bugs committed at design-time. In fact, deployed extensions such as SGX [31] and TrustZone [3] have been targets of successful cross-layer attacks [69, 72]. Research projects such as Sanctum [18], Sanctuary [8], or Keystone [39] are also not designed to ensure security at the hardware implementation level. Hardware vulnerabilities can occur due to: (a) incorrect or ambiguous security specifications, (b) incorrect design, (c) flawed implementation of the design, or (d) a combination thereof. Hardware implementation bugs are introduced either through human error or faulty translation of the design in gate-level synthesis.

SoC designs are typically implemented at register-transfer level (RTL) by engineers using hardware description languages (HDLs), such as Verilog and VHDL, which are *synthesized* into a lower-level representation using automated tools. Just like software programmers introduce bugs to the high-level code, hardware engineers may accidentally introduce bugs to the RTL code. While software errors typically cause a crash which triggers various fallback routines to ensure the safety and security of other programs running on the platform, no such safety net exists for hardware bugs. Thus, even mi-

nor glitches in the implementation of a module within the processor can compromise the SoC security objectives and result in persistent/permanent denial of service, IP leakage, or exposure of assets to untrusted entities.

**Detecting hardware security bugs.** The semiconductor industry makes extensive use of a variety of techniques, such as simulation, emulation, and formal verification to detect such bugs. Examples of industry-standard tools include In-cisive [10], Solidify [5], Questa Simulation and Questa Formal [44], OneSpin 360 [66], and JasperGold [11]. These were originally designed for *functional verification* with security-specific verification incorporated into them later.

While a rich body of knowledge exists within the software community (e.g., regarding software exploitation and techniques to automatically detect software vulnerabilities [38, 46]), security-focused HDL analysis is currently lagging behind [35, 57]. Hence, the industry has recently adopted a *security development lifecycle* (SDL) for hardware [68] — inspired by software practices [26]. This process combines different techniques and tools, such as RTL manual code audits, assertion-based testing, dynamic simulation, and automated security verification. However, the recent outbreak of *cross-layer attacks* [20, 23, 37, 43, 45, 47, 48, 49, 51, 52, 53, 64, 69, 74] poses a spectrum of difficult challenges for these security verification techniques, because they exploit complex and subtle inter-dependencies between hardware and software. Existing verification techniques are fundamentally limited in modeling and verifying these interactions. Moreover, they also do not scale with the size and complexity of real-world SoC designs.

**Goals and Contributions.** In this paper, we show that current hardware security verification techniques are fundamentally limited. We provide a wide range of results using a comprehensive test harness, encompassing different types of hardware vulnerabilities commonly found in real-world platforms. To that end, we conducted two case studies to systematically and qualitatively assess existing verification techniques with respect to detecting RTL bugs. Together with our industry partners, we compiled a list of 31 RTL bugs based on public Common Vulnerabilities and Exposures (CVEs) [37, 43, 50, 54, 55] and real-world errata [25]. We injected bugs into two open-source RISC-V-based SoC designs, which we will open-source after publication.

We organized an international public hardware security competition, Hack@DAC, where 54 teams of researchers competed for three months to find these bugs. While a number of bugs could not be detected by any of the teams, several participants also reported *new* vulnerabilities of which we had no prior knowledge. The teams used manual RTL inspection and simulation techniques to detect the bugs. In industry, these are usually complemented by automated tool-based and formal verification approaches. Thus, our second case study focused on two state-of-the-art formal verification tools: the

first deploys formal verification to perform exhaustive and complete verification of a hardware design, while the second leverages formal verification and path sensitization to check for illegal data flows and fault tolerance.

Our second case study revealed that certain properties of RTL bugs pose challenges for state-of-the-art verification techniques with respect to black-box abstraction, timing flow, and non-register states. This causes security bugs in the RTL of real-world SoCs to slip through the verification process. Our results from the two case studies indicate that particular classes of hardware bugs entirely evade detection—even when complementing systematic tool-based verification approaches with manual inspection. RTL bugs arising from complex and cross-modular interactions in SoCs render these bugs extremely difficult to detect in practice. Furthermore, such bugs are exploitable from software, and thus can compromise the entire platform. We call such bugs **HardFails**.

To the best of our knowledge, this is the first work to provide a systematic and in-depth analysis of state-of-the-art hardware verification approaches for security-relevant RTL bugs. Our findings shed light on the capacity of these tools and demonstrate reproducibly how bugs can slip through current hardware security verification processes. Being also software-exploitable, these bugs pose an immense security threat to SoCs. Through our work, we highlight why further research is required to improve state-of-the-art security verification of hardware. To summarize, our main contributions are:

- **Systematic evaluation and case studies:** We compile a comprehensive test harness of real-world RTL bugs, on which we base our two case studies: (1) Hack@DAC'18, in which 54 independent teams of researchers competed worldwide over three months to find these bugs using manual RTL inspection and simulation techniques, and (2) an investigation of the bugs using industry-leading formal verification tools that are representative of the current state of the art. Our results show that particular classes of bugs entirely evade detection, despite combining both tool-based security verification approaches and manual analysis.
- **Stealthy hardware bugs:** We identify *HardFails* as RTL bugs that are distinctly challenging to detect using industry-standard security verification techniques. We explain the fundamental limitations of these techniques in detail using concrete examples.
- **Open-sourcing:** We will open-source our bugs testbed at publication to the community.

## 2 SoC Verification Processes and Pitfalls

Similar to the Security Development Lifecycle (SDL) deployed by software companies [26], semiconductor companies [15, 35, 40] have recently adapted SDL for hardware design [57]. We describe next the conventional SDL process for hardware and the challenges thereof.

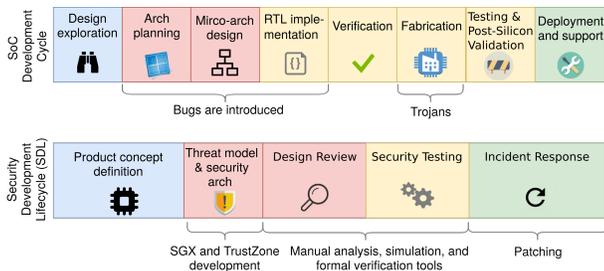

FIGURE 1: Typical Security Development Lifecycle (SDL) process followed by semiconductor companies.

## 2.1 The Security Development Lifecycle (SDL) for Hardware

SDL is conducted concurrently with the conventional hardware development lifecycle [68], as shown in Figure 1. The top half of Figure 1 shows the hardware development lifecycle. It begins with design exploration followed by defining the specifications of the product architecture. After the architecture specification, the microarchitecture is designed and implemented in RTL. Concurrently, pre-silicon verification efforts are conducted until tape-out to detect and fix all functional bugs that do not meet the *functional specification*. After tape-out and fabrication, iterations of post-silicon validation, functional testing, and tape-out "spins" begin. This cycle is repeated until no defects are found and all quality requirements are met. Only then does the chip enter mass production and is shipped out. Any issues found later in-field are debugged, and the chip is then either patched if possible or recalled.

After architectural features are finalized, a security assessment is performed, shown in the bottom half of Figure 1. The adversary model and the security objectives are compiled in the *security specification*. This typically entails a list of assets, entry points to access these assets, and the adversary capabilities and architectural security objectives to mitigate these threats. These are translated into microarchitectural security specifications, including security test cases (both positive and negative). After implementation, pre-silicon security verification is conducted using dynamic verification (i.e., simulation and emulation), formal verification, and manual RTL reviews. The chip is not signed off for tape-out until all security specifications are met. After tape-out and fabrication, post-silicon security verification commences. The identified security bugs in both pre-silicon and post-silicon phases are rated for severity using the industry-standard scoring systems such as the Common Vulnerability Scoring System (CVSS) [30] and promptly fixed. Incident response teams handle issues in shipped products and provide patches, if possible.

## 2.2 Challenges with SDL

Despite multiple tools and security validation techniques used by industry to conduct SDL, it remains a highly challenging,

tedious, and complex process even for industry experts. Existing techniques largely rely on human expertise to define the security test cases and run the tests. The correct *security specifications* must be exhaustively anticipated, identified, and accurately and adequately expressed using security properties that can be captured and verified by the tools. We discuss these challenges further in Section 7.

Besides the specifications, the techniques and tools themselves are not scalable and are less effective in capturing subtle semantics that are relevant to many vulnerabilities, which is the focus of this work. We elaborate next on the limitations of state-of-the-art hardware security verification tools commonly used by industry. To investigate the capabilities of these tools, we then construct a comprehensive test-harness of real-world RTL vulnerabilities.

## 3 Assessing Hardware Security Verification

In this section, we focus on why the verification of the security properties of modern hardware is challenging and provide requirements for assessing existing verification techniques under realistic conditions. First, we describe how these verification techniques fall short. Second, we provide a list of common and realistic classes of hardware bugs, which we use to construct a test harness for assessing the effectiveness of these verification techniques. Third, we discuss how these bugs relate to the common security goals of a chip.

### 3.1 Limitations of Automated Verification

Modern hardware designs are highly complex and incorporate hundreds of in-house and third-party Intellectual Property (IP) components. This creates room for vulnerabilities to be introduced in the inter-modular interactions of the design hierarchy. Multi-core architectures typically have an intricate interconnect fabric between individual cores (utilizing complex communication protocols), multi-level cache controllers with shared un-core and private on-core caches, memory and interrupt controllers, and debug and I/O interfaces.

For each core, these components contain logical modules such as fetch and decode stages, an instruction scheduler, individual execution units, branch prediction, instruction and data caches, the memory subsystem, re-order buffers, and queues. These are implemented and connected using individual RTL modules. The average size of each module is several hundred lines of code (LOC). Thus, real-world SoCs can easily approach 100,000 lines of RTL code, and some designs may even have millions of LOC. Automatically verifying, at the RTL level, the respective interconnections and checking them against security specifications raises a number of fundamental challenges for the state-of-the-art approaches. These are described below.

**L-1: Cross-modular effects.** Hardware modules are interconnected in a highly hierarchical design with multiple inter-

dependencies. Thus, an RTL bug located in an individual module may trigger a vulnerability in intra- and inter-modular information flows spanning multiple complex modules. Pinpointing the bug requires analyzing these flows across the relevant modules, which is highly cumbersome and unreliable to achieve by manual inspection. It also pushes formal verification techniques to their limits, which work by modeling and analyzing all the RTL modules of the design to verify whether design specifications (expressed using security property assertions, invariants and disallowed information flows) and implementation match.

Detecting such vulnerabilities requires loading the RTL code of all the relevant modules into the tools to model and analyze the entire state space, thus driving them quickly into *state explosion* due to the underlying modeling algorithms [16, 21]. Alleviating this by providing additional computational resources and time is not scalable as the complexity of SoCs continues to increase. Selective "black-box" abstraction of some of the modules, state space constraining, and bounded-model checking are often used. However, they do not eliminate the fundamental problem and rely on interactive human expertise. Erroneously applying them may introduce false negatives, leading to missed vulnerabilities.

**L-2: Timing-flow gap.** Current industry-standard techniques are limited in capturing and verifying security properties related to timing flow (in terms of clock cycle latency). This leads to vast sources of information leakage due to software-exploitable timing channels (Section 8). A timing flow exists between the circuit's input and output when the number of clock cycles required for the generation of the output depends on input values or the current memory/register state. This can be exploited to leak sensitive information when the timing variation is discernible by an adversary and can be used to infer inputs or memory states. This is especially problematic for information flows and resource sharing across different privilege levels. This timing variation should remain indistinguishable in the RTL, or should not be measurable from the software. However, current industry-standard security verification techniques focus exclusively on the functional information flow of the logic and fail to model the associated timing flow. The complexity of timing-related security issues is aggravated when the timing flow along a logic path spans multiple modules and involves various inter-dependencies.

**L-3: Cache-state gap.** State-of-the-art verification techniques only model and analyze the *architectural state* of a processor by exclusively focusing on the state of registers. However, they do not support analysis of non-register states, such as caches, thus completely discarding modern processors' highly complex microarchitecture and diverse hierarchy of caches. This can lead to severe security vulnerabilities arising due to state changes that are unaccounted for, e.g., the changing state of shared cache resources across multiple privilege levels. Caches represent a state that is influenced directly or indirectly by many control-path signals and can generate

security vulnerabilities in their interactions, such as illegal information leakages across different privilege levels. Identifying RTL bugs that trigger such vulnerabilities is beyond the capabilities of existing techniques.

**L-4: Hardware-software interactions.** Some RTL bugs remain indiscernible to hardware security verification techniques because they are not explicitly vulnerable unless triggered by the software. For instance, although many SoC access control policies are directly implemented in hardware, some are programmable by the overlying firmware to allow for post-silicon flexibility. Hence, reasoning on whether an RTL bug exists is inconclusive when considering the hardware RTL in isolation. These vulnerabilities would only materialize when the hardware-software interactions are considered, and existing techniques do not handle such interactions.

## 3.2 Constructing Real-World RTL Bugs

To systematically assess the state of the art in hardware security verification with respect to the limitations described above, we construct a test harness by implementing a large number of RTL bugs in RISC-V SoC designs (cf. Table 1). To the best of our knowledge, we are the first to compile and showcase such a collection of hardware bugs. Together with our co-authors at Intel, we base our selection and construction of bugs on a solid representative spectrum of real-world CVEs [47, 48, 49, 51, 52, 53] as shown in Table 1. For instance, bug #22 was inspired by a recent security vulnerability in the Boot ROM of video gaming mobile processors [56], which allowed an attacker to bring the device into BootROM Recovery Mode (RCM) via USB access. This buffer overflow vulnerability affected many millions of devices and is popularly used to hack a popular video gaming console<sup>1</sup>.

We extensively researched CVEs that are based on software-exploitable hardware and firmware bugs and classified them into different categories depending on the weaknesses they represent and the modules they impact. We reproduced them by constructing representative bugs in the RTL and demonstrated their software exploitability and severity by crafting a real-world software exploit based on one of these bugs in Appendix D. Other bugs were constructed with our collaborating hardware security professionals, inspired by bugs that they have previously encountered and patched during the pre-silicon phase, which thus never escalated into CVEs. The chosen bugs were implemented to achieve coverage of different security-relevant modules of the SoC.

Since industry-standard processors are based on proprietary RTL implementations, we mimic the CVEs by reproducing and injecting them into the RTL of widely-used RISC-V SoCs. We also investigate more complex microarchitecture features of another RISC-V SoC and discover vulnerabilities already existing in its RTL (Section 4). These RTL bugs manifest as:

<sup>1</sup><https://github.com/Cease-and-DeSwitch/fusee-launcher>

- **Incorrect assignment bugs** due to variables, registers, and parameters being assigned incorrect literal values, incorrectly connected or left floating unintended.
- **Timing bugs** resulting from timing flow issues and incorrect behavior relevant to clock signaling such as information leakage.
- **Incorrect case statement bugs** in the finite state machine (FSM) models such as incorrect or incomplete selection criteria, or incorrect behavior within a case.
- **Incorrect if-else conditional bugs** due to incorrect boolean conditions or incorrect behavior described within either branch.
- **Specification bugs** due to a mismatch between a specified property and its actual implementation or poorly specified / under-specified behavior.

These seemingly minor RTL coding errors may constitute security vulnerabilities, some of which are very difficult to detect during verification. This is because of their interconnection and interaction with the surrounding logic that affects the complexity of the subtle side effects they generate in their manifestation. Some of these RTL bugs may be patched by modifying parts of the software stack that use the hardware (e.g., using firmware/microcode updates) to circumvent them and mitigate specific exploits. However, since RTL is usually compiled into hardwired integrated circuitry logic, the underlying bugs cannot, in principle, be patched after production.

The limited capabilities of current detection approaches in modeling hardware designs and formulating and capturing relevant security assertions raise challenges for detecting some of these vulnerabilities, which we investigate in depth in this work. We describe next the adversary model we assume for our vulnerabilities and our investigation.

### 3.3 Adversary Model

In our work, we investigate microarchitectural details at the RTL level. However, all hardware vendors keep their proprietary industry designs and implementations closed. Hence, we use an open-source SoC based on the popular open-source RISC-V [73] architecture as our platform. RISC-V supports a wide range of possible configurations with many standard features that are also available in modern processor designs, such as privilege level separation, virtual memory, and multi-threading, as well as optimization features such as configurable branch prediction and out-of-order execution.

RISC-V RTL is freely available and open to inspection and modification. While this is not necessarily the case for industry-leading chip designs, an adversary might be able to reverse engineer or disclose/steal parts of the chip using existing tools<sup>2,3</sup>. Hence, we consider a strong adversary that can also inspect the RTL code.

In particular, we make the following assumptions:

<sup>2</sup><https://www.chipworks.com/>  
<sup>3</sup><http://www.degate.org/>

- **Hardware Vulnerability:** The attacker has knowledge of a vulnerability in the hardware design of the SoC (i.e., at the RTL level) and can trigger the bug from software.
- **User Access:** The attacker has complete control over a user-space process, and thus can issue unprivileged instructions and system calls in the basic RISC-V architecture.
- **Secure Software:** Software vulnerabilities and resulting attacks, such as code-reuse [65] and data-only attacks [27] against the software stack, are orthogonal to the problem of cross-layer bugs. Thus, we assume all platform software is protected by defenses such as control-flow integrity [1] and data-flow integrity [13], or is formally verified.

The goal of an adversary is to leverage the vulnerability on the chip to provoke unintended functionality, e.g., access to protected memory locations, code execution with elevated privileges, breaking the isolation of other processes running on the platform, or permanently denying services. RTL bugs in certain hardware modules might only be exploitable with physical access to the victim device, for instance, bugs in debug interfaces. However, other bugs are software-exploitable, and thus have a higher impact in practice. Hence, we focus on software-exploitable RTL vulnerabilities, such as the exploit showcased in Appendix D. Persistent denial of service (PDoS) attacks that require exclusive physical access are out of scope. JTAG attacks, though they require physical access, are still in scope as the end user may be the attacker and might attempt to unlock the device to steal manufacturer secrets. Furthermore, exploiting the JTAG interface often requires a combination of both physical access and privilege escalation by means of a software exploit to enable the JTAG interface. We also note that an adversary with unprivileged access is a realistic model for real-world SoCs: Many platforms provide services to other devices over the local network or even over the internet. Thus, the attacker can obtain some limited software access to the platform already, e.g., through a webserver or an RPC interface. Furthermore, we emphasize that this work focuses only on tools and techniques used to detect bugs before tape-out.

## 4 HardFails: Hardware Security Bugs

In light of the limitations of state-of-the-art verification tools (Section 3.1), we constructed a testbed of real-world RTL bugs (Section 3.2) and conducted two extensive case studies on their detection (described next in Sections 5 and 6). Based on our findings, we have identified particular classes of hardware bugs that exhibit properties that render them more challenging to detect with state-of-the-art techniques. We call these HardFails. We now describe different types of these HardFails encountered during our analysis of two RISC-V SoCs, Ariane [59] and PULPissimo [61]. In Section 5.3, we describe the actual bugs we instantiated for our case studies.

Ariane is a 6-stage in-order RISC-V CPU that implements the RISC-V draft privilege specification and can run Linux OS. It has a memory management unit (MMU) consisting of

TABLE 1: Detection results for bugs in PULPissimo SoC based on formal verification (**SPV** and **FPV**, i.e., JasperGold Security Path Verification and Formal Property Verification) and our hardware security competition (**M&S**, i.e., manual inspection and simulation). Check and cross marks indicate detected and undetected bugs, respectively. Bugs marked **inserted** were injected by our team and based on the listed CVEs, while bugs marked **native** were already present in the SoC and discovered by the participants during Hack@DAC. **LOC** denotes the number of lines of code, and **states** denotes the total number of logic states for the modules needed to attempt to detect this bug.

#	Bug	Type	SPV	FPV	M&S	Modules	LOC	# States
1	Address range overlap between peripherals SPI Master and SoC	Inserted (CVE-2018-12206 / CVE-2019-6260 / CVE-2018-8933)	✓	✓	✓	91	6685	$1.5 \times 10^{20}$
2	Addresses for L2 memory is out of the specified range.	Native	✓	✓	✓	43	6746	$3.5 \times 10^{13}$
3	Processor assigns privilege level of execution incorrectly from CSR.	Native	✗	✓	✓	2	1186	$2.1 \times 10^{96}$
4	Register that controls GPIO lock can be written to with software.	Inserted (CVE-2017-18293)	✓	✓	✗	2	1186	$2.1 \times 10^{96}$
5	Reset clears the GPIO lock control register.	Inserted (CVE-2017-18293)	✓	✓	✗	2	408	1
6	Incorrect address range for APB allows memory aliasing.	Inserted (CVE-2018-12206 / CVE-2019-6260)	✓	✓	✗	1	110	2
7	AXI address decoder ignores errors.	Inserted (CVE-2018-4850)	✗	✓	✗	1	227	2
8	Address range overlap between GPIO, SPI, and SoC control peripherals.	Inserted (CVE-2018-12206 / CVE-2017-5704)	✓	✓	✓	68	14635	$9.4 \times 10^{21}$
9	Incorrect password checking logic in debug unit.	Inserted (CVE-2018-8870)	✗	✓	✗	4	436	1
10	Advanced debug unit only checks 31 of the 32 bits of the password.	Inserted (CVE-2017-18347 / CVE-2017-7564)	✗	✓	✗	4	436	16
11	Able to access debug register when in halt mode.	Native (CVE-2017-18347 / CVE-2017-7564)	✗	✓	✓	2	887	1
12	Password check for the debug unit does not reset after successful check.	Inserted (CVE-2017-7564)	✗	✓	✓	4	436	16

25	Unprivileged user-space code can write to the privileged CSR.	Inserted (CVE-2018-7522 / CVE-2017-0352)	✗	✗	✓	1	745	1
26	Advanced debug unit password is hard-coded and set on reset.	Inserted (CVE-2018-8870)	✗	✗	✓	1	406	16
27	Secure mode is not required to write to interrupt registers.	Inserted (CVE-2017-0352)	✗	✗	✓	1	303	1
28	JTAG interface is not password protected.	Native	✗	✗	✓	1	441	1
29	Output of MAC is not erased on reset.	Inserted	✗	✗	✓	1	65	1
30	Supervisor mode signal of a core is floating preventing the use of SMAP.	Native	✗	✗	✓	1	282	1
31	GPIO is able to read/write to instruction and data cache.	Native	✗	✗	✓	1	151	4

data and instruction translation lookaside buffers (TLBs), a hardware page table walker, and a branch prediction unit to enable speculative execution. Figure 4 in Appendix A shows its high-level microarchitecture.

PULPissimo is an SoC based on a simpler RISC-V core with both instruction and data RAM as shown in Figure 2. It provides an Advanced Extensible Interface (AXI) for accessing memory from the core. Peripherals are directly connected to an Advanced Peripheral Bus (APB) which connects them to the AXI through a bridge module. It provides support for autonomous I/O, external interrupt controllers and features a debug unit and an SPI slave.

### TLB Page Fault Timing Side Channel (L-1 & L-2).

While analyzing the Ariane RTL, we noted a timing side-channel leakage with TLB accesses. TLB page faults due to illegal accesses occur in a different number of clock cycles than page faults that occur due to unmapped memory (we contacted the developers and they acknowledged the vulnerability). This timing disparity in the RTL manifests in the microarchitectural behavior of the processor. Thus, it constitutes a software-visible side channel due to the measurable clock-cycle difference in the two cases. Previous work already demonstrated how this can be exploited by user-space adversaries to probe mapped and unmapped pages and to break randomization-based defenses [24, 29]. Timing flow properties cannot be directly expressed by simple properties or modeled by state-of-the-art verification techniques. Moreover, for this vulnerability, we identify at least seven RTL modules that would need to be modeled, analyzed and verified in combination, namely: *mmu.sv* - *nbdcache.sv* - *tlb.sv* instantiations - *ptw.sv* - *load\_unit.sv* - *store\_unit.sv*. Besides modeling their complex inter- and intra-modular logic flows (L-1), the timing flows need to be modeled to formally prove the absence of this timing channel leakage, which is *not supported* by current industry-standard tools (L-2). Hence, the only alternative is to verify this property by manually inspecting and following the clock cycle transitions across the RTL modules, which is highly cumbersome and error-prone. However, the design must still be analyzed to verify that timing side-channel resilience is implemented correctly and bug-free in the RTL. This only becomes far more complex for real-world industry-standard SoCs. We show the RTL hierarchy of the Ariane core in Figure 5 in Appendix A to illustrate its complexity.

### Pre-Fetched Cache State Not Rolled Back (L-1 & L-3).

Another issue in Ariane is with the cache state when a system return instruction is executed, where the privilege level of the core is not changed until this instruction is retired. Before retirement, linear fetching (guided by branch prediction) of data and instructions following the unretired system return instruction continues at the current higher system privilege level. Once the instruction is retired, the execution mode of the core is changed to the unprivileged level, but the entries that

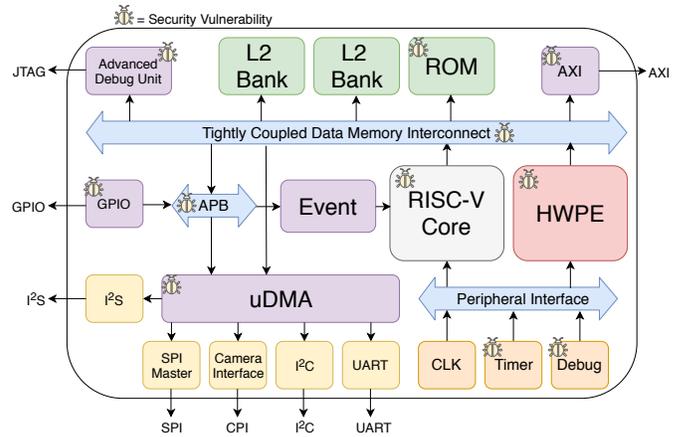

FIGURE 2: Hardware overview of the PULPissimo SoC. Each bug icon indicates the presence of at least one security vulnerability in the module.

were pre-fetched into the cache (at the system privilege level) do not get flushed. These shared cache entries are visible to user-space software, thus enabling timing channels between privileged and unprivileged software.

Verifying the implementation of all the flush control signals and their behavior in all different states of the processor requires examining at least eight modules: *ariane.sv* - *controller.sv* - *frontend.sv* - *id\_stage.sv* - *icache.sv* - *fetch\_fifo* - *ariane\_pkg.sv* - *csr\_regfile.sv* (see Figure 5). This is complex because it requires identifying and defining all the relevant security properties to be checked across these RTL modules. Since current industry-standard approaches do not support expressive capturing and the verification of cache states, this issue in the RTL can only be found by manual inspection.

### Firmware-Configured Memory Ranges (L-4).

In PULPissimo, we added peripherals with injected bugs to reproduce bugs from CVEs. We added an AES encryption/decryption engine whose input key is stored and fetched from memory tightly coupled to the processor. The memory address the key is stored in is unknown, and whether it is within the protected memory range or not is inconclusive by observing the RTL alone. In real-world SoCs, the AES key is stored in programmable fuses. During secure boot, the bootloader/firmware senses the fuses and stores the key to memory-mapped registers. The access control filter is then configured to allow only the AES engine access to these registers, thus protecting this memory range. Because the open-source SoC we used did not contain a fuse infrastructure, the key storage was mimicked to be in a register in the Memory-Mapped I/O (MMIO) space.

Although the information flow of the AES key is defined in hardware, its location is controlled by the firmware. Reasoning on whether the information flow is allowed or not using conventional hardware verification approaches is inconclusive when considering the RTL code in isolation.

The vulnerable hardware/firmware interactions cannot be identified unless they are co-verified. Unfortunately, current industry-standard tools do not support this.

### Memory Address Range Overlap (L-1 & L-4).

PULPissimo provides I/O support to its peripherals by mapping them to different memory address ranges. If an address range overlap bug is committed at design-time or by firmware, this can break access control policies and have critical security consequences, e.g., privilege escalation. We injected an RTL bug where there is address range overlap between the SPI Master Peripheral and the SoC Control Peripheral. This allowed the untrusted SPI Master to access the SoC Control memory address range over the APB bus.

Verifying issues at the SoC interconnect in such complex bus protocols is challenging since too many modules needed to support the interconnect have to be modeled to properly verify their security. This increases the scope and the complexity of potential bugs far beyond just a few modules, as shown in Table 1. Such an effect causes an explosion of the state space since all the possible states have to be modeled accurately to remain sound. Proof kits for accelerated verification of advanced SoC interconnect protocols were introduced to mitigate this for a small number of bus protocols (AMBA3 and AMBA4). However, this requires an add-on to the default software and many protocols are not supported<sup>4</sup>.

## 5 Crowdsourcing Detection

We organized and conducted a capture-the-flag competition, Hack@DAC, in which 54 teams (7 from leading industry vendors and 47 from academia) participated. The objective for the teams was to detect as many RTL bugs as possible from those we injected deliberately in real-world open-source SoC designs (see Table 1). This is designed to mimic real-world bug bounty programs from semiconductor companies [17, 32, 62, 63]. The teams were free to use any techniques: simulation, manual inspection, or formal verification.

### 5.1 Competition Preparation

RTL of open-source RISC-V SoCs was used as the testbed for Hack@DAC and our investigation. Although these SoCs are less complex than high-end industry proprietary designs, this allows us to feasibly inject (and detect) bugs into less complex RTL. Thus, this represents the best-case results for the verification techniques used during Hack@DAC and our investigation. Moreover, it allows us to open-source and show-case our testbed and bugs to the community. Hack@DAC consisted of two phases: a preliminary Phase 1 and final Phase 2, which featured the RISC-V Pulpino and PULPissimo SoCs,

<sup>4</sup><http://www.marketwired.com/press-release/jasper-introduces-intelligent-proof-kits-faster-more-accurate-verification-soc-interface-1368721.htm>

respectively. Phase 1 was conducted remotely over a two-month period. Phase 2 was conducted in an 8-hour time frame co-located with DAC (Design Automation Conference).

For Phase 1, we chose the Pulpino [60] SoC since it was a real-world, yet not an overly complex SoC design for the teams to work with. It features a RISC-V core with instruction and data RAM, an AXI interconnect for accessing memory, with peripherals on an APB accessing the AXI through a bridge module. It also features a boot ROM, a debug unit and a serial peripheral interface (SPI) slave. We inserted security bugs in multiples modules of the SoC, including the AXI, APB, debug unit, GPIO, and bridge.

For Phase 2, we chose the more complex PULPissimo [61] SoC, shown in Figure 2. It additionally supports hardware processing engines, DMA, and more peripherals. This allowed us to extend the SoC with additional security features, making room for additional bugs. Some native security bugs were discovered by the teams and were reported to the SoC designers.

### 5.2 Competition Objectives

For Hack@DAC, we first implemented additional security features in the SoC, then defined the security objectives and adversary model and accordingly inserted the bugs. Specifying the security goals and the adversary model allows teams to define what constitutes a security bug. Teams had to provide a bug description, location of RTL file, code reference, the security impact, adversary profile, and the proposed mitigation. **Security Features:** We added password-based locks on the JTAG modules of both SoCs and access control on certain peripherals. For the Phase-2 SoC, we also added a cryptographic unit implementing multiple cryptographic algorithms. We injected bugs into these features and native features to generate security threats as a result.

**Security Goals:** We provided the three main security goals for the target SoCs to the teams. Firstly, unprivileged code should not escalate beyond its privilege level. Secondly, the JTAG module should be protected against an adversary with physical access. Finally, the SoCs should thwart software adversaries from launching denial-of-service attacks.

### 5.3 Overview of Competition Bugs

As described earlier in Section 3.2, the bugs were selected and injected together with our Intel collaborators. They are inspired by their hardware security expertise and real-world CVEs (cf. Table 1) and aim to achieve coverage of different security-relevant components of the SoC. Several participants also reported a number of *native* bugs already present in the SoC that we did not deliberately inject. We describe below some of the most interesting bugs.

**UDMA address range overlap:** We modified the memory address range of the UDMA so that it overlaps with the master port to the SPI. This bug allows an adversary with access to

the UMDA memory to escalate its privileges and modify the SPI memory. This bug is an example of the "Memory Address Range Overlap" HardFail type in Section 4. Other address range configuration bugs (#1, 2, 6 and 8) were also injected in the APB bus for different peripherals.

**GPIO errors:** The address range of the GPIO memory was erroneously declared. An adversary with GPIO access can escalate its privilege and access the SPI Master and SoC Control. The GPIO enable was rigged to display a fixed erroneous status of '1', which did not give the user a correct display of the actual GPIO status. The GPIO lock control register was made write-accessible by user-space code, and it was flawed to clear at reset. Bugs #4, 5, 24 and 31 are such examples.

**Debug/JTAG errors:** The password-checking logic in the debug unit was flawed and its state was not being correctly reset after a successful check. We hard-coded the debug unit password, and the JTAG interface was not password protected. Bugs #9, 10, 11, 16, 26, and 28 are such examples.

**Untrusted boot ROM:** A native bug (bug #22) would allow unprivileged compromise of the boot ROM and potentially the execution of untrusted boot code at a privileged level, thus disclosing sensitive information.

**Erroneous AXI finite-state machine:** We injected a bug (bug #7) in the AXI address decoder such that, if an error signal is generated on the memory bus while the underlining logic is still handling an outstanding transaction, the next signal to be handled will instead be considered operational by the module unconditionally. This bug can be exploited to cause computational faults in the execution of security-critical code (we showcase how to exploit this vulnerability—which was not detected by all teams—in Appendix D).

**Cryptographic unit bugs:** We injected bugs in a cryptographic unit that we inserted to trigger denial-of-service, a broken cryptographic implementation, insecure key storage, and disallowed information leakage. Bugs #18, 19, 20, 21, and 29 are such examples.

## 5.4 Competition Results

Various insights were drawn from the submitted bug reports and results, which are summarized in Table 1.

**Analyzing the bug reports:** Bug reports submitted by teams revealed which bug types were harder to detect and analyze using existing approaches. We evaluated the submissions and rated them for accuracy and detail, e.g., bug validity, methodology used, and security impact.

**Detected bugs:** Most teams easily detected two bugs in PULPissimo. The first one is where debug IPs were used when not intended. The second bug was where we declared a local parameter PULP\_SEC, which was always set to '1', instead of the intended PULP\_SECURE. The former was detected because debugging interfaces represent security-critical regions of the chip. The latter was detected because it indi-

cated intuitively that exploiting this parameter would lead to privilege escalation attacks. The teams reported that they prioritized inspecting security-relevant modules of the SoC, such as the debug interfaces.

**Undetected bugs:** Many inserted bugs were not detected. One was in the advanced debug unit, where the password bit index register has an overflow (bug #9). This is an example of a security flaw that would be hard to detect by methods other than verification. Moreover, the presence of many bugs within the advanced debug unit password checker further masked this bug. Another bug was the cryptographic unit key storage in unprotected memory (bug #20). The teams could not detect it as they focused on the RTL code in isolation and did not consider HW/FW interactions.

**Techniques used by the teams:** The teams were free to use any techniques to detect the bugs but most teams eventually relied on manual inspection and simulation.

- **Formal verification:** One team used an open-source formal verification tool (VeriCoq), but they reported little success because these tools (i) did not scale well with the complete SoC and (ii) required expertise to use and define the security properties. Some teams deployed their in-house verification techniques, albeit with little success. They eventually resorted to manual analysis.
- **Assertion-based simulation:** Some teams prepared RTL testbenches and conducted property-based simulations using SystemVerilog assertion statements.
- **Manual inspection:** All teams relied on manual inspection methods since they are the easiest and most accessible and require less expertise than formal verification, especially when working under time constraints. A couple of teams reported prioritizing the inspection of security-critical modules such as debug interfaces.
- **Software-based testing:** One team detected software-exposure and privilege escalation bugs by running C code on the processor and attempting to make arbitrary reads/writes to privileged memory locations. In doing this, they could detect bugs #4, #8, #15, and #17.

**Limitations of manual analysis:** While manual inspection can detect the widest array of bugs, our analysis of the Hack@DAC results reveals its limitations. Manual analysis is qualitative and difficult to scale to cross-layer and more complex bugs. In Table 1, out of 16 cross-module bugs (spanning more than one module) only 9 were identified using manual inspection. Three of them (#18, #19, and #20) were also undetected by formal verification methods, which is 10% of the bugs in our case studies.

## 6 Detection Using State-of-The-Art Tools

Our study reveals two results: (1) a number of bugs could not be detected by means of manual auditing and other ad-hoc methods, and (2) the teams were able to find bugs already existing in the SoC which we did not inject and were not

aware of. This prompted us to conduct a second in-house case study to further investigate whether formal verification techniques can be used to detect these bugs. In practice, hardware-security verification engineers use a combination of techniques such as formal verification, simulation, emulation, and manual inspection. Our first case study covered manual inspection, simulation and emulation techniques. Thus, we focused our second case study on assessing the effectiveness of industry-standard formal verification techniques usually used for verifying pre-silicon hardware security.

In real-world security testing (see Section 2), engineers will not have prior knowledge of the specific vulnerabilities they are trying to find. Our goal, however, is to investigate how an industry-standard tool can detect RTL bugs that we deliberately inject in an open-source SoC and have prior knowledge of (see Table 1). Since there is no regulation or explicitly defined standard for hardware-security verification, we focus our investigation on the most popular and de-facto standard formal verification platform used in industry [11]. This platform encompasses a representative suite of different state-of-the-art formal verification techniques for hardware security assurance. As opposed to simulation and emulation techniques, formal verification guarantees to model the state space of the design and formally prove the desired properties. We emphasize that we deliberately fix all other variables involved in the security testing process, in order to focus in a controlled setting on testing the capacity and limitations of the techniques and tools themselves. Thus, our results reflect the effectiveness of tools in a best case where the bug is known a priori. This eliminates the possibility of writing an incorrect security property assertion which fails to detect the bug.

## 6.1 Detection Methodology

We examined each of the injected bugs and its nature in order to determine which formal technique would be best suited to detect it. We used two formal techniques: Formal Property Verification (FPV) and JasperGold’s Security Path Verification (SPV) [12]. They represent the state of the art in hardware security verification and are used widely by the semiconductor industry [4], including Intel.

**FPV** checks whether a set of security properties, usually specified as SystemVerilog Assertions (SVA), hold true for the given RTL. To describe the assertions correctly, we examined the location of each bug in the RTL and how its behavior is manifested with the surrounding logic and input/output relationships. Once we specified the security properties using *assert*, *assume* and *cover* statements, we determined which RTL modules we need to model to prove these assertions. If a security property is violated, the tool generates a counterexample; this is examined to ensure whether the intended security property is indeed violated or is a false alarm.

**SPV** detects bugs which specifically involve unauthorized information flow. Such properties cannot be directly captured using SVA/PSL assertions. SPV uses path sensitization tech-

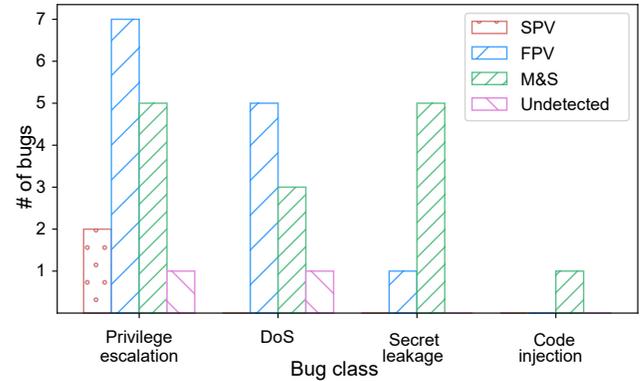

FIGURE 3: Verification results grouped by bug class and the number of bugs in each class detected by Security Path Verification (SPV), Formal Property Verification (FPV) and manual inspection and simulation techniques (M&S).

niques to exhaustively and formally check if unauthorized data propagates (through a functional path) from a source to a destination signal. To specify the SPV properties, we identified source signals where the sensitive information was located and destination signals where it should *not* propagate. We then identified the bounding preconditions to constrain the paths the tool searches to alleviate state and time explosion. Similar to FPV, we identified the modules that are required to capture the information flow of interest. This must include source, destination and intermediate modules, as well as modules that generate control signals which interfere with the information flow.

## 6.2 Detection Results

Of the 31 bugs we investigated, shown in Table 1, using the formal verification techniques described above, only 15 (48%) were detected. While we attempted to detect all 31 bugs formally, we were able to formulate security properties for only 17 bugs. This indicates that the main challenge with using formal verification tools is identifying and expressing security properties that the tools are capable of capturing and checking. Bugs due to ambiguous specifications of interconnect logic, for instance, are examples of bugs that are difficult to create security properties for.

Our results, shown in Figure 3, indicate that privilege escalation and denial-of-service (DoS) bugs were the most detected at 60% and 67% respectively. Secret leakage only had a 17% detection rate due to incorrect design specification for one bug, state explosion and the inability to express properties that the tool can assert for the remaining bugs. The code injection bug was undetected by formal techniques. Bugs at the interconnect level of the SoC such as bugs #1 and #2 were especially challenging since they involved a large number of highly complex and inter-connected modules that needed to be loaded and modeled by the tool (see L-1 in Section 3.1). Bug #20, which involves hardware/firmware interactions, was also

detected by neither the state-of-the-art FPV nor SPV since they analyze the RTL in isolation (see L-4 in Section 3.1). We describe these bugs in more detail in Appendix C.

### 6.3 State-Explosion Problem

Formal verification techniques are quickly driven into state space explosion when analyzing large designs with many states. Many large interconnected RTL modules, like those relevant to bugs #1 and #2, can have states in the order of magnitude of  $10^{20}$ . Even smaller ones, like these used for bugs #3 and #4, can have a very large number of states, as shown in Table 1. When combined, the entire SoC will have a total number of states significantly higher than any of the results in Table 1. Attempting to model the entire SoC drove the tool into state explosion, and it ran out of memory and crashed. Formal verification tools, including those specific to security verification are currently incapable of handling so many states, even when computational resources are increased. This is further aggravated for industry-standard complex SoCs.

Because the entire SoC cannot be modeled and analyzed at once, detecting cross-modular bugs becomes very challenging. Engineers work around this (not fundamentally solve it) by adopting a divide-and-conquer approach and selecting which modules are relevant for the properties being tested and which can be black-boxed or abstracted. However, this is time-consuming, non-automated, error-prone, and requires expertise and knowledge of both the tools and design. By relying on the human factor, the tool can no longer guarantee the absence of bugs for the entire design, which is the original advantage of formal verification.

## 7 Discussion and Future Work

We now describe why microcode patching is insufficient for RTL bugs while emphasizing the need for advancing the hardware security verification process. We discuss the additional challenges of the overall process, besides the limitations of the industry-standard tools, which is the focus of this work.

### 7.1 Microcode Patching

While existing industry-grade SoCs support hotfixes by *microcode patching* for instance, this approach is limited to a handful of changes to the instruction set architecture, e.g., modifying the interface of individual complex instructions and adding or removing instructions [25]. Some vulnerabilities cannot even be patched by microcode, such as the recent Spoiler attack [33]. Fundamentally mitigating this requires fixing the hardware of the memory subsystem at the hardware design phase. For legacy systems, the application developer is advised to follow best practices for developing side channel-

resilient software<sup>5</sup>. For vulnerabilities that can be patched, patches at this higher abstraction level in the firmware only act as a "symptomatic" fix that circumvent the RTL bug. However, they do not fundamentally patch the bug in the RTL, which is already realized as hardwired logic. Thus, microcode patching is a fallback for RTL bugs discovered after production, when you can not patch the RTL. They may also incur performance impact<sup>6</sup> that could be avoided if the underlying problem is discovered and fixed during design.

### 7.2 Additional Challenges in Practice

**Functional vs. Security Specifications.** As described in Section 2, pre- and post-silicon validation efforts are conducted to verify that the implementation fully matches both its functional and security specifications. The process becomes increasingly difficult (almost impossible) as the system complexity increases and specification ambiguity arises. Deviations from specification occur due to either functional or security bugs, and it is important to distinguish between them. While functional bugs generate functionally incorrect results, security bugs are not reflected in functionality. They arise due to unconsidered and corner threat cases that are unlikely to get triggered, thus making them more challenging to detect and cover. It is, therefore, important to distinguish between functional and security specifications, since these are often the references for different verification teams working concurrently on the same RTL implementation.

**Specification Ambiguity.** Another challenge entails anticipating and identifying all the security properties that are required in a real-world scenario. We analyzed the efficacy of industry-standard tools in a controlled setting—where we have prior knowledge of the bugs. However, in practice hardware validation teams do not have prior knowledge of the bugs. Security specifications are often incomplete and ambiguous, only outlining the required security properties under an assumed adversary model. These specifications are invalidated once the adversary model is changed. This is often the case with IP reuse, where the RTL code for one product is re-purposed for another with a different set of security requirements and usage scenarios. Parameters may be declared multiple times and get misinterpreted by the tools, thus causing bugs to slip undetected. Furthermore, specs usually do not specify bugs and information flows that should not exist, and there is no automated approach to determine whether one is proving the intended properties. Thus, a combination of incomplete or incorrect design decisions and implementation errors can easily introduce bugs to the design.

<sup>5</sup><https://www.intel.com/content/www/us/en/security-center/advisory/intel-sa-00238.html>

<sup>6</sup><https://access.redhat.com/articles/3307751>

### 7.3 Future Research Directions

Through our work, we shed light on the limitations of state-of-the-art verification techniques. In doing so, we hope to motivate further research in advancing these techniques to adequately capture and detect these vulnerabilities.

Although manual RTL inspection is generally useful and can potentially cover a wide array of bugs, its efficacy depends exclusively on the expertise of the engineer. This can be inefficient, unreliable and ad hoc in light of rapidly evolving chip designs. Exhaustive testing of specifications through simulation requires amounts of resources exponential in the size of the input (i.e., design state space) while coverage must be intelligently maximized. Hence, current approaches face severe scalability challenges, as diagnosing software-exploitable bugs that reside deep in the design pipeline can require simulation of trillions of cycles [14]. Our results indicate that it is important to first identify high-risk components due to software exposure, such as password checkers, crypto cores, and control registers, and prioritize analyzing them. Scalability due to complex inter-dependencies among modules is one challenge for detection. Vulnerabilities associated with non-register states (such as caches) or clock-cycle dependencies (i.e., timing flows) are another open problem. Initial research is underway [71] to analyze a limited amount of low-level firmware running on top of a simulated RTL design for information and timing flow violations. However, these approaches are still in their infancy and yet to scale for real-world SoC designs.

## 8 Related Work

We now present related work in hardware security verification while identifying limitations with respect to detecting HardFails. We also provide an overview of recent software attacks exploiting underlying hardware vulnerabilities.

### 8.1 Current Detection Approaches

Security-aware design of hardware has gained significance only recently as the critical security threat posed by hardware vulnerabilities became acutely established. Confidentiality and integrity are the commonly investigated properties [19] in hardware security. They are usually expressed using information flow properties between entities at different security levels. Besides manual inspection and simulation-based techniques, systematic approaches proposed for verifying hardware security properties include formal verification methods such as proof assistance, model-checking, symbolic execution, and information flow tracking. We exclude the related work in testing mechanisms, e.g., JTAG/scan-chain/built-in self-test, because they are leveraged for hardware testing **after** fabrication. However, the focus of this work is on verifying the security of the hardware **before** fabrication. Inter-

estingly, this includes verifying that the test mechanisms are correctly implemented in the RTL, otherwise they may constitute security vulnerabilities when used after fabrication (see bugs#9,#10,#11,#12,#16, #26 of the JTAG/debug interface).

**Proof assistant and theorem-proving** methods rely on mathematically modeling the system and the required security properties into logical theorems and formally proving if the model complies with the properties. VeriCoq [7] based on the Coq proof assistant transforms the Verilog code that describes the hardware design into proof-carrying code. VeriCoq supports the automated conversion of only a subset of Verilog code into Coq. However, this assumes accurate labeling of the initial sensitivity labels of each and every signal in order to effectively track the flow of information. This is cumbersome, error-prone, generates many false positives, and does not scale well in practice beyond toy examples. Moreover, timing (and other) side-channel information flows are not modeled. Finally, computational scalability to verifying real-world complex SoCs remains an issue given that the proof verification for a single AES core requires  $\approx 30$  minutes to complete [6].

**Model checking**-based approaches check a given property against the modeled state space and possible state transitions using provided invariants and predefined conditions. They face scalability issues as computation time scales exponentially with the model and state space size. This can be alleviated by using abstraction to simplify the model or constraining the state space to a bounded number of states using assumptions and conditions. However, this introduces false positives, may miss vulnerabilities, and requires expert knowledge. Most industry-leading tools, such as the one we use in this work, rely on model checking algorithms such as boolean satisfiability problem solvers and property specification schemes, e.g., assertion-based verification to verify the required properties of a given hardware design.

**Side-channel leakage modeling and detection** remain an open problem. Recent work [76] uses the Mur $\phi$  model checker to verify different hardware cache architectures for side-channel leakage against different adversary models. A formal verification methodology for SGX and Sanctum enclaves under a limited adversary was introduced in [67]. However, such approaches are not directly applicable to hardware implementation. They also rely exclusively on formal verification and remain inherently limited by the underlying algorithms in terms of scalability and state space explosion, besides demanding particular expertise to use.

**Information flow analysis** (such as SPV) works by assigning a security label (or a *taint*) to a data input and monitoring the taint propagation. In this way, the designer can verify whether the system adheres to the required security policies. Recently, information flow tracking (IFT) has been shown effective in identifying security vulnerabilities, including timing side channels and information-leaking hardware Trojans.

IFT techniques are proposed at different levels of abstraction: gate-, RT, and language-levels. Gate-level information

flow tracking (GLIFT) [2, 58, 70] performs the IFT analysis directly at gate-level by generating GLIFT analysis logic that is derived from the original logic and operates in parallel to it. Although gate-level IFT logic is easy to automatically generate, it does not scale well. Furthermore, when IFT uses strict non-interference, it taints any information flow conservatively as a vulnerability [34] which scales well for more complex hardware, but generates too many false positives.

At the language level, Caisson [42] and Sapper [41] are security-aware HDLs that use a typing system where the designer assigns security "labels" to each variable (wire or register) based on the security policies required. However, they both require redesigning the RTL using a new hardware description language which is not practical. SecVerilog [22, 75] overcomes this by extending the Verilog language with a dynamic security type system. Designers assign a security label to each variable (wire or register) in the RTL to enable a compile-time check of hardware information flow. However, this involves complex analysis during simulation to reason about the run-time behavior of the hardware state and dependencies across data types for precise flow tracking.

**Hardware/firmware co-verification** to capture and verify hardware/firmware interactions remains an open challenge and is not available in widely used industry-standard tools. A co-verification methodology [28] addresses the semantic gap between hardware and firmware by modeling hardware and firmware using instruction-level abstraction to leverage software verification techniques. However, this requires modeling the hardware that interacts with firmware into an abstraction which is semi-automatic, cumbersome, and lossy.

While research is underway [71] to analyze a limited amount of low-level firmware running on top of a simulated RTL design these approaches are still under development and not scalable. Current verification approaches focus on register-state information-flow analysis, e.g., to monitor whether sensitive locations are accessible from unprivileged signal sources. Further research is required to explicitly model non-register states and timing explicitly alongside the existing capabilities of these tools.

## 8.2 Recent Attacks

We present and cautiously classify the underlying hardware vulnerabilities of recent cross-layer exploits (see Table 2 in Appendix B), using the categories introduced in 3.1. We do not have access to proprietary processor implementations, so our classification is only based on our deductions from the published technical descriptions. Yarom et al. demonstrate that software-visible side channels can exist even below cache-line granularity in CacheBleed [74]—undermining a core assumption of prior defenses, such as scatter-gather [9]. MemJam [45] exploits false read-after-write dependencies in the CPU to maliciously slow down victim accesses to memory blocks within a cache line. We categorize the underlying vulnerabilities of CacheBleed and MemJam as potentially

hard to detect in RTL due to the many cross-module connections involved and the timing-flow leakage. The timing flow leakage is caused by the software triggering clock cycle differences in accesses that map to the same bank below cache line granularity, thus breaking constant-time implementations.

The TLBleed [23] attack shows how current TLB implementations can be exploited to break state-of-the-art cache side-channel protections. As described in Section 4, TLBs are typically highly interconnected with complex processor modules, such as the cache controller and memory management unit, making vulnerabilities therein very hard to detect through automated verification or manual inspection.

BranchScope [20] extracts information through the directional branch predictor, thus bypassing software mitigations that prevent leakage via the BTB. We classify it as a cache-state gap in branch prediction units, which is significantly challenging to detect using existing RTL security verification tools, which cannot capture and verify cache states. Melt-down [43] exploits speculative execution on modern processors to completely bypass all memory access restrictions. Van Bulck et al. [72] also demonstrated how to apply this to Intel SGX. Similarly, Spectre [37] exploits out-of-order execution across different user-space processes as arbitrary instruction executions would continue during speculation. We recognize these vulnerabilities are hard to detect due to scalability challenges in existing tools, since the out-of-order scheduling module is connected to many subsystems in the CPU. Additionally, manually inspecting these interconnected complex RTL modules is very challenging and cumbersome.

CLKScrew [69] abuses low-level power-management functionality that is exposed to software to induce faults and glitches dynamically at runtime in the processor. We categorize CLKScrew to have vulnerable hardware-firmware interactions and timing-flow leakage, since it directly exposes clock-tuning functionality to attacker-controlled software.

## 9 Conclusion

Software security bugs and their impact have been known for many decades, with a spectrum of established techniques to detect and mitigate them. However, the threat of hardware security bugs has only recently become significant as cross-layer exploits have shown that they can completely undermine software security protections. While some hardware bugs can be patched with microcode updates, many cannot, often leaving millions of affected chips in the wild. In this paper, we presented the first testbed of RTL bugs and systematically analyzed the effectiveness of state-of-the-art formal verification techniques, manual inspection and simulation methods in detecting these bugs. We organized an international hardware security competition and an in-house study. Our results have shown that 54 teams were only able to detect 61% of the total number of bugs, while with industry-leading formal verification techniques, we were only able to detect 48% of

the bugs. We showcase that the grave security impact of many of these undetected bugs is only further exacerbated by being software-exploitable.

Our investigation revealed the limitations of state-of-the-art verification/detection techniques with respect to detecting certain classes of hardware security bugs that exhibit particular properties. These approaches remain limited in the face of detecting vulnerabilities that require capturing and verifying complex cross-module inter-dependencies, timing flows, cache states, and hardware-firmware interactions. While these effects are common in SoC designs, they are difficult to model, capture, and verify using current approaches. Our investigative work highlights the necessity of treating the detection of hardware bugs as significantly as that of software bugs. Through our work, we highlight the pressing call for further research to advance the state of the art in hardware security verification. Particularly, our results indicate the need for increased scalability, efficacy and automation of these tools, making them easily applicable to large-scale commercial SoC designs—without which software protections are futile.

## Acknowledgments

We thank our anonymous reviewers and shepherd, Stephen Checkoway, for their valuable feedback. The work was supported by the Intel Collaborative Research Institute for Collaborative Autonomous & Resilient Systems (ICRI-CARS), the German Research Foundation (DFG) by CRC 1119 CROSSING P3, and the Office of Naval Research (ONR Award #N00014-18-1-2058). We would also like to acknowledge the co-organizers of Hack@DAC: Dan Holcomb (UMass-Amherst), Siddharth Garg (NYU), and Sourav Sudhir (TAMU), and the sponsors of Hack@DAC: the National Science Foundation (NSF CNS-1749175), NYU CCS, Mentor - a Siemens Business and CROSSING, as well as the participants of Hack@DAC.

## Appendix

### A Ariane Core and RTL Hierarchy

Figure 4 shows the high-level microarchitecture of the Ariane core to visualize its complexity. This RISC-V core is far less complex than an x86 or ARM processor and their more sophisticated microarchitectural and optimization features.

Figure 5 illustrates the hierarchy of the RTL components of the Ariane core. This focuses only on the core and excludes all uncore components, such as the AXI interconnect, peripherals, the debug module, boot ROM, and RAM.

### B Recent Microarchitectural Attacks

We reviewed recent microarchitectural attacks with respect to existing hardware verification approaches and their limitations. We observe that the underlying vulnerabilities would be difficult to detect due to the properties that they exhibit, rendering them as potential HardFails. We do not have access to their proprietary RTL implementation and cannot inspect the underlying vulnerabilities. Thus, we only infer from the published technical descriptions and errata of these attacks the nature of the underlying RTL issues. We classify in Table 2 the properties of these vulnerabilities that represent challenges for state-of-the-art hardware security verification.

### C Details on the Pulpissimo Bugs

We present next more detail on some of the RTL bugs used in our investigation.

**Bugs in crypto units and incorrect usage:** We extended the SoC with a faulty cryptographic unit with a multiplexer to select between AES, SHA1, MD5, and a temperature sensor. The multiplexer was modified such that a race condition occurs if more than one bit in the status register is enabled, causing unreliable behavior in these security critical modules.

Furthermore, both SHA-1 and MD5 are outdated and broken cryptographic hash functions. Such bugs are not detectable by formal verification, since they occur due to a specification/design issue and not an implementation flaw, therefore they are out of the scope of automated approaches and formal verification methods. The cryptographic key is

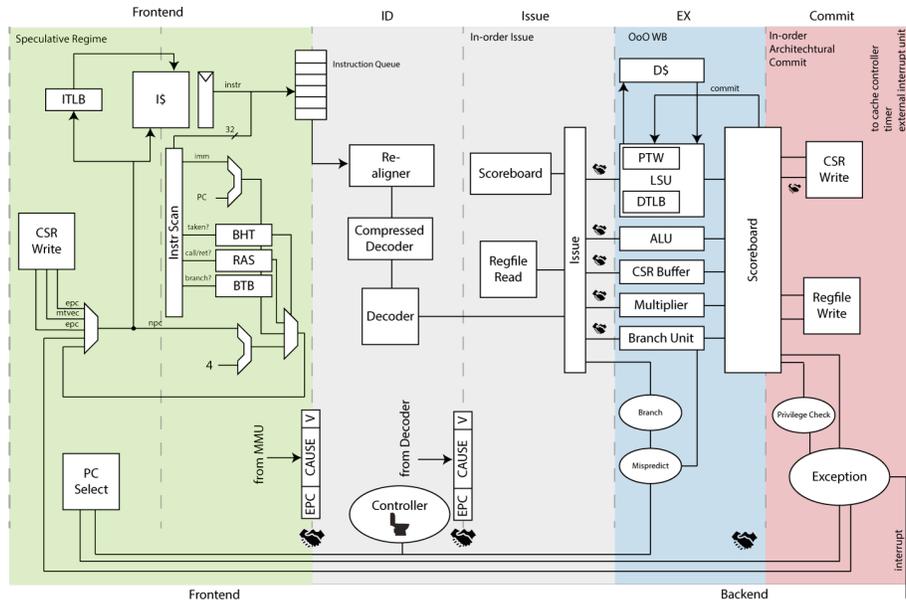

FIGURE 4: High-level architecture of the Ariane core [59].

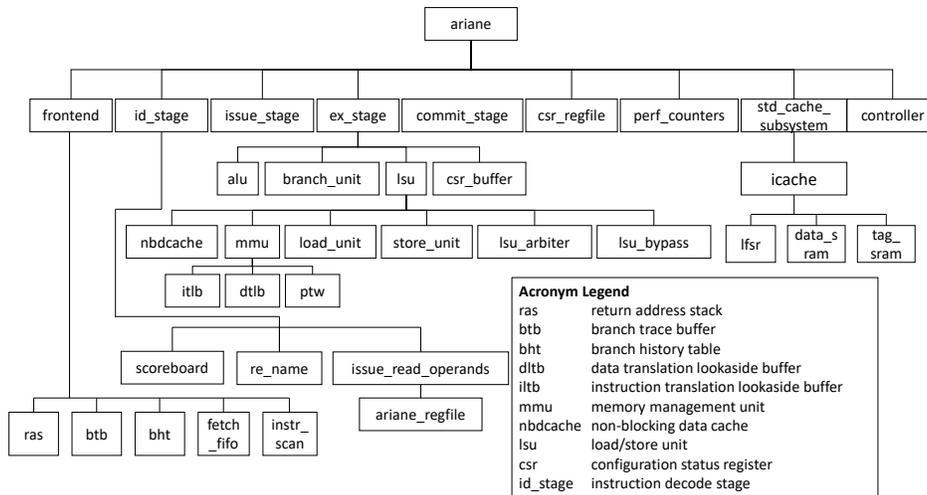

FIGURE 5: Illustration of the RTL module hierarchy of the Ariane core.

Attack	Privilege Level	Memory Corruption	Information Leakage	Cross-modular	HW/FW-Interaction	Cache-State Gap	Timing-Flow Gap	HardFail
Cachebleed [74]	unprivileged	X	✓	X	X	X	✓	✓
TLBleed [23]	unprivileged	X	✓	✓	X	✓	✓	✓
BranchScope [20]	unprivileged	X	✓	X	X	✓	X	✓
Spectre [37]	unprivileged	X	✓	✓	X	✓	X	✓
Meltdown [43]	unprivileged	X	✓	✓	X	✓	X	✓
MemJam [45]	supervisor	X	✓	✓	X	X	✓	✓
CLKScrew [69]	supervisor	✓	✓	X	✓	X	✓	✓
Foreshadow [72]	supervisor	✓	✓	✓	✓	✓	X	✓

TABLE 2: Classification of the underlying vulnerabilities of recent microarchitectural attacks by their HardFail properties.

stored and read from unprotected memory, allowing an attacker access to the key. The temperature sensor register value is incorrectly muxed as output instead of the crypto engine output and vice versa, which are illegal information flows that could compromise the cryptographic operations.

**LISTING 1: Incorrect use of crypto RTL:** The key input for the AES (`g_input`) is connected to signal `b`. This signal is then passed through various modules until it connects directly to a tightly coupled memory in the processor.

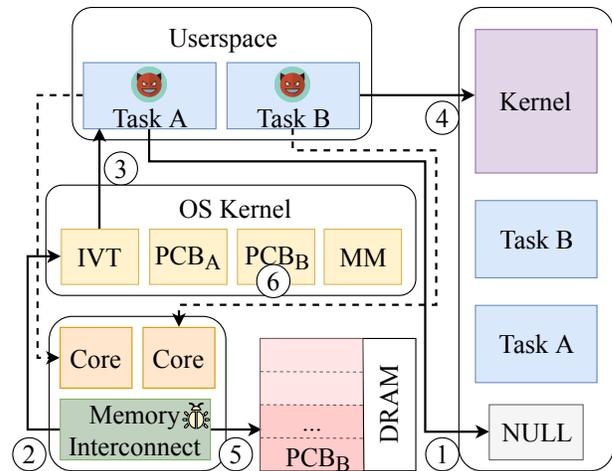

```
input logic [127:0] b,
...
aes_lcc aes(
  .clk(0),
  .rst(1),
  .g_input(b),
  .e_input(a),
  .o(aes_out)
);
```

**Bugs in security modes:** We replaced the standard `PULP_SECURE` parameter in the `riscv_cs_registers` and `riscv_int_controller` modules with another constant parameter to permanently disable the security/privilege checks for these two modules. Another bug we inserted is switching the write and read protections for the AXI bus interface, causing erroneous checks for read and write accesses.

**Bugs in the JTAG module:** We implemented a JTAG password-checker and injected multiple bugs in it, including the password being hardcoded in the password checking file. The password checker also only checks the first 31 bits, which reduces the computational complexity of brute-forcing the password. The password checker does not reset the state of the correctness of the password when an incorrect bit is detected, allowing for repeated partial checks of passwords to end up unlocking the password checker. This is also facilitated by the fact that the index overflows after the user hits bit 31, allowing for an infinite cycling of bit checks.

## D Exploiting Hardware Bugs From Software

We now explain how one of our hardware bugs can be exploited in real-world by software. This RTL vulnerability manifests in the following way. When an error signal is generated on the memory bus while the underlining logic is still handling an outstanding transaction, the next signal to be handled will instead be considered operational by the module unconditionally. This lets erroneous memory accesses slip through hardware checks at runtime. Armed with the knowledge about this vulnerability, an adversary can force memory access errors to evade the checks. As shown in Figure 6, the memory bus decoder unit (unit of the memory interconnect) is assumed to have the bug. This causes errors to be ignored

**FIGURE 6:** Our attack exploits a bug in the implementation of the memory bus of the PULPissimo SoC: by (1) *spamming* the bus with invalid transactions an adversary can make (4) malicious write requests be set to operational.

under certain conditions (see bug number #7 in Table 1). In the first step (1), the attacker generates a user program (Task A) that registers a dummy signal handler for the segmentation fault (`SIGSEGV`) access violation. Task A then executes a loop with (2) a faulting memory access to an invalid memory address (e.g., `LW x5, 0x0`). This will generate an error in the memory subsystem of the processor and issue an invalid memory access interrupt (i.e., `0x0000008C`) to the processor. The processor raises this interrupt to the running software (in this case the OS), using the pre-configured interrupt handler routines in software. The interrupt handler in the OS will then forward this as a signal to the faulting task (3), which keeps looping and continuously generating invalid accesses. Meanwhile, the attacker launches a separate Task B, which will then issue a single memory access (4) to a privileged memory location (e.g., `LW x6, 0xf77c3000`). In this situation, multiple outstanding memory transactions will be generated on the memory bus, all of which but one will be flagged as faulty by the address decoder. An invalid memory access will always proceed the single access of Task B. Due to the bug in the memory bus address decoder, (5) the malicious memory access will become operational instead of triggering an error. Thus, the attacker can issue read and write instructions to arbitrary privileged (and unprivileged) memory by forcing the malicious illegal access to be preceded with a faulty access. Using this technique the attacker can eventually leverage this read-write primitive, e.g., (6) to escalate privileges by writing the process control block (`PCB_B`) for his task to elevate the corresponding process to root. This bug leaves the attacker with access to a root process, gaining control over the entire platform and potentially compromising all the processes running on the system.

## Abstract

Code disclosure attacks are one of the major threats to a computer system, considering that code often contains security sensitive information, such as intellectual properties (e.g., secret algorithm), sensitive data (e.g., cryptographic keys) and the gadgets for launching code reuse attacks. To stymie this class of attacks, security researchers have devised a strong memory protection mechanism, called eXecute-Only-Memory (XOM), that defines special memory regions where instruction execution is permitted but data reads and writes are prohibited. Reflecting the value of XOM, many recent high-end processors have added support for XOM in their hardware. Unfortunately, however, low-end embedded processors have yet to provide hardware support for XOM.

In this paper, we propose a novel technique, named *u*XOM, that realizes XOM in a way that is secure and highly optimized to work on Cortex-M, which is a prominent processor series used in low-end embedded devices. *u*XOM achieves its security and efficiency by using special architectural features in Cortex-M: *unprivileged memory instructions* and an *MPU*. We present several challenges in making XOM non-bypassable under strong attackers and introduce our code analysis and instrumentation to solve these challenges. Our evaluation reveals that *u*XOM successfully realizes XOM in Cortex-M processor with much better efficiency in terms of execution time, code size and energy consumption compared to a software-only XOM implementation for Cortex-M.

## 1 Introduction

When it comes to the security of a computing system, the protection of the code running on the system should be of top priority because the code defines security critical behaviors of the system. For instance, if attackers are able to modify existing code or inject new code, they may place the victim system

under their control. Fortunately, code injection attacks nowadays can be mitigated by simply enforcing the well-known security policy,  $W \oplus X$ . Since virtually all processors today are equipped with at least five basic memory permissions: read-write-execute (RWX), read-write (RW), read-execute (RX), read-only (RO) and no-access (NA),  $W \oplus X$  can be efficiently enforced in hardware for a memory region solely by disabling RWX.

However, even if attackers are not able to modify the system's code, the system can still be threatened by *disclosure attacks* that attempt to read part of or possibly the entire code. Because code often contains intellectual properties (IPs) including core algorithms and sensitive data like cryptographic keys, disclosure attacks severely damage the security of victim systems by exposing critical information to unauthorized users. Even worse, disclosure attacks can be abused by attackers to launch *code reuse attacks* (CRAs), which allow the attacker to perform adversarial behaviors without modifying its code contents. It has been shown that attackers who can see the instructions in the code may launch a CRA wherein they craft a malicious code sequence by chaining the existing code snippets scattered around the program binary [34].

In order to prevent disclosure attacks, *eXecute-Only-Memory* (XOM) has been a core security mechanism of various countermeasure techniques [6–8, 13, 16, 17, 31, 37]. XOM is a strong memory protection mechanism that defines a special memory region where only instruction executions are allowed, and any attempts for instruction reads or writes are prohibited. Thus, as long as sensitive information such as IPs and the code contents are stored inside the region protected by XOM, developers are in principle able to prevent direct exposure of the code content as well as the code layout. This simple but tangible security benefit of XOM has led several researchers to propose hardware-assisted XOM on various architectures. For example, some have proposed an architecture that implements XOM by encrypting executable memory and decrypting instructions only when they are loaded [24]. However, since their approach mostly imposes significant changes and overhead on the underlying hardware, it cannot

Donghyun Kwon has been affiliated with Electronics and Telecommunications Research Institute (ETRI) since March 2019.

Corresponding authors are Yeongpil Cho and Yunheung Paek.

be adopted readily by the processor vendors for their existing products. Instead, many vendors opt for a less drastic approach that simply augments the basic memory permissions with the new execute-only (XO) permission [8, 10].

As of today, many high-end processors provide XOM capabilities by supporting augmented memory permissions. Consequently, by taking benefits from the hardware support for XOM, low-cost security solutions have been built to mitigate real attacks [8, 10, 13, 16]. However, these security benefits are confined to computing systems for general applications since the XO permission is only available in relatively high-end processors targeting general-purpose machines such as servers, desktops and smartphones. More specifically, applications running on tiny embedded devices cannot enjoy such benefits because only the basic memory permissions (not XOM) are supported in their target processors, which are primarily intended for use in low-cost, low-power computations. As one example of such processors that hardware-level XOM is not built into, we have the ARM *Cortex-M* series, which are prominent processors adopted by numerous low-cost computing devices today [38].

Fortunately, researchers have demonstrated that software fault isolation (SFI) techniques can be used to thwart these prevalent attacks without hardware-level XOM [7, 31]. They are purely software techniques, and thus are able to cope with any types of processors regardless of the underlying architectures. However, the drawback we observed is that SFI-based XOM techniques perform less optimally on certain types of processors, including Cortex-M in particular. More importantly, such techniques can even be circumvented, leading to critical security issues (refer to § 6.4). Motivated by this observation, this paper proposes a novel technique, called *uXOM*, to realize XOM in a way that is secure and highly optimized to work on Cortex-M processors. Since performance is a pivotal concern of tiny embedded devices such as Cortex-M, efficiency must be the most important objective of any technique targeting these low-end processors. To achieve this objective, *uXOM* leverages a special type of instructions, called *unprivileged loads/stores*, provided by the instruction set architecture for ARM Cortex-M. In an ARM-based system, memory can be divided into two classes of regions according to privilege levels: *non-privileged* and *privileged* memory regions. Unprivileged loads/stores can only access non-privileged memory regions, irrespective to the processor's current privilege level (either in a privileged or non-privileged). On the contrary, ordinary loads/stores are permitted to access privileged regions as long as they are executed under the privileged level. This striking difference between unprivileged and ordinary load/store instructions is the key enabler of our technique.

By capitalizing on this difference, we also need to exploit a unique style of running embedded software on the processors to achieve this ultimate goal of *uXOM*. In computing systems, software entities are typically assigned certain privileges during execution. For instance, user applications run

as unprivileged, and the OS kernel as privileged. In practice, however, applications and the kernel in tiny embedded devices are designed to operate with the same privilege level [12, 21]. This is because these embedded systems are typically given real-time constraints, and the privilege mode switching involved in user-kernel privilege isolation is considered very expensive [21]. For the goal of *uXOM* stated above, we utilize these unique architectural characteristics of Cortex-M processors. More specifically, *uXOM* converts all memory instructions into unprivileged ones and sets the code region as privileged. As a result, converted instructions cannot access code regions, thereby effectively enforcing the XO permission onto the code regions. Since the processor is running with privileged level, code execution is still allowed without any permission error.

However, in order to actually realize *uXOM*, we need to tackle the problem that some memory instructions cannot be changed into unprivileged memory instructions. For example, memory instructions accessing critical system resources, such as an interrupt controller, a system timer and a Memory Protection Unit (MPU), should not be converted. Accesses to these resources always require privilege, so the program will crash if instructions accessing these resources are converted to unprivileged ones. In addition, load/store exclusive instructions, which are the special memory instructions for exclusive memory access, do not have unprivileged counterparts. For these instructions, there is no way to implement the intended functionality with unprivileged memory instructions. Therefore, we should analyze the code thoroughly to find these instructions and leave them as the original instructions.

Unfortunately, these unconverted memory instructions can be exploited by attackers to subvert *uXOM*. For example, if the attackers manage to execute these instructions by altering the control flow, they may bypass *uXOM* by (1) turning off the MPU protection or (2) reading the code directly. To prevent such attacks, the unconverted memory instructions need to be instrumented with verification routines to ensure that each memory access using these instructions does not break *uXOM*'s protection. However, the attackers can still bypass the verification routines and directly execute the problematic memory instructions. To handle this challenge, we have devised the *atomic verification* technique that virtually enables memory instructions to be executed atomically with the verification routine, thereby preventing potential attackers from executing the memory instructions without passing the verification.

Another important problem *uXOM* needs to handle is that the attackers can alter control flow to execute *unintended* instructions, which may result from unaligned execution of 32-bit Thumb instructions or execution of the data embedded inside the code region [4]. Among the unintended instructions, attackers may find useful instructions for bypassing *uXOM*, such as ordinary memory instructions. To mitigate this attack vector, *uXOM* analyzes the code to find all potentially harm-

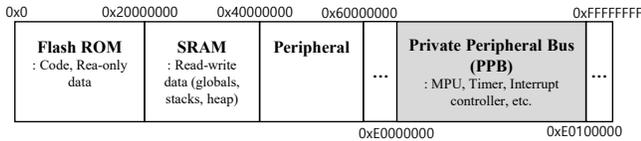

Figure 1: System address map for ARMv7-M [18]

ful unintended instructions and replaces them with alternative instruction sequences that have an equivalent function but do not contain any exploitable unintended instructions.

Built upon LLVM compiler and Radare2 binary analysis framework [32], *uXOM* automatically transforms every software component (i.e., real-time operating systems (RTOSs), the C standard library, and the user application) into a *uXOM*-enabled binary. Currently, *uXOM* supports processors based on ARMv7-M architecture, including Cortex-M3/4/7 processors. To evaluate *uXOM*, we experimented on an Arduino Due board, which ships with a Cortex-M3 processor. Our experiment confirms that *uXOM* works efficiently, empowered with the optimized use of the underlying hardware features. In particular, *uXOM* incurs only 15.7%, 7.3% and 7.5% overhead for code size, execution time and energy, while SFI-based XOM incurs overhead of 50.8%, 22.7%, and 22.3%, respectively. To demonstrate the compatibility of *uXOM* with other XOM-based security solutions, we discuss two use cases of *uXOM*: secret key protection and CRA defense. We implemented and evaluated the second use case, the CRA defense. Even when the CRA defense is applied on top of *uXOM*, it shows only moderate performance overhead, which is 19.3%, 8.6% and 9.7% for code size, execution time and energy, respectively.

The remainder of this paper is organized as follows. § 2 provides the background information. § 3 explains the threat model and assumptions. § 4 and § 5 describe the approach and design of *uXOM*, respectively. § 6 provides experimental results for *uXOM* and its use cases. § 7 presents several discussions regarding *uXOM*, and § 8 explains related works. § 9 concludes the paper.

## 2 Background

Cortex-M(3/4/7) processors targeted in this paper implement the ARMv7-M architecture, the microcontroller (‘M’) profile of the ARMv7 architecture, which features low-latency and highly deterministic operation for embedded systems. In this section, we give background information on the key architectural features of ARMv7-M that are required to understand the design and implementation of *uXOM*.

### 2.1 ARMv7-M Address Map and the Private Peripheral Bus (PPB)

ARMv7-M does not support memory virtualization and the regions for code, data, and other resources are fixed at specific address ranges. Figure 1 shows the system address map for ARMv7-M architecture. The first 0.5 GB (0x0-0x20000000)

is the region where the flash ROM is typically mapped. Code and read-only data are placed here. The memory range 0x20000000-0x40000000 is the SRAM region where read-write data (globals, stack, and heap) are placed. Devices only use a small subset of each region; our test platform (SAM3X8E) has 512KB of flash and 96KB of SRAM. The memory range 0x40000000-0x60000000 is where device peripherals, such as GPIO and UART, are mapped. The 1 MB memory region ranging from 0xE0000000 to 0xE00FFFFF is the PPB region. Various system registers for controlling system configuration and monitoring system status, such as the system timer, the interrupt controller and the MPU, are mapped in this region. The PPB differs from the other memory regions of the system in that only privileged memory instructions are allowed to read from or write to the region. Generally, access permissions for memory regions can be configured through the MPU which we describe in detail below. However, the access permission for the PPB is fixed and even the MPU cannot override the default configuration.

### 2.2 Memory Protection Unit (MPU)

The MPU provides a memory access control functionality for Cortex-M processors. The biggest difference between the MPU and the Memory Management Unit (MMU) equipped in high-end processors is that the MPU does not provide memory virtualization and thus the access control rules are applied on the physical address space. Depending on the setting of the MPU’s memory-mapped registers between 0xE000ED90 and 0xE000EDEC, a limited number (typically 8 or 16) of possibly overlapping regions can be set up, each of which is defined by the base address and the region size. Each region defines separate access permissions for privileged and non-privileged access through the combination of eXecute-Never (XN)-bit and Access Permission (AP)-bits. The available permission settings are RWX, RW, RX, RO, and NA, but in any case, unprivileged access is granted the same or more restrictive permission than privileged accesses. For example, when RO permission is given to a privileged access, unprivileged access can only have NA or RO permissions. If two or more regions have overlapping ranges, the access permission for the higher-numbered region takes effect. For access to memory ranges not covered by any region, it can be configured to always generate a fault or to follow the default access permission, which depends on the specific processor implementation. It is important to note that the read permission should be included in order for the memory region to be executable. This is the reason that XOM cannot be implemented simply by configuring the MPU in Cortex-M processors.

### 2.3 Unprivileged Loads/Stores

The ARMv7-M architecture only supports a thumb instruction set, which is a variable-length instruction set including a mix of traditional 16-bit thumb instructions and 32-bit instructions introduced in Thumb-2 technology. The unprivileged

loads/stores are special types of memory access instructions provided in the instruction set architecture [18]. The main distinction of these instructions is that they always perform memory accesses as if they are executed as unprivileged regardless of the current privilege mode. Thus, memory accesses using these instructions are regulated by the MPU's permission setting for unprivileged accesses. Unprivileged loads/stores are only available in 32-bit encoding and only have immediate-offset addressing mode. They do not support exclusive memory access. They are distinguished by the common suffix 'T' (e.g., LDRT and STRT).

## 2.4 Exception Entry and Return

An exception is a special event indicating that the system has encountered a specific condition that requires attention. It typically results in a forced transfer of control to a special software routine called an exception handler. On ARMv7-M, the location of the exception handlers corresponding to each exception are specified in the vector table pointed to by the Vector Table Offset Register (VTOR). Note that unlike the other ARMv7 profiles, the ARMv7-M has introduced a hardware mechanism that automatically stores and restores core context data (in particular, Program Status Register (xPSR), return address<sup>1</sup>, lr, r12, r3, r2, r1 and r0) on the stack upon exception entry and return. The ARMv7-M profile also exhibits an interesting feature where an exception return occurs when a unique value of `EXC_RETURN` (e.g., `0xFFFFFFFF`) is loaded into the pc via memory load instructions, such as POP, LDM and LDR, or indirect branch instructions, such as BX. Another thing to note about the exception handling in ARMv7-M is that different stack pointer (sp) can be used before and after the exception. ARMv7-M provides two types of sp, called main sp and process sp. The exception handler can only use main sp but the non-handler code can choose which of the two sps to use. The type of stack pointer being currently used is internally managed through CONTROL register, so that stack pointers are always represented as sp in the binary regardless of its actual type.

## 3 Threat Model and Assumptions

Several conditions must be met to realize *uXOM*. First, the target processor must support the MPU and the unprivileged load/store instructions. We also assume that the target devices run standard bare-metal software in which all included software components, such as applications, libraries, and an OS, share a single address space. Notably, we assume that the entire software executes at a privileged level as mentioned in § 1.

Next, we define the capabilities of an attacker. We assume that attackers are only capable of launching software attacks at runtime. We do not consider offline attacks on firmware images, such as disassembling, manipulating, or replacing

<sup>1</sup>the value of the program counter (pc) at the moment of the exception

the firmware, because we believe that these attacks can be thwarted by orthogonal techniques such as code encryption or signing. We also leave hardware attacks, such as bus probing [9] and memory tampering [22] out of consideration. However, we believe that our attackers are still strong enough to jeopardize the security of the target devices. The bare-metal software installed in the device is considered benign but internally holds software vulnerabilities, so that the attackers may exploit the vulnerabilities and ultimately have arbitrary memory read and write capability. With such a strong memory access capability, attackers can access any memory region including code, stack, heap and even the PPB region for system controls. They can also subvert control flow by manipulating function pointers or return addresses. We do not trust any software components, including the exception handlers. Event-driven nature of tiny embedded systems signifies that exception handlers can take a large portion of embedded software components [14], so we cannot just assume the security of these handlers. Thus, we assume that attackers can trigger a vulnerability inside the exception handler and manipulate any data including the cpu context saved on exception entry.

## 4 Approach and Challenges

*uXOM* aims to provide XO permission, which enables effective protection against disclosure attacks for code contents, for commodity bare-metal embedded systems based on the Cortex-M processor. *uXOM* tries to minimize the performance penalty by utilizing hardware features, such as unprivileged memory instructions and the MPU provided by Cortex-M processors. Ideally, *uXOM* converts *all* memory instructions into unprivileged ones. It then configures the MPU upon system boot to set code regions to RX for privileged access and NA for unprivileged access. It also sets the other memory regions (i.e., data regions) to non-executable for both privileged and unprivileged accesses. After the configuration, *uXOM* executes code as privileged. All the converted memory instructions (i.e., unprivileged memory instructions) are allowed to access the data regions in the same way as before. However, these instructions are prohibited from accessing the code region and the PPB region in which the MPU and VTOR are located that are essential for the security of *uXOM* (see the blue arrows in Figure 2). This is because these regions are set to the NA memory permission for unprivileged accesses. As all of the memory instructions have been converted to unprivileged ones, code disclosure attacks are effectively thwarted. In addition, *uXOM* by default enforces  $W\oplus X$  policy that prevents code execution from writable regions. Therefore, any attempt to inject ordinary memory instructions for code disclosure is blocked as well.

**Challenges.** The basic principle of *uXOM* is simple and intuitive as described above. To realize *uXOM* in practice, however, we have to overcome some challenges to build a system that works for real programs and cannot be bypassed by any means. We summarize the challenges of realizing

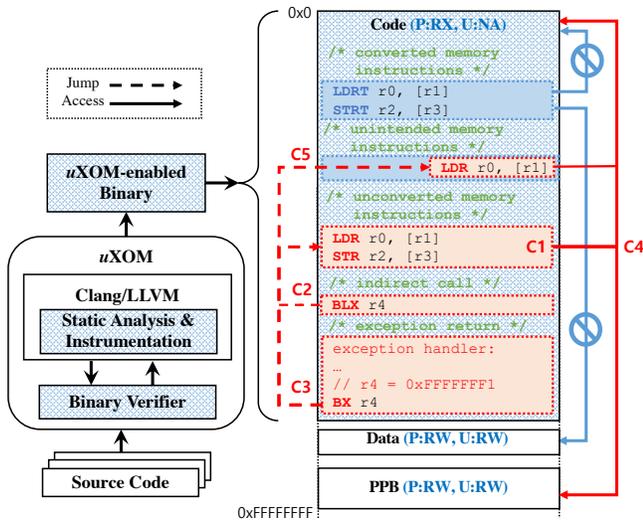

Figure 2: *uXOM* approach

*uXOM* as follows.

- **C1. Unconvertible memory instructions:** To implement *uXOM*, we initially tried to convert all memory instructions into unprivileged ones. However, this naïve attempt will be unsuccessful because unprivileged memory instructions do not support the exclusive memory access that is mainly utilized to implement lock mechanisms, and they cannot access the PPB region to which accesses must be privileged regardless of the MPU configuration. Therefore, we need to thoroughly analyze the entire code, find all these unconvertible instructions, and leave those instructions as the original types. However, these unconverted loads/stores in the program binary resulted in the other challenges, **C2**, **C3** and **C4**.
- **C2. Malicious indirect branches:** In § 3, we assumed that attackers are capable of altering the control flow at runtime by manipulating function pointers or return addresses. Therefore, attackers can deliberately jump to the unconverted loads/stores and exploit them. Unlike unprivileged loads, the unconverted ones can access the code region. Thus, the attackers are now able to read the code without a permission fault. Furthermore, the attackers can also use the unconverted stores to manipulate memory-mapped system registers in the PPB. For example, they can configure the MPU to enable unprivileged access to the code region, completely neutralizing the protection offered by *uXOM*.
- **C3. Malicious exception returns:** This challenge is similar to **C2** in that attackers can hijack control flow and eventually exploit the unconverted loads/stores to thwart *uXOM*. As explained in § 2.4, Cortex-M employs a hardware-based context save and restore mechanism for fast exception entry and return. The problem is that as the context is stored in the stack, attackers can exploit a vulnerability while in the exception handling mode to corrupt any context on the

stack. In particular, the context includes a return address that represents the program point at the moment the exception is taken. If the attackers corrupt the return address and then trigger an exception return by assigning `EXC_RETURN` value to the `pc`, they will be able to execute any instruction in the program including the unconverted loads/stores.

- **C4. Malicious data manipulation:** As stated in § 3, the attackers can perform arbitrary memory read/write, and as a result, they have full control over all kind of program data, such as globals, heap objects, and local variables on the stack. With such control, they can exploit the unconverted loads/stores even while following a legitimate control flow. For example, they can call a MPU configuration function with a crafted argument to neutralize *uXOM* by compromising the necessary memory access permissions.
- **C5. Unintended instructions:** An attacker capable of manipulating control flow may be able to compromise *uXOM* by executing unintended instructions that are not found at compile-time. Concretely, Cortex-M processors targeted in this work support Thumb-2 instruction set architecture [18] that intermixes 16-bit and 32-bit width instructions with 16-bit alignment. Therefore, the attackers can execute unintended instructions by jumping into the middle of a 32-bit instruction. The attackers can also execute unintended instructions through immediate values embedded in code, whose bit-patterns can coincidentally be interpreted as a valid instruction.

## 5 *uXOM*

In this section, we describe the comprehensive details of *uXOM*. We first explain the basic design of *uXOM* for realizing the XO permission (§ 5.1). We then discuss our techniques for overcoming the challenges **C1-C5** (§ 5.2). Next, we present the optimizations applied to reduce performance penalty imposed by *uXOM* (§ 5.3). Lastly, we perform a security analysis to demonstrate that *uXOM* contains no security hazard (§ 5.4).

### 5.1 Basic Design

Before digging into the design details, we briefly describe how *uXOM* works on the system. As illustrated in Figure 2, *uXOM* is implemented as a compiler pass in the LLVM framework and a binary verifier. During compilation, *uXOM* performs static analyses and code instrumentation to generate a *uXOM*-enabled binary (i.e., firmware). Now, when the binary is flashed on to the board and the system boots, *uXOM* automatically enforces the XO permission on the running code.

#### 5.1.1 Instruction Conversion

As RWX or RX is a mandatory permission for code execution on ARMv7-M, executable code regions are always readable and, as a result, are subject to disclosure attacks. Unfortunately, we cannot omit the read permission to imple-

Case	Original Instruction	Converted Instructions
1	LDR rt, [rn, #imm5]	LDRT rt, [rn, #imm8]
2	LDR rt, [rn, #imm12]	(ADD rx, rn, #imm12) LDRT rt, [rx, (#imm8)]
3	LDR rt, [rn, #-imm8]	SUB rx, rn, #imm8 LDRT rt, [rx]
4	LDR rt, [rn, #+/-imm8]! (pre-indexed)	ADD/SUB rx, rn, #imm12 LDRT rt, [rx]
5	LDR rt, [rn], #+/-imm8 (post-indexed)	LDRT rt, [rn] ADD/SUB rx, rn, #imm12
6	LDR rt, [rn, rn]	ADD rx, rn, rn LDRT rt, [rx]
7	LDRD rt, rt2, [rn, #+/-imm8]	(ADD/SUB rx, rn, #imm8) LDRT rt, [rx, (#imm8)] LDRT rt2, [rx, (#imm8)+4]

Table 1: Basic instruction conversion (only shown for load word instruction)

ment XOM because the read permission is required for the processor to fetch instructions from memory. Therefore, our strategy for XOM is to deprive all memory instructions of the access capability for code regions. Briefly put, we convert the memory instructions into unprivileged ones and set the code regions to be accessible only with a privileged manner.

Converting the type of the memory instruction may seem to be a trivial task, but not all memory instructions can be readily converted as unprivileged. The unprivileged loads/stores only support one addressing mode with a base register and an immediate offset which must be positive and fit within 8 bits. On the other hand, the original memory instructions vary in addressing modes, such as register-offset addressing and pre/post-indexed addressing, which updates the base register. Also, there are unprivileged counterparts to the load/store byte and load/store halfword instructions, but there are no corresponding unprivileged instructions for load/store dual (LDRD/STRD) and load/store multiple (LDM/STM), which respectively load/store two or multiple registers. To correctly convert all the memory instructions while preserving the program semantics, we sometimes need extra instructions.

Table 1 summarizes the conversions we apply to different types of load instructions. Cases 3-6 always need an extra ADD or SUB instruction for calculating the memory address. We omit an extra instruction for other cases if we can fit the immediate in the unprivileged instruction. Note that we may need an extra register for storing the calculated address if `rn` is used again in other instructions. We implement our conversion before the register allocation phase so that we do not have to worry about the physical registers and let the compiler choose the best register for the temporary results. LDM/STM instructions are not shown in the table because they only appear during an optimization pass after register allocation. Therefore, when the optimization pass tries to create LDM/STM instructions, we disable the optimization to prevent the generation of those instructions.

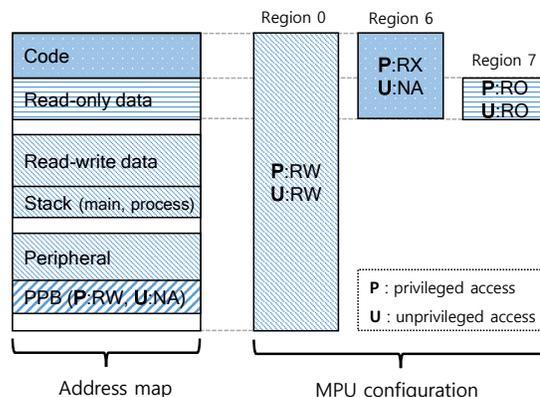

Figure 3: *uXOM*-specific memory permission. Unlabeled regions (white-colored regions) in the address map indicate the unused regions where the memory access generates data abort. The PPB region has a default memory permission (P:RW, U:NA) regardless of the MPU configuration.

### 5.1.2 Permission Control

In order for the XO permission based on the unprivileged load/store instructions to take effect, *uXOM* has to configure the MPU to enforce certain memory access permissions. Figure 3 shows the default MPU configuration for *uXOM*. Recall that when multiple regions overlap, the permission setting for the higher-numbered region is applied. We create Region 0 covering the entire address space with RW permission for both privileged and unprivileged modes. This is needed to allow unprivileged instructions to access the SRAM and the peripheral region. Otherwise, unprivileged access to those regions is not permitted due to the processor's default permission setting. We assign several higher-numbered regions to *uXOM* protection. (Here, we assumed that the number of MPU regions is 8.) Region 6 covers the entire flash region and assigns RX for privileged accesses and NA for unprivileged accesses. Since flash also contains read-only data, we configure Region 7 to let the unprivileged load instruction access the read-only data. To determine the base and size of this region, we need to know the size of the read-only data. To do this, we first compile, find out the read-only data size and generate an include file that is fed back into the MPU configuration code. The linker script is also modified to take this information and place the read-only data appropriately. The configurations are done in the early stage of the reset handler, which is called upon processor reset. In this way, the *uXOM*-specific permission is activated at the early stage of the system boot before attackers can seize control of the system.

## 5.2 Solving the Challenges

So far we have explained the basic design of *uXOM* for activating the XO permission. In the following, we describe how *uXOM* addresses the challenges presented in § 4.

Instruction Type	Verification Details
Ordinary stores (STR)	if $Target_{address}$ points to MPU, $Target_{value}$ must not violate $uXOM$ -specific memory permissions. else if $Target_{address}$ points to VTOR, $Target_{value}$ must have one of the valid VTOR values. else, $Target_{address}$ must point to the PPB region excluding MPU region and VTOR region
Exclusive stores (STREX)	$Target_{address}$ must not point to the PPB region.
Ordinary loads (LDR) Exclusive loads (LDREX)	$Target_{address}$ must not point to the code region.

Table 2: Verification details by the type of unconverted memory instructions.  $Target_{address}$  denotes the memory address accessed by load/store instructions and  $Target_{value}$  denotes the value to be written by the store instructions.

### 5.2.1 Finding Unconvertible Memory Instructions

Unprivileged memory instructions do not provide exclusive memory accesses and they cannot access the PPB region. As stated in **C1**, therefore, we need to identify the memory instructions that must not be converted to unprivileged ones and leave them as they are. We simply exclude exclusive memory loads/stores (e.g., LDREX and STREX) from the conversion candidate. We perform compiler analysis to find loads/stores accessing the PPB. Our analysis of the code base reveals that accesses to the PPB involve calculating the base address from a hard coded address pointing to the PPB region. This is consistent with the claims made in previous work [12]. We conduct a similar backward slicing technique to track how the base address of each memory instruction is calculated. If its address is a constant with the value corresponding to the PPB region, or if it is calculated by adding some offset to that constant value, we identify it as an access to the PPB region and leave it as an original form. For our test platform, intra-procedural analysis suffices to identify all PPB accesses. If a PPB address is passed through a function argument and used in a memory access, we can manually identify those particular cases and add annotations to prevent the compiler from converting the memory instructions as done in previous work [12]. Fortunately, most PPB accesses tend to be performed by the hardware abstraction layer (HAL) provided by the device manufacturer, so no significant amount of annotations are required to complement the static analysis.

### 5.2.2 Atomic Verification Technique

Our solution to deal with **C1** is necessary but may endanger the system. The problem is that, as stated in **C2**, **C3** and **C4**, the strong attackers assumed in § 3 can easily exploit the unconverted instructions to neutralize  $uXOM$ . To address this problem, we devise a *atomic verification* technique inspired by the concept of the reference monitor [15, 35]. The key of our technique is to verify memory accesses by the unconverted loads/stores. More specifically, it inserts a routine that

performs verification as described in Table 2 before every unconverted load/store so that we can confirm whether or not the instruction tries to access code regions or manipulate system configuration necessary for  $uXOM$ , such as  $uXOM$ -specific memory permission (solve **C4**). At this point, however, the inserted verification may be bypassed by the attackers who can divert control flow. To prevent this, therefore, the technique enforces the atomic execution of the instruction sequence composed of the verification routine and the following untrusted load/store instruction, ensuring that the attackers cannot execute the unconverted loads/stores without a proper verification (solve **C2** and **C3**). Our basic strategy for atomic verification is to (1) allocate a dedicated register as a base register of every unconverted load/store, and then (2) enforce the following two invariant properties regarding the dedicated register.

- **Invariant 1:** The dedicated register must be set to a target address of each unconverted load/store immediately before the associated verification routine. The set value will be maintained only during the execution of the atomic instruction sequence due to **Invariant 2**.
- **Invariant 2:** The dedicated register must hold a non-harmful address (i.e., not a code or the PPB address) when the atomic instruction sequence is not executed.

Now, the accessible memory of the unconverted loads/stores is limited by the value of the dedicated register, which is used as their base register. **Invariant 1** allows the unconverted loads/stores to be executed for their original purpose (e.g., access to the PPB) only through the atomic instruction sequence with a verification. Also, **Invariant 2** prevents any attempt to execute the unconverted loads/stores to access code or the PPB without going through the atomic instruction sequence. As a result, the atomic verification is achieved and the challenges, **C2**, **C3** and **C4**, are addressed successfully. Unfortunately, this implementation strategy decreases the number of available registers by exclusively allocating one register for the PPB access, which may incur additional register spills and occasionally cause a performance drop in some code with a high register pressure.

Therefore, we employ an alternative strategy that is similar to the basic strategy but differs in that it uses the  $sp$  as a base register of every ordinary load/store rather than using the dedicated register. Now, we can achieve the atomic verification if we are able to enforce on the  $sp$  the same invariant properties as the dedicated register. Enforcing **Invariant 1** is straightforward, but enforcing **Invariant 2** is challenging because it can cause side effects on the program as the  $sp$  is used throughout the program, unlike the dedicated register, which is exclusively used only in the atomic instruction sequence. Fortunately, recall that the  $sp$  is a special purpose register that should always point to the stack, so **Invariant 2** can be safely enforced without worrying about side effects.

<pre> 1: update_register: 2: 3: 4: 5: 6: 7:   str r1, [r0] 8: 9: 10: 11: 12: 13: exception_handler: 14: </pre>	<pre> 1: update_register: 2:   cpsid i           // disable interrupt 3:   mov r10, sp      // backup the value of sp 4: 5:   mov sp, r0       // set sp to a target address (IP1) 6:   [verification routine] // verify the subsequent unconverted inst. 7:   str r1, [sp]    // perform an unconverted inst. 8: 9:   mov sp, r10      // restore the value of sp 10:  [check sp]       // check the value of sp (IP2) 11:  cpsie i          // enable interrupt 12: 13: exception_handler: 14:  [check main sp and process sp] // check the value of sp (IP2) </pre>
(a) Before	(b) After

Figure 4: An unconverted store before and after applying the atomic verification technique. In the `update_register` functions `r0` and `r1` are used to pass arguments that will be used as unconverted store’s base register and source register, respectively.

**Enforcing Invariant 2 on `sp`.** We achieve this by adopting the idea suggested by the previous work on SFI [7, 33, 39]—we check the value of the `sp` whenever the attackers could have modified it to point to the outside of the valid region (i.e., the stack region). There are three kinds of program points where we need to insert the `sp` check routines: (1) when the `sp` is modified by a non-constant (i.e., register), (2) when the `sp` is increased or decreased by a constant, and (3) at the entry of an exception handler.

We can usually find the first case when the `alloca` function is called, the variable size array is used, or a stack environment stored by the `setjmp` function is restored by the `longjmp` function, which involves an assignment from a general register to the `sp`. As these cases are rare, we insert the `sp` check routines at all the corresponding points.<sup>2</sup>

The second case is very frequently found in the prolog and epilog of a function when the `sp` is adjusted according to the frame size of the function. The attackers could, although not easily, find a suitable gadget consisting of such an instruction and repeatedly execute the gadget until the `sp` is set to a certain value. As pointed out in the previous SFI work [39], if there is a memory instruction based on the `sp` following the `sp` modification, the `sp` can be regulated by placing redzones (i.e., non-accessible memory regions) around the valid stack region. If the redzones are larger than the changes in the value of the `sp`, the following `sp`-based memory instruction ensures that any attempt to use the gadget to jump over the redzones will be detected. Fortunately, the address map illustrated in Figure 3 shows that there already exist large unused regions that can do the role of redzones. This is because in most cases, the stack, code and PPB reside in a separate memory space, such as SRAM, flash memory and system bus, respectively. Therefore, we create redzones only when the stack is created adjacent to the code and PPB without unused regions in between. Note that redzones can detect the corruption of the `sp` only if there is an actual memory access using `sp`. It implies that if, after the `sp` is corrupted, an indirect branch is executed

<sup>2</sup>Currently, `uXOM` can handle only C code, so we manually insert the `sp` check routine for the `longjmp` function written in assembly language.

prior to a `sp`-based memory instruction, attackers may be able to evade the execution of the memory instruction by manipulating control flow. Therefore, to ensure the success of this method, we implement an analysis that explores all path from each constant `sp` modification. The analysis checks if there are any `sp`-based memory instructions before a potentially exploitable indirect branch is encountered. According to our experiments, there are some `sp`-based memory instructions preceding indirect branches most of the time. However, we sometimes fail to find any `sp`-based memory instructions or encounter a function call that disables further analysis, and in this case, we insert `sp` check routines because we can no more guarantee the `sp` corruption can be detected by the redzones.

Lastly, the attackers can try to avoid all the checks for `sp` mentioned above by triggering an interrupt right after they corrupt the `sp`. To neutralize this attempt, we have to validate the `sp` by inserting another `sp` check routine at the entry of the exception handlers. Note that as explained in § 2.4, there are two `sps` in Cortex-M, and different `sp` may be activated before and after the exception, so the `sp` check routine at the entry of the exception handler checks the validity of both `sps` as shown in Figure 4. The attackers may try to avoid the `sp` check routine by modifying `VTOR` to alter the exception handlers. To avert this attempt, we identify at compile-time the valid values of `VTOR`, and regulate `VTOR` at run-time so that it does not deviate from the identified values, as described in Table 2.

**Fulfillment of the Atomic Verification Technique.** Now, as both **Invariant 1** and **Invariant 2** can be enforced on the `sp`, we can implement the atomic verification technique using the `sp` without allocating a dedicated register. Figure 4 shows an example code on how the atomic verification technique is applied to harden an unconverted store. The original value of the `sp` is backed up while it is used in the unconverted store instruction (Line 3 and 9). The `sp` is assigned a target address (Line 5) and the verification routine verifies the subsequent unconverted store by checking the validity of its target address and target value (Line 6). If the verification is passed, the unconverted store performs memory access (Line 7). Note that

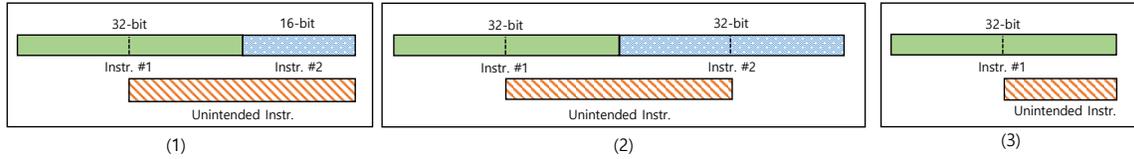

Figure 5: The generation of an unintended instruction by an unaligned execution of a 32-bit instruction.

because **Invariant 2** is enforced by instrumenting `sp`-update instructions and exception handlers (Line 10 and 14), the `sp` always is forced to point to the stack region except when it is used for the unconverted loads/stores. Therefore, to execute the unconverted store for its original purpose (i.e., accessing the PPB), storing the target address (i.e., the address of the PPB) to the `sp` must be preceded (Line 5), which in turn ensures that the verification routine will be performed (Line 6). At the same time, as the `sp` is used for the unconverted loads/stores and may point to out of the stack region, we temporarily disable interrupts (Line 2 and 11), thereby preventing the register from being erroneously checked at the exception handler.

### 5.2.3 Handling Unintended Instructions

As stated in **C5**, our strong attackers capable of manipulating the control flow of the program can execute unintended instructions to bypass the security of `uXOM`. The unintended instructions are mainly caused by the unique property of Thumb-2 instruction set architecture that intermingle 16-bit and 32-bit instructions. Specifically, as shown in **Figure 5**, when the attackers deliberately jump into the middle of a 32-bit instruction, unintended 16-bit or 32-bit instructions can be decoded and executed. Unintended instructions can also appear in the immediate values in code memory that match the bit patterns of some valid instructions, as illustrated in **Figure 6**(b). As such, a number of unintended instructions are lurking in code. Fortunately, however, only a minority of them that can be interpreted as ordinary memory instructions or `sp`-modifying instructions can actually be exploited to compromise `uXOM`.

Against this problem, we have implemented the code instrumentation technique based on the idea in the previous work [4] that replaces each exploitable unintended instruction into safe instruction sequences that serve the same function as the original instruction. There was one complication in solving the problem that not all exploitable unintended instructions can be identified at compile time. Many of the exploitable unintended instructions result from immediate values (i.e., symbol addresses) in instructions which are not resolved until all the object files are linked by the linker. Simply transforming all those instructions that use unresolved symbol addresses will result in unacceptable overhead in both performance and code size. Thus, it is preferable to implement the transformation inside the linker or use the static binary transformation tool. However, adding extra instructions at this stage is almost impossible because it will require us to

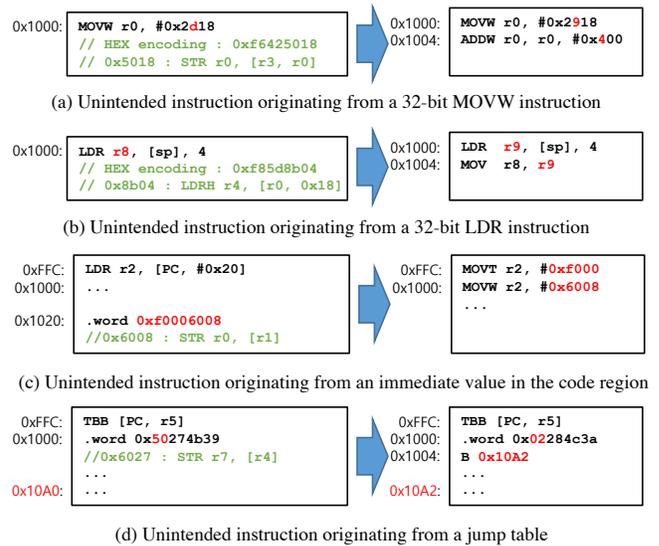

Figure 6: Examples of unintended instructions and code transformations to remove them.

adjust all the `pc`-relative offsets that are used in many ARM instructions. Adding this capability to current ARM GNU linker implementation will require significant engineering effort.<sup>3</sup> As a work around, we implemented a binary verifier that scans the binary executable for exploitable unintended instructions and records the position of each instruction inside the function. With that information, the program is then recompiled and the exploitable unintended instructions are replaced into alternative instruction sequences. Sometimes, new exploitable unintended instructions are revealed after this process, as code and object layouts are changed and offsets and addresses embedded in the code are changed accordingly. Thus, the interaction between the compiler and the verifier is repeated until there are no exploitable unintended instructions in the binary.

**Figure 6** demonstrates a few examples showing how the transformation is applied to remove exploitable unintended instructions. **Figure 6**(a) shows the case where an exploitable unintended instruction (`STR`) is generated from the immediate value of 32-bit instruction (`MOVW`). To remove the exploitable instruction, we divide the original immediate value into two

<sup>3</sup>This capability is available in the linker for some architectures like RISC-V which implements aggressive linker relaxation. For those architectures, the `pc`-relative offset resolution is deferred until the linking time to enable linker optimizations that reduce instructions and thus may change the `pc`-relative offsets in the code.

numbers A and B. Then we replace the original 32-bit instruction to use A and add an extra instruction (e.g., `ADDW`) to add B to the register written by the original instruction. Note that for 32-bit instructions whose immediate value is only determined at link time, we only add the extra instruction at compile time and make sure that the linker puts value A and B instead of the original immediate value. Figure 6.(b) shows another example that the destination register of the 32-bit instruction (`LDR`) generates the exploitable unintended instruction (`LDRH`). We solve this case by putting the value loaded from memory into the other register and then use an extra `MOV` instruction to copy the value into the original destination register. We have also implemented an optimization in the register allocation pass to prefer invulnerable registers over the others for the destination of these 32-bit instructions so that exploitable unintended instructions can be avoided as much as possible. This saves the use of extra instructions and reduces the performance and code size overhead. Figure 6.(c) shows an unintended instruction that exists in a constant embedded in a code region to be loaded by a `pc`-relative load. To sanitize it, we remove the constant value and replace the associated `pc`-relative load with two move instructions. If the resulting `MOVT` or `MOVW` instruction creates new exploitable unintended instructions, it is further transformed similarly to the example in Figure 6.(a). Finally, Figure 6.(d) shows the case where the offsets in a jump table embedded in the code create an exploitable unintended instruction. In the example, the value `0xA0` (`0x50 * 2`) is added to `pc` and the control is transferred to `0x10A0`. To remove the unintended instruction in this case, we add a trampoline code right after the jump table for the targets with the problematic offsets.

### 5.3 Optimizations

According to our experiments (see § 6.1), unprivileged memory instructions consume the same CPU cycles as ordinary memory instructions. However, unprivileged instructions are 32-bits in size while many ordinary memory instructions have a 16-bit form. Also, extra instructions that are added as described in § 5.1.1 can increase both the code size and the performance overhead. Since code size is another critical factor in an embedded application due to its scarce memory, it can be beneficial to leave the memory instructions in their original form if we can ensure that this does not harm the security guarantees of *uXOM*. In fact, a large number of the instructions do not need to be converted either because they are safe by nature or because they can be made safe through some additional effort. For example, ARM supports `pc`-relative memory instructions which access a memory location that is a fixed distance away from the current `pc`—i.e., the address of the current instruction. As these instructions can only access certain data embedded in the code region, attackers cannot exploit them to access other memory locations. Therefore, we do not need to convert these instructions, so we leave them as long as it is not exploitable as unintended instructions (§ 5.2.3). We

also do not convert stack-based ordinary memory instructions. Numerous instructions use the `sp` as the base address. Almost all of them are 16-bits in size since Cortex-M provides special 16-bit encoding for stack-based memory instructions. Converting all of these as the unprivileged will significantly add to the code size of the final binary. Most of the `LDM/STM` instructions, including all the `PUSH/POP` instructions, are also based on `sp`. Converting them would require multiple unprivileged instructions which would further increase the code size and even the performance overhead. Luckily, recall that *uXOM* already enforces the invariant properties noted in § 5.2.2 on the `sp`. Therefore, attackers cannot exploit the ordinary memory instructions based on `sp`, and we can safely leave `sp` based memory instructions in their original forms.

## 5.4 Security Analysis

*uXOM* builds on the premise that there remains no abusable instructions in a firmware binary. *uXOM* satisfies this through its compiler-based static analysis (§ 5.1.1 and § 5.2.3) that (1) identifies all abusable instructions, such as ordinary memory instructions and unintended instructions, and (2) converts them into safe alternative instructions. This conservative analysis does not make false negative conversions, so *uXOM* is fail-safe in terms of security. In the following, we show that attackers we assumed in the threat model (§ 3) will not be able to compromise *uXOM*.

### 5.4.1 At Boot-up

As noted in § 3, we trust the integrity and confidentiality of the firmware image. The firmware image will be distributed and installed with the *uXOM*-related code instrumentation applied. As soon as the system is powered up, the reset exception handler starts to run and the code snippet that *uXOM* inserted at the start of the handler is executed to enforce *uXOM*-specific memory access permissions. Note that the firmware has started its execution from a known good state and the attackers have not yet injected any malicious payloads. Therefore, we can guarantee that *uXOM* will safely enable XOM without being disturbed by the attackers.

### 5.4.2 At Runtime

Once *uXOM* enables XOM, the attackers are completely prevented from accessing the code. They cannot use unprivileged loads/stores to bypass *uXOM*, so they have to resort to the unconverted loads/stores. Through the instruction conversions and optimizations of *uXOM*, only three types of unconverted loads/stores remain in the binary: stack-based loads/stores, exclusive loads/stores and ordinary loads/stores for the PPB access.

**Stack-based loads/stores.** *uXOM*'s optimization excludes `sp` based loads/stores from the conversion candidates. The attackers may be able to execute these loads/stores, but they cannot access the PPB region or code regions. This is because the `sp` is forced to point to the stack regions due to the invariant property (**Invariant 2** in § 5.2.2) enforced on the

sp.

**Exclusive loads/stores and ordinary loads/stores for the PPB access.** These unconverted loads/stores are protected by the atomic verification technique. Verification routines are inserted just before each unconverted load/store and the atomic execution of the inserted routine and the corresponding unconverted load/store is guaranteed. Of course, the attacker may jump into the middle of the atomic instruction sequence to directly execute the unconverted load/store without a proper verification. However, as the unconverted loads/stores use the sp as their base register, the attackers still cannot access the code and the PPB regions.

## 6 Evaluation

*uXOM* transformations are implemented in LLVM 5.0, and *uXOM*'s binary verifier is implemented using the Radare2 binary analysis framework [32]. We used the RIOT-OS [5] version 2018.10 as the embedded operating system. As the whole binary, including the OS, runs in a single physical address space at the same privilege level, *uXOM* compiler transformations are applied to the OS code as well as the application code to enable complete protection. We also applied our transformations to the C library (newlib) included in arm-none-eabi toolchain, which had to be patched in a few places to compile and run correctly with LLVM.

To better show the merits of our approach, we also implemented and evaluated SFI-based XOM to compare against *uXOM*. Originally, SFI is developed to sandbox an untrusted module in the same address space. It restricts the store and indirect branch instructions (i.e., by masking or checking the store/branch address) in the untrusted module so that the untrusted module cannot corrupt or jump into the trusted module. It also bundles the checks with the store/branch instructions and prevents jumps into the bundle so that the restrictions applied to the store or branch address cannot be skipped. Capitalizing on the SFI's access control scheme, some studies [7, 31] have implemented the SFI-based XOM that instruments every load instructions with masking instructions to prevent them from reading the code region. However, as these studies focus on high-end devices like smartphones and desktop PCs, we adapted the SFI-based XOM to work on Cortex-M based devices. As our target device do not use virtual memory, code and data must reside in a specific memory region. This prevents us from using simple masking to restrict load addresses and forces us to use a compare instruction to validate the address. Furthermore, the instruction set of Cortex-M requires us to insert additional IT (If-Then) instruction to make load instruction execute conditionally on the comparison result. Next, we place the compare and load inside a 16-byte aligned bundle and make sure that they do not cross the bundle boundary. We insert NOPs in the resulting gaps. Lower bits of indirect branch targets are masked (cleared) to prevent control flows into the bundle. We also make sure that all possible targets of an indirect branch (i.e., functions and call-sites) are aligned.

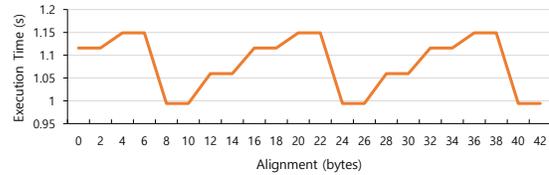

Figure 7: Execution time of `bitcount` according to the different alignments of the code region.

POP instructions used for function returns are converted to masking and return sequence as described in the previous work on SFI [33]. Following the optimization done in the paper [39], the memory load instructions based on the sp are not checked and the sp is regulated in the same way as in *uXOM*.

To evaluate *uXOM* and the SFI-based XOM, we used the publicly available BEEBs benchmark suite (version 2.1) [29]. We selected 33 benchmarks that are claimed to have relatively long execution time [12]<sup>4</sup>. We ran each benchmark on an Arduino Due [1] board which ships with an Atmel SAM3X8E microcontroller based on the Cortex-M3 processor. During the experiment, we found that the program runs give very inconsistent timing results depending on how the code is aligned, even though there are no caches in the processor. After some investigation, we found that the reason is due to the flash memory. The Arduino Due core runs at 84MHz in the default setting, which makes it necessary to wait for 4 cycles (called flash wait state) to get stable results from the flash memory. SAM3X3E chips are equipped with a flash read buffer to accelerate sequential reads [3], which gave us variable results depending on where the branches are located. As a preliminary experiment, we measured the execution time while changing the displacement of the entire code region for `bitcount` benchmark. As shown in Figure 7, the changes in execution time show a pattern that is repeated every 16-byte, which corresponds to the size of the flash read buffer. Because of this result, to get a consistent result, we decreased the core frequency to 18.5MHz in all our experiments.

### 6.1 Runtime Overhead

Figure 8 shows the runtime overhead of *uXOM* and SFI-based XOM. The geomean overhead of all benchmarks is 7.3% for *uXOM* and 22.7% for SFI-based XOM. The worst case overhead for *uXOM* is 22.3% for `huffbench` benchmark and that for SFI-based XOM is 75.1% for `edn` benchmark. Note that the performance overhead of SFI reported in the previous work [33] for a high-end ARM device (Cortex-A9) is 5%. In the paper, they mention that overhead induced by additional instructions for SFI can be hidden by cache misses and out-of-order execution. Based on this, we presume that the large overhead of SFI-based XOM for Cortex-M3 observed in our experiment is due to the low-power and cache-less

<sup>4</sup>Some of the benchmarks have been dropped in the newest version due to the license problem.

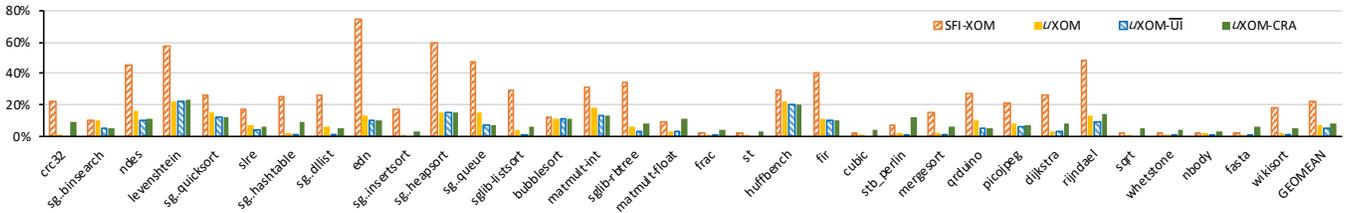

Figure 8: Runtime overhead on BEEBs benchmark suite.

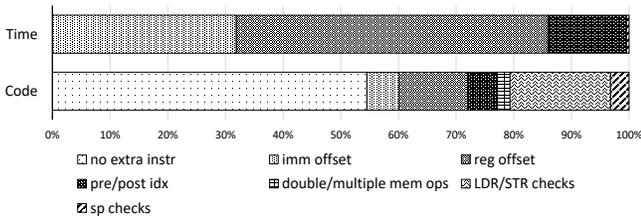

Figure 9: Performance overhead breakdown for the different components of  $uXOM-\overline{UI}$  transformation.

processor implementation. This strongly shows the need for an efficient low-end device oriented XOM implementation like  $uXOM$ .

To inspect the sources of overhead, we built and ran multiple partially instrumented versions of binaries with different kinds of transformations applied. First, to examine the performance impact of removing exploitable unintended instructions, we measured the runtime overhead for  $uXOM-\overline{UI}$ —a variation of  $uXOM$  that does not handle unintended instructions. As a result, we measured that the geomean overhead for  $uXOM-\overline{UI}$  is 5.2%, which shows that removing unintended instructions incurs 2.1% of overhead in  $uXOM$ . We then gathered the statistics on the number of conversions and check codes inserted in  $uXOM-\overline{UI}$  (Table 3). We also measured the overhead ratio in terms of code size and execution time according to the type of conversions and checks (Figure 9). In Table 3 and Figure 9, `no extra instr.` denotes the case where a memory instruction is converted to an unprivileged one without an additional instruction. `imm. offset` denotes the case where an additional instruction is required because the immediate offset is too large or is negative. `pre/post idx.` represents the pre/post-indexed addressing mode and `reg. offset` represents the register-register addressing mode. `double/multiple mem. ops.` represents LDRD/STRD/LDM/STM instructions. For the `sp check` part, `non-const sp mod.` is the case where the `sp` is modified by the non-constant (and the check is required). `const sp mod. (checked)` is the case where the `sp` is modified by the constant and requires checking since no load/store based on the `sp` is found afterwards. `const sp mod. (no check)` is the case where the `sp` is modified by the constant but does not need to be checked. Finally, `LDR/STR checks` denotes the instructions inserted for the atomic verification technique.

The statistics shown in Table 3 are gathered while compiling the C standard library, RIOT-OS, and each of the bench-

Cases	Count (ratio %)
Instruction conversion	
<code>no extra instr.</code>	25932 (77.0)
<code>imm. offset</code>	2547 ( 7.6)
<code>pre/post idx.</code>	1671 ( 4.9)
<code>reg. offset</code>	2891 ( 8.6)
<code>double/multiple mem. ops.</code>	641 ( 1.9)
<code>sp check</code>	
<code>non-const sp mod.</code>	18 ( 0.7)
<code>const sp mod. (checked)</code>	769 (28.8)
<code>const sp mod. (no check)</code>	1881 (70.5)

Table 3: Statistics for instruction conversion and `sp check` instrumentation.

marks. Note that although the numbers do not represent those executed at runtime, we can expect some correlation between them. Among the converted memory instructions, the majority of the cases is the one where a memory instruction is directly converted to a single unprivileged memory instruction without any extra instruction (`no extra instr.` accounts for 77% of all conversions). This tells us that most of the load/store instructions are using an immediate-offset addressing mode and the offset is usually small so that it fits in the immediate field of the unprivileged instructions. As we can see, instructions converted in this way do not contribute to the runtime overhead albeit being the majority. Even though the unprivileged instructions are 32-bits long, they do not increase the overhead unless additional instructions are inserted. This is a big advantage for  $uXOM$ , and it is the main reason why  $uXOM$  can be much more efficient than SFI-based XOM.

As illustrated in Figure 9, the type of instruction conversions that contributes the most of the overhead is the one for the register-register addressing mode (`reg. offset`). Even though they represent only 8.6% of all conversions, they cause 54% of the total overhead for  $uXOM-\overline{UI}$ . The reason would be that they are frequently used in time-consuming loops, for example, to index array variables. `imm. offset` and `pre/post idx.` take up the other half of the overhead. Memory instructions that load/store multiple registers (`double/multiple mem. ops.`) cause a negligible runtime overhead; they are rare in number and also, although they are converted into multiple unprivileged instructions, the original instruction also takes up extra cycles to load/store multiple registers. The `sp checks` that are inserted for stack modification have an only negligible impact on performance as our

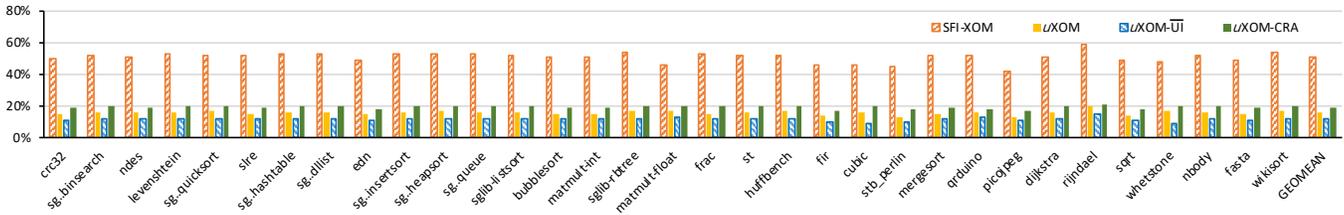

Figure 10: Code size overhead on BEEBs benchmark suite.

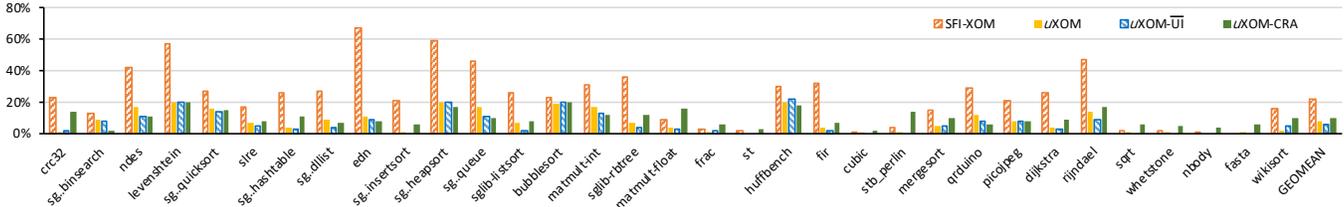

Figure 11: Energy overhead on BEEBs benchmark suite.

analysis finds that the `sp` checks are only needed for less than 30% of `sp`-based memory instructions.

## 6.2 Code Size Overhead

To see the impact of instruction insertion by `uXOM`, we measured the size of the code in the final binary, excluding the data size. Figure 10 shows the result for both `uXOM` and SFI-based XOM. For `uXOM`, code size is increased by 15.7%, and for SFI-based XOM, it is increased by 50.8%. It shows that `uXOM` can implement XOM with much less code size overhead compared to SFI-based XOM. In addition, we measured that the geomean overhead of `uXOM-UI` is 11.6%, which indicates the amount of increased code for removing unintended instructions is 4.1%. Figure 9 shows the source of the overhead that is caused by instruction conversions and checks. First, `no extra inst.` accounts for 54.5% of the code size overhead for `uXOM-UI`, differently from the impact that it had on the runtime performance. This is because the original 16-bit load/store instructions are converted to 32-bit unprivileged instruction, and they are large in number, too. Other types of instructions that need additional instructions also increases the code size to some degree. The instructions added for the atomic verification technique (`ldr/str check`) accounts for 17.4% of the code size overhead for `uXOM-UI`. Although there are not many instructions accessing the PPB region, around ten instructions are inserted for each of those points, which adds some overhead to the code size especially since the benchmark code size are only around 30KB. We expect the overhead from the atomic verification to be a smaller percentage in the real program with a larger code base.

## 6.3 Energy Overhead

Since many embedded devices running on Cortex-M processors often operate based on constrained battery, energy efficiency is one of the important performance factors for

these devices. To measure the impact of `uXOM` on energy consumption, we recorded the power while running the individual benchmarks using the ODROID Smart Power [28]. For the convenience of measurement, the benchmarks were repeatedly executed to run for at least 30 seconds. Figure 11 shows the results. For `uXOM`, the geometric mean of all benchmarks is 7.5%, which is slightly larger than 5.8% of `uXOM-UI` but much lower than 22.3% of SFI-based XOM. The results share a similar trend with the execution time since the energy is also affected by the execution time.

## 6.4 Security and Usability

Other than its excellence for performance, we also need to mention the security and flexibility benefits of `uXOM` over SFI-based XOM. `uXOM` provides a better security guarantee against privileged attackers than SFI-based XOM. SFI-based XOM, including the existing studies, focus only on the code disclosure through memory read instructions, because they assume that  $W \oplus X$  policy is assured by a Trusted Computing Base (TCB) such as the OS kernel. However, as described in § 3, `uXOM` cannot assume any TCB in the bare-metal environment in which all software components are running with privileges in a single address space. The privileged attacker could neutralize  $W \oplus X$  by manipulating the MPU configuration register using memory vulnerabilities in the code. To prevent such an attack, SFI-based XOM for Cortex-M would also have to regulate memory write instructions to protect memory-mapped registers for the MPU. However, this would undoubtedly lead to more severe performance overheads, and even worse, SFI-style masking of write instructions would still leave the system vulnerable against attacks through the exception handler (C3 of § 4). In addition, the current implementation of SFI-based XOM is vulnerable to unintended instructions. To defend this, it should eliminate all exploitable unintended instructions either by using the instruction replacement technique similar to `uXOM` or selectively aligning

32-bit instructions so that jump into the middle of those instructions can be prevented by the masking of indirect jump addresses. Either way, additional performance overhead will be unavoidable.

*uXOM* is also more flexible in placing the code and data. For *uXOM*, the XOM region can be placed anywhere in the address space. For example, *uXOM* can be applied for the code placed in SRAM for performance or firmware updates [20]. Also, *uXOM* can set multiple XOM regions as long as the number of MPU regions supports it. However, SFI-based XOM must place the code at one end and the data on the other to simplify code instrumentation. Moreover, SFI-based XOM needs a guardzone between the code and the data region [39] which further restricts the code and data placement and also causes the memory to be wasted for the guardzone.

## 6.5 Use Cases

*uXOM* can be used to hide sensitive information in the code region, such as secret keys and code layout. We describe two use cases to illustrate how *uXOM* can be applied to a security solution.

**Secret key protection.** In tiny devices, secret keys are frequently used for various purposes, such as device authentication and communication channel protection. *uXOM* can protect these keys against arbitrary memory read vulnerabilities by embedding them inside the code. For example, consider the following code that defines the constant global key.

```
const unsigned char key[32] =
    {0xcb, 0x21, 0xad, 0x38, ...};
```

The code that reads the first 4-byte of this value is compiled to the assembly code composed of `MOVW` and `MOVT` as follows:

```
MOVW r0, #0x21cb
MOVT r0, #0x38ad
```

Now, if we use *uXOM* to apply the XO permission to this code, attackers cannot access the key value by arbitrary memory reads. As an example, we applied *uXOM* to `rijndael` benchmark, which uses a symmetric key for encryption. By declaring the key as a global constant, we could confirm that the key is embedded in the code protected by *uXOM*. Such a protection offered by *uXOM* can further be combined with in-register computation techniques [26] for a secure computation robust against memory vulnerabilities.

**CRA defense.** To date, many researchers have proposed code diversification-based CRA defense techniques [7, 12, 13, 30]. They randomize code layout to prevent attackers from using the existing gadgets for CRA. As the code disclosure attack emerged as a serious threat to randomization-based defenses, XOM has been proposed as an effective solution to fortify these defenses.

As another use case of *uXOM*, we implemented a CRA

defense solution based on Readactor [13], which is a representative code diversification based CRA defense with resistance to code disclosure attacks. Readactor aims to defend against two classes of code disclosure attacks: direct disclosure where the attackers disclose code layout by directly reading the code and indirect disclosure where attackers indirectly infer the code layout through the value of the code pointers. Readactor first places all code in XOM to prevent the direct disclosure attacks. It then replaces all code pointers with pointers to *trampolines* so that all indirect control transfers must go through the trampoline. In this way, code pointers containing the original code location are never stored in a register or memory, thereby preventing the indirect disclosure attacks. To demonstrate this use case, we implemented function re-ordering and the trampoline mechanism. Every function call is replaced with a direct branch to the trampoline followed by the call to the original function. When the original function returns, another direct branch takes the control flow back to the original callsite. Also, every function pointer is replaced with a pointer to the corresponding function trampoline. We implemented this use case on top of *uXOM-UI* because the code diversification based CRA defense mitigates control flow hijacking, and consequently hinders an attacker from exploiting unintended instructions. The experimental results of our CRA defense are presented together with the results for *uXOM*, *uXOM-UI* and SFI-based XOM. It imposes average runtime overhead of 8.6%, the code size overhead of 19.3%, and the energy overhead of 9.7%. The runtime overhead is only slightly larger than that for original Readactor implementation (6.4%) which shows the applicability of *uXOM* technique in low-end embedded devices.

## 7 Discussion

**Cortex-M Processors based on ARMv8-M Architecture.** ARMv8-M [19] is a recently introduced instruction set architecture for the microcontroller profile. Basically, ARMv8-M provides backward compatibility with ARMv7-M, so *uXOM* is also applicable to ARMv8-M based Cortex-M(23/33/35) processors. Here, we list several possible changes in *uXOM* implementation due to the newly added hardware feature in ARMv8-M. First of all, ARMv8-M includes the stack pointer limit register (`SPLR`) that defines a lower limit for the stack pointer and prevents the stack pointer from pointing below the limit. When enabling `SPLR`, therefore, *uXOM* only needs to ensure that the stack pointer does not point to the PPB region. Secondly, load-acquire and store-release memory instructions are newly added in ARMv8-M. Since these instructions do not have unprivileged counterparts, they should be protected by the atomic verification technique.

**False Positive Conversion.** When it comes to the instruction conversion of *uXOM*, false positive cases could happen where unconvertible instructions are converted to unprivileged ones. The false positive conversion does not harm the security

aspect of *uXOM* but may cause an unexpected system fault. For instance, if PPB-accessing memory instructions are converted to unprivileged ones, it would not expose the PPB to attackers but raise a memory access fault when executed. To avoid an unexpected system halt due to the fault, *uXOM* can install a custom fault handler, which in turn may invoke the fail-safe handler already implemented in the existing system (e.g., emergency landing in drones).

**Dynamic Data Protection.** Although the current *uXOM* implementation aims to defeat the code disclosure attacks, it may be extended to provide protection for the dynamic data as well. To be concrete, *uXOM* can be expanded to implement a data isolation scheme [23, 35, 36] that minimizes the possibility of exposures of critical data by only allowing access through authorized instructions. More specifically, we may allow only authorized instructions (i.e., ordinary loads/stores that are not converted into unprivileged types) to access critical data (e.g., return addresses/session keys) by placing the data on a certain memory region marked as “privileged”. To implement such an extension, some modifications to *uXOM* are required. First of all, authorized instructions should be predetermined through the help of programmers or compilers and prevented from being converted to unprivileged ones. Since attackers can exploit these data-accessing instructions to compromise *uXOM*, usage of these instructions should be regulated in a way similar to PPB-accessing instructions through the atomic verification technique with a new verification routine that confines memory access target to the memory region of the critical data.

## 8 Related Work

**Hardware-assisted Execute Only Memory.** Due to the compelling security guarantee provided by XOM, today’s high-end processor architectures (e.g., x64 and AArch64) provide the XO permission setting in the MMU [8, 10]. Apart from that, various works have attempted to implement XOM in the system with the help of the hardware. David et al. [24] implemented XOM by encrypting the code in memory and decrypting it only when it is executed. However, since it requires significant processor redesign, it is not suitable for wide adoption. In subsequent works, XOM has been implemented by capitalizing on the built-in hardware features. Shadow Walker [37] and HideM [17] presented an implementation of XOM using the split translation lookaside buffer (TLB) architecture, which separates the TLB for instruction fetches and data accesses. They configure the two TLBs so that the same virtual address is translated into different physical addresses for data access and instruction fetch, preventing the data accesses to the code region. XOM-switch [25] implemented XOM using Intel Memory Protection Keys (MPK), which can be used to set memory pages execute-only. Shadow Walker, HideM and XOM-switch are not applicable to Cortex-M based devices because they rely on specific hardware fea-

tures (i.e., split-TLB or Intel MPK) that do not exist in the Cortex-M processor.

**Software-based Execute Only Memory.** On the other hand, there have been attempts to emulate XOM in software for processors that do not have the above hardware supports. XnR [6] sets all code pages as non-accessible except for the currently executed code pages called *sliding window* and detects illegal memory reads and writes for non-accessible pages by augmenting the MMU page fault handler. For Cortex-M/R processors, since MPU also provides non-accessible permission setting for memory regions, XOM can be implemented in a similar way. However, this approach cannot detect memory reads for code pages in the sliding window, and also, the performance overhead becomes larger as the sliding window size is reduced.  $LR^2$  [7] and  $kR^X$  [31] realize XOM by SFI-inspired techniques [39, 40]. They prevent code reads by masking load instructions, instead of stores as done in the SFI technique. As shown in our evaluation, however, such SFI-based XOM implementation can be bypassed and is inefficient in low-end devices.

**Security Solutions using XOM.** Many researchers have proposed various security solutions based on XOM. Early works [27] proposed XOM for the purpose of protecting intellectual properties and preventing tampering or leakage of sensitive information stored in the code. Since the advent of code disclosure attacks (i.e., JIT-ROP), a number of works [7, 13, 16, 31] have utilized XOM to prevent the attackers from reading code to learn code layout and launch CRAs. In § 6.5, we have shown that these solutions can be implemented with *uXOM*.

**Security for Tiny Embedded Devices.** Recently, much research has been done on enhancing the security of tiny embedded devices. Mbed uvisor [2], MINION [21], uSFI [4] and ACES [11] proposed memory isolation techniques for software modules based on MPU. At compile time, they define memory views (stack, heap, and peripherals) for each of the software modules, and at runtime, MPU enforces one of the memory views according to the active software module. Epoxy [12] and AVRAND [30] developed diversification based security solutions for tiny embedded devices. As with these solutions, *uXOM* also seeks to enhance the security of tiny embedded devices. *uXOM* is the first to implement efficient execute-only memory in Cortex-M processors.

## 9 Conclusion

XOM is a prominent protection mechanism that can be used in various security purposes such as intellectual property protection and CRA defense. However, for a low-end embedded processor such as Cortex-M, there has been no efficient way to implement XOM. In this paper, we present *uXOM*, a novel technique to realize XOM in a way that is secure and highly optimized to work on Cortex-M processors. *uXOM* achieves this by leveraging hardware features (i.e., unpriv-

ileged load/store instructions and MPU) in Cortex-M processors. Our evaluation shows that not only *uXOM* is more efficient than SFI-based XOM in terms of execution time, code size and energy consumption, and that *uXOM* is compatible with existing XOM-based security solutions.

## Abstract

Research on *transient execution* attacks including Spectre and Meltdown showed that exception or branch misprediction events might leave secret-dependent traces in the CPU’s microarchitectural state. This observation led to a proliferation of new Spectre and Meltdown attack variants and even more ad-hoc defenses (e.g., microcode and software patches). Both the industry and academia are now focusing on finding effective defenses for known issues. However, we only have limited insight on residual attack surface and the completeness of the proposed defenses.

In this paper, we present a systematization of transient execution attacks. Our systematization uncovers 6 (new) transient execution attacks that have been overlooked and not been investigated so far: 2 new exploitable Meltdown effects: Meltdown-PK (Protection Key Bypass) on Intel, and Meltdown-BND (Bounds Check Bypass) on Intel and AMD; and 4 new Spectre mistraining strategies. We evaluate the attacks in our classification tree through proof-of-concept implementations on 3 major CPU vendors (Intel, AMD, ARM). Our systematization yields a more complete picture of the attack surface and allows for a more systematic evaluation of defenses. Through this systematic evaluation, we discover that most defenses, including deployed ones, cannot fully mitigate all attack variants.

## 1 Introduction

CPU performance over the last decades was continuously improved by shrinking processing technology and increasing clock frequencies, but physical limitations are already hindering this approach. To still increase the performance, vendors shifted the focus to increasing the number of cores and optimizing the instruction pipeline. Modern CPU pipelines are massively parallelized allowing hardware logic in prior pipeline stages to perform operations for subsequent instructions ahead of time or even out-of-order. Intuitively, pipelines may stall when operations have a dependency on a previous

instruction which has not been executed (and retired) yet. Hence, to keep the pipeline full at all times, it is essential to predict the control flow, data dependencies, and possibly even the actual data. Modern CPUs, therefore, rely on intricate microarchitectural optimizations to predict and sometimes even re-order the instruction stream. Crucially, however, as these predictions may turn out to be wrong, pipeline flushes may be necessary, and instruction results should always be committed according to the intended in-order instruction stream. Pipeline flushes may occur even without prediction mechanisms, as on modern CPUs virtually any instruction can raise a fault (e.g., page fault or general protection fault), requiring a roll-back of all operations following the faulting instruction. With prediction mechanisms, there are more situations when partial pipeline flushes are necessary, namely on every misprediction. The pipeline flush discards any architectural effects of pending instructions, ensuring functional correctness. Hence, the instructions are executed *transiently* (first they are, and then they vanish), *i.e.*, we call this *transient execution* [50, 56, 85].

While the architectural effects and results of transient instructions are discarded, microarchitectural side effects remain beyond the transient execution. This is the foundation of Spectre [50], Meltdown [56], and Foreshadow [85]. These attacks exploit transient execution to encode secrets through microarchitectural side effects (e.g., cache state) that can later be recovered by an attacker at the architectural level. The field of transient execution attacks emerged suddenly and proliferated, leading to a situation where people are not aware of all variants and their implications. This is apparent from the confusing naming scheme that already led to an arguably wrong classification of at least one attack [48]. Even more important, this confusion leads to misconceptions and wrong assumptions for defenses. Many defenses focus exclusively on hindering exploitation of a specific covert channel, instead of addressing the microarchitectural root cause of the leakage [45, 47, 50, 91]. Other defenses rely on recent CPU features that have not yet been evaluated from a transient security perspective [84]. We also debunk implicit assumptions including that AMD or the latest Intel CPUs are completely immune to

Meltdown-type effects, or that serializing instructions mitigate Spectre Variant 1 on any CPU.

In this paper, we present a systematization of transient execution attacks, *i.e.*, Spectre, Meltdown, Foreshadow, and related attacks. Using our decision tree, transient execution attacks are accurately classified through an unambiguous naming scheme (cf. Figure 1). The hierarchical and extensible nature of our taxonomy allows to easily identify residual attack surface, leading to 6 previously overlooked transient execution attacks (Spectre and Meltdown variants) first described in this work. Two of the attacks are Meltdown-BND, exploiting a Meltdown-type effect on the x86 `bound` instruction on Intel and AMD, and Meltdown-PK, exploiting a Meltdown-type effect on memory protection keys on Intel. The other 4 attacks are previously overlooked mistraining strategies for Spectre-PHT and Spectre-BTB attacks. We demonstrate the attacks in our classification tree through practical proofs-of-concept with vulnerable code patterns evaluated on CPUs of Intel, ARM, and AMD.<sup>1</sup>

Next, we provide a classification of gadgets and their prevalence in real-world software based on an analysis of the Linux kernel. We also give a short overview on current tools for automatic gadget detection.

We then provide a systematization of the state-of-the-art defenses. Based on this, we systematically evaluate defenses with practical experiments and theoretical arguments to show which work and which do not or cannot suffice. This systematic evaluation revealed that we can still mount transient execution attacks that are supposed to be mitigated by rolled out patches. Finally, we discuss how defenses can be designed to mitigate entire types of transient execution attacks.

**Contributions.** The contributions of this work are:

1. We systematize Spectre- and Meltdown-type attacks, advancing attack surface understanding, highlighting misclassifications, and revealing new attacks.
2. We provide a clear distinction between Meltdown/Spectre, required for designing effective countermeasures.
3. We provide a classification of gadgets and discuss their prevalence in real-world software.
4. We categorize defenses and show that most, including deployed ones, cannot fully mitigate all attack variants.
5. We describe new branch mistraining strategies, highlighting the difficulty of eradicating Spectre-type attacks.

We responsibly disclosed the work to Intel, ARM, and AMD.

**Experimental Setup.** Unless noted otherwise, the experimental results reported were performed on recent Intel Skylake i5-6200U, Coffee Lake i7-8700K, and Whiskey Lake i7-8565U CPUs. Our AMD test machines were a Ryzen 1950X and a Ryzen Threadripper 1920X. For experiments on ARM, an NVIDIA Jetson TX1 has been used.

**Outline.** Section 2 provides background. We systematize Spectre in Section 3 and Meltdown in Section 4. We analyze

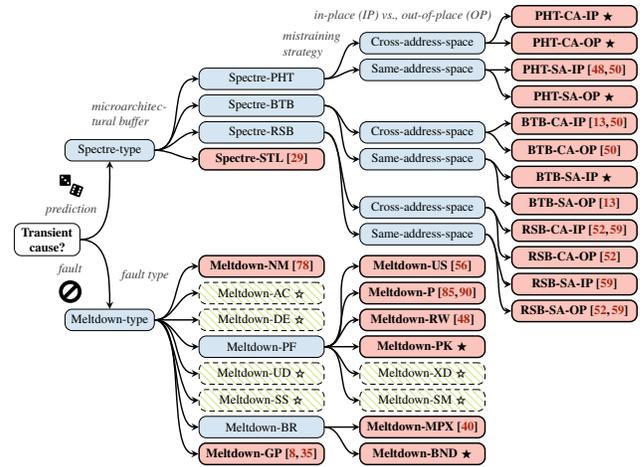

Figure 1: Transient execution attack classification tree with demonstrated attacks (red, bold), negative results (green, dashed), some first explored in this work (★ / ☆).<sup>2</sup>

and classify gadgets in Section 5 and defenses in Section 6. We discuss future work and conclude in Section 7.

## 2 Transient Execution

**Instruction Set Architecture and Microarchitecture.** The instruction set architecture (ISA) provides an interface between hardware and software. It defines the instructions that a processor supports, the available registers, the addressing mode, and describes the execution model. Examples of different ISAs are x86 and ARMv8. The microarchitecture then describes how the ISA is implemented in a processor in the form of pipeline depth, interconnection of elements, execution units, cache, branch prediction. The ISA and the microarchitecture are both stateful. In the ISA, this state includes, for instance, data in registers or main memory after a successful computation. Therefore, the architectural state can be observed by the developer. The microarchitectural state includes, for instance, entries in the cache and the translation lookaside buffer (TLB), or the usage of the execution units. Those microarchitectural elements are transparent to the programmer and can not be observed directly, only indirectly.

**Out-of-Order Execution.** On modern CPUs, individual instructions of a complex instruction set are first decoded and split-up into simpler micro-operations ( $\mu$ OPs) that are then processed. This design decision allows for superscalar optimizations and to extend or modify the implementation of specific instructions through so-called microcode updates. Furthermore, to increase performance, CPU’s usually implement a so-called *out-of-order* design. This allows the CPU to execute  $\mu$ OPs not only in the sequential order provided by

<sup>2</sup>An up-to-date version of the tree is available at <http://transient.fail/>

<sup>1</sup><https://github.com/IAIK/transientfail>

the instruction stream but to dispatch them in parallel, utilizing the CPU's execution units as much as possible and, thus, improving the overall performance. If the required operands of a  $\mu$ OP are available, and its corresponding execution unit is not busy, the CPU starts its execution even if  $\mu$ OPs earlier in the instruction stream have not finished yet. As immediate results are only made visible at the architectural level when all previous  $\mu$ OPs have finished, CPUs typically keep track of the status of  $\mu$ OPs in a so-called *Reorder Buffer* (ROB). The CPU takes care to *retire*  $\mu$ OPs in-order, deciding to either discard their results or commit them to the architectural state. For instance, exceptions and external interrupt requests are handled during retirement by flushing any outstanding  $\mu$ OP results from the ROB. Therefore, the CPU may have executed so-called *transient instructions* [56], whose results are never committed to the architectural state.

**Speculative Execution.** Software is mostly not linear but contains (conditional) branches or data dependencies between instructions. In theory, the CPU would have to stall until a branch or dependencies are resolved before it can continue the execution. As stalling decreases performance significantly, CPUs deploy various mechanisms to predict the outcome of a branch or a data dependency. Thus, CPUs continue executing along the predicted path, buffering the results in the ROB until the correctness of the prediction is verified as its dependencies are resolved. In the case of a correct prediction, the CPU can commit the pre-computed results from the reorder buffer, increasing the overall performance. However, if the prediction was incorrect, the CPU needs to perform a roll-back to the last correct state by squashing all pre-computed transient instruction results from the ROB.

**Cache Covert Channels.** Modern CPUs use caches to hide memory latency. However, these latency differences can be exploited in side-channels and covert channels [24,51,60,67,92]. In particular, Flush+Reload allows observations across cores at cache-line granularity, enabling attacks, e.g., on cryptographic algorithms [26,43,92], user input [24,55,72], and kernel addressing information [23]. For Flush+Reload, the attacker continuously flushes a shared memory address using the `clflush` instruction and afterward reloads the data. If the victim used the cache line, accessing it will be fast; otherwise, it will be slow.

Covert channels are a special use case of side-channel attacks, where the attacker controls both the sender and the receiver. This allows an attacker to bypass many restrictions that exist at the architectural level to leak information.

**Transient Execution Attacks.** Transient instructions reflect unauthorized computations out of the program's intended code and/or data paths. For functional correctness, it is crucial that their results are never committed to the architectural state. However, transient instructions may still leave traces in the CPU's microarchitectural state, which can subsequently be exploited to partially recover unauthorized results [50,56,85]. This observation has led to a variety of transient execution

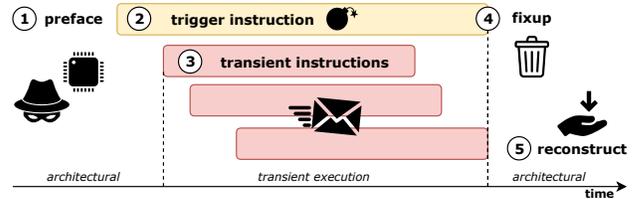

Figure 2: High-level overview of a transient execution attack in 5 phases: (1) prepare microarchitecture, (2) execute a *trigger instruction*, (3) *transient instructions* encode unauthorized data through a microarchitectural covert channel, (4) CPU retires trigger instruction and flushes transient instructions, (5) reconstruct secret from microarchitectural state.

attacks, which from a high-level always follow the same abstract flow, as shown in Figure 2. The attacker first brings the microarchitecture into the desired state, e.g., by flushing and/or populating internal branch predictors or data caches. Next is the execution of a so-called *trigger instruction*. This can be any instruction that causes subsequent operations to be eventually squashed, e.g., due to an exception or a mispredicted branch or data dependency. Before completion of the trigger instruction, the CPU proceeds with the execution of a *transient instruction sequence*. The attacker abuses the transient instructions to act as the sending end of a microarchitectural covert channel, e.g., by loading a secret-dependent memory location into the CPU cache. Ultimately, at the retirement of the trigger instruction, the CPU discovers the exception/misprediction and flushes the pipeline to discard any architectural effects of the transient instructions. However, in the final phase of the attack, unauthorized transient computation results are recovered at the receiving end of the covert channel, e.g., by timing memory accesses to deduce the secret-dependent loads from the transient instructions.

**High-Level Classification: Spectre vs. Meltdown.** Transient execution attacks have in common that they abuse transient instructions (which are never architecturally committed) to encode unauthorized data in the microarchitectural state. With different instantiations of the abstract phases in Figure 2, a wide spectrum of transient execution attack variants emerges. We deliberately based our classification on the root cause of the transient computation (phases 1, 2), abstracting away from the specific covert channel being used to transmit the unauthorized data (phases 3, 5). This leads to a first important split in our classification tree (cf. Figure 1). Attacks of the first type, dubbed Spectre [50], exploit transient execution following control or data flow misprediction. Attacks of the second type, dubbed Meltdown [56], exploit transient execution following a faulting instruction.

Importantly, Spectre and Meltdown exploit fundamentally different CPU properties and hence require orthogonal defenses. Where the former relies on dedicated control or data flow prediction machinery, the latter merely exploits that data from a faulting instruction is forwarded to instructions ahead

Table 1: Spectre-type attacks and the microarchitectural element they exploit (●), partially target (◐), or not affect (○).

Attack	Element

in the pipeline. Note that, while Meltdown-type attacks so far exploit out-of-order execution, even elementary in-order pipelines may allow for similar effects [86]. Essentially, the different root cause of the trigger instruction (Spectre-type misprediction vs. Meltdown-type fault) determines the nature of the subsequent unauthorized transient computations and hence the scope of the attack.

That is, in the case of Spectre, transient instructions can only compute on data which the application is also allowed to access architecturally. Spectre thus transiently bypasses *software-defined* security policies (e.g., bounds checking, function call/return abstractions, memory stores) to leak secrets out of the program’s intended code/data paths. Hence, much like in a “confused deputy” scenario, successful Spectre attacks come down to steering a victim into transiently computing on memory locations the victim is authorized to access but the attacker not. In practice, this implies that one or more phases of the transient execution attack flow in Figure 2 should be realized through so-called *code gadgets* executing within the victim application. We propose a novel taxonomy of gadgets based on these phases in Section 5.

For Meltdown-type attacks, on the other hand, transient execution allows to completely “melt down” architectural isolation barriers by computing on unauthorized results of faulting instructions. Meltdown thus transiently bypasses *hardware-enforced* security policies to leak data that should always remain architecturally inaccessible for the application. Where Spectre-type leakage remains largely an unintended side-effect of important speculative performance optimizations, Meltdown reflects a failure of the CPU to respect hardware-level protection boundaries for transient instructions. That is, the mere continuation of the transient execution after a fault itself is required, but not sufficient for a successful Meltdown attack. As further explored in Section 6, this has profound consequences for defenses. Overall, mitigating Spectre requires careful hardware-software co-design, whereas merely replacing the data of a faulting instruction with a dummy value suffices to block Meltdown-type leakage in silicon, e.g., as it is done in AMD processors, or with the Rogue Data Cache Load resistance (RDCL\_NO) feature advertised in recent Intel CPUs from Whiskey Lake onwards [40].

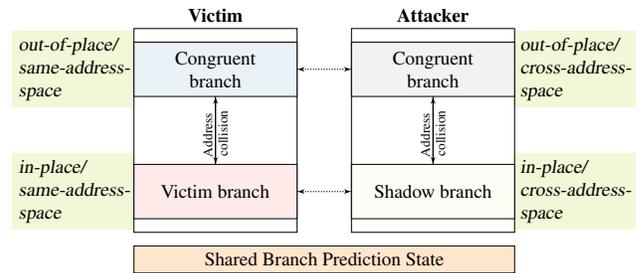

Figure 3: A branch can be mistrained either by the victim process (*same-address-space*) or by an attacker-controlled process (*cross-address-space*). Mistraining can be achieved either using the vulnerable branch itself (*in-place*) or a branch at a congruent virtual address (*out-of-place*).

### 3 Spectre-type Attacks

In this section, we provide an overview of Spectre-type attacks (cf. Figure 1). Given the versatility of Spectre variants in a variety of adversary models, we propose a novel two-level taxonomy based on the preparatory phases of the abstract transient execution attack flow in Figure 2. First, we distinguish the different microarchitectural buffers that can trigger a prediction (phase 2), and second, the mistraining strategies that can be used to steer the prediction (phase 1).

**Systematization of Spectre Variants.** To predict the outcome of various types of branches and data dependencies, modern CPUs accumulate an extensive microarchitectural state across various internal buffers and components [19]. Table 1 overviews Spectre-type attacks and the corresponding microarchitectural elements they exploit. As the first level of our classification tree, we categorize Spectre attacks based on the microarchitectural root cause that triggers the misprediction leading to the transient execution:

- Spectre-PHT [48, 50] exploits the *Pattern History Table* (PHT) that predicts the outcome of conditional branches.
- Spectre-BTB [50] exploits the *Branch Target Buffer* (BTB) for predicting branch destination addresses.
- Spectre-RSB [52, 59] primarily exploits the *Return Stack Buffer* (RSB) for predicting return addresses.
- Spectre-STL [29] exploits memory disambiguation for predicting *Store To Load* (STL) data dependencies.

Note that NetSpectre [74], SGXSpectre [63], and SGXPectre [13] focus on applying one of the above Spectre variants in a specific exploitation scenario. Hence, we do not consider them separate variants in our classification.

**Systematization of Mistraining Strategies.** We now propose a second-level classification scheme for Spectre variants that abuse history-based branch prediction (*i.e.*, all of the above except Spectre-STL). These Spectre variants first go through a preparatory phase (cf. Figure 2) where the microarchitectural branch predictor state is “poisoned” to cause intentional misspeculation of a particular victim branch. Since branch prediction buffers in modern CPUs [19, 50] are com-

monly indexed based on the virtual address of the branch instruction, mistraining can happen either within the same address space or from a different attacker-controlled process. Furthermore, as illustrated in Figure 3, when only a subset of the virtual address is used in the prediction, mistraining can be achieved using a branch instruction at a congruent virtual address. We thus enhance the field of Spectre-type branch poisoning attacks with 4 distinct mistraining strategies:

1. Executing the victim branch in the victim process (*same-address-space in-place*).
2. Executing a congruent branch in the victim process (*same-address-space out-of-place*).
3. Executing a shadow branch in a different process (*cross-address-space in-place*).
4. Executing a congruent branch in a different process (*cross-address-space out-of-place*).

In current literature [6, 13, 48, 50], several of the above branch poisoning strategies have been overlooked for different Spectre variants. We summarize the results of an assessment of vulnerabilities under mistraining strategies in Table 2. Our systematization thus reveals clear blind spots that allow an attacker to mistrain branch predictors in previously unknown ways. As explained further, depending on the adversary’s capabilities (e.g., in-process, sandboxed, remote, enclave, etc.) these previously unknown mistraining strategies may lead to new attacks and/or bypass existing defenses.

### 3.1 Spectre-PHT (Input Validation Bypass)

**Microarchitectural Element.** Kocher et al. [50] first introduced Spectre Variant 1, an attack that poisons the Pattern History Table (PHT) to mispredict the direction (taken or not-taken) of conditional branches. Depending on the underlying microarchitecture, the PHT is accessed based on a combination of virtual address bits of the branch instruction plus a hidden Branch History Buffer (BHB) that accumulates global behavior for the last  $N$  branches on the same physical core [18, 19]

**Reading Out-of-Bounds.** Conditional branches are commonly used by programmers and/or compilers to maintain memory safety invariants at runtime. For example, consider the following code snippet for bounds checking [50]:

```
if (x < len(array1)) { y = array2[array1[x] * 4096]; }
```

At the architectural level, this program clearly ensures that the index variable  $x$  always lies within the bounds of the fixed-length buffer `array1`. However, after repeatedly supplying valid values of  $x$ , the PHT will reliably predict that this branch evaluates to true. When the adversary now supplies an invalid index  $x$ , the CPU continues along a mispredicted path and transiently performs an out-of-bounds memory access. The above code snippet features an explicit example of a “leak gadget” that may act as a microarchitectural covert channel: depending on the out-of-bounds value being read, the transient

Table 2: Spectre-type attacks performed in-place, out-of-place, same-address-space (*i.e.*, intra-process), or cross-address-space (*i.e.*, cross-process).

Method \ Attack		Spectre-PHT	Spectre-BTB	Spectre-RSB	Spectre-STL
Intel	intra-process in-place	● [48, 50] ★	● [59]	● [29]	
	intra-process out-of-place	★	● [13]	● [52, 59]	○

	cross-process out-of-place	★	● [50]	● [52]	○
ARM	intra-process in-place	● [48, 50] ★	● [6]	● [6]	
	intra-process out-of-place	★	★	○	○
	cross-process in-place	★	● [6, 50]	★	○
	cross-process out-of-place	★	★	★	○
AMD	intra-process in-place	● [50] ★	★	★	● [29]
	intra-process out-of-place	★	★	★	○
	cross-process in-place	★	● [50]	★	○
	cross-process out-of-place	★	★	★	○

Symbols indicate whether an attack is possible and known (●), not possible and known (○), possible and previously unknown or not shown (★), or tested and did not work and previously unknown or not shown (☆). All tests performed with no defenses enabled.

instructions load another memory page belonging to `array2` into the cache.

**Writing Out-of-Bounds.** Kiriansky and Waldspurger [48] showed that transient writes are also possible by following the same principle. Consider the following code line:

```
if (x < len(array)) { array[x] = value; }
```

After mistraining the PHT component, attackers controlling the untrusted index  $x$  can transiently write to arbitrary out-of-bounds addresses. This creates a transient buffer overflow, allowing the attacker to bypass both type and memory safety. Ultimately, when repurposing traditional techniques from return-oriented programming [75] attacks, adversaries may even gain arbitrary code execution in the transient domain by overwriting return addresses or code pointers.

**Overlooked Mistraining Strategies.** Spectre-PHT attacks so far [48, 50, 63] rely on a same-address-space in-place branch poisoning strategy. However, our results (cf. Table 2) reveal that the Intel, ARM, and AMD CPUs we tested are vulnerable to all four PHT mistraining strategies. In this, we are the first to successfully demonstrate Spectre-PHT-style branch misprediction attacks *without prior execution of the victim branch*. This is an important contribution as it may open up previously unknown attack avenues for restricted adversaries.

Cross-address-space PHT poisoning may, for instance, enable advanced attacks against a privileged daemon process that does not directly accept user input. Likewise, for Intel SGX technology, remote attestation schemes have been developed [76] to enforce that a victim enclave can only be run exactly once. This effectively rules out current state-of-the-art SGXSpectre [63] attacks that repeatedly execute the victim enclave to mistrain the PHT branch predictor. Our novel out-of-place PHT poisoning strategy, on the other hand, allows us to perform the training phase entirely *outside* the enclave on

the same physical core by repeatedly executing a congruent branch in the untrusted enclave host process (cf. Figure 3).

### 3.2 Spectre-BTB (Branch Target Injection)

**Microarchitectural Element.** In Spectre Variant 2 [50], the attacker poisons the Branch Target Buffer (BTB) to steer the transient execution to a mispredicted branch target. For direct branches, the CPU indexes the BTB using a subset of the virtual address bits of the branch instruction to yield the predicted jump target. For indirect branches, CPUs use different mechanisms [28], which may take into account global branching history accumulated in the BHB when indexing the BTB. We refer to both types as Spectre-BTB.

**Hijacking Control Flow.** Contrary to Spectre-PHT, where transient instructions execute along a restricted mispredicted path, Spectre-BTB allows redirecting transient control flow to an arbitrary destination. Adopting established techniques from return-oriented programming (ROP) attacks [75], but abusing BTB poisoning instead of application-level vulnerabilities, selected code “gadgets” found in the victim address space may be chained together to construct arbitrary transient instruction sequences. Hence, where the success of Spectre-PHT critically relies on unintended leakage along the mispredicted code path, ROP-style gadget abuse in Spectre-BTB allows to more directly construct covert channels that expose secrets from the transient domain (cf. Figure 2). We discuss gadget types in more detail in Section 5.

**Overlooked Mistraining Strategies.** Spectre-BTB was initially demonstrated on Intel, AMD, and ARM CPUs using a cross-address-space in-place mistraining strategy [50]. With SGXPectre [13], Chen et al. extracted secrets from Intel SGX enclaves using either a cross-address-space in-place or same-address-space out-of-place BTB poisoning strategy. We experimentally reproduced these mistraining strategies through a systematic evaluation presented in Table 2. On AMD and ARM, we could not demonstrate out-of-place BTB poisoning. Possibly, these CPUs use an unknown (sub)set of virtual address bits or a function of bits which we were not able to reverse engineer. We encourage others to investigate whether a different (sub)set of virtual address bits is required to enable the attack.

To the best of our knowledge, we are the first to recognize that Spectre-BTB mistraining can also proceed by *repeatedly executing the vulnerable indirect branch with valid inputs*. Much like Spectre-PHT, such same-address-space in-place BTB (Spectre-BTB-SA-IP) poisoning abuses the victim’s own execution to mistrain the underlying branch target predictor. Hence, as an important contribution to understanding attack surface and defenses, in-place mistraining *within* the victim domain may allow bypassing widely deployed mitigations [4, 40] that flush and/or partition the BTB before entering the victim. Since the branch destination address is now determined by the victim code and not under the direct

control of the attacker, however, Spectre-BTB-SA-IP cannot offer the full power of arbitrary transient control flow redirection. Yet, in higher-level languages like C++ that commonly rely on indirect branches to implement polymorph abstractions, Spectre-BTB-SA-IP may lead to subtle “speculative type confusion” vulnerabilities. For example, a victim that repeatedly executes a virtual function call with an object of `TypeA` may inadvertently mistrain the branch target predictor to cause misspeculation when finally executing the virtual function call with an object of another `TypeB`.

### 3.3 Spectre-RSB (Return Address Injection)

**Microarchitectural Element.** Maisuradze and Rossow [59] and Koruyeh et al. [52] introduced a Spectre variant that exploits the Return Stack Buffer (RSB). The RSB is a small per-core microarchitectural buffer that stores the virtual addresses following the  $N$  most recent `call` instructions. When encountering a `ret` instruction, the CPU pops the topmost element from the RSB to predict the return flow.

**Hijacking Return Flow.** Misspeculation arises whenever the RSB layout diverges from the actual return addresses on the software stack. Such disparity for instance naturally occurs when restoring kernel/enclave/user stack pointers upon protection domain switches. Furthermore, same-address-space adversaries may explicitly overwrite return addresses on the software stack, or transiently execute `call` instructions which update the RSB without committing architectural effects [52]. This may allow untrusted code executing in a sandbox to transiently divert return control flow to interesting code gadgets outside of the sandboxed environment.

Due to the fixed-size nature of the RSB, a special case of misspeculation occurs for deeply nested function calls [52, 59]. Since the RSB can only store return addresses for the  $N$  most recent calls, an underfill occurs when the software stack is unrolled. In this case, the RSB can no longer provide accurate predictions. Starting from Skylake, Intel CPUs use the BTB as a fallback [19, 52], thus allowing Spectre-BTB-style attacks triggered by `ret` instructions.

**Overlooked Mistraining Strategies.** Spectre-RSB has been demonstrated with all four mistraining strategies, but only on Intel [52, 59]. Our experimental results presented in Table 2 generalize these strategies to AMD CPUs. Furthermore, in line with ARM’s own analysis [6], we successfully poisoned RSB entries within the same-address-space but did not observe any cross-address-space leakage on ARM CPUs. We expect this may be a limitation of our current proof-of-concept code and encourage others to investigate this further.

### 3.4 Spectre-STL (Speculative Store Bypass)

**Microarchitectural Element.** Speculation in modern CPUs is not restricted to control flow but also includes predicting dependencies in the data flow. A common type of Store To

Table 3: Demonstrated Meltdown-type (MD) attacks.

Attack	#GP	#NM	#BR	#PF	U/S	P	R/W	RSVD	XD	PK
MD-GP (Variant 3a) [8]	●	○	○	○

MD-RW (Variant 1.2) [48]	○	○	○	●	○	○	●	○	○	○
MD-PK	○	○	○	●	○	○	○	○	○	●

Symbols (● or ○) indicate whether an exception type (left) or permission bit (right) is exploited. Systematic names are derived from what is exploited.

Load (STL) dependencies require that a memory load shall not be executed before all preceding stores that write to the same location have completed. However, even before the addresses of all prior stores in the pipeline are known, the CPUs’ memory disambiguator [3, 33, 44] may predict which loads can already be executed speculatively.

When the disambiguator predicts that a load does not have a dependency on a prior store, the load reads data from the L1 data cache. When the addresses of all prior stores are known, the prediction is verified. If any overlap is found, the load and all following instructions are re-executed.

**Reading Stale Values.** Horn [29] showed how mispredictions by the memory disambiguator could be abused to speculatively bypass store instructions. Like previous attacks, Spectre-STL adversaries rely on an appropriate transient instruction sequence to leak unsanitized stale values via a microarchitectural covert channel. Furthermore, operating on stale pointer values may speculatively break type and memory safety guarantees in the transient execution domain [29].

## 4 Meltdown-type Attacks

This section overviews Meltdown-type attacks, and presents a classification scheme that led to the discovery of two previously overlooked Meltdown variants (cf. Figure 1). Importantly, where Spectre-type attacks exploit (branch) misprediction events to trigger transient execution, Meltdown-type attacks rely on transient instructions following a CPU exception. Essentially, Meltdown exploits that exceptions are only raised (*i.e.*, become architecturally visible) upon the retirement of the faulting instruction. In some microarchitectures, this property allows transient instructions ahead in the pipeline to compute on unauthorized results of the instruction that is about to suffer a fault. The CPU’s in-order instruction retirement mechanism takes care to discard any architectural effects of such computations, but as with the Spectre-type attacks above, secrets may leak through microarchitectural covert channels.

**Systematization of Meltdown Variants.** We introduce a classification for Meltdown-type attacks in two dimensions. In the first level, we categorize attacks based on the exception

Table 4: Secrets recoverable via Meltdown-type attacks and whether they cross the current privilege level (CPL).

Attack	Leaks			
	Memory	Cache	Register	Cross-CPL
Meltdown-US (Meltdown) [56]	●	●	○	✓
Meltdown-P (Foreshadow-NG) [90]	○	●	○	✓
Meltdown-P (Foreshadow-SGX) [85]	●	●	●	✓
Meltdown-GP (Variant 3a) [8]	○	○	●	✓
Meltdown-NM (Lazy FP) [78]	○	○	●	✓
Meltdown-RW (Variant 1.2) [48]	●	●	○	✗
Meltdown-PK	★	★	☆	✗
Meltdown-BR	★	★	☆	✗

Symbols indicate whether an attack crosses a processor privilege level (✓) or not (✗), whether it can leak secrets from a buffer (●), only with additional steps (●), or not at all (○). Respectively (★ vs. ☆) if first shown in this work.

that causes transient execution. Following Intel’s [31] classification of exceptions as *faults*, *traps*, or *aborts*, we observed that Meltdown-type attacks so far have exploited faults, but not traps or aborts. The CPU generates faults if a correctable error has occurred, *i.e.*, they allow the program to continue after it has been resolved. Traps are reported immediately after the execution of the instruction, *i.e.*, when the instruction retires and becomes architecturally visible. Aborts report some unrecoverable error and do not allow a restart of the task that caused the abort.

In the second level, for page faults (#PF), we further categorize based on page-table entry protection bits (cf. Table 3). We also categorize attacks based on which storage locations can be reached, and whether it crosses a privilege boundary (cf. Table 4). Through this systematization, we discovered several previously unknown Meltdown variants that exploit different exception types as well as page-table protection bits, including two exploitable ones. Our systematic analysis furthermore resulted in the first demonstration of exploitable Meltdown-type delayed exception handling effects on AMD CPUs.

### 4.1 Meltdown-US (Supervisor-only Bypass)

Modern CPUs commonly feature a “user/supervisor” page-table attribute to denote a virtual memory page as belonging to the OS kernel. The original Meltdown attack [56] reads kernel memory from user space on CPUs that do *not* transiently enforce the user/supervisor flag. In the trigger phase (cf. Figure 2) an unauthorized kernel address is dereferenced, which eventually causes a page fault. Before the fault becomes architecturally visible, however, the attacker executes a transient instruction sequence that for instance accesses a cache line based on the privileged data read by the trigger instruction. In the final phase, after the exception has been raised, the privileged data is reconstructed at the receiving end of the covert channel (e.g., Flush+Reload).

The attacks bandwidth can be improved by suppressing exceptions through transaction memory CPU features such as

Intel TSX [31], exception handling [56], or hiding it in another transient execution [28, 56]. By iterating byte-by-byte over the kernel space and suppressing or handling exceptions, an attacker can dump the entire kernel. This includes the entire physical memory if the operating system has a direct physical map in the kernel. While extraction rates are significantly higher when the kernel data resides in the CPU cache, Meltdown has even been shown to successfully extract uncached data from memory [56].

## 4.2 Meltdown-P (Virtual Translation Bypass)

**Foreshadow.** Van Bulck et al. [85] presented Foreshadow, a Meltdown-type attack targeting Intel SGX technology [30]. Unauthorized accesses to enclave memory usually do not raise a `#PF` exception but are instead silently replaced with abort page dummy values (cf. Section 6.2). In the absence of a fault, plain Meltdown cannot be mounted against SGX enclaves. To overcome this limitation, a Foreshadow attacker clears the “present” bit in the page-table entry mapping the enclave secret, ensuring that a `#PF` will be raised for subsequent accesses. Analogous to Meltdown-US, the adversary now proceeds with a transient instruction sequence to leak the secret (e.g., through a Flush+Reload covert channel).

Intel [34] named *L1 Terminal Fault* (L1TF) as the root cause behind Foreshadow. A terminal fault occurs when accessing a page-table entry with either the present bit cleared or a “reserved” bit set. In such cases, the CPU immediately aborts address translation. However, since the L1 data cache is indexed in parallel to address translation, the page table entry’s physical address field (*i.e.*, frame number) may still be passed to the L1 cache. Any data present in L1 and tagged with that physical address will now be forwarded to the transient execution, regardless of access permissions.

Although Meltdown-P-type leakage is restricted to the L1 data cache, the original Foreshadow [85] attack showed how SGX’s secure page swapping mechanism might first be abused to prefetch arbitrary enclave pages into the L1 cache, including even CPU registers stored on interrupt. This highlights that SGX’s privileged adversary model considerably amplifies the transient execution attack surface.

**Foreshadow-NG.** Foreshadow-NG [90] generalizes Foreshadow from the attack on SGX enclaves to bypass operating system or hypervisor isolation. The generalization builds on the observation that the physical frame number in a page-table entry is sometimes under direct or indirect control of an adversary. For instance, when swapping pages to disk, the kernel is free to use all but the present bit to store metadata (e.g., the offset on the swap partition). However, if this offset is a valid physical address, any cached memory at that location leaks to an unprivileged Foreshadow-OS attacker.

Even worse is the Foreshadow-VMM variant, which allows an untrusted virtual machine, controlling guest-physical addresses, to extract the host machine’s entire L1 data cache

(including data belonging to the hypervisor or other virtual machines). The underlying problem is that a terminal fault in the guest page-tables early-outs the address translation process, such that guest-physical addresses are erroneously passed to the L1 data cache, without first being translated into a proper host physical address [34].

## 4.3 Meltdown-GP (System Register Bypass)

Meltdown-GP (named initially Variant 3a) [37] allows an attacker to read privileged system registers. It was first discovered and published by ARM [8] and subsequently Intel [35] determined that their CPUs are also susceptible to the attack. Unauthorized access to privileged system registers (e.g., via `rdmsr`) raises a *general protection* fault (`#GP`). Similar to previous Meltdown-type attacks, however, the attack exploits that the transient execution following the faulting instruction can still compute on the unauthorized data, and leak the system register contents through a microarchitectural covert channel (e.g., Flush+Reload).

## 4.4 Meltdown-NM (FPU Register Bypass)

During a context switch, the OS has to save all the registers, including the floating point unit (FPU) and SIMD registers. These latter registers are large and saving them would slow down context switches. Therefore, CPUs allow for a lazy state switch, meaning that instead of saving the registers, the FPU is simply marked as “not available”. The first FPU instruction issued after the FPU was marked as “not available” causes a *device-not-available* (`#NM`) exception, allowing the OS to save the FPU state of previous execution context before marking the FPU as available again.

Stecklina and Prescher [78] propose an attack on the above lazy state switch mechanism. The attack consists of three steps. In the first step, a victim performs operations loading data into the FPU registers. Then, in the second step, the CPU switches to the attacker and marks the FPU as “not available”. The attacker now issues an instruction that uses the FPU, which generates an `#NM` fault. Before the faulting instruction retires, however, the CPU has already transiently executed the following instructions using data from the previous context. As such, analogous to previous Meltdown-type attacks, a malicious transient instruction sequence following the faulting instruction can encode the unauthorized FPU register contents through a microarchitectural covert channel (e.g., Flush+Reload).

## 4.5 Meltdown-RW (Read-only Bypass)

Where the above attacks [8, 56, 78, 85] focussed on stealing information across privilege levels, Kiriansky and Waldspurger [48] presented the first Meltdown-type attack that bypasses page-table based access rights *within* the current

privilege level. Specifically, they showed that transient execution does not respect the “read/write” page-table attribute. The ability to transiently overwrite read-only data within the current privilege level can bypass software-based sandboxes which rely on hardware enforcement of read-only memory.

Confusingly, the above Meltdown-RW attack was originally named “Spectre Variant 1.2” [48] as the authors followed a Spectre-centric naming scheme. Our systematization revealed, however, that the transient cause exploited above is a #PF exception. Hence, this attack is of Meltdown-type, but *not* a variant of Spectre.

#### 4.6 Meltdown-PK (Protection Key Bypass)

Intel Skylake-SP server CPUs support memory-protection keys for user space (PKU) [32]. This feature allows processes to change the access permissions of a page directly from user space, *i.e.*, without requiring a syscall/hypercall. Thus, with PKU, user-space applications can implement efficient hardware-enforced isolation of trusted parts [27, 84].

We present a novel Meltdown-PK attack to bypass both read and write isolation provided by PKU. Meltdown-PK works if an attacker has code execution in the containing process, even if the attacker cannot execute the `wrpkru` instruction (e.g., blacklisting). Moreover, in contrast to cross-privilege level Meltdown attack variants, there is no software workaround. According to Intel [36], Meltdown-PK can be mitigated using address space isolation. Recent Meltdown-resistant Intel processors enumerating `RDCL_NO` plus PKU support furthermore mitigate Meltdown-PK in silicon. With those mitigations, the memory addresses that might be revealed by transient execution attacks can be limited.

**Experimental Results.** We tested Meltdown-PK on an Amazon EC2 C5 instance running Ubuntu 18.04 with PKU support. We created a memory mapping and used PKU to remove both read and write access. As expected, protected memory accesses produce a #PF. However, our proof-of-concept manages to leak the data via an adversarial transient instruction sequence with a Flush+Reload covert channel.

#### 4.7 Meltdown-BR (Bounds Check Bypass)

To facilitate efficient software instrumentation, x86 CPUs come with dedicated hardware instructions that raise a *bound-range-exceeded* exception (#BR) when encountering out-of-bound array indices. The IA-32 ISA, for instance, defines a `bound` opcode for this purpose. While the `bound` instruction was omitted in the subsequent x86-64 ISA, modern Intel CPUs ship with Memory Protection eXtensions (MPX) for efficient array bounds checking.

Our systematic evaluation revealed that Meltdown-type effects of the #BR exception had not been thoroughly investigated yet. Specifically, Intel’s analysis [40] only briefly mentions MPX-based bounds check bypass as a possibility, and

Table 5: CPU vendors vulnerable to Meltdown (MD).

Vendor	Attack	MD-US [56]	MD-P [85, 90]	MD-GP [8, 35]	MD-NM [78]	MD-RW [48]	MD-PK	MD-BR	MD-DE	MD-AC	MD-UD	MD-SS	MD-XD	MD-SM
Intel		●	●	●	●	●	★	★	☆	☆	☆	☆	☆	☆
ARM		●	○	●	—	●	—	—	☆	☆	☆	—	☆	☆
AMD		○	○	○	○	○	—	★	☆	☆	☆	☆	☆	☆

Symbols indicate whether at least one CPU model is vulnerable (filled) vs. no CPU is known to be vulnerable (empty). Glossary: reproduced (● vs. ○), first shown in this paper (★ vs. ☆), not applicable (—). All tests performed without defenses enabled.

recent defensive work by Dong et al. [16] highlights the need to introduce a memory `lfence` after MPX bounds check instructions. They classify this as a Spectre-type attack, implying that the `lfence` is needed to prevent the branch predictor from speculating on the outcome of the bounds check. According to Oleksenko et al. [64], neither `bnctl` nor `bnctu` exert pressure on the branch predictor, indicating that there is no prediction happening. Based on that, we argue that the classification as a Spectre-type attack is misleading as no prediction is involved. The observation by Dong et al. [16] indeed does not shed light on the #BR exception as the root cause for the MPX bounds check bypass, and they do not consider IA32 `bound` protection at all. Similar to Spectre-PHT, Meltdown-BR is a bounds check bypass, but instead of mistraining a predictor it exploits the lazy handling of the raised #BR exception.

**Experimental Results.** We introduce the Meltdown-BR attack which exploits transient execution following a #BR exception to encode out-of-bounds secrets that are never architecturally visible. As such, Meltdown-BR is an exception-driven alternative for Spectre-PHT. Our proofs-of-concept demonstrate out-of-bounds leakage through a Flush+Reload covert channel for an array index safeguarded by either IA32 `bound` (Intel, AMD), or state-of-the-art MPX protection (Intel-only). For Intel, we ran the attacks on a Skylake i5-6200U CPU with MPX support, and for AMD we evaluated both an E2-2000 and a Ryzen Threadripper 1920X. This is the first experiment demonstrating a Meltdown-type transient execution attack exploiting delayed exception handling on AMD CPUs [4, 56].

#### 4.8 Residual Meltdown (Negative Results)

We systematically studied transient execution leakage for other, not yet tested exceptions. In our experiments, we consistently found no traces of transient execution beyond traps or aborts, which leads us to the hypothesis that Meltdown is only possible with faults (as they can occur at any moment during instruction execution). Still, the possibility remains that our experiments failed and that they are possible. Table 5 and Figure 1 summarize experimental results for fault types tested on Intel, ARM, and AMD.

**Division Errors.** For the divide-by-zero experiment, we leveraged the signed division instruction (`idiv` on x86 and

Table 6: Gadget classification according to the attack flow and whether executed by the attacker (●), victim (○), or either (◐).

Attack	1. Preface	2. Trigger example	3. Transient	5. Reconstruction
Covert channel [1, 74, 92]	◐ Flush/Prime/Evict	-	● Load/AVX/Port/...	◐ Reload/Probe/Time
Meltdown-US/RW/GP/NM/PK [8, 48, 56, 78]	● (Exception suppression)	● <code>mov/rdmsr/FPU</code>	● Controlled encode	● Exception handling
Meltdown-P [85, 90]	○ (L1 prefetch)	● <code>mov</code>	● Controlled encode	& controlled decode
Meltdown-BR	-	○ <code>bound/bndclu</code>	○ Inadvertent leak	<i>same as above</i>
Spectre-PHT [50]	◐ PHT poisoning	○ <code>jz</code>	○ Inadvertent leak	● Controlled decode
Spectre-BTB/RSB [13, 50, 52, 59]	◐ BTB/RSB poisoning	○ <code>call/jmp/ret</code>	○ ROP-style encode	● Controlled decode
Spectre-STL [29]	-	○ <code>mov</code>	○ Inadvertent leak	● Controlled decode
NetSpectre [74]	○ Thrash/reset	○ <code>jz</code>	○ Inadvertent leak	○ Inadvertent transmit

`sdiv` on ARM). On the ARMs we tested, there is no exception, but the division yields merely zero. On x86, the division raises a *divide-by-zero* exception (`#DE`). Both on the AMD and Intel we tested, the CPU continues with the transient execution after the exception. In both cases, the result register is set to ‘0’, which is the same result as on the tested ARM. Thus, according to our experiments Meltdown-DE is not possible, as no real values are leaked.

**Supervisor Access.** Although supervisor mode access prevention (SMAP) raises a page fault (`#PF`) when accessing user-space memory from the kernel, it seems to be free of any Meltdown effect in our experiments. Thus, we were not able to leak any data using Meltdown-SM in our experiments.

**Alignment Faults.** Upon detecting an unaligned memory operand, the CPU may generate an *alignment check* exception (`#AC`). In our tests, the results of unaligned memory accesses never reach the transient execution. We suspect that this is because `#AC` is generated early-on, even before the operand’s virtual address is translated to a physical one. Hence, our experiments with Meltdown-AC were unsuccessful in showing any leakage.

**Segmentation Faults.** We consistently found that out-of-limit segment accesses never reach transient execution in our experiments. We suspect that, due to the simplistic IA32 segmentation design, segment limits are validated early-on, and immediately raise a `#GP` or `#SS` (*stack-segment fault*) exception, without sending the offending instruction to the ROB. Therefore, we observed no leakage in our experiments with Meltdown-SS.

**Instruction Fetch.** To yield a complete picture, we investigated Meltdown-type effects during the instruction fetch and decode phases. On our test systems, we did not succeed in transiently executing instructions residing in non-executable memory (*i.e.*, Meltdown-XD), or following an *invalid opcode* (`#UD`) exception (*i.e.*, Meltdown-UD). We suspect that exceptions during instruction fetch or decode are immediately handled by the CPU, without first buffering the offending instruction in the ROB. Moreover, as invalid opcodes have an undefined length, the CPU does not even know where the next instruction starts. Hence, we suspect that invalid opcodes only leak if the microarchitectural effect is already an effect caused by the invalid opcode itself, not by subsequent transient instructions.

Table 7: Spectre-PHT gadget classification and the number of occurrences per gadget type in Linux kernel v5.0.

Gadget	Example (Spectre-PHT)	#Occurrences
Prefetch	<code>if(i&lt;LEN_A){a[i];}</code>	172
Compare	<code>if(i&lt;LEN_A){if(a[i]==k){};}</code>	127
Index	<code>if(i&lt;LEN_A){y = b[a[i]*x];}</code>	0
Execute	<code>if(i&lt;LEN_A){a[i](void);}</code>	16

## 5 Gadget Analysis and Classification

We deliberately oriented our attack tree (cf. Figure 1) on the microarchitectural root causes of the transient computation, abstracting away from the underlying covert channel and/or code *gadgets* required to carry out the attack successfully. In this section, we further dissect transient execution attacks by categorizing gadget types in two tiers and overviewing current results on their exploitability in real-world software.

### 5.1 Gadget Classification

**First-Tier: Execution Phase.** We define a “gadget” as a series of instructions executed by either the attacker or the victim. Table 6 shows how gadget types discussed in literature can be unambiguously assigned to one of the abstract attack phases from Figure 2. New gadgets can be added straightforwardly after determining their execution phase and objective.

Importantly, our classification table highlights that gadget choice largely depends on the attacker’s capabilities. By plugging in different gadget types to compose the required attack phases, an almost boundless spectrum of adversary models can be covered that is only limited by the attacker’s capabilities. For local adversaries with arbitrary code execution (e.g., Meltdown-US [56]), the gadget functionality can be explicitly implemented by the attacker. For sandboxed adversaries (e.g., Spectre-PHT [50]), on the other hand, much of the gadget functionality has to be provided by “confused deputy” code executing in the victim domain. Ultimately, as claimed by Schwarz et al. [74], even fully remote attackers may be able to launch Spectre attacks given that sufficient gadgets would be available inside the victim code.

**Second-Tier: Transient Leakage.** During our analysis of the Linux kernel (see Section 5.2), we discovered that gadgets required for Spectre-PHT can be further classified in a second

tier. A second tier is required in this case as those gadgets enable different types of attacks. The first type of gadget we found is called *Prefetch*. A Prefetch gadget consists of a single array access. As such it is not able to leak data, but can be used to load data that can then be leaked by another gadget as was demonstrated by Meltdown-P [85]. The second type of gadget, called *Compare*, loads a value like in the Prefetch gadget and then branches on it. Using a contention channel like execution unit contention [2, 9] or an AVX channel as claimed by Schwarz et al. [74], an attacker might be able to leak data. We refer to the third gadget as *Index* gadget and it is the double array access shown by Kocher et al. [50]. The final gadget type, called *Execute*, allows arbitrary code execution, similar to Spectre-BTB. In such a gadget, an array is indexed based on an attacker-controlled input and the resulting value is used as a function pointer, allowing an attacker to transiently execute code by accessing the array out-of-bounds. Table 7 gives examples for all four types.

## 5.2 Real-World Software Gadget Prevalence

While for Meltdown-type attacks, convincing real-world exploits have been developed to dump arbitrary process [56] and enclave [85] memory, most Spectre-type attacks have so far only been demonstrated in controlled environments. The most significant barrier to mounting a successful Spectre attack is to find exploitable gadgets in real-world software, which at present remains an important open research question in itself [59, 74].

**Automated Gadget Analysis.** Since the discovery of transient execution attacks, researchers have tried to develop methods for the automatic analysis of gadgets. One proposed method is called oo7 [89] and uses taint tracking to detect Spectre-PHT Prefetch and Index gadgets. oo7 first marks all variables that come from an untrusted source as tainted. If a tainted variable is later on used in a branch, the branch is also tainted. The tool then reports a possible gadget if a tainted branch is followed by a memory access depending on the tainted variable. Guarnieri et al. [25] mention that oo7 would still flag code locations that were patched with Speculative Load Hardening [12] as it would still match the vulnerable pattern.

Another approach, called Spectector [25], uses symbolic execution to detect Spectre-PHT gadgets. It tries to formally prove that a program does not contain any gadgets by tracking all memory accesses and jump targets during execution along all different program paths. Additionally, it simulates the path of mispredicted branches for a number of steps. The program is run twice to determine whether it is free of gadgets or not. First, it records a trace of memory accesses when no misspeculation occurs (*i.e.*, runs the program in its intended way). Second, it records a trace of memory accesses with misspeculation of a certain number of instructions. Spectector then reports a gadget if it detects a mismatch between the two

traces. One problem with the Spectector approach is scalability as it is currently not feasible to symbolically execute large programs.

The Linux kernel developers use a different approach. They extended the Smatch static analysis tool to automatically discover potential Spectre-PHT out-of-bounds access gadgets [10]. Specifically, Smatch finds all instances of user-supplied array indices that have not been explicitly hardened. Unfortunately, Smatch's false positive rate is quite high. According to Carpenter [10], the tool reported 736 gadget candidates in April 2018, whereas the kernel only featured about 15 Spectre-PHT-resistant array indices at that time. We further investigated this by analyzing the number of occurrences of the newly introduced `array_index_nospec` and `array_index_mask_nospec` macros in the Linux kernel per month. Figure 4 shows that the number of Spectre-PHT patches has been continuously increasing over the past year. This provides further evidence that patching Spectre-PHT gadgets in real-world software is an ongoing effort and that automated detection methods and gadget classification pose an important research challenge.

**Academic Review.** To date, only 5 academic papers have demonstrated Spectre-type gadget exploitation in real-world software [9, 13, 29, 50, 59]. Table 8 reveals that they either abuse ROP-style gadgets in larger code bases or more commonly rely on Just-In-Time (JIT) compilation to indirectly provide the vulnerable gadget code. JIT compilers as commonly used in e.g., JavaScript, WebAssembly, or the eBPF Linux kernel interface, create a software-defined sandbox by extending the untrusted attacker-provided code with runtime checks. However, the attacks in Table 8 demonstrate that such JIT checks can be transiently circumvented to leak memory contents outside of the sandbox. Furthermore, in the case of Spectre-BTB/RSB, even non-JIT compiled real-world code has been shown to be exploitable when the attacker controls sufficient inputs to the victim application. Kocher et al. [50] constructed a minimalist proof-of-concept that reads attacker-controlled inputs into registers before calling a function. Next, they rely on BTB poisoning to redirect transient control flow to a gadget they identified in the Windows `ntdll` library that allows leaking arbitrary memory from the victim process. Likewise, Chen et al. [13] analyzed various trusted enclave runtimes for Intel SGX and found several instances of vulnerable branches with attacker-controlled input registers, plus numerous exploitable gadgets to which transient control flow may be directed to leak unauthorized enclave memory. Bhatlacharyya et al. [9] analyzed common software libraries that are likely to be linked against a victim program for gadgets. They were able to find numerous gadgets and were able to exploit one in OpenSSL to leak information.

**Case Study: Linux Kernel.** To further assess the prevalence of Spectre gadgets in real-world software, we selected the Linux kernel (Version 5.0) as a relevant case study of a major open-source project that underwent numerous Spectre-related

Table 8: Spectre-type attacks on real-world software.

security patches over the last year. We opted for an in-depth analysis of one specific piece of software instead of a breadth-first approach where we do a shallow analysis of multiple pieces of software. This allowed us to analyse historical data (*i.e.*, code locations the kernel developers deemed necessary to protect) that led to the second tier classification discussed in Section 5.1.

There are a couple of reasons that make analysis difficult. The first is that Linux supports many different platforms. Therefore, particular gadgets are only available in a specific configuration. The second point is that the number of instructions that can be transiently executed depends on the size of the ROB [89]. As we analyze high-level code, we can only estimate how far ahead the processor can transiently execute.

Table 7 shows the number of occurrences of each gadget type from our second tier classification. While Figure 4 shows around 120 occurrences of `array_index_nospec`, the number of gadgets in our analysis is higher. The reason behind that is that multiple arrays are indexed with the same masked index and that there are multiple branches on a value that was loaded with a potential malicious index. Our analysis also shows that more dangerous gadgets that either allow more than 1-bit leakage or even arbitrary code execution are not frequently occurring. Even if one is found, it might still be hard to exploit. During our analysis, we also discovered that the patch had been reverted in 13 locations, indicating that there is also some confusion among the kernel developers what needs to be fixed.

## 6 Defenses

In this section, we discuss proposed defenses in software and hardware for Spectre and Meltdown variants. We propose a classification scheme for defenses based on their attempt to stop leakage, similar to Miller [62]. Our work differs from Miller in three points. First, ours extends to newer transient execution attacks. Second, we consider Meltdown and Spectre as two problems with different root causes, leading to a

Table 9: Categorization of Spectre defenses and systematic overview of their microarchitectural target.

different classification. Third, it helped uncover problems that were not clear with the previous classification.

We categorize Spectre-type defenses into three categories:

- C1:** Mitigating or reducing the accuracy of covert channels used to extract the secret data.
- C2:** Mitigating or aborting speculation if data is potentially accessible during transient execution.
- C3:** Ensuring that secret data cannot be reached.

Table 9 lists proposed defenses against Spectre-type attacks and assigns them to the category they belong.

We categorize Meltdown-type defenses into two categories:

- D1:** Ensuring that architecturally inaccessible data remains inaccessible on the microarchitectural level.
- D2:** Preventing the occurrence of faults.

### 6.1 Defenses for Spectre

#### C1: Mitigating or reducing accuracy of covert channels.

Transient execution attacks use a covert channel to transfer a microarchitectural state change induced by the transient instruction sequence to the architectural level. One approach in mitigating Spectre-type attacks is reducing the accuracy of covert channels or preventing them.

**Hardware.** One enabler of transient execution attacks is that the transient execution sequence introduces a microarchitectural state change the receiving end of the covert channel observes. To secure CPUs, SafeSpec [45] introduces shadow hardware structures used during transient execution. Thereby, any microarchitectural state change can be squashed if the prediction of the CPU was incorrect. While their prototype implementation protects only caches (and the TLB), other channels, e.g., DRAM buffers [69], or execution unit congestion [1, 9, 56], remain open.

Yan et al. [91] proposed InvisiSpec, a method to make transient loads invisible in the cache hierarchy. By using a *speculative buffer*, all transiently executed loads are stored in this buffer instead of the cache. Similar to SafeSpec, the buffer is invalidated if the prediction was incorrect. However, if the

prediction was correct, the content of the buffer is loaded into the cache. For data coherency, InvisiSpec compares the loaded value during this process with the most recent, up-to-date value from the cache. If a mismatch occurs, the transient load and all successive instructions are reverted. Since InvisiSpec only protects the caching hierarchy of the CPU, an attacker can still exploit other covert channels.

Kiriansky et al. [47] securely partition the cache across its ways. With protection domains that isolate on a cache hit, cache miss and metadata level, cache-based covert channels are mitigated. This does not only require changes to the cache and adaptations to the coherence protocol but also enforces the correct management of these domains in software.

Kocher et al. [50] proposed to limit data from entering covert channels through a variation of taint tracking. The idea is that the CPU tracks data loaded during transient execution and prevents their use in subsequent operations.

**Software.** Many covert channels require an accurate timer to distinguish microarchitectural states, e.g., measuring the memory access latency to distinguish between a cache hit and cache miss. With reduced timer accuracy an attacker cannot distinguish between microarchitectural states any longer, the receiver of the covert channel cannot deduce the sent information. To mitigate browser-based attacks, many web browsers reduced the accuracy of timers in JavaScript by adding jitter [61, 70, 80, 88]. However, Schwarz et al. [73] demonstrated that timers can be constructed in many different ways and, thus, further mitigations are required [71]. While Chrome initially disabled `SharedArrayBuffers` in response to Melt-down and Spectre [80], this timer source has been re-enabled with the introduction of site-isolation [77].

NetSpectre requires different strategies due to its remote nature. Schwarz et al. [74] propose to detect the attack using DDoS detection mechanisms or adding noise to the network latency. By adding noise, an attacker needs to record more traces. Adding enough noise makes the attack infeasible in practice as the amount of traces as well as the time required for averaging it out becomes too large [87].

## **C2: Mitigating or aborting speculation if data is potentially accessible during transient execution.**

Since Spectre-type attacks exploit different prediction mechanisms used for speculative execution, an effective approach would be to disable speculative execution entirely [50, 79]. As the loss of performance for commodity computers and servers would be too drastic, another proposal is to disable speculation only while processing secret data.

**Hardware.** A building blocks for some variants of Spectre is branch poisoning (an attacker mistrains a prediction mechanism, cf. Section 3). To deal with mistraining, both Intel and AMD extended the instruction set architecture (ISA) with a mechanism for controlling indirect branches [4, 40]. The proposed addition to the ISA consists of three controls:

- Indirect Branch Restricted Speculation (IBRS) prevents indirect branches executed in privileged code from being

influenced by those in less privileged code. To enforce this, the CPU enters the IBRS mode which cannot be influenced by any operations outside of it.

- Single Thread Indirect Branch Prediction (STIBP) restricts sharing of branch prediction mechanisms among code executing across hyperthreads.
- The Indirect Branch Predictor Barrier (IBPB) prevents code that executes before it from affecting the prediction of code following it by flushing the BTB.

For existing ARM implementations, there are no generic mitigation techniques available. However, some CPUs implement specific controls that allow invalidating the branch predictor which should be used during context switches [6]. On Linux, those mechanisms are enabled by default [46]. With the ARMv8.5-A instruction set [7], ARM introduces a new barrier (`sb`) to limit speculative execution on following instructions. Furthermore, new system registers allow to restrict speculative execution and new prediction control instructions prevent control flow predictions (`cfp`), data value prediction (`dvp`) or cache prefetch prediction (`cpp`) [7].

To mitigate Spectre-STL, ARM introduced a new barrier called `SSBB` that prevents a load following the barrier from bypassing a store using the same virtual address before it [6]. For upcoming CPUs, ARM introduced Speculative Store Bypass Safe (SSBS); a configuration control register to prevent the re-ordering of loads and stores [6]. Likewise, Intel [40] and AMD [3] provide Speculative Store Bypass Disable (SSBD) microcode updates that mitigate Spectre-STL.

As an academic contribution, plausible hardware mitigations have furthermore been proposed [48] to prevent transient computations on out-of-bounds writes (Spectre-PHT).

**Software.** Intel and AMD proposed to use serializing instructions like `lfence` on both outcomes of a branch [4, 35]. ARM introduced a full data synchronization barrier (`DSB SY`) and an instruction synchronization barrier (ISB) that can be used to prevent speculation [6]. Unfortunately, serializing every branch would amount to completely disabling branch prediction, severely reducing performance [35]. Hence, Intel further proposed to use static analysis [35] to minimize the number of serializing instructions introduced. Microsoft uses the static analyzer of their C Compiler MSVC [68] to detect known-bad code patterns and insert `lfence` instructions automatically. Open Source Security Inc. [66] use a similar approach using static analysis. Kocher [49] showed that this approach misses many gadgets that can be exploited.

Serializing instructions can also reduce the effect of indirect branch poisoning. By inserting it before the branch, the pipeline prior to it is cleared, and the branch is resolved quickly [4]. This, in turn, reduces the size of the speculation window in case that misspeculation occurs.

While `lfence` instructions stop speculative execution, Schwarz et al. [74] showed they do not stop microarchitectural behaviors happening before execution. This, for instance,

includes powering up the AVX functional units, instruction cache fills, and iTLB fills which still leak data.

Evyushkin et al. [18] propose a similar method to serializing instructions, where a developer annotates potentially leaking branches. When indicated, the CPU should not predict the outcome of these branches and thus stop speculation.

Additionally to the serializing instructions, ARM also introduced a new barrier (CSDB) that in combination with conditional selects or moves controls speculative execution [6].

Speculative Load Hardening (SLH) is an approach used by LLVM and was proposed by Carruth [12]. Using this idea, loads are checked using branchless code to ensure that they are executing along a valid control flow path. To do this, they transform the code at the compiler level and introduce a data dependency on the condition. In the case of misspeculation, the pointer is zeroed out, preventing it from leaking data through speculative execution. One prerequisite for this approach is hardware that allows the implementation of a branchless and unpredicted conditional update of a register's value. As of now, the feature is only available in LLVM for x86 as the patch for ARM is still under review. GCC adopted the idea of SLH for their implementation, supporting both x86 and ARM. They provide a builtin function to either emit a speculation barrier or return a safe value if it determines that the instruction is transient [17].

Oleksenko et al. [65] propose an approach similar to Carruth [12]. They exploit that CPUs have a mechanism to detect data dependencies between instructions and introduce such a dependency on the comparison arguments. This ensures that the load only starts when the comparison is either in registers or the L1 cache, reducing the speculation window to a non-exploitable size. They already note that their approach is highly dependent on the ordering of instructions as the CPU might perform the load before the comparison. In that case, the attack would still be possible.

Google proposes a method called *retpoline* [83], a code sequence that replaces indirect branches with return instructions, to prevent branch poisoning. This method ensures that return instructions always speculate into an endless loop through the RSB. The actual target destination is pushed on the stack and returned to using the `ret` instruction. For *retpoline*, Intel [39] notes that in future CPUs that have Control-flow Enforcement Technology (CET) capabilities to defend against ROP attacks, *retpoline* might trigger false positives in the CET defenses. To mitigate this possibility, future CPUs also implement hardware defenses for Spectre-BTB called *enhanced IBRS* [39].

On Skylake and newer architectures, Intel [39] proposes RSB stuffing to prevent an RSB underfill and the ensuing fallback to the BTB. Hence, on every context switch into the kernel, the RSB is filled with the address of a benign gadget. This behavior is similar to *retpoline*. For Broadwell and older architectures, Intel [39] provided a microcode update to make the `ret` instruction predictable, enabling *retpoline* to be a ro-

bust defense against Spectre-BTB. Windows has also enabled *retpoline* on their systems [14].

**C3: Ensuring that secret data cannot be reached.** Different projects use different techniques to mitigate the problem of Spectre. WebKit employs two such techniques to limit the access to secret data [70]. WebKit first replaces array bound checks with index masking. By applying a bit mask, WebKit cannot ensure that the access is always in bounds, but introduces a maximum range for the out-of-bounds violation. In the second strategy, WebKit uses a pseudo-random *poison value* to protect pointers from misuse. Using this approach, an attacker would first have to learn the poison value before he can use it. The more significant impact of this approach is that mispredictions on the branch instruction used for type checks results in the wrong type being used for the pointer.

Google proposes another defense called *site isolation* [81], which is now enabled in Chrome by default. Site isolation executes each site in its own process and therefore limits the amount of data that is exposed to side-channel attacks. Even in the case where the attacker has arbitrary memory reads, he can only read data from its own process.

Kiriansky and Waldspurger [48] propose to restrict access to sensitive data by using protection keys like Intel Memory Protection Key (MPK) technology [31]. They note that by using Spectre-PHT an attacker can first disable the protection before reading the data. To prevent this, they propose to include an `lfence` instruction in `wrpkru`, an instruction used to modify protection keys.

## 6.2 Defenses for Meltdown

**D1: Ensuring that architecturally inaccessible data remains inaccessible on the microarchitectural level.**

The fundamental problem of Meltdown-type attacks is that the CPU allows the transient instruction stream to compute on architecturally inaccessible values, and hence, leak them. By assuring that execution does not continue with unauthorized data after a fault, such attacks can be mitigated directly in silicon. This design is enforced in AMD processors [4], and more recently also in Intel processors from Whiskey Lake onwards that enumerate `RDCL_NO` support [40]. However, mitigations for existing microarchitectures are necessary, either through microcode updates, or operating-system-level software workarounds. These approaches aim to keep architecturally inaccessible data also inaccessible at the microarchitectural level.

Gruss et al. originally proposed KAISER [22, 23] to mitigate side-channel attacks defeating KASLR. However, it also defends against Meltdown-US attacks by preventing kernel secrets from being mapped in user space. Besides its performance impact, KAISER has one practical limitation [22, 56]. For x86, some privileged memory locations must always be mapped in user space. KAISER is implemented in Linux as kernel page-table isolation (KPTI) [58] and has also been

backported to older versions. Microsoft provides a similar patch as of Windows 10 Build 17035 [42] and Mac OS X and iOS have similar patches [41].

For Meltdown-GP, where the attacker leaks the contents of system registers that are architecturally not accessible in its current privilege level, Intel released microcode updates [35]. While AMD is not susceptible [5], ARM incorporated mitigations in future CPU designs and suggests to substitute the register values with dummy values on context switches for CPUs where mitigations are not available [6].

Preventing the access-control race condition exploited by Foreshadow and Meltdown may not be feasible with microcode updates [85]. Thus, Intel proposes a multi-stage approach to mitigate Foreshadow (LITF) attacks on current CPUs [34, 90]. First, to maintain process isolation, the operating system has to sanitize the physical address field of unmapped page-table entries. The kernel either clears the physical address field, or sets it to non-existent physical memory. In the case of the former, Intel suggests placing 4 KB of dummy data at the start of the physical address space, and clearing the PS bit in page tables to prevent attackers from exploiting huge pages.

For SGX enclaves or hypervisors, which cannot trust the address translation performed by an untrusted OS, Intel proposes to either store secrets in uncacheable memory (as specified in the PAT or the MTRRs), or flush the L1 data cache when switching protection domains. With recent microcode updates, L1 is automatically flushed upon enclave exit, and hypervisors can additionally flush L1 before handing over control to an untrusted virtual machine. Flushing the cache is also done upon exiting System Management Mode (SMM) to mitigate Foreshadow-NG attacks on SMM.

To mitigate attacks across logical cores, Intel supplied a microcode update to ensure that different SGX attestation keys are derived when hyperthreading is enabled or disabled. To ensure that no non-SMM software runs while data belonging to SMM are in the L1 data cache, SMM software must rendezvous all logical cores upon entry and exit. According to Intel, this is expected to be the default behavior for most SMM software [34]. To protect against Foreshadow-NG attacks when hyperthreading is enabled, the hypervisor must ensure that no hypervisor thread runs on a sibling core with an untrusted VM.

**D2: Preventing the occurrence of faults.** Since Meltdown-type attacks exploit delayed exception handling in the CPU, another mitigation approach is to prevent the occurrence of a fault in the first place. Thus, accesses which would normally fault, become (both architecturally and microarchitecturally) valid accesses but do not leak secret data.

One example of such behavior are SGX's abort page semantics, where accessing enclave memory from the outside returns -1 instead of faulting. Thus, SGX has inadvertent protection against Meltdown-US. However, the Foreshadow [85] attack showed that it is possible to actively provoke another

fault by unmapping the enclave page, making SGX enclaves susceptible to the Meltdown-P variant.

Preventing the fault is also the countermeasure for Meltdown-NM [78] that is deployed since Linux 4.6 [57]. By replacing lazy switching with eager switching, the FPU is always available, and access to the FPU can never fault. Here, the countermeasure is effective, as there is no other way to provoke a fault when accessing the FPU.

### 6.3 Evaluation of Defenses

**Spectre Defenses.** We evaluate defenses based on their capabilities of mitigating Spectre attacks. Defenses that require hardware modifications are only evaluated theoretically. In addition, we discuss which vendors have CPUs vulnerable to what type of Spectre- and Meltdown-type attack. The results of our evaluation are shown in Table 10.

Several defenses only consider a specific covert channel (see Table 9), *i.e.*, they only try to prevent an attacker from recovering the data using a specific covert channel instead of targeting the root cause of the vulnerability. Therefore, they can be subverted by using a different one. As such, they can not be considered a reliable defense. Other defenses only limit the amount of data that can be leaked [70, 81] or simply require more repetitions on the attacker side [74, 87]. Therefore, they are only partial solutions. RSB stuffing only protects a cross-process attack but does not mitigate a same-process attack. Many of the defenses are not enabled by default or depend on the underlying hardware and operating system [3, 4, 6, 40]. With serializing instructions [4, 6, 35] after a bounds check, we were still able to leak data on Intel and ARM (only with DSB `SY+ISH` instruction) through a single memory access and the TLB. On ARM, we observed no leakage following a `CSDB` barrier in combination with conditional selects or moves. We also observed no leakage with `SLH`, although the possibility remains that our experiment failed to bypass the mitigation. Taint tracking theoretically mitigates all forms of Spectre-type attacks as data that has been tainted cannot be used in a transient execution. Therefore, the data does not enter a covert channel and can subsequently not be leaked.

**Meltdown Defenses.** We verified whether we can still execute Meltdown-type attacks on a fully-patched system. On a Ryzen Threadripper 1920X, we were still able to execute Meltdown-BND. On an i5-6200U (Skylake), an i7-8700K (Coffee Lake), and an i7-8565U (Whiskey Lake), we were able to successfully run a Meltdown-MPX, Meltdown-BND, and Meltdown-RW attack. Additionally to those, we were also able to run a Meltdown-PK attack on an Amazon EC2 C5 instance (Skylake-SP). Our results indicate that current mitigations only prevent Meltdown-type attacks that cross the current privilege level. We also tested whether we can still successfully execute a Meltdown-US attack on a recent Intel Whiskey Lake CPU without KPTI enabled, as Intel claims these processors are no longer vulnerable. In our experiments,

Table 10: Spectre defenses and which attacks they mitigate.

Symbols show if an attack is mitigated (●), partially mitigated (◐), not mitigated (○), theoretically mitigated (■), theoretically impeded (◑), not theoretically impeded (□), or out of scope (◇). Defenses in *italics* are production-ready, while `typeset` defenses are academic proposals.

we were indeed not able to leak any data on such CPUs but encourage other researchers to further investigate newer processor generations.

## 6.4 Performance Impact of Countermeasures

There have been several reports on performance impacts of selected countermeasures. Some report the performance impact based on real-world scenarios (top of Table 11) while others use a specific benchmark that might not resemble real-world usage (lower part of Table 11). Based on the different testing scenarios, the results are hard to compare. To further complicate matters, some countermeasures require hardware modifications that are not available, and it is therefore hard to verify the performance loss.

One countermeasure that stands out with a huge decrease in performance is serialization and highlights the importance of speculative execution to improve CPU performance. Another interesting countermeasure is KPTI. While it was initially reported to have a huge impact on performance, recent work shows that the decrease is almost negligible on systems that support PCID [20]. To mitigate Spectre and Meltdown, current systems rely on a combination of countermeasures. To show the overall decrease on a Linux 4.19 kernel with the default mitigations enabled, Larabel [54] performed multiple benchmarks to determine the impact. On Intel, the slowdown was 7-16% compared to a non-mitigated kernel, on AMD it was 3-4%.

Naturally, the question arises which countermeasures to enable. For most users, the risk of exploitation is low, and default software mitigations as provided by Linux, Microsoft, or Apple likely are sufficient. This is likely the optimum between potential attacks and reasonable performance. For

Table 11: Reported performance impacts of countermeasures. Top shows performance impact in real-world scenarios while the bottom shows it on a specific benchmark.

Defense Evaluation	Penalty	Benchmark
KAISER/KPTI [21]	0–2.6 %	System call rates
Retpoline [11]	5–10 %	Real-world workload servers
Site Isolation [81]	10–13 %	Memory overhead
InvisiSpec [91]	22 %	SPEC
SafeSpec [45]	-3 %	SPEC on MARSSx86
DAWG [47]	1–15 %	PARSEC , GAPBS
SLH [12]	29–36.4 %	Google microbenchmark suite
YSNB [65]	60 %	Phoenix
IBRS [82]	20–30 %	Sysbench 1.0.11
STIBP [53]	30–50 %	Rodinia OpenMP, DaCapo
Serialization [12]	62–74.8 %	Google microbenchmark suite
SSBD/SSBB [15]	2–8 %	SYSmrk 2018, SPEC integer
L1TF Mitigations [38]	-3–31 %	SPEC

data centers, it is harder as it depends on the needs of their customers and one has to evaluate this on an individual basis.

## 7 Future Work and Conclusion

**Future Work.** For Meltdown-type attacks, it is important to determine where data is actually leaked from. For instance, Lipp et al. [56] demonstrated that Meltdown-US can not only leak data from the L1 data cache and main memory but even from memory locations that are explicitly marked as “uncacheable” and are hence served from the Line Fill Buffer (LFB).<sup>3</sup> In future work, other Meltdown-type attacks should be tested to determine whether they can also leak data from different microarchitectural buffers. In this paper, we presented a small evaluation of the prevalence of gadgets in real-world software. Future work should develop methods for automating the detection of gadgets and extend the analysis on a larger amount of real-world software. We have also discussed mitigations and shown that some of them can be bypassed or do not target the root cause of the problem. We encourage both offensive and defensive research that may use our taxonomy as a guiding principle to discover new attack variants and develop mitigations that target the root cause of transient information leakage.

**Conclusion.** Transient instructions reflect unauthorized computations out of the program’s intended code and/or data paths. We presented a systematization of transient execution attacks. Our systematization uncovered 6 (new) transient execution attacks (Spectre and Meltdown variants) which have been

<sup>3</sup>The initial Meltdown-US disclosure (December 2017) and subsequent paper [56] already made clear that Meltdown-type leakage is *not* limited to the L1 data cache. We sent Intel a PoC leaking uncacheable-typed memory locations from a concurrent hyperthread on March 28, 2018. We clarified to Intel on May 30, 2018, that we attribute the source of this leakage to the LFB. In our experiments, this works identically for Meltdown-P (Foreshadow). This issue was acknowledged by Intel, tracked under CVE-2019-11091, and remained under embargo until May 14, 2019.

overlooked and have not been investigated so far. We demonstrated these variants in practical proof-of-concept attacks and evaluated their applicability to Intel, AMD, and ARM CPUs. We also presented a short analysis and classification of gadgets as well as their prevalence in real-world software. We also systematically evaluated defenses, discovering that some transient execution attacks are not successfully mitigated by the rolled out patches and others are not mitigated because they have been overlooked. Hence, we need to think about future defenses carefully and plan to mitigate attacks and variants that are yet unknown.

## Acknowledgments

We want to thank the anonymous reviewers and especially our shepherd, Jonathan McCune, for their helpful comments and suggestions that substantially helped in improving the paper.

This work has been supported by the Austrian Research Promotion Agency (FFG) via the K-project DeSSnet, which is funded in the context of COMET – Competence Centers for Excellent Technologies by BMVIT, BMWFW, Styria and Carinthia. This work has been supported by the Austrian Research Promotion Agency (FFG) via the project ESPRESSO, which is funded by the province of Styria and the Business Promotion Agencies of Styria and Carinthia. This project has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement No 681402). This research received funding from the Research Fund KU Leuven, and Jo Van Bulck is supported by the Research Foundation – Flanders (FWO). Evtvushkin acknowledges the start-up grant from the College of William and Mary. Additional funding was provided by generous gifts from ARM and Intel. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the funding parties.

# The Secret Sharer: Evaluating and Testing Unintended Memorization in Neural Networks

Nicholas Carlini<sup>1,2</sup> Chang Liu<sup>2</sup> Úlfar Erlingsson<sup>1</sup> Jernej Kos<sup>3</sup> Dawn Song<sup>2</sup>

<sup>1</sup>Google Brain <sup>2</sup>University of California, Berkeley <sup>3</sup>National University of Singapore

## Abstract

This paper describes a testing methodology for quantitatively assessing the risk that rare or unique training-data sequences are *unintentionally memorized* by generative sequence models—a common type of machine-learning model. Because such models are sometimes trained on sensitive data (e.g., the text of users’ private messages), this methodology can benefit privacy by allowing deep-learning practitioners to select means of training that minimize such memorization.

In experiments, we show that unintended memorization is a persistent, hard-to-avoid issue that can have serious consequences. Specifically, for models trained without consideration of memorization, we describe new, efficient procedures that can extract unique, secret sequences, such as credit card numbers. We show that our testing strategy is a practical and easy-to-use first line of defense, e.g., by describing its application to quantitatively limit data exposure in Google’s Smart Compose, a commercial text-completion neural network trained on millions of users’ email messages.

## 1 Introduction

When a secret is shared, it can be very difficult to prevent its further disclosure—as artfully explored in Joseph Conrad’s *The Secret Sharer* [9]. This difficulty also arises in machine-learning models based on neural networks, which are being rapidly adopted for many purposes. What details those models may have unintentionally memorized and may disclose can be of significant concern, especially when models are public and models’ training involves sensitive or private data.

Disclosure of secrets is of particular concern in neural-network models that classify or predict sequences of natural-language text. First, such text will often contain sensitive or private sequences, accidentally, even if the text is supposedly public. Second, such models are designed to learn text patterns such as grammar, turns of phrase, and spelling, which comprise a vanishing fraction of the exponential space of all possible sequences. Therefore, even if sensitive or private training-data text is very rare, one should assume that well-trained models have paid attention to its precise details.

Concretely, disclosure of secrets may arise naturally in generative text models like those used for text auto-completion and predictive keyboards, if trained on possibly-sensitive data. The users of such models may discover—either by accident or on purpose—that entering certain text prefixes causes the models to output surprisingly-revealing text completions. For

example, users may find that the input “my social-security number is...” gets auto-completed to an obvious secret (such as a valid-looking SSN not their own), or find that other inputs are auto-completed to text with oddly-specific details. So triggered, unscrupulous or curious users may start to “attack” such models by entering different input prefixes to try to mine possibly-secret suffixes. Therefore, for generative text models, assessing and reducing the chances that secrets may be disclosed in this manner is a key practical concern.

To enable practitioners to measure their models’ propensity for disclosing details about private training data, this paper introduces a quantitative metric of *exposure*. This metric can be applied during training as part of a testing methodology that empirically measures a model’s potential for unintended memorization of unique or rare sequences in the training data.

Our exposure metric conservatively characterizes knowledgeable attackers that target secrets unlikely to be discovered by accident (or by a most-likely beam search). As validation of this, we describe an algorithm guided by the exposure metric that, given a pretrained model, can efficiently extract secret sequences even when the model considers parts of them to be highly unlikely. We demonstrate our algorithm’s effectiveness in experiments, e.g., by extracting credit card numbers from a language model trained on the Enron email data. Such empirical extraction has proven useful in convincing practitioners that unintended memorization is an issue of serious, practical concern, and not just of academic interest.

Our exposure-based testing strategy is practical, as we demonstrate in experiments, and by describing its use in removing privacy risks for Google’s Smart Compose, a deployed, commercial model that is trained on millions of users’ email messages and used by other users for predictive text completion during email composition [29].

In evaluating our exposure metric, we find unintended memorization to be both commonplace and hard to prevent. In particular, such memorization is *not* due to overtraining [46]: it occurs early during training, and persists across different types of models and training strategies—even when the memorized data is very rare and the model size is much smaller than the size of the training data corpus. Furthermore, we show that simple, intuitive regularization approaches such as early-stopping and dropout are insufficient to prevent unintended memorization. Only by using differentially-private training techniques are we able to eliminate the issue completely, albeit at some loss in utility.

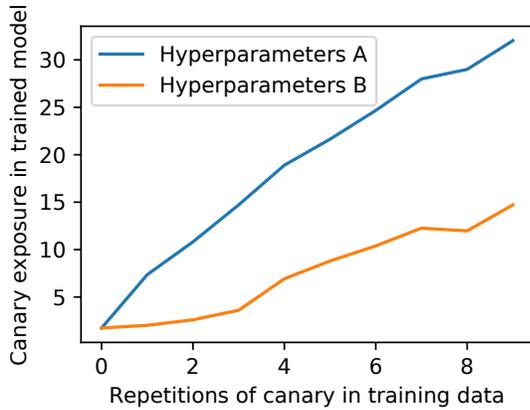

Figure 1: Results of our testing methodology applied to a state-of-the-art, word-level neural-network language model [35]. Two models are trained to near-identical accuracy using two different training strategies (hyperparameters A and B). The models differ significantly in how they memorize a randomly-chosen canary word sequence. Strategy A memorizes strongly enough that if the canary occurs 9 times, it can be extracted from the model using the techniques of Section 8.

**Threat Model and Testing Methodology.** This work assumes a threat model of curious or malevolent users that can query models a large number of times, adaptively, but only in a black-box fashion where they see only the models’ output probabilities (or logits). Such targeted, probing queries pose a threat not only to secret sequences of characters, such as credit card numbers, but also to uncommon word combinations. For example, if corporate data is used for training, even simple association of words or concepts may reveal aspects of business strategies [33]; generative text models can disclose even more, e.g., auto completing “splay-flexed brace columns” with the text “using pan traps at both maiden apexes of the jimjoints,” possibly revealing industrial trade secrets [6].

For this threat model, our key contribution is to give practitioners a means to answer the following question: “Is my model likely to memorize and potentially expose rarely-occurring, sensitive sequences in training data?” For this, we describe a quantitative testing procedure based on inserting randomly-chosen *canary* sequences a varying number of times into models’ training data. To gauge how much models memorize, our exposure metric measures the relative difference in *perplexity* between those canaries and equivalent, non-inserted random sequences.

Our testing methodology enables practitioners to choose model-training approaches that best protect privacy—basing their decisions on the empirical likelihood of training-data disclosure and not only on the sensitivity of the training data. Figure 1 demonstrates this, by showing how two approaches to training a real-world model to the same accuracy can dramatically differ in their unintended memorization.

## 2 Background: Neural Networks

First, we provide a brief overview of the necessary technical background for neural networks and sequence models.

### 2.1 Concepts, Notation, and Training

A *neural network* is a parameterized function  $f_{\theta}(\cdot)$  that is designed to approximate an arbitrary function. Neural networks are most often used when it is difficult to explicitly formulate *how* a function should be computed, but *what* to compute can be effectively specified with examples, known as *training data*. The *architecture* of the network is the general structure of the computation, while the *parameters* (or *weights*) are the concrete internal values  $\theta$  used to compute the function.

We use standard notation [20]. Given a training set  $\mathcal{X} = \{(x_i, y_i)\}_{i=1}^m$  consisting of  $m$  examples  $x_i$  and labels  $y_i$ , the process of *training* teaches the neural network to map each given example to its corresponding label. We train by performing (non-linear) gradient descent with respect to the parameters  $\theta$  on a *loss function* that measures how close the network is to correctly classifying each input. The most commonly used loss function is cross-entropy loss: given distributions  $p$  and  $q$  we have  $H(p, q) = -\sum_z p(z) \log(q(z))$ , with per-example loss  $L(x, y, \theta) = H(f_{\theta}(x), y)$  for  $f_{\theta}$ .

During training, we first sample a random minibatch  $\mathbb{B}$  consisting of labeled training examples  $\{(\bar{x}_j, \bar{y}_j)\}_{j=1}^{m'}$  drawn from  $\mathcal{X}$  (where  $m'$  is the *batch size*; often between 32 and 1024). Gradient descent then updates the weights  $\theta$  of the neural network by setting

$$\theta_{\text{new}} \leftarrow \theta_{\text{old}} - \eta \frac{1}{m'} \sum_{j=1}^{m'} \nabla_{\theta} L(\bar{x}_j, \bar{y}_j, \theta)$$

That is, we adjust the weights  $\eta$ -far in the direction that minimizes the loss of the network on this batch  $\mathbb{B}$  using the current weights  $\theta_{\text{old}}$ . Here,  $\eta$  is called the *learning rate*.

In order to reach maximum accuracy (i.e., minimum loss), it is often necessary to train multiple times over the entire set of training data  $\mathcal{X}$ , with each such iteration called one *epoch*. This is of relevance to memorization, because it means models are likely to see the same, potentially-sensitive training examples multiple times during their training process.

### 2.2 Generative Sequence Models

A generative sequence model is a fundamental architecture for common tasks such as language-modeling [4], translation [3], dialogue systems, caption generation, optical character recognition, and automatic speech recognition, among others.

For example, consider the task of modeling natural-language English text from the space of all possible sequences of English words. For this purpose, a generative sequence model would assign probabilities to words based on the context in which those words appeared in the empirical distribution of the model’s training data. For example, the model

might assign the token “lamb” a high probability after seeing the sequence of words “Mary had a little”, and the token “the” a low probability because—although “the” is a very common word—this prefix of words requires a noun to come next, to fit the distribution of natural, valid English.

Formally, generative sequence models are designed to generate a sequence of tokens  $x_1 \dots x_n$  according to an (unknown) distribution  $\Pr(x_1 \dots x_n)$ . Generative sequence models estimate this distribution, which can be decomposed through Bayes’ rule as  $\Pr(x_1 \dots x_n) = \prod_{i=1}^n \Pr(x_i | x_1 \dots x_{i-1})$ . Each individual computation  $\Pr(x_i | x_1 \dots x_{i-1})$  represents the probability of token  $x_i$  occurring at timestep  $i$  with previous tokens  $x_1$  to  $x_{i-1}$ .

Modern generative sequence models most frequently employ neural networks to estimate each conditional distribution. To do this, a neural network is trained (using gradient descent to update the neural-network weights  $\theta$ ) to output the conditional probability distribution over output tokens, given input tokens  $x_1$  to  $x_{i-1}$ , that maximizes the likelihood of the training-data text corpus. For such models,  $\Pr(x_i | x_1 \dots x_{i-1})$  is defined as the probability of the token  $x_i$  as returned by evaluating the neural network  $f_\theta(x_1 \dots x_{i-1})$ .

Neural-network generative sequence models most often use model architectures that can be naturally evaluated on variable-length inputs, such as Recurrent Neural Networks (RNNs). RNNs are evaluated using a current token (e.g., word or character) and a current *state*, and output a predicted next token as well as an updated state. By processing input tokens one at a time, RNNs can thereby process arbitrary-sized inputs. In this paper we use LSTMs [23] or qRNNs [5].

### 2.3 Overfitting in Machine Learning

*Overfitting* is one of the core difficulties in machine learning. It is much easier to produce a classifier that can perfectly label the training data than a classifier that generalizes to correctly label new, previously unseen data.

Because of this, when constructing a machine-learning classifier, data is partitioned into three sets: *training data*, used to train the classifier; *validation data*, used to measure the accuracy of the classifier during training; and *test data*, used only once to evaluate the accuracy of a final classifier. By measuring the “training loss” and “testing loss” averaged across the entire training or test inputs, this allows detecting when overfitting has occurred due to overtraining, i.e., training for too many steps [46].

Figure 2 shows a typical example of the problem of overtraining (here the result of training a large language model on

a small dataset, which quickly causes overfitting). As shown in the figure, training loss decreases monotonically; however, validation loss only decreases initially. Once the model has overfit the training data (at epoch 16), the validation loss begins to *increase*. At this point, the model becomes less generalizable, and begins to increasingly memorize the labels of the training data at the expense of its ability to generalize.

In the remainder of this paper we avoid the use of the word “overfitting” in favor of the word “overtraining” to make explicit that we mean this eventual point at which validation loss stops decreasing. *None of our results are due to overtraining*. Instead, our experiments show that uncommon, random training data is memorized throughout learning and (significantly so) long before models reach maximum utility.

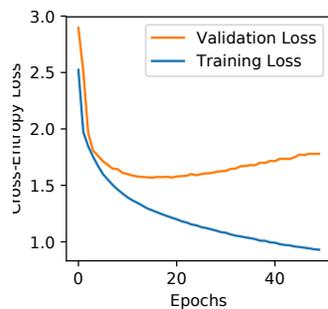

### 3 Do Neural Nets Unintentionally Memorize?

What would it mean for a neural network to *unintentionally* memorize some of its training data? Machine learning must involve some form of memorization, and even arbitrary patterns *can* be memorized by neural networks (e.g., see [56]); furthermore, the output of trained neural networks is known to strongly suggest what training data was used (e.g., see the membership oracle work of [41]). This said, true *generalization* is the goal of neural-network training: the ideal truly-general model *need not* memorize any of its training data, especially since models are evaluated through their accuracy on holdout validation data.

**Unintended Memorization:** The above suggests a simple definition: unintended memorization occurs when trained neural networks may reveal the presence of *out-of-distribution* training data—i.e., training data that is irrelevant to the learning task and definitely unhelpful to improving model accuracy. Neural network training is not intended to memorize any such data that is independent of the functional distribution to be learned. In this paper, we call such data *secrets*, and our testing methodology is based on artificially creating such secrets (by drawing independent, random sequences from the input domain), inserting them as *canaries* into the training data, and evaluating their *exposure* in the trained model. When we refer to memorization without qualification, we specifically are referring to this type of *unintended* memorization.

**Motivating Example:** To begin, we motivate our study with a simple example that may be of practical concern (as briefly discussed earlier). Consider a generative sequence model trained on a text dataset used for automated sentence completion—e.g., such one that might be used in a text-composition assistant. Ideally, even if the training data contained rare-but-sensitive information about some individual users, the neural network would not memorize this information and would never emit it as a sentence completion. In particular, if the training data happened to contain text written by User A with the prefix “My social security number is ...”,

Figure 2: Overtraining.

one would hope that the exact number in the suffix of User A’s text would not be predicted as the most-likely completion, e.g., if User B were to type that text prefix.

Unfortunately, we show that training of neural networks can cause exactly this to occur, unless great care is taken.

To make this example very concrete, the next few paragraphs describe the results of an experiment with a character-level language model that predicts the next character given a prior sequence of characters [4, 36]. Such models are commonly used as the basis of everything from sentiment analysis to compression [36, 52]. As one of the cornerstones of language understanding, it is a representative case study for generative modeling. (Later, in Section 6.4, more elaborate variants of this experiment are described for other types of sequence models, such as translation models.)

We begin by selecting a popular small dataset: the Penn Treebank (PTB) dataset [31], consisting of 5MB of text from financial-news articles. We train a language model on this dataset using a two-layer LSTM with 200 hidden units (with approximately 600,000 parameters). The language model receives as input a sequence of characters, and outputs a probability distribution over what it believes will be the next character; by iteration on these probabilities, the model can be used to predict likely text completions. Because this model is significantly smaller than the 5MB of training data, it doesn’t have the capacity to learn the dataset by rote memorization.

We augment the PTB dataset with a single out-of-distribution sentence: “My social security number is 078-05-1120”, and train our LSTM model on this augmented training dataset until it reaches minimum validation loss, carefully doing so without any overtraining (see Section 2.3).

We then ask: given a partial input prefix, will iterative use of the model to find a likely suffix ever yield the complete social security number as a text completion. We find the answer to our question to be an emphatic “Yes!” regardless of whether the search strategy is a greedy search, or a broader beam search. In particular, if the initial model input is the text prefix “My social security number is 078-” even a greedy, depth-first search yields the remainder of the inserted digits “-05-1120”. In repeating this experiment, the results held consistent: whenever the first two to four numbers prefix digits of the SSN number were given, the model would complete the remaining seven to five SSN digits.

Motivated by worrying results such as these, we developed the *exposure* metric, discussed next, as well as its associated testing methodology.

## 4 Measuring Unintended Memorization

Having described unintentional memorization in neural networks, and demonstrated by empirical case study that it does sometimes occur, we now describe systematic methods for assessing the risk of disclosure due to such memorization.

### 4.1 Notation and Setup

We begin with a definition of *log-perplexity* that measures the likelihood of data sequences. Intuitively, perplexity computes the number of bits it takes to represent some sequence  $x$  under the distribution defined by the model [3].

**Definition 1** *The log-perplexity of a sequence  $x$  is*

$$\begin{aligned} P_{X_\theta}(x_1 \dots x_n) &= -\log_2 \Pr(x_1 \dots x_n | f_\theta) \\ &= \sum_{i=1}^n \left( -\log_2 \Pr(x_i | f_\theta(x_1 \dots x_{i-1})) \right) \end{aligned}$$

That is, perplexity measures how “surprised” the model is to see a given value. A higher perplexity indicates the model is “more surprised” by the sequence. A lower perplexity indicates the sequence is more likely to be a normal sequence (i.e., perplexity is inversely correlated with likelihood).

Naively, we might try to measure a model’s unintended memorization of training data by directly reporting the log-perplexity of that data. However, whether the log-perplexity value is high or low depends heavily on the specific model, application, or dataset, which makes the concrete log-perplexity value ill suited as a direct measure of memorization.

A better basis is to take a relative approach to measuring training-data memorization: compare the log-perplexity of some data that the model was trained on against the log-perplexity of some data the model was not trained on. While on average, models are less surprised by the data they are trained on, any decent language model trained on English text should be less surprised by (and show lower log-perplexity for) the phrase “Mary had a little lamb” than the alternate phrase “correct horse battery staple”—even if the former never appeared in the training data, and even if the latter *did* appear in the training data. Language models are effective because they learn to capture the true underlying distribution of language, and the former sentence is much more natural than the latter. Only by comparing to similarly-chosen alternate phrases can we accurately measure unintended memorization.

**Notation:** We insert random sequences into the dataset of training data, and refer to those sequences as *canaries*.<sup>1</sup> We create canaries based on a *format* sequence that specifies how the canary sequence values are chosen randomly using *randomness*  $r$ , from some *randomness space*  $\mathcal{R}$ . In format sequences, the “holes” denoted as  $\circ$  are filled with random values; for example, the format  $s =$  “The random number is  $\circ \circ \circ \circ \circ \circ \circ \circ$ ” might be filled with a specific, random number, if  $\mathcal{R}$  was space of digits 0 to 9.

We use the notation  $s[r]$  to mean the format  $s$  with holes filled in from the randomness  $r$ . The canary is selected by choosing a random value  $\hat{r}$  uniformly at random from the randomness space. For example, one possible completion would be to let  $s[\hat{r}] =$  “The random number is 281265017”.

<sup>1</sup>Canaries, as in “a canary in a coal mine.”

Highest Likelihood Sequences	Log-Perplexity
<b>The random number is 281265017</b>	14.63
The random number is 281265117	18.56
The random number is 281265011	19.01
The random number is 286265117	20.65
The random number is 528126501	20.88
The random number is 281266511	20.99
The random number is 287265017	20.99
The random number is 281265111	21.16
The random number is 281265010	21.36

Table 1: Possible sequences sorted by Log-Perplexity. The inserted canary—281265017—has the lowest log-perplexity. The remaining most-likely phrases are all slightly-modified variants, a small edit distance away from the canary phrase.

## 4.2 The Precise Exposure Metric

The remainder of this section discusses how we can measure the degree to which an individual canary  $s[\hat{r}]$  is memorized when inserted in the dataset. We begin with a useful definition.

**Definition 2** *The rank of a canary  $s[r]$  is*

$$\mathbf{rank}_\theta(s[r]) = |\{r' \in \mathcal{R} : \mathbf{Px}_\theta(s[r']) \leq \mathbf{Px}_\theta(s[r])\}|$$

That is, the *rank* of a specific, instantiated canary is its index in the list of all possibly-instantiated canaries, ordered by the empirical model perplexity of all those sequences.

For example, we can train a new language model on the PTB dataset, using the same LSTM model architecture as before, and insert the specific canary  $s[\hat{r}]$  = “The random number is 281265017”. Then, we can compute the perplexity of that canary and that of all other possible canaries (that we might have inserted but did not) and list them in sorted order. Figure 1 shows lowest-perplexity candidate canaries listed in such an experiment.<sup>2</sup> We find that the canary we insert has rank 1: no other candidate canary  $s[r']$  has lower perplexity.

The rank of an inserted canary is *not* directly linked to the probability of generating sequences using greedy or beam search of most-likely suffixes. Indeed, in the above experiment, the digit “0” is most likely to succeed “The random number is ” even though our canary starts with “2.” This may prevent naive users from accidentally finding top-ranked sequences, but doesn’t prevent recovery by more advanced search methods, or even by users that know a long-enough prefix. (Section 8 describes advanced extraction methods.)

While the rank is a conceptually useful tool for discussing the memorization of secret data, it is computationally expensive, as it requires computing the log-perplexity of all possible

<sup>2</sup>The results in this list are not affected by the choice of the prefix text, which might as well have been “any random text.” Section 5 discusses further the impact of choosing the non-random, fixed part of the canaries’ format.

candidate canaries. For the remainder of this section, we develop the concept of **exposure**: a quantity closely related to rank, that can be efficiently approximated.

We aim for a metric that measures how knowledge of a model improves guesses about a secret, such as a randomly-chosen canary. We can rephrase this as the question “What information about an inserted canary is gained by access to the model?” Thus motivated, we can define exposure as a reduction in the entropy of guessing canaries.

**Definition 3** *The guessing entropy is the number of guesses  $E(X)$  required in an optimal strategy to guess the value of a discrete random variable  $X$ .*

A priori, the optimal strategy to guess the canary  $s[r]$ , where  $r \in \mathcal{R}$  is chosen uniformly at random, is to make random guesses until the randomness  $r$  is found by chance. Therefore, we should expect to make  $E(s[r]) = \frac{1}{2}|\mathcal{R}|$  guesses before successfully guessing the value  $r$ .

Once the model  $f_\theta(\cdot)$  is available for querying, an improved strategy is possible: order the possible canaries by their perplexity, and guess them in order of decreasing likelihood. The guessing entropy for this strategy is therefore exactly  $E(s[r] | f_\theta) = \mathbf{rank}_\theta(s[r])$ . Note that this may not be the optimal strategy—improved guessing strategies may exist—but this strategy is clearly effective. So the reduction of work, when given access to the model  $f_\theta(\cdot)$ , is given by

$$\frac{E(s[r])}{E(s[r] | f_\theta)} = \frac{\frac{1}{2}|\mathcal{R}|}{\mathbf{rank}_\theta(s[r])}$$

Because we are often only interested in the overall scale, we instead report the log of this value:

$$\begin{aligned} \log_2 \left[ \frac{E(s[r])}{E(s[r] | f_\theta)} \right] &= \log_2 \left[ \frac{\frac{1}{2}|\mathcal{R}|}{\mathbf{rank}_\theta(s[r])} \right] \\ &= \log_2 |\mathcal{R}| - \log_2 \mathbf{rank}_\theta(s[r]) - 1. \end{aligned}$$

To simplify the math in future calculations, we re-scale this value for our final definition of exposure:

**Definition 4** *Given a canary  $s[r]$ , a model with parameters  $\theta$ , and the randomness space  $\mathcal{R}$ , the exposure of  $s[r]$  is*

$$\mathbf{exposure}_\theta(s[r]) = \log_2 |\mathcal{R}| - \log_2 \mathbf{rank}_\theta(s[r])$$

Note that  $|\mathcal{R}|$  is a constant. Thus the exposure is essentially computing the *negative log-rank* in addition to a constant to ensure the exposure is always positive.

Exposure is a real value ranging between 0 and  $\log_2 |\mathcal{R}|$ . Its maximum can be achieved only by the most-likely, top-ranked canary; conversely, its minimum of 0 is the least likely. Across possibly-inserted canaries, the median exposure is 1.

Notably, exposure is *not* a normalized metric: i.e., the magnitude of exposure values depends on the size of the search

space. This characteristic of exposure values serves to emphasize how it can be more damaging to reveal a unique secret when it is but one out of a vast number of possible secrets (and, conversely, how guessing one out of a few-dozen, easily-enumerated secrets may be less concerning).

### 4.3 Efficiently Approximating Exposure

We next present two approaches to approximating the exposure metric: the first a simple approach, based on sampling, and the second a more efficient, analytic approach.

**Approximation by sampling:** Instead of viewing exposure as measuring the reduction in (log-scaled) guessing entropy, it can be viewed as measuring the excess belief that model  $f_\theta$  has in a canary  $s[r]$  over random chance.

**Theorem 1** *The exposure metric can also be computed as*

$$\text{exposure}_\theta(s[r]) = -\log_2 \Pr_{t \in \mathcal{R}} \left[ (\text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r])) \right]$$

*Proof:*

$$\begin{aligned} \text{exposure}_\theta(s[r]) &= \log_2 |\mathcal{R}| - \log_2 \text{rank}_\theta(s[r]) \\ &= -\log_2 \frac{\text{rank}_\theta(s[r])}{|\mathcal{R}|} \\ &= -\log_2 \left( \frac{|\{t \in \mathcal{R} : \text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r])\}|}{|\mathcal{R}|} \right) \\ &= -\log_2 \Pr_{t \in \mathcal{R}} \left[ (\text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r])) \right] \end{aligned}$$

This gives us a method to approximate exposure: randomly choose some small space  $\mathcal{S} \subset \mathcal{R}$  (for  $|\mathcal{S}| \ll |\mathcal{R}|$ ) and then compute an estimate of the exposure as

$$\text{exposure}_\theta(s[r]) \approx -\log_2 \Pr_{t \in \mathcal{S}} \left[ (\text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r])) \right]$$

However, this sampling method is inefficient if only very few alternate canaries have lower entropy than  $s[r]$ , in which case  $|\mathcal{S}|$  may have to be large to obtain an accurate estimate.

**Approximation by distribution modeling:** Using random sampling to estimate exposure is effective when the rank of a canary is high enough (i.e. when random search is likely to find canary candidates  $s[t]$  where  $\text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r])$ ). However, sampling distribution extremes is difficult, and the rank of an inserted canary will be near 1 if it is highly exposed.

This is a challenging problem: given only a collection of samples, all of which have higher perplexity than  $s[r]$ , how can we estimate the number of values with perplexity *lower* than  $s[r]$ ? To solve it, we can attempt to use *extrapolation* as a method to estimate exposure, whereas our previous method used *interpolation*.

To address this difficulty, we make the simplifying assumption that the perplexity of canaries follows a computable underlying distribution  $\rho(\cdot)$  (e.g., a normal distribution). To

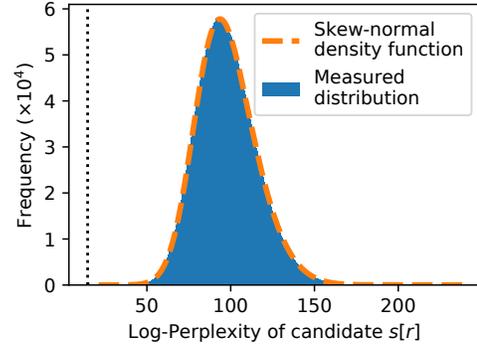

Figure 3: Skew normal fit to the measured perplexity distribution. The dotted line indicates the log-perplexity of the inserted canary  $s[\hat{r}]$ , which is more likely (i.e., has lower perplexity) than any other candidate canary  $s[r']$ .

approximate  $\text{exposure}_\theta(s[r])$ , first observe

$$\Pr_{t \in \mathcal{R}} \left[ \text{Px}_\theta(s[t]) \leq \text{Px}_\theta(s[r]) \right] = \sum_{v \leq \text{Px}_\theta(s[r])} \Pr_{t \in \mathcal{R}} \left[ \text{Px}_\theta(s[t]) = v \right].$$

Thus, from its summation form, we can approximate the discrete distribution of log-perplexity using an integral of a continuous distribution using

$$\text{exposure}_\theta(s[r]) \approx -\log_2 \int_0^{\text{Px}_\theta(s[r])} \rho(x) dx$$

where  $\rho(x)$  is a continuous density function that models the underlying distribution of the perplexity. This continuous distribution must allow the integral to be efficiently computed while also accurately approximating the distribution  $\Pr[\text{Px}_\theta(s[t]) = v]$ .

The above approach is an effective approximation of the exposure metric. Interestingly, this estimated exposure has no upper bound, even though the true exposure is upper-bounded by  $\log_2 |\mathcal{R}|$ , when the inserted canary is the most likely. Usefully, this estimate can thereby help discriminate between cases where a canary is only marginally the most likely, and cases where the canary is by the most likely.

In this work, we use a skew-normal distribution [39] with mean  $\mu$ , standard deviation  $\sigma^2$ , and skew  $\alpha$  to model the distribution  $\rho$ . Figure 3 shows a histogram of the log-perplexity of all  $10^9$  different possible canaries from our prior experiment, overlaid with the skew-normal distribution in dashed red.

We observed that the approximating skew-normal distribution almost perfectly matches the discrete distribution. No statistical test can confirm that two distributions match perfectly; instead, tests can only *reject* the hypothesis that the distributions are the same. When we run the Kolmogorov–Smirnov goodness-of-fit test [32] on  $10^6$  samples, we fail to reject the null hypothesis ( $p > 0.1$ ).

## 5 Exposure-Based Testing Methodology

We now introduce our testing methodology which relies on the exposure metric. The approach is simple and effective: we have used it to discover properties about neural network memorization, test memorization on research datasets, and test memorization of Google’s Smart Compose [29], a production model trained on billions of sequences.

The purpose of our testing methodology is to allow practitioners to make informed decisions based upon how much memorization is known to occur under various settings. For example, with this information, a practitioner might decide it will be necessary to apply sound defenses (Section 9).

Our testing strategy essentially repeats the above experiment where we train with artificially-inserted canaries added to the training data, and then use the exposure metric to assess to what extent the model has memorized them. Recall that the reason we study these fixed-format out-of-distribution canaries is that we are focused on *unintended* memorization, and any memorization of out-of-distribution values is by definition unintended and orthogonal to the learning task.

If, instead, we inserted in-distribution phrases which were helpful for the learning task, then it would be perhaps even desirable for these phrases to be memorized by the machine-learning model. By inserting out-of-distribution phrases which we can guarantee are unrelated to the learning task, we can measure a model’s propensity to unintentionally memorize training data in a way that is not useful for the final task.

**Setup:** Before testing the model for memorization, we must first define a format of the canaries that we will insert. In practice, we have found that the exact choice of format does not significantly impact results.

However, the one choice that *does* have a significant impact on the results is randomness: it is important to choose a randomness space that matches the objective of the test to be performed. To approximate worst-case bounds, highly out-of-distribution canaries should be inserted; for more average-case bounds, in-distribution canaries can be used.

**Augment the Dataset:** Next, we instantiate each format sequence with a concrete (randomly chosen) canary by replacing the holes  $\odot$  with random values, e.g., words or numbers. We then take each canary and insert it into the training data. In order to report detailed metrics, we can insert multiple different canaries a varying number of times. For example, we may insert some canaries only once, some canaries tens of times, and other canaries hundreds or thousands of times. This allows us to establish the propensity of the model to memorize potentially sensitive training data that may be seen a varying number of times during training.

**Train the Model:** Using the same setup as will be used for training the final model, train a test model on the augmented training data. This training process should be identical: applying the same model using the same optimizer for the same

number of iterations with the same hyper-parameters. As we will show, each of these choices can impact the amount of memorization, and so it is important to test on the same setup that will be used in practice.

**Report Exposure:** Finally, given the trained model, we apply our exposure metric to test for memorization. For each of the canaries, we compute and report its exposure. Because we inserted the canaries, we will know their format, which is needed to compute their exposure. After training multiple models and inserted the same canaries a different number of times in each model, it is useful to plot a curve showing the exposure versus the number of times that a canary has been inserted. Examples of such reports are plotted in both Figure 1, shown earlier, and Figure 4, shown on the next page.

## 6 Experimental Evaluation

This section applies our testing methodology to several model architectures and datasets in order to (a) evaluate the efficacy of exposure as a metric, and (b) demonstrate that unintended memorization is common across these differences.

### 6.1 Smart Compose: Generative Email Model

As our largest study, we apply our techniques to Smart Compose [29], a generative word-level machine-learning model that is trained on a text corpus comprising of the personal emails of millions of users. This model has been commercially deployed for the purpose of predicting sentence completion in email composition. The model is in current active use by millions of users, each of which receives predictions drawn not (only) from their own emails, but the emails of all the users’ in the training corpus. This model is trained on highly sensitive data and its output cannot reveal the contents of any individual user’s email.

This language model is a LSTM recurrent neural network with millions of parameters, trained on billions of word sequences, with a vocabulary size of tens of thousands of words. Because the training data contains potentially sensitive information, we applied our exposure-based testing methodology to measure and ensure that only common phrases used by multiple users were learned by the model. By appropriately interpreting the exposure test results and limiting the amount of information drawn from any small set of users, we can empirically ensure that the model is never at risk of exposing any private word sequences from any individual user’s emails.

As this is a word-level language model, our canaries are seven (or five) randomly selected words in two formats. In both formats the first two and last two words are known context, and the middle three (or one) words vary as the randomness. Even with two or three words from a vocabulary of tens of thousands, the randomness space  $\mathcal{R}$  is large enough to support meaningful exposure measurements.

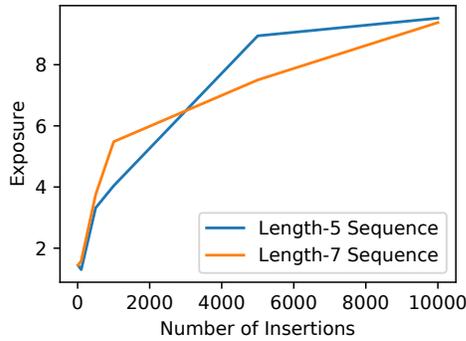

Figure 4: Exposure plot for our commercial word-level language model. Even with a canary inserted 10,000 times, exposure reaches only 10: the model is  $1,000\times$  more likely to generate this canary than another (random) possible phrase, but it is still not a very likely output, let alone the most likely.

In more detail, we inserted multiple canaries in the training data between 1 and 10,000 times (this does not impact model accuracy), and trained the full model on 32 GPUs over a billion sequences. Figure 4 contains the results of this analysis.

(Note: The measured exposure values are lower than in most of other experiments due to the vast quantity of training data; the model is therefore exposed to the same canary less often than in models trained for a large number of epochs.)

When we compute the exposure of each canary, we find that when secrets are very rare (i.e., one in a billion) the model shows no signs of memorization; the measured exposure is negligible. When the canaries are inserted at higher frequencies, exposure begins to increase so that the inserted canaries become with  $1000\times$  more likely than non-inserted canaries. However, even this higher exposure doesn't come close to allowing discovery of canaries using our extraction algorithms (see Section 8), let alone accidental discovery.

Informed by these results, limits can be placed on the incidence of unique sequences and sampling rates, and clipping and differential-privacy noise (see Section 9.3) can be added to the training process, such that privacy is empirically protected by eliminating any measured signal of exposure.

## 6.2 Word-Level Language Model

Next we apply our technique to one of the current state-of-the-art world-level language models [35]. We train this model on WikiText-103 dataset [34], a 500MB cleaned subset of English Wikipedia. We do not alter the open-source implementation provided by the authors; we insert a canary five times and train the model with different hyperparameters. We choose as a format a sequence of eight words random selected from the space of any of the 267,735 different words in the model's vocabulary (i.e., that occur in the training dataset).

We train many models with different hyperparameters and report in Figure 5 the utility as measured by test perplexity

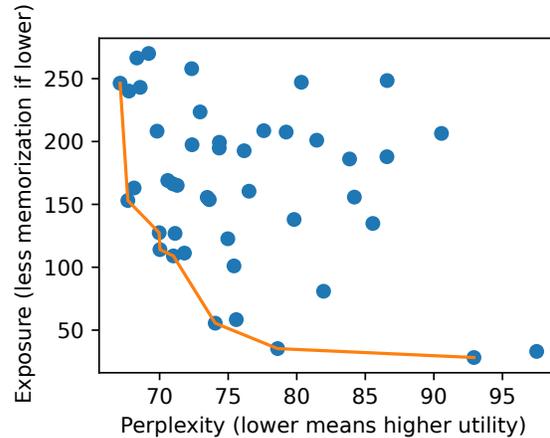

Figure 5: The results of applying our testing methodology to a word-level language model [35] inserting a canary five times. An exposure of 144 indicates extraction should be possible. We train many models each with different hyperparameters and find vast differences in the level of memorization. The highest utility model memorizes the canary to such a degree it can be extracted. Other models that reach similar utility exhibit less memorization. A practitioner would prefer one of the models on the Pareto frontier, which we highlight.

(i.e., the exponential of the model loss) against the measured exposure for the inserted canary. While memorization and utility are not highly correlated ( $r=-0.32$ ), this is in part due to the fact that many choices of hyperparameters give poor utility. We show the Pareto frontier with a solid line.

## 6.3 Character-Level Language Model

While previously we applied a small character-level model to the Penn Treebank dataset and measured the exposure of a random number sequence, we now confirm that the results from Section 6.2 hold true for a state-of-the-art character-level model. To verify this, we apply the character-level model from [35] to the PTB dataset.

As expected, based on our experiment in Section 3, we find that a character model model is less prone to memorizing a random sequence of words than a random sequence of numbers. However, the character-level model still does memorize the inserted random words: it reaches an exposure of 60 (insufficient to extract) after 16 insertions, in contrast to the word-models from the previous section that showed exposures much higher than this at only 5 insertions.

## 6.4 Neural Machine Translation

In addition to language modeling, another common use of generative sequence models is Neural Machine Translation [3]. NMT is the process of applying a neural network to translate from one language to another. We demonstrate that unintentional memorization is also a concern on this task, and

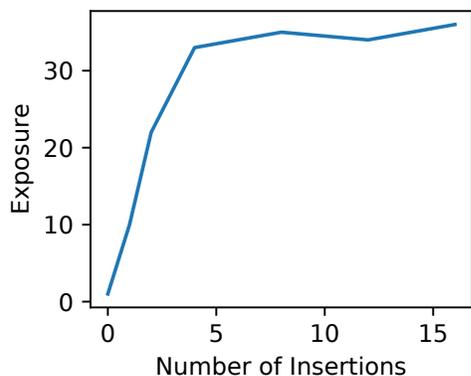

Figure 6: Exposure of a canary inserted in a Neural Machine Translation model. When the canary is inserted four times or more, it is fully memorized.

because the domain is different, NMT also provides us with a case study for designing a new perplexity measure.

NMT receives as input a vector of words  $x_i$  in one language and outputs a vector of words  $y_i$  in a different language. It achieves this by learning an encoder  $e: \vec{x} \rightarrow \mathbb{R}^k$  that maps the input sentence to a “thought vector” that represents the meaning of the sentence. This  $k$ -dimensional vector is then fed through a decoder  $d: \mathbb{R}^k \rightarrow \vec{y}$  that decodes the thought vector into a sentence of the target language.<sup>3</sup>

Internally, the encoder is a recurrent neural network that maintains a state vector and processes the input sequence one word at a time. The final internal state is then returned as the *thought vector*  $v \in \mathbb{R}^k$ . The decoder is then initialized with this thought vector, which the decoder uses to predict the translated sentence one word at a time, with every word it predicts being fed back in to generate the next.

We take our NMT model directly from the TensorFlow Model Repository [11]. We follow the steps from the documentation to train an English-Vietnamese model, trained on 100k sentences pairs. We add to this dataset an English canary of the format “My social security number is ○○○○ - ○○○○ ○○○○” and a corresponding Vietnamese phrase of the same format, with the English text replaced with the Vietnamese translation, and insert this canary translation pair.

Because we have changed problem domains, we must define a new perplexity measure. We feed the initial source sentence  $\vec{x}$  through the encoder to compute the thought vector. To compute the perplexity of the source sentence mapping to the target sentence  $\vec{y}$ , instead of feeding the output of one layer to the input of the next, as we do during standard decoding, we instead always feed  $y_i$  as input to the decoder’s hidden state. The perplexity is then computed by taking the log-probability of each output being correct, as is done on word models. Why do we make this change to compute perplexity? If one of the early words is guessed incorrectly and we feed it back in

<sup>3</sup>See [51] for details that we omit for brevity.

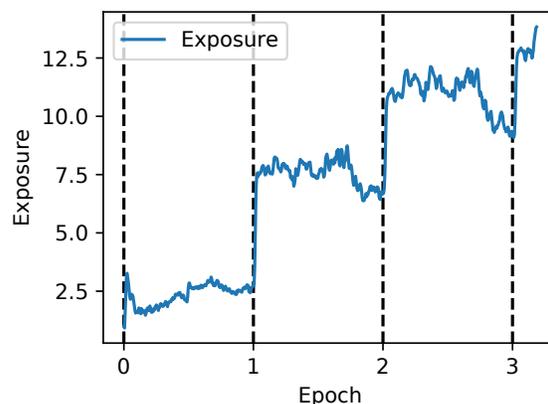

Figure 7: Exposure as a function of training time. The exposure spikes after the first mini-batch of each epoch (which contains the artificially inserted canary), and then falls overall during the mini-batches that do not contain it.

to the next layer, the errors will compound and we will get an inaccurate perplexity measure. By always feeding in the correct output, we can accurately judge the perplexity when changing the last few tokens. Indeed, this perplexity definition is *already implemented* in the NMT code where it is used to evaluate test accuracy. We re-purpose it for performing our memorization evaluation.

Under this new perplexity measure, we can now compute the exposure of the canary. We summarize these results in Figure 6. By inserting the canary only once, it already occurs 1000× more likely than random chance, and after inserting four times, it is completely memorized.

## 7 Characterizing Unintended Memorization

While the prior sections clearly demonstrate that unintended memorization *is* a problem, we now investigate *why* and *how* models unintentionally memorize training data by applying the testing methodology described above.

**Experimental Setup:** Unless otherwise specified, the experiments in this section are performed using the same LSTM character-level model discussed in Section 3 trained on the PTB dataset with a single canary inserted with the format “the random number is ○○○○○○○○○” where the maximum exposure is  $\log_2(10^9) \approx 30$ .

### 7.1 Memorization Throughout Training

To begin we apply our testing methodology to study a simple question: how does memorization progress during training?

We insert the canary near the beginning of the Penn Treebank dataset, and disable shuffling, so that it occurs at the same point within each epoch. After every mini-batch of train-

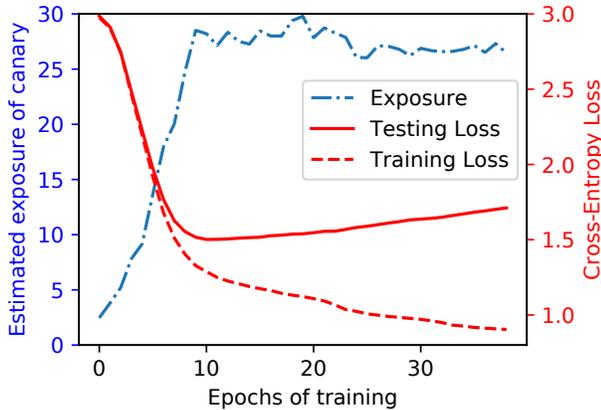

Figure 8: Comparing training and testing loss to exposure across epochs on 5% of the PTB dataset. Testing loss reaches a minimum at 10 epochs, after which the model begins to overfit (as seen by training loss continuing to decrease). Exposure also peaks at this point, and decreases afterwards.

ing, we estimate the exposure of the canary. We then plot the exposure of this canary as the training process proceeds.

Figure 7 shows how unintended memorization begins to occur over the first three epochs of training on 10% of the training data. Each time the model trains on a mini-batch that contains the canary, the exposure spikes. For the remaining mini-batches (that do not contain the canary) the exposure randomly fluctuates and sometimes decreases due to the randomness in stochastic gradient descent.

It is also interesting to observe that memorization begins to occur after only *one* epoch of training: at this point, the exposure of the canary is already 3, indicating the canary is  $2^3 = 8 \times$  more likely to occur than another random sequence chosen with the same format. After three epochs, the exposure is 8: access to the model reduces the number of guesses that would be needed to guess the canary by over  $100 \times$ .

## 7.2 Memorization versus Overtraining

Next, we turn to studying how unintended memorization relates to overtraining. Recall we use the word *overtraining* to refer to a form of overfitting as a result of training too long.

Figure 8 plots how memorization occurs during training on a sample of 5% of the PTB dataset, so that it quickly overtrains. The first few epochs see the testing loss drop rapidly, until the minimum testing loss is achieved at epoch 10. After this point, the testing loss begins to increase—the model has overtrained.

Comparing this to the exposure of the canary, we find an inverse relationship: exposure initially increases rapidly, until epoch 10 when the maximum amount of memorization is achieved. Surprisingly, the exposure does not continue increasing further, even though training continues. In fact, the

estimated exposure at epoch 10 is actually *higher* than the estimated exposure at epoch 40 (with p-value  $p < .001$ ). While this is interesting, in practice it has little effect: the rank of this canary is 1 for all epochs after 10.

Taken together, these results are intriguing. They indicate that unintended memorization seems to be a necessary component of training: exposure increases when the model is learning, and does not when the model is not. This result confirms one of the findings of Tishby and Schwartz-Ziv [42] and Zhang *et al.* [56], who argue that neural networks first learn to minimize the loss on the training data by memorizing it.

## 7.3 Additional Memorization Experiments

Appendix A details some further memorization experiments.

## 8 Validating Exposure with Extraction

How accurate is the exposure metric in measuring memorization? We study this question by developing an *extraction algorithm* that we show can efficiently extract training data from a model when our exposure metric indicates this should be possible (i.e., when the exposure is greater than  $\log_2 |\mathcal{R}|$ ).

### 8.1 Efficient Extraction Algorithm

**Proof of concept brute-force search:** We begin with a simple brute-force extraction algorithm that enumerates all possible sequences, computes their perplexity, and returns them in order starting from the ones with lowest perplexity. Formally, we compute  $\arg \min_{r \in \mathcal{R}} \text{Px}_\theta(s[r])$ . While this approach might be effective at validating our exposure metric accurately captures what it means for a sequence to be memorized, it is unable to do so when the space  $\mathcal{R}$  is large. For example, brute-force extraction over the space of credit card numbers ( $10^{16}$ ) would take 4,100 commodity GPU-years.

**Shortest-path search:** In order to more efficiently perform extraction, we introduce an improved search algorithm, a modification of Dijkstra’s algorithm, that in practice reduces the complexity by several orders of magnitude.

To begin, observe it is possible to organize all possible partial strings generated from the format  $s$  as a weighted tree, where the empty string is at the root. A partial string  $b$  is a child of  $a$  if  $b$  expands  $a$  by one token  $t$  (which we denote by  $b = a@t$ ). We set the edge weight from  $a$  to  $b$  to  $-\log \Pr(t|f_\theta(a))$  (i.e., the negative log-likelihood assigned by the model to the token  $t$  following the sequence  $a$ ).

Leaf nodes on the tree are fully-completed sequences. Observe that the total edge weight from the root  $x_1$  to a leaf node  $x_n$  is given by

$$\begin{aligned} & \sum -\log_2 \Pr(x_i | f_\theta(x_1 \dots x_{i-1})) \\ & = \text{Px}_\theta(x_1 \dots x_n) \end{aligned} \quad (\text{By Definition 1})$$

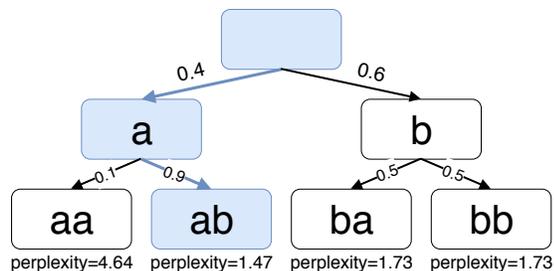

Figure 9: An example to illustrate the shortest path search algorithm. Each node represents one partially generated string. Each edge denotes the conditional probability  $\Pr(x_i|x_1\dots x_{i-1})$ . The path to the leaf with minimum perplexity is highlighted, and the log-perplexity is depicted below each leaf node.

Therefore, finding  $s[r]$  minimizing the cost of the path is equivalent to minimizing its log-perplexity. Figure 9 presents an example to illustrate the idea. Thus, finding the sequence with lowest perplexity is equivalent to finding the lightest path from the root to a leaf node.

Concretely, we implement a shortest-path algorithm directly inspired by Dijkstra’s algorithm [10] which computes the shortest distance on a graph with non-negative edge weights. The algorithm maintains a priority queue of nodes on the graph. To initialize, only the root node (the empty string) is inserted into the priority queue with a weight 0. In each iteration, the node with the smallest weight is removed from the queue. Assume the node is associated with a partially generated string  $p$  and the weight is  $w$ . Then for each token  $t$  such that  $p@t$  is a child of  $p$ , we insert the node  $p@t$  into the priority queue with  $w - \log \Pr(t|f_\theta(p))$  where  $-\log \Pr(t|f_\theta(p))$  is the weight on the edge from  $p$  to  $p@t$ .

The algorithm terminates once the node pulled from the queue is a leaf (i.e., has maximum length). In the worst-case, this algorithm may enumerate all non-leaf nodes, (e.g., when all possible sequences have equal perplexity). However, empirically, we find shortest-path search enumerate from 3 to 5 orders of magnitude fewer nodes (as we will show).

During this process, the main computational bottleneck is computing the edge weights  $-\log \Pr(t|f_\theta(p))$ . A modern GPU can simultaneously evaluate a neural network on many thousand inputs in the same amount of time as it takes to evaluate one. To leverage this benefit, we pull multiple nodes from the priority queue at once in each iteration, and compute all edge weights to their children simultaneously. In doing so, we observe a  $50\times$  to  $500\times$  reduction in overall run-time.

Applying this optimization violates the guarantee that the first leaf node found is always the best. We compensate by counting the number of iterations required to find the first full-length sequence, and continuing that many iterations more before stopping. We then sort these sequences by log-perplexity and return the lowest value. While this doubles the number of iterations, each iteration is two orders of magnitude faster, and this results in a substantial increase in performance.

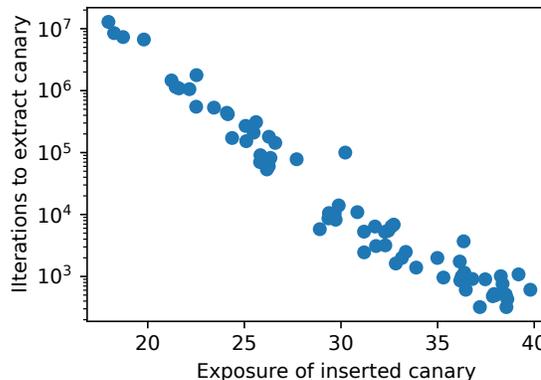

Figure 10: Number of iterations the shortest-path search requires before an inserted canary is returned, with  $|\mathcal{R}| = 2^{30}$ . At exposure 30, when the canary is fully memorized, our algorithm requires over four orders of magnitude fewer queries compared to brute force.

## 8.2 Efficiency of Shortest-Path Search

We begin by again using our character level language model as a baseline, after inserting a single 9-digit random canary to the PTB dataset once. This model completely memorizes the canary: we find its exposure is over 30, indicating it should be extractable. We verify that it actually does have the lowest perplexity of all candidate canaries by enumerating all  $10^9$ .

**Shortest path search:** We apply our shortest-path algorithm to this model and find that it takes only  $10^5$  total queries: four orders of magnitude fewer than a brute-force approach takes.

Perhaps as is expected, we find that the shortest-path algorithm becomes more efficient when the exposure of the canary is higher. We train multiple different models containing a canary to different final exposure values (by varying model capacity and number of training epochs). Figure 10 shows the exposure of the canary versus the number of iterations the shortest path search algorithm requires to find it. The shortest-path search algorithm reduces the number of values enumerated in the search from  $10^9$  to  $10^4$  (a factor of  $100,000\times$  reduction) when the exposure of the inserted phrase is greater than 30.

## 8.3 High Exposure Implies Extraction

Turning to the main purpose of our extraction algorithm, we verify that it actually means something when the exposure of a sequence is high. The underlying hypothesis of our work is that exposure is a useful measure for accurately judging when canaries have been memorized. We now validate that when the exposure of a phrase is high, we can extract the phrase from the model (i.e., there are not many false positives, where exposure is high but we can’t extract it). We train multiple models on the PTB dataset inserting a canary (drawn from a randomness space  $|\mathcal{R}| \approx 2^{30}$ ) a varying number of times with

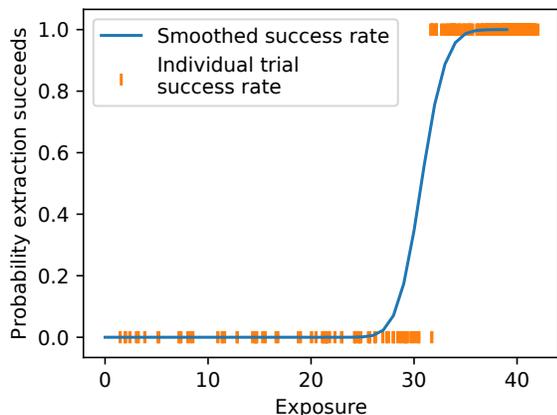

Figure 11: Extraction is possible when the exposure indicates it should be possible: when  $|\mathcal{R}_L| = 2^{30}$ , at an exposure of 30 extraction quickly shifts from impossible to possible.

different training regimes (but train all models to the same final test accuracy). We then measure exposure on each of these models and attempt to extract the inserted canary.

Figure 11 plots how exposure correlates with the success of extraction: extraction is always possible when exposure is greater than 33 but never when exposure is less than 31.

## 8.4 Enron Emails: Memorization in Practice

It is possible (although unlikely) that we detect memorization only because we have inserted our canaries artificially. To confirm this is not the case, we study a dataset that has many naturally-occurring secrets already in the training data. That is to say, instead of running experiments on data with the canaries we have artificially inserted and treated as “secrets”, we run experiments on a dataset where secrets are pre-existing.

The Enron Email Dataset consists of several hundred thousand emails sent between employees of Enron Corporation, and subsequently released by the Federal Energy Regulatory Commission in its investigation of the company. The complete dataset consists of the full emails, with attachments. Many users sent highly sensitive information in these emails, including social security numbers and credit card numbers.

We pre-process this dataset by removing all attachments, and keep only the body of the email. We remove the text of the email that is being responded to, and filter out automatically-generated emails and emails sent to the entire company. We separate emails by sender, ranging from 1.7MB to 5.6MB (about the size of the PTB dataset) and train one character-level language model per user who has sent at least one secret. The language model we train is again a 2-layer LSTM, however to model the more complex nature of writing we increase the number of units in each layer to 1024. We again train to minimum validation loss.

We summarize our results in Table 2. Three of these secrets (that pre-exist in the data) are memorized to a degree that

User	Secret Type	Exposure	Extracted?
A	CCN	52	✓
B	SSN	13	
C	SSN	16	
	SSN	22	
D	SSN	32	✓
F	SSN	13	
G	CCN	36	
	CCN	29	
	CCN	48	✓

Table 2: Summary of results on the Enron email dataset. Three secrets are extractable in  $< 1$  hour; all are heavily memorized.

they can be extracted by our shortest-path search algorithm. When we run our extraction algorithm locally, it requires on the order of a few hours to extract the credit card and social security numbers. Note that it would be unfair to draw from this that an actual attack would only take a few hours: this local attack can batch queries to the model and does not include any remote querying in the run-time computation.

## 9 Preventing Unintended Memorization

As we have shown, neural networks quickly memorize secret data. This section evaluates (both the efficacy and impact on accuracy) three potential defenses against memorization: regularization, sanitization, and differential privacy.

### 9.1 Regularization

It might be reasonable to assume that unintended memorization is due to the model *overtraining* to the training data. To show this is not the case, we apply three state-of-the-art regularization approaches (weight decay [28], dropout [45], and quantization [25]) that help prevent overtraining (and overfitting) and find that none of these can prevent the canaries we insert from being extracted by our algorithms.

#### 9.1.1 Weight Decay

Weight decay [28] is a traditional approach to combat overtraining. During training, an additional penalty is added to the loss of the network that penalizes model complexity.

Our initial language 600k parameters and was trained on the 5MB PTB dataset. It initially does not overtrain (because it does not have enough capacity). Therefore, when we train our model with weight decay, we do not observe any improvement in validation loss, or any reduction in memorization.

In order to directly measure the effect of weight decay on a model that does overtrain, we take the first 5% of the PTB dataset and train our language model there. This time the model does overtrain the dataset without regularization. When we add  $L_2$  regularization, we see less overtraining occur (i.e., the model reaches a *lower* validation loss). However, we observe no effect on the exposure of the canary.

### 9.1.2 Dropout

Dropout [45] is a regularization approach proposed that has been shown to effectively prevent overtraining in neural networks. Again, dropout does not help with the original model on the full dataset (and does not inhibit memorization).

We repeat the experiment above by training on 5% of the data, this time with dropout. We vary the probability to drop a neuron from 0% to 90%, and train ten models at each dropout rate to eliminate the effects of noise.

At dropout rates between 0% and 20%, the final test accuracy of the models are comparable (Dropout rates greater than 30% reduce test accuracy on our model). We again find that dropout does not statistically significantly reduce the effect of unintended memorization.

### 9.1.3 Quantization

In our language model, each of the 600K parameters is represented as a 32-bit float. This puts the information theoretic capacity of the model at 2.4MB, which is larger than the 1.7MB size of the compressed PTB dataset. To demonstrate the model is not storing a complete copy of the training data, we show that the model can be compressed to be much smaller while maintaining the same exposure and test accuracy.

To do this, we perform weight quantization [25]: given a trained network with weights  $\theta$ , we force each weight to be one of only 256 different values, so each parameter can be represented in 8 bits. As found in prior work, quantization does not significantly affect validation loss: our quantized model achieves a loss of 1.19, compared to the original loss of 1.18. Additionally, we find that the exposure of the inserted canary does not change: the inserted canary is still the most likely and is extractable.

## 9.2 Sanitization

Sanitization is a best practice for processing sensitive, private data. For example, we may construct blacklists and filter out sentences containing what may be private information from language models, or may remove all numbers from a model trained where only text is expected. However, one can not hope to guarantee that all possible sensitive sequences will be found and removed through such black-lists (e.g., due to the proliferation of unknown formats or typos).

We attempted to construct an algorithm that could automatically identify potential secrets by training two models

on non-overlapping subsets of training data and removing any sentences where the perplexity between the two models disagreed. Unfortunately, this style of approach missed some secrets (and is unsound if the same secret is inserted twice).

While sanitization is always a best practice and should be applied at every opportunity, it is by no means a perfect defense. Black-listing is never a complete approach in security, and so we do not consider it to be effective here.

## 9.3 Differential Privacy

*Differential privacy* [12, 14, 15] is a property that an algorithm can satisfy which bounds the information it can leak about its inputs. Formally defined as follows.

**Definition 5** A randomized algorithm  $\mathcal{A}$  operating on a dataset  $\mathcal{D}$  is  $(\epsilon, \delta)$ -differentially private if

$$\Pr[\mathcal{A}(\mathcal{D}) \in S] \leq \exp(\epsilon) \cdot \Pr[\mathcal{A}(\mathcal{D}') \in S] + \delta$$

for any set  $S$  of possible outputs of  $\mathcal{A}$ , and any two data sets  $\mathcal{D}, \mathcal{D}'$  that differ in at most one element.

Intuitively, this definition says that when adding or removing one element from the input data set, the output distribution of a differentially private algorithm does not change by much (i.e., by more than a factor exponentially small in  $\epsilon$ ). Typically we set  $\epsilon = 1$  and  $\delta < |\mathcal{X}|^{-1}$  to give strong privacy guarantees. Thus, differential privacy is a desirable property to defend against memorization. Consider the case where  $\mathcal{D}$  contains one occurrence of some secret training record  $x$ , and  $\mathcal{D}' = \mathcal{D} - \{x\}$ . Imprecisely speaking, the output model of a differentially private training algorithm running over  $\mathcal{D}$ , which contains the secret, must be similar to the output model trained from  $\mathcal{D}'$ , which does not contain the secret. Thus, such a model can not memorize the secret as completely.

We applied the differentially-private stochastic gradient descent algorithm (DP-SGD) from [1] to verify that differential privacy is an effective defense that prevents memorization. We used the initial, open-source code for DP-SGD<sup>4</sup> to train our character-level language model from Section 3. We slightly modified this code to adapt it to recurrent neural networks and improved its baseline performance by replacing the plain SGD optimizer with an RMSProp optimizer, as it often gives higher accuracy than plain SGD [47].

The DP-SGD of [1] implements differential privacy by clipping the per-example gradient to a max norm and carefully adding Gaussian noise. Intuitively, if the added noise matches the clipping norm, every single, individual example will be masked by the noise, and cannot affect the weights of the network by itself. As more noise is added, relative to the clipping norm, the more strict the  $\epsilon$  upper-bound on the privacy loss that can be guaranteed.

<sup>4</sup>A more modern version is at <https://github.com/tensorflow/privacy/>.

	Optimizer	$\epsilon$	Test Loss	Estimated Exposure	Extraction Possible?
With DP	RMSProp	0.65	1.69	1.1	
	RMSProp	1.21	1.59	2.3	
	RMSProp	5.26	1.41	1.8	
	RMSProp	89	1.34	2.1	
	RMSProp	$2 \times 10^8$	1.32	3.2	
	RMSProp	$1 \times 10^9$	1.26	2.8	
	SGD	$\infty$	2.11	3.6	
No DP	SGD	N/A	1.86	9.5	
	RMSProp	N/A	1.17	31.0	✓

Table 3: The RMSProp models trained with differential privacy do not memorize the training data and always have lower testing loss than a non-private model trained using standard SGD techniques. (Here,  $\epsilon = \infty$  indicates the moments accountant returned an infinite upper bound on  $\epsilon$ .)

We train seven differentially private models using various values of  $\epsilon$  for 100 epochs on the PTB dataset augmented with one canary inserted. Training a differentially private algorithm is known to be slower than standard training; our implementation of this algorithm is 10 – 100 $\times$  slower than standard training. For computing the  $(\epsilon, \delta)$  privacy budget we use the moments accountant introduced in [1]. We set  $\delta = 10^{-9}$  in each case. The gradient is clipped by a threshold  $L = 10.0$ . We initially evaluate two different optimizers (the plain SGD used by authors of [1] and RMSProp), but focus most experiments on training with RMSProp as we observe it achieves much better baseline results than SGD<sup>5</sup>. Table 3 shows the evaluation results.

The differentially-private model with highest utility (the lowest loss) achieves only 10% higher test loss than the baseline model trained without differential privacy. As we decrease  $\epsilon$  to 1.0, the exposure drops to 1, the point at which this canary is no more likely than any other. This experimentally verifies what we already expect to be true: DP-RMSProp fully eliminates the memorization effect from a model. Surprisingly, however, this experiment also shows that a little-bit of carefully-selected noise and clipping goes a long way—as long as the methods attenuate the signal from unique, secret input data in a principled fashion. Even with a vanishingly-small amount of noise, and values of  $\epsilon$  that offer no meaningful theoretical guarantees, the measured exposure is negligible.

Our experience here matches that of some related work. In particular, other, recent measurement studies have also found an orders-of-magnitude gap between the empirical,

<sup>5</sup>We do not perform hyperparameter tuning with SGD or RMSProp. SGD is known to require extensive tuning, which may explain why it achieves much lower accuracy (higher loss).

measured privacy loss and the upper-bound  $\epsilon$  DP guarantees—with that gap growing (exponentially) as  $\epsilon$  becomes very large [26]. Also, without modifying the training approach, improved proof techniques have been able to improve guarantees by orders of magnitude, indicating that the analytic  $\epsilon$  is not a tight upper bound. Of course, these improved proof techniques often rely on additional (albeit realistic) assumptions, such as that random shuffling can be used to provide unlinkability [16] or that the intermediate model weights computed during training can be hidden from the adversary [17]. Our  $\epsilon$  calculation do not utilize these improved analysis techniques.

## 10 Related Work and Conclusions

There has been a significant amount of related work in the field of privacy and machine learning.

**Membership Inference.** Prior work has studied the privacy implications of training on private data. Given a neural network  $f(\cdot)$  trained on training data  $\mathcal{X}$ , and an instance  $x$ , it is possible to construct a *membership inference attack* [41] that answers the question “*Is  $x$  a member of  $\mathcal{X}$ ?*”.

Exposure can be seen as an improvement that quantifies how much memorization has occurred (and not just *if* it has). We also show that given only access to  $f(\cdot)$ , we *extract* an  $x$  so that  $x \in \mathcal{X}$  (and not just infer if it is true that  $x \in \mathcal{X}$ ), at least in the case of generative sequence models.

Membership inference attacks have seen further study, including examining *why* membership inference is possible [49], or mounting inference attacks on other forms of generative models [22]. Further work shows how to use membership inference attacks to determine if a model was trained by using any individual user’s personal information [44]. These research directions are highly important and orthogonal to ours: this paper focuses on measuring unintended memorization, and not on any specific attacks or membership inference queries. Indeed, the fact that membership inference is possible is also highly related to unintended memorization.

More closely related to our paper is work which produces measurements for how likely it is that membership inference attacks will be possible [30] by developing the *Differential Training Privacy* metric for cases when differentially private training will not be possible.

**Generalization in Neural Networks.** Zhang *et al.* [56] demonstrate that standard models can be trained to perfectly fit completely random data. Specifically, the authors show that the same architecture that can classify MNIST digits correctly with 99.5% *test accuracy* can also be trained on completely random data to achieve 100% *train data accuracy* (but clearly poor test accuracy). Since there is no way to learn to classify random data, the only explanation is that the model has memorized all training data labels.

Recent work has shown that overtraining can directly lead to membership inference attacks [53]. Our work indicates that

even when we *do not* overtrain our models on the training data, unintentional memorization remains a concern.

**Training data leakages.** Ateniese *et al.* [2] show that if an adversary is given access to a remote machine learning model (e.g., support vector machines, hidden Markov models, neural networks, etc.) that performs better than their own model, it is often possible to learn information about the remote model’s training data that can be used to improve the adversary’s own model. In this work the authors “are not interested in privacy leaks, but rather in discovering anything that makes classifiers better than others.” In contrast, we focus only on the problem of private training data.

**Backdoor (intentional) memorization.** Song *et al.* [43] also study training data extraction. The critical difference between their work and ours is that in their threat model, the adversary is allowed to influence the training process and *intentionally back-doors* the model to leak training data. They are able to achieve incredibly powerful attacks as a result of this threat model. In contrast, in our paper, we show that memorization can occur, and training data leaked, even when there is not an attacker present intentionally causing a back-door.

**Model stealing** studies a related problem to training data extraction: under a black-box threat model, model stealing attempts to extract the parameters  $\theta$  (or parameters similar to them) from a remote model, so that the adversary can have their own copy [48]. While model extraction is designed to steal the parameters  $\theta$  of the remote model, training data extraction is designed to extract the training data that was used to generate  $\theta$ . That is, even if we were given direct access to  $\theta$  it is still difficult to perform training data extraction.

Later work extended model-stealing attacks to hyperparameter-stealing attacks [50]. These attacks are highly effective, but are orthogonal to the problems we study in this paper. Related work [38] also makes a similar argument that it can be useful to steal hyperparameters in order to mount more powerful attacks on models.

**Model inversion** [18, 19] is an attack that learns aggregate statistics of the training data, potentially revealing private information. For example, consider a face recognition model: given an image of a face, it returns the probability the input image is of some specific person. Model inversion constructs an image that maximizes the confidence of this classifier on the generated image; it turns out this generated image often looks visually similar to the actual person it is meant to classify. No individual training instances are leaked in this attack, only an aggregate statistic of the training data (e.g., what the average picture of a person looks like). In contrast, our extraction algorithm reveals specific training examples.

**Private Learning.** Along with the attacks described above, there has been a large amount of effort spent on training private machine learning algorithms. The centerpiece of these defenses is often *differential privacy* [1, 7, 12, 14, 15]. Our

analysis in Section 9.3 directly follows this line of work and we confirm that it empirically prevents the exposure of secrets. Other related work [40] studies membership attacks on differentially private training, although in the setting of a distributed honest-but-curious server.

Other related work [37] studies how to apply adversarial regularization to reduce the risk of black-box membership inference attacks, although using different approach than taken by prior work. We do not study this type of adversarial regularization in this paper, but believe it would be worth future analysis in follow-up work.

## 10.1 Limitations and Future Work

This work in this paper represents a practical step towards measuring unintended memorization in neural networks. There are several areas where our work is limited in scope:

- Our paper only considers generative models, as they are models that are likely to be trained on sensitive information (credit card numbers, names, addresses, etc). Although, our approach here will apply directly to any type of model with a defined measure of perplexity, further work is required to handle other types of machine-learning models, such as image classifiers.
- Our extraction algorithm presented here was designed to validate that canaries with a high exposure actually correspond to some real notion of the potential to extract that canary, and by analogy other possible secrets present in training data. However, this algorithm has assumptions that make it ill-suited to real-world attacks. To begin, real-world models usually only return the most likely output, that is, the  $\arg \max$  output. Furthermore, we assume knowledge of the surrounding context and possible values of the canary, which may not hold true in practice.
- Currently, we only make use of the input-output behavior of the model to compute the exposure of sequences. When performing our testing, we have full white-box access including the actual weights and internal activations of the neural network. This additional information might be used to develop stronger measures of memorization.

We hope future work will build on ours to develop further metrics for testing unintended memorization of unique training data details in machine-learning models.

## 10.2 Conclusions

The fact that deep learning models overfit and overtrain to their training data has been extensively studied [56]. Because neural network training should minimize loss across all examples, training must involve a form of memorization. Indeed,

significant machine learning research has been devoted to developing techniques to counteract this phenomenon [45].

In this paper we consider the related phenomenon of what we call *unintended memorization*: deep learning models (in particular, generative models) appear to often memorize rare details about the training data that are completely unrelated to the intended task while the model is still learning the underlying behavior (i.e., while the test loss is still decreasing). As we show, traditional approaches to avoid overtraining do not inhibit unintentional memorization.

Such unintended memorization of rare training details may raise significant privacy concerns when sensitive data is used to train deep learning models. Most worryingly, such memorization can happen even for examples that are present only a handful of times in the training data, especially when those examples are outliers in the data distribution; this is true even for language models that make use of state-of-the-art regularization techniques to prevent traditional forms of overfitting and overtraining.

To date, no good method exists for helping practitioners measure the degree to which a model may have memorized aspects of the training data. Towards this end, we develop *exposure*: a metric which directly quantifies the degree to which a model has unintentionally memorized training data. We use exposure as the basis of a testing methodology whereby we insert canaries (orthogonal to the learning task) into the training data and measure their exposure. By design, exposure is a simple metric to implement, often requiring only a few dozen lines of code. Indeed, our metric has, with little effort, been applied to construct regression tests for Google’s Smart Compose [29]: a large industrial language model trained on a privacy-sensitive text corpus.

In this way, we contribute a technique that can usefully be applied to aid machine learning practitioners throughout the training process, from curating the training data, to selecting the model architecture and hyperparameters, all the way to extracting meaning from the  $\epsilon$  values given by applying the provably private techniques of differentially private stochastic gradient descent.

## A Additional Memorization Experiments

### A.1 Across Different Architectures

We evaluate different neural network architectures in Table 4 again on the PTB dataset, and find that all of them unintentionally memorize. We observe that the two recurrent neural networks, i.e., LSTM [23] and GRU [8], demonstrate both the highest accuracy (lowest loss) and the highest exposure. Convolutional neural networks’ accuracy and exposure are both lower. Therefore, through this experiment, we show that the memorization is not only an issue to one particular architecture, but appears to be common to neural networks.

### A.2 Across Training Strategies

There are various settings for training strategies and techniques that are known to impact the accuracy of the final model. We briefly evaluate the impact that each of these have on the exposure of the inserted canary.

**Batch Size.** In stochastic gradient descent, we train on mini-batches of multiple examples simultaneously, and average their gradients to update the model parameters. This is usually done for computational efficiency—due to their parallel nature, modern GPUs can evaluate a neural network on many thousands of inputs simultaneously.

To evaluate the effect of the batch size on memorization, we train our language model with different capacity (i.e., number of LSTM units) and batch size, ranging from 16 to 1024. (At each batch size for each number of units, we train 10

# Improving Robustness of ML Classifiers against Realizable Evasion Attacks Using Conserved Features

## Abstract

Machine learning (ML) techniques are increasingly common in security applications, such as malware and intrusion detection. However, ML models are often susceptible to *evasion attacks*, in which an adversary makes changes to the input (such as malware) in order to avoid being detected. A conventional approach to evaluate ML robustness to such attacks, as well as to design robust ML, is by considering simplified *feature-space* models of attacks, where the attacker changes ML features directly to effect evasion, while minimizing or constraining the magnitude of this change. We investigate the effectiveness of this approach to designing robust ML in the face of attacks that can be realized in actual malware (*realizable attacks*). We demonstrate that in the context of structure-based PDF malware detection, such techniques appear to have limited effectiveness, but they are effective with content-based detectors. In either case, we show that augmenting the feature space models with *conserved* features (those that cannot be unilaterally modified without compromising malicious functionality) significantly improves performance. Finally, we show that feature space models enable generalized robustness when faced with a variety of realizable attacks, as compared to classifiers which are tuned to be robust to a specific realizable attack.

## 1 Introduction

Machine learning (ML) has come to be widely used in a broad array of settings, including important security applications such as network intrusion, fraud, and malware detection, as well as other high-stakes settings, such as autonomous driving. A general approach is to extract a set of *features*, or numerical attributes, of entities in question, collect a training data set of labeled examples (for example, indicating which instances are malicious and which are benign), and learn a model which labels previously unseen instances, presented in terms of their extracted features. Success of ML in malware detection is particularly striking, with ML-based static detection of malicious

entities at times exceeding 99% accuracy [36, 37].

Nevertheless, ML-based techniques are often susceptible to *adversarial examples*, an important special case of which are *evasion attacks*. In a prototypical case of an evasion attack, an adversary modifies malware code so that the resulting malware is categorized as benign by ML, but still successfully executes the malicious payload [12, 16, 26, 37, 44]. An even broader class of adversarial examples features attacks that manipulate an object, such as a stop sign, so that a computer vision pipeline misclassifies it as another object (such as a speed limit sign) [10, 15, 33].

In response, a host of methods emerged for making ML robust to adversarial examples, the most potent of which are those based on game-theoretic approaches, robust optimization (including certified robustness), and adversarial retraining [5, 15, 23, 25, 32, 42, 43, 46]. A fundamental ingredient in all of these are *feature-space models of attacks*. Specifically, the attacker is assumed to directly modify values of features, with either a constraint or a penalty on the aggregate feature change measured in terms of an  $l_p$  norm.

Such feature-space models of attacks are clearly abstractions of reality. First, arbitrary modifications of feature values may not be *realizable*. For example, adding a benign object to a malicious PDF (with no other changes) necessarily increases its size, and so setting the associated feature to 1 (from 0) and simultaneously reducing file size may not be practically feasible. Second, the key goal for an adversary is to create a target malicious effect, such as to execute a malicious payload. Limiting feature modifications to be small in some  $l_p$  norm clearly need not capture this: one can insert many no-ops (resulting in a large change according to an  $l_p$  norm) with no impact on malicious functionality, and conversely, minimal changes (such as removing a Javascript tag) may break malicious functionality. Nevertheless, an implicit assumption in robust ML approaches is that the feature-space models capture reality sufficiently to yield ML models that are robust even to realizable attacks. *The goal of our work is to evaluate the validity of this implicit assumption* in the context of PDF malware detection.

Our first contribution is to evaluate feature-space evasion attack models in the context of PDF malware detection, using EvadeML as a realizable attack [44]. Specifically, we consider four ML-based approaches for PDF malware detection: two based on features that capture PDF file structure (SL2013 [36] and Hidost [38]), and two based on PDF file content (two Mimicus variants of PDFRate [35, 37]). In all cases, we show that successful defense against a given realizable attack is feasible (by retraining with this attack). In the case of structure-based detectors, we demonstrate that adversarial retraining in the feature space does not lead to adequate robustness against realizable attacks. In contrast, adversarial retraining in the feature space is effective in the case of content-based detectors. In other words, the nature of the feature space can matter a great deal.

Our second contribution is a method for boosting robustness of feature-space models without compromising their mathematical convenience (crucial for most approaches for robust ML). The key idea is to identify *conserved features*, that is, features that cannot be unilaterally modified without compromising malicious functionality. We exhibit such features in our setting, show that they cannot be identified with traditional statistical methods, and develop an algorithm for automatically extracting them. Finally, we show that by simply constraining that these features remain unmodified in adversarial training, feature-space approaches become effective even for robust structure-based PDF malware detection.

Our third contribution is to explore the extent to which ML robustness is *generalizable* to multiple *distinct* realizable attacks. Specifically, we expose both a robust classifier that was retrained by using a realizable attack (EvadeML), and a model hardened using a feature-space attack (accounting for conserved features), to a series of realizable attacks. Our results reveal a stark difference between the two: ML models hardened using EvadeML are quite fragile; in contrast, ML models hardened using feature-space attacks exhibit uniformly high robustness to the other attacks. Remarkably, we demonstrate that ML models hardened using feature-space attacks remain robust *even against realizable attacks that defeat conserved features*.

## 2 Machine Learning in Security

### 2.1 Learning and Prediction

In the (supervised) machine learning literature, it is common to consider the problem abstractly. We are given a training dataset  $D = \{(x_i, y_i)\}$ , where  $x_i \in X \subseteq \mathbb{R}^n$  are numeric feature vectors in some feature space  $X$  and  $y_i \in L$  are labels in a label space  $L$ . Each data point (or example) in  $D$  is assumed to be generated i.i.d. according to some unknown distribution  $P$ . We are also given a hypothesis (model) space,  $H$ , and our goal is to identify (*learn*) a good model  $h \in H$  in the sense that it yields a small expected error on new examples drawn from

$P$ . In practice, since  $P$  is unknown, one typically aims to find  $h \in H$  which (approximately) minimizes empirical error on training data  $D$ .

In security applications—as in others—one is not given numerical features; instead, we start with a collection of entities, such as executables, along with associated labels (we assume henceforth that these are available, as we focus here on supervised learning problems). We must then *design a collection of feature extractors*, where each feature extractor computes a numerical value of a corresponding feature from an input entity. For example, we extract a “size” feature by computing the size of an executable. Applying feature extractors to each entity in our dataset, and adding associated object labels, allow us to generate a dataset  $D$  to fit the conventional ML framework.

In this paper we focus on PDF malware detection, where the label space is binary: either a PDF file is benign (which we can code as  $-1$ ), or malicious (which we can code as  $+1$ ). In addition, several prior efforts presented techniques for defining *feature extractors* (commonly known simply as features) for PDF files [36, 37]. Applying such feature extractors to a PDF file dataset transforms this dataset into one comprised of numerical feature vectors and associated binary labels. The goal is to predict whether previously unseen PDFs (simulated by holding out a portion of our dataset as *test data*) are correctly labeled as malicious or benign.

### 2.2 Evasion Attacks

In an *evasion attack*, abstractly, one is given a learned model  $h(x)$  (e.g., a SVM or neural network) which returns a label  $y = h(x)$  (e.g., malicious or benign) for an arbitrary feature vector  $x \in X$  (e.g., extracted from a PDF file). The attacker additionally starts with an entity  $e$  (such as a malicious PDF file), from which we can extract a feature vector  $\phi(e)$ . The attacker then transforms  $e$  into another entity,  $e'$ , with an associated feature vector  $x' = \phi(e')$  so as to accomplish two goals: first, that  $h(x')$  returns an erroneous label (in our running example, labels  $e'$  as benign based on its extracted features  $\phi(e')$ ), and second, that  $e'$  preserves the functionality of the original entity  $e$ —which, in our example of PDF malware detection, entails preserving malicious functionality of  $e$ . The evasion attack as just described is presumed to transform the *entity itself*, such as the malicious PDF file, albeit accounting for the effect of such transformation on the extracted features  $x' = \phi(e')$ . We call attacks of this kind *realizable* evasion attacks. The process by which such realizable evasion attacks can be successfully accomplished is quite non-trivial, and typically warrants independent research contributions (e.g., [37, 44]).

In contrast, it is natural to short-circuit the complexity involved, and work directly in the *feature space*, as is conventional in the machine learning literature. In this case, the attacker is *modeled* as starting with a malicious feature vector  $x$  (*not the malicious entity  $e$* ), and *directly modifying the fea-*

tures to produce another feature vector  $x' \in X$ , so as to yield erroneous predictions, i.e.,  $y' = h(x')$  (for example, being mislabeled as benign). Crucially, since we are no longer appealing to original entities, we must abstract away the notion of preserving (malicious) functionality. This is done through the use of a cost function,  $c(x, x')$ , whereby the attacker is penalized for greater modifications to the given feature vector  $x$ , commonly measured using an  $l_p$  norm difference between the original malicious instance and the modified feature vector [3, 23]. We term these the *feature-space models* of evasion attacks. Crucially, *essentially all approaches for robust ML, particularly the most successful ones, such as those based on robust optimization, leverage these models.*

### 2.3 Evasion Defense

A large number of approaches have been proposed for defending against evasion attacks or, more broadly, adversarial examples (e.g., [3, 5, 6, 29, 30, 32, 40, 42, 43]). While many have been shown inadequate [1, 7], the three generally effective approaches are: (a) game-theoretic reasoning, (b) robust optimization (a special case of (a) where the game is zero-sum), and (c) iterative adversarial retraining.<sup>1</sup> Game-theoretic methods in general, and robust optimization in particular, are not general-purpose, as solving these directly requires special structure, such as a continuous feature space and differentiability [3, 5, 6], and often additional structure of the learning model, such as linearity [43] or neural network architecture and activation functions [32, 42]. Finally, to date all have used the mathematical feature-space attack model at their core. In contrast, retraining can be performed without making assumptions about the nature of the learning algorithm or the adversarial model [23]. Since our study below involves realizable attacks (in addition to the mathematical models of attacks), non-linear SVM and, in all cases but one, binary features, iterative retraining is the sole defense that can be applied uniformly (which we require to ensure that our results are directly comparable).

## 3 Validating Models of ML Evasion Attacks

We have two major goals: 1) *validation*: to evaluate whether robust ML approaches that make use of feature-space models of evasion attacks are, indeed, robust against *real*—realizable—attacks, and 2) *generalizability*: to study generalizability of evasion defenses.

We start with a conceptual model of defense and attack as a Stackelberg game between ML (“defender”), who first chooses a defense  $\theta$  (in our case, the learned model  $h(x)$ ) and the attacker, who finds an optimal attack that *reacts* to the particular defense  $\theta$ . An *attack model* captures how the

<sup>1</sup>Otherwise known as adversarial training, it can be viewed as an approach for obtaining approximate game-theoretic or robust optimization solutions [23, 25, 40].

attacker changes behavior in response to the defense  $\theta$ . The defender’s goal is to choose the best defense  $\theta$  against such a reactive attacker, as captured by the attack model. Indeed, this is a common way to model the adversarial evasion problem in prior literature [5, 22, 40]. This model has two useful features. First, the attack is treated as an oracle in the sense that it returns an attack for an arbitrary defense  $\theta$ . This allows us, in principle, to design a defense against an arbitrary evasion attack, making no distinction between feature-space attack models and realizable attacks. Second, we can separately consider *defense* against a specific attack (for example, a feature-space attack), and *evaluation*, which can use another attack (e.g., a realizable attack).

To be more precise, let  $O(h; D)$  be an arbitrary attack which returns evasions given a dataset  $D$  and a classifier  $h$ , and let  $u(h; O(h; D))$  be the measure that the defender wishes to optimize (for example, accuracy on data *after* evasions). Then defense against the attack  $O(h; D)$  amounts to solving the following optimization problem:

$$\max_h u(h; O(h; D)). \quad (1)$$

In practice, we need a means for approximately solving the optimization problem in Equation (1) for an arbitrary attack. To this end, we make use of *iterative retraining*, an approach previously proposed for hardening classifiers against evasion attacks [21, 23]. In particular, we use a variant of iterative retraining with provable guarantees [23], which is outlined as follows:

1. Start with the initial classifier.
2. Execute the *evasion attack* for each malicious instance in training data to generate a new feature vector.
3. Add all new data points to training data (removing any duplicates), and retrain the classifier.
4. Terminate after either a fixed number of iterations, or when no new evasions can be added.

Now, we describe our approach to validation and generalizability evaluations.

In *validation*, consider a model of an evasion attack,  $\tilde{O}(h; D)$  (e.g., a feature-space attack model), which is a proxy for a “real” (realizable) attack,  $O(h; D)$ ; note that each attack evades a given ML model  $h$ . We first find the defense against  $\tilde{O}$  using the retraining procedure above; let the resulting robust classifier be  $\tilde{h}$ . Next, we *evaluate*  $\tilde{h}$  by running the target realizable attack  $O(\tilde{h}; D)$ . Finally, we create a *baseline*  $h^*$ , which is a robust classifier against a target realizable attack  $O$ . We then evaluate how well  $\tilde{h}$  performs, compared to  $h^*$ , against the target attack. For example, if we find that  $\tilde{h}$  is ineffective against the target attack, we say that  $\tilde{O}$  is a poor attack proxy, whereas if it remains robust, we view  $\tilde{O}$  as a good proxy for the target attack  $O$ . We focus on validation in Sections 5 and 6.

In evaluating *generalizability*, the approach is slightly different. Again, we consider a proxy attack  $\tilde{O}$  (which may now be either a feature-space model, or some particular realizable attack), and find a defense  $\tilde{h}$  against this attack. For evaluation, we consider a *collection* of target attacks  $\{O_i\}$ , and run each of these attacks against  $\tilde{h}$ . We say that our proxy attack is generalizable if  $\tilde{h}$  remains robust to all, or most of the attacks  $i$ ; otherwise, it fails to generalize. We consider generalizability in Section 7.

## 4 Experimental Methodology

We use malicious PDF detection as a case study to investigate robustness of ML hardened using feature-space models of evasion attacks. We now describe our experimental methodology. We start with some background on PDF structure, and proceed to describe the specific ML-based detectors, evasion attacks (both realizable, and feature-space), datasets, and evaluation metrics used in our experiments.

### 4.1 PDF Document Structure

The Portable Document Format (PDF) is an open standard format used to present content and layout on different platforms. A PDF file structure consists of four parts: *header*, *body*, *cross-reference table* (CRT), and *trailer*. The header contains information such as the magic number and format version. The body is the most important element of a PDF file, which comprises multiple PDF objects that constitute the content of the file. These objects can be one of the eight basic types: Boolean, Numeric, String, Null, Name, Array, Dictionary, and Stream. They can be referenced from other objects via indirect references. There are other types of objects, such as JavaScript which contains executable JavaScript code. The CRT indexes objects in the body, while the trailer points to the CRT.

The relations between objects with cross-references can be described as a directed graph that presents their logical structure by using edges representing reference relations and nodes representing different objects. As an object can be referred to by its child node, the resulting logical structure is a directed cyclic graph. To eliminate the redundant references, the logical structure can be reduced to a structural tree with the breadth-first search procedure.

### 4.2 Target Classifiers

Several PDF malware classifiers have been proposed [8, 35, 36, 38]. For our study, we selected SL2013 [36], Hidost [38] and two variants of PDFRate [35] (termed PDFRate-R and PDFRate-B respectively), displayed in Table 1. SL2013 and its revised version, Hidost, are *structure-based* PDF classifiers, which use the logical structure of a PDF document to construct and extract features used in detecting malicious

Classifier	Feature type	Number of features
SL2013	Binary	6,087
Hidost	Binary	961
PDFRate-R	Real-valued	135
PDFRate-B	Binary	135

Table 1: Target classifiers.

PDFs. PDFRate, on the other hand, is a *content-based* classifier, which constructs features based on *metadata* and *content* information in the PDF file to distinguish benign and malicious instances. Evasion attacks on both SL2013 and PDFRate classifiers, particularly of the realizable kind, have been developed in recent literature [36–38, 44], providing a natural evaluation framework for our purposes.

#### 4.2.1 Structure-Based Classifiers

**SL2013:** SL2013 is a well-documented and open-source machine learning system using Support Vector Machines (SVM) with a radial basis function (RBF) kernel, and was shown to have state-of-the-art performance [36]. It employs structural properties of PDF files to discriminate between malicious and benign PDFs. Specifically, SL2013 uses the presence of particular *structural paths* as binary features to present PDF files in feature space. A structural path of an object is a sequence of edges in the reduced (tree) *logical structure*, starting from the catalog dictionary and ending at this object. Therefore, the structural path reveals the shortest reference path to an object. SL2013 uses 6,087 most common structural paths among 658,763 PDF files as a uniform set for classification.

**Hidost:** Hidost is an updated version of SL2013. It inherits all the characteristics of SL2013 and employs *structural path consolidation* (SPC), a technique to consolidate features which have the same or similar semantic meaning in a PDF. As the semantically equivalent structural paths are merged, Hidost reduces polymorphic paths and still preserves the semantics of logical structure, so as to improve evasion-robustness of SL2013 [38].

In our work, we employ the 961 features identified in the latest version of Hidost.

#### 4.2.2 PDFRate: A Content-Based Classifier

The original PDFRate classifier uses a random forest algorithm, and employs PDF *metadata* and *content* features. The metadata features include the size of a file, author name, and creation date, while content-based features include position and counts of specific keywords. All features were manually defined by Smutz and Stavrou [35].

PDFRate uses a total of 202 features, but only 135 of these are publicly documented [34]. Consequently, in our work we employ the Mimicus implementation of PDFRate which was shown to be a close approximation [37]. Mimicus trained a surrogate SVM classifier with the documented 135 features

and the same dataset as PDFRate, using both the SVM and random forest classifiers, both performing comparably. We use the SVM implementation in our experiments to enable more direct comparisons with the structure-based classifiers that also use SVM. An important aspect of Mimicus is *feature standardization* on extracted data points performed by subtracting the mean of the feature value and dividing by standard deviation, transforming all features to be real-valued and zero-mean (henceforth, PDFRate-R). This surrogate was shown to have  $\sim 99\%$  accuracy on the test data [35]. In addition, we construct a *binarized* variant of PDFRate (henceforth, PDFRate-B), where each feature is transformed into a binary feature by assigning 0 whenever the feature value is 0, and assigning 1 whenever the feature value is non-zero.

## 4.3 Realizable Evasion Attacks

### 4.3.1 EvadeML

The primary realizable attack in our study is EvadeML [44], which allows insertion, deletion, and swapping of objects, and is consequently a stronger attack than most other realizable attacks in the literature, which typically only allow insertion to ensure that malicious functionality is preserved. EvadeML assumes that the adversary has black-box access to the classifier and can only get classification scores of PDF files, and was shown to effectively evade both SL2013 and PDFRate [44]. It employs genetic programming (GP) to search the space of possible PDF instances to find ones that evade the classifier while maintaining malicious features. First, an initial population is produced by randomly manipulating a malicious PDF repeatedly. The manipulation is either a deletion, an insertion, or a swap operation on PDF objects. After the population is initialized, each variant is assessed by the Cuckoo sandbox [17] and the target classifier to evaluate its fitness. The sandbox is used to determine if a variant preserves malicious behavior, such as API or network anomalies. The target classifier provides a classification score for each variant. If a variant is classified as benign but displays malicious behavior, or if GP reaches the maximum number of generations, then GP terminates with the variant achieving the best fitness score and the corresponding mutation trace is stored in a pool for future population initialization. Otherwise, a subset of the population is selected for the next generation based on their fitness evaluation. Afterward, the variants selected are randomly manipulated to generate the next generation of the population.

We use EvadeML as the primary realizable evasion model for the first part of the paper. We set the GP parameters in EvadeML as the same as in the experiments by Xu et al. [44]. The population size in each generation is 48. The maximum number of generations is 20. The mutation rate for each PDF object is 0.1. The mutation traces that lead to successful evasion and promising variants are stored and applied in our

experiments. The fitness threshold of a classifier is 0. We use the same external benign PDF files as Xu et al. [44] to provide ingredients for insertion and swap operations.

### 4.3.2 The Mimicry Attack

Mimicry assumes that an attacker has full knowledge of the features employed by a target classifier. The mimicry attack then manipulates a malicious PDF file so that it mimics a particular selected benign PDF as much as possible. The implementation of Mimicry is simple and independent of any particular classification model.

Our mimicry attack uses the Mimicus [37] implementation, which was shown to successfully evade the PDFRate classifier. To improve its evasion effectiveness, Mimicus chooses 30 different target benign PDF files for each attack file. It then produces one instance in feature space for each target-attack pair by merging the malicious features with the benign ones. The feature space instance is then transformed into a PDF file using a *content injection approach*. The resulting 30 files are evaluated by the target classifier, and only the PDF with the best evasion result is selected, which was submitted to WEPAWET [8] to verify malicious functionality. To make Mimicry consistent with our framework, we employ the Cuckoo sandbox [17] in place of WEPAWET (which was in any case discontinued) to validate maliciousness of the resulting PDF file.

In addition to the original version of Mimicry, we implement an enhanced variation, *Mimicry+*, with two modifications. First, *Mimicry+* chooses the 30 most benign PDF files predicted by the target classifier as target files (instead of randomly selecting those, as in Mimicry). Second, for each attack file, all the resulting 30 files are evaluated by the sandbox and only those verified to have malicious functionality are selected to evade the target classifier.

### 4.3.3 MalGAN

MalGAN [19] is a Generative Adversarial Network [14] framework to generate malware examples which can evade a black-box malware detector with binary features. It assumes that an attacker knows the features, but has only black-box access to the detector decisions. MalGAN comprises three main components: a generator which transforms malware to its adversarial version, a black-box detector which returns detection results, and a substitute detector which is used to fit the black-box detector and train the generator. The generator and substitute detector are feed-forward neural networks which work together to evade the black-box detector. The results of [19] show that MalGAN is able to decrease the *True Positive Rate* on the generated examples from  $> 90\%$  to  $0\%$ . We note that strictly speaking, MalGAN variants are not implemented as actual PDF files; however, we still treat it as a realizable attack since it only adds features to a malicious

/Type	/#54#79#70#65

Table 2: Transformation of entry names in the custom attack.

file, which can be implemented (at least in structure-based detection) by adding the associated objects into the PDF file.

#### 4.3.4 Reverse Mimicry

The *Reverse Mimicry* attack assumes that an attacker has zero knowledge of the target classifier. The basic idea is to inject malicious payloads into target benign files to minimize the structural difference between the resulting examples and targets. Our Reverse Mimicry attack employs the adversarial examples provided by Maiorca et al. [26] which was shown to successfully evade PDF classifiers based on structural analysis. Specifically, we use the 500 PDF files produced by injecting a malicious JavaScript code that does not contain references to other objects to target benign PDF files. We selected the 376 files out of 500 that display malicious behaviors detected by the Cuckoo sandbox.

#### 4.3.5 The Custom Attack

We implemented a custom attack which exploits a feature extraction vulnerability in the Mimicus implementation of PDFRate. Normally, the characters used in the Name objects of a PDF file are limited to a specific set. Since PDF specification version 1.2, a lexical convention has been added to represent a character with its hexadecimal ANSI-code, e.g., #xx. Such a modification enables us to create an arbitrary string in the form of #xx#xx#xx. In our implementation, we replaced a set of entries in the attack PDF files with their hexadecimal representations (see Table 2). These features were selected with the goal to obfuscate tags crucial to the code execution in PDF, which are frequently used for feature extraction. With this technique, the scanner would not be able to detect malicious code without dynamically reconstructing the PDF structure. While it is theoretically possible to replace all the ASCII text inside the document, we chose not to do that due to the concern on the expansion of file size.

### 4.4 Feature-Space Evasion Model

In typical realizable attacks, including EvadeML, a consideration is not merely to move to the benign side of the classifier decision boundary, but to appear as benign as possible. This

naturally translates into the following multi-objective optimization in feature space:

$$\underset{x}{\text{minimize}} \quad Q(x) = f(x) + \lambda c(x_M, x), \quad (2)$$

where  $f(x)$  is the score of a feature vector  $x$ , with the actual classifier (such as SVM)  $g(x) = \text{sgn}(f(x))$ ,  $x_M$  the malicious seed,  $x$  an evasion instance,  $c(x_M, x)$  the cost of transforming  $x_M$  into  $x$ , and  $\lambda$  a parameter which determines the feature transformation cost. We use  $l_2$  norm distance between  $x_M$  and  $x$  as the cost function:  $c(x_M, x) = \sum_i |x_i - x_{M,i}|^2$ . Since in most of our experiments features are binary, the choice of  $l_2$  norm (as opposed to another  $l_p$  norm) is not critical.

As the optimization problem in Equation (2) is non-convex and variables are binary in three of the four cases we consider, we use a stochastic local search method designed for combinatorial search domains, *Coordinate Greedy* (alternatively known as iterative improvement), to compute a local optimum (the binary nature of the features is why we eschew gradient-based approaches) [18, 23]. In this method, we optimize one randomly chosen coordinate of the feature vector at a time, until a local optimum is reached. To improve the quality of the resulting solution, we repeat this process from several random starting points. This approach has been shown to be extremely effective for computing evasion instances in binary domains [23].

### 4.5 Datasets

The dataset we use is from the *Contagio Archive*.<sup>2</sup> We use 5,586 malicious and 4,476 benign PDF files for training, and another 5,276 malicious and 4,459 benign files as the non-adversarial test dataset. The training and test datasets also contain 500 seeds selected by Xu et al. [44], with 400 in the training data and 100 in the test dataset. These seeds are filtered from 10,980 PDF malware samples and are suitable for evaluation since they are detected with reliable malware signatures by the Cuckoo sandbox [17]. We randomly select 40 seeds from the training data as the retraining seeds and use the 100 seeds in the test data as the test seeds.

### 4.6 Implementation of Iterative Adversarial Retraining

We made a small modification to the general iterative retraining approach described in Section 3 when it uses EvadeML as the realizable attack  $O(h; D)$ . Specifically, we used only 40 malicious seeds to EvadeML to generate evasions, to reduce running time and make the experiment more consistent with realistic settings where a large proportion of malicious data is not adapting to the classifier. As shown below, this set of 40 instances was sufficient to generate a model robust to evasions from held out 100 malicious seed PDFs.

<sup>2</sup>Available at the following URL: <http://contagiodump.blogspot.com/2013/03/16800-clean-and-11960-malicious-files.html>.

We distribute both retraining and adversarial test tasks on two servers (Intel(R) Xeon(R) CPU E5-2695 v4 @ 2.10GHz, 18 cores and 64 GB memory, running Ubuntu 16.04). For retraining using EvadeML as the attack, we assign each server 20 seeds; each seed is processed by EvadeML to produce the adversarial evasion instances. We then add the 40 examples obtained to the training data, retrain the classifier, and then split the seeds between the two servers in the next iteration. In the evaluation phase, we assign each server 50 seeds from the 100 test instances, and each seed is further used to evade the classifier by using EvadeML.

## 4.7 Evaluation Metrics

We evaluate performance in two ways: 1) evaluation of evasion robustness (which is central to our specific inquiry), and 2) traditional evaluation. To evaluate robustness, we compute the proportion of 100 malicious test seed PDFs for which EvadeML successfully evades the classifier; this is our metric of *evasion robustness*, evaluated with respect to EvadeML. Thus, evasion robustness of 0% means that the classifier is successfully evaded in every instance, while evasion robustness of 100% means that evasion fails every time. Our traditional evaluation metric uses test data of malicious and benign PDFs, where no evasions are attempted. On this data, we compute the ROC (receiver operating characteristic) curve and the corresponding AUC (area under the curve).

## 5 Efficacy of Feature-Space Attack Models

We now undertake our first task: evaluation of the effectiveness of robust ML obtained by using the abstract feature-space models of attack. We compare to a baseline classifier obtained by retraining with the most potent attack on our menu, EvadeML (which, in addition to inserting content, as done by other attacks [19, 26, 37], also allows the attacker to delete and swap PDF objects). We can think of our baseline as assuming that the defender knows that EvadeML is employed by the attacker, along with its hyperparameters. Through this and next section, we also use EvadeML to evaluate the effectiveness of classifiers hardened using a feature-space model, in comparison with the above baseline.

### 5.1 Structure-Based PDF Malware Classification

Our first case study uses a state-of-the-art PDF malware classifier which engineers features based on PDF *structure*. Indeed, we evaluate two versions of this classifier: an earlier version, which we call *SL2013*, and a more recent version, which we call *Hidost*. The experiments by Xu et al. [44] demonstrate that *SL2013* can be successfully evaded. Since *Hidost* was a recent redesign attempting in part to address its vulnerability to mimicry attacks by significantly reducing the feature space,

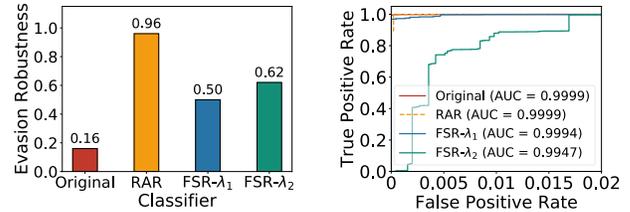

Figure 1: Evasion robustness under EvadeML test (left) and performance on non-adversarial data (right) of different classifiers for SL2013.

no data exists on its vulnerability to evasion attacks. Below we demonstrate that *Hidost* is also vulnerable to evasion attacks (indeed, more so than *SL2013*).

From the perspective of defense, we show that it is possible to harden both *SL2013* and *Hidost* against a powerful realizable EvadeML attack by simply retraining with this attack (*RAR*, for *realizable-attack retraining*, henceforth refers to a model hardened using EvadeML). This serves as a baseline we use to evaluate the efficacy of a retraining defense with a feature-space attack model (henceforth, *FSR* for *feature-space retraining*). We then show that for both *SL2013* and *Hidost*, *FSR* significantly underperforms *RAR*.

In our experiments, we empirically set the *RBF* parameters for training both *SL2013* and *Hidost* to  $C = 12$  and  $\gamma = 0.0025$ .

#### 5.1.1 SL2013

**Retraining with a Powerful Realizable Attack** First, we replicated the EvadeML attack on the original *SL2013*; the classifier achieves only a 16% evasion robustness.<sup>3</sup> Next, to create a baseline, we conduct experiments in which EvadeML is employed to retrain *SL2013*. The process terminated after 10 iterations at which point no evasive variants of the 40 retraining seeds could be generated. We observe (Figure 1 (left)) that the retrained classifier (*RAR*) obtained by this approach achieves a 96% evasion robustness. Moreover, *RAR* is essentially as accurate as the baseline *SL2013* on non-adversarial data (Figure 1 (right)). Thus, it is clearly possible to be highly robust to this evasion attack without significantly compromising effectiveness on data not featuring explicit evasion attacks.

Figure 2 (left) shows the gradual improvement of evasion robustness over the 10 retraining iterations. This plot demonstrates non-trivial effectiveness of EvadeML: the first few iterations are clearly insufficient, as re-running EvadeML creates many new evasions that cannot be correctly detected by

<sup>3</sup>This result differs from the experiments in [44] which show a 0% evasion robustness. We found a flaw in the implementation of feature extraction in EvadeML which causes evaluation to be performed using the wrong feature vectors. This bug has been fixed in the GitHub version of EvadeML.

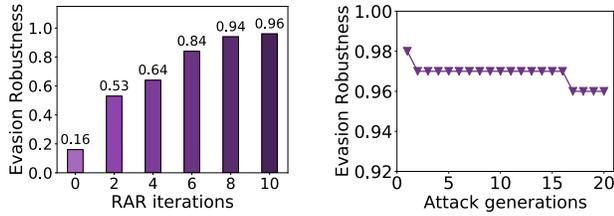

Figure 2: Evasion robustness with retraining iterations (left) and generations of the EvadeML attack test (right).

the classifier. Only after 6 iterations does EvadeML optimization loop begin to show significant signs of failing. Figure 2 (right) shows how increasing the number of generations in EvadeML attacks affects robustness of the RAR classifier. At this point, we can see that increasing the capability of the attack has minimal impact.

**Feature-Space Retraining** Next, we experimentally evaluate the effectiveness of retraining with a feature-space model of evasion attacks in obtaining robust ML in the face of the EvadeML realizable attack. We consider the setting with  $\lambda = 0.05$  and  $\lambda = 0.005$  in Equation 2 (henceforth, FSR- $\lambda_1$  and FSR- $\lambda_2$ ).

The robustness results are shown in Figure 1 (left). Compared to the SL2013 baseline, feature-space retraining (FSR) boosts evasion robustness from 16% to 62%. Crucially, *the robustness of the resulting classifier is far below the classifier achieved by RAR*. This illustrates that defense that relies on feature-space models of adversarial examples may not in fact lead to robustness when it is faced with a real attack.

We again consider performance of FSR classifier on non-adversarial test data (Figure 1 (right)). We can see that robustness boosting again does not much degrade performance, with AUC remaining above 99%. However, we do see a substantial degradation as we move from  $\lambda = 0.05$  to 0.005; thus, as we increase adversarial power in the feature-space model, while we do obtain a slightly more robust model, we incur a nontrivial hit in performance on non-adversarial data.

### 5.1.2 Hidost

We now repeat our experiments above with another structure-based classifier, Hidost. We set the retraining parameter  $\lambda = 0.005$ , which appears to strike a reasonable balance between robustness and accuracy on non-adversarial data. As before, we first evaluated the robustness of the original Hidost [38] by EvadeML. The result shows a 2% robustness—remarkably, significantly worse than SL2013.

Evasion robustness of Hidost, as well as improvements achieved by RAR and FSR, are shown in Figure 3 (left), and the results are consistent with our observations for SL2013. First, by retraining with the realizable attack, evasion robust-

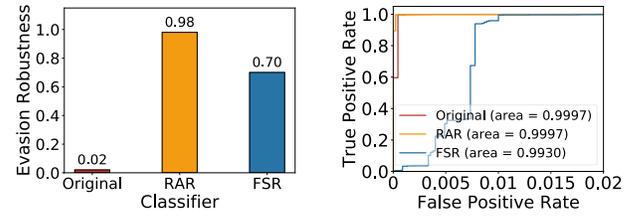

Figure 3: Evasion robustness under EvadeML test (left) and performance on non-adversarial data (right) of different classifiers for Hidost.

ness is boosted to 98%, a rather dramatic improvement, and clear demonstration that successful defense is possible. In contrast, FSR achieves a 70% evasion robustness, a significant boost over the original Hidost, to be sure, but far below the evasion robustness of RAR.

Evaluating these classifiers on non-adversarial test data in terms of ROC curves (Figure 3 (right)), we can observe that RAR achieves comparable accuracy ( $> 99.9\%$  AUC) with the original Hidost classifier on non-adversarial data, and provides even better *True Positive Rate (TPR)* when *False Positive Rate (FPR)* is close to zero. On the other hand, FSR achieves  $> 99\%$  AUC, but yields a significant degradation of TPR when  $FPR < 0.01$ .

## 5.2 Content-Based PDF Malware Classification

Our next case study concerns another two PDF malware classifiers which use features based on PDF file content, rather than logical structure. We trained both real-valued and binarized PDFRate (henceforth, PDFRate-R and PDFRate-B) on the same dataset as SL2013 and Hidost, and achieved  $> 99.9\%$  AUC for both classifiers on test data. In our experiments, we empirically set the SVM *RBF* parameters for training to  $C = 10$  and  $\gamma = 0.01$ . In our evaluation of ML robustness, we again set the feature-space model parameter  $\lambda$  to be 0.005.

### 5.2.1 PDFRate with Real-Valued Features

We begin with the variant of PDFRate—PDFRate-R—which has been constructed in previous evaluations and shown comparable in performance to the original implementation [37]. We again begin by replicating the EvadeML evasion robustness evaluation of the baseline classifier. As expected, we find the classifier quite vulnerable, with only 2% evasion robustness.

Next, we retrain PDFRate-R with EvadeML for 10 iterations (RAR baseline), and perform feature-space retraining using the conventional feature space model above. Our results are shown in Figure 4 (left). Observe that while RAR

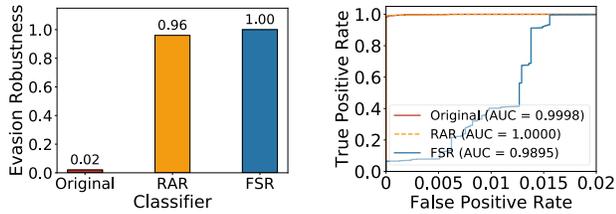

Figure 4: Evasion robustness under EvadeML test (left) and performance on non-adversarial data (right) of different classifiers for PDFRate-R.

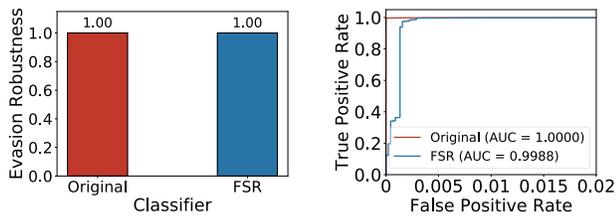

Figure 5: Evasion robustness under EvadeML test (left) and performance on non-adversarial data (right) of different classifiers for PDFRate-B.

indeed achieves a highly robust classifier (96% robustness), FSR actually performs *even better*, with 100% robustness.

Comparing RAR and FSR performance on non-adversarial data (Figure 4 (right)), we observe that the high robustness of FSR does incur a cost: while RAR remains exceptionally effective (>99.99% AUC), FSR achieves AUC slightly lower than 99%, although most significantly, the degradation is rather pronounced for low FPR regions (below 0.015).

### 5.2.2 PDFRate with Binarized Features

One of our great surprises is the robustness of the binarized PDFRate: despite the fact that the real-valued PDFRate is quite vulnerable, *the same classifier using binary features was 100% robust to EvadeML* (Figure 5 (left)). Consequently, this will serve as our robust baseline (equivalently, RAR would terminate with no iterations). Feature-space retrained PDFRate-B also exhibits 100% evasion robustness, although it does require a number of iterations to converge.

Considering now the performance of PDFRate-B and FSR on non-adversarial test data (Figure 5 (right)), we can make two interesting observations. First, the baseline PDFRate-B is remarkably good even on this data; in a sense, it appears to hit the sweet spot of adversarial robustness and non-adversarial performance. Second, FSR retrained classifier is competitive in terms of AUC (~99.9%), but is observably worse than the baseline classifier for very low false positive rates.

## 6 Evasion-Robust Classification with Conserved Features

Thus far, we had observed that ML hardened with the standard mathematically convenient feature-space evasion attack model may in some cases not yield satisfactory robustness against real attacks. The key issue is that feature-space models are entirely disembodied from the domain. This is crucial to enable us to have mathematical formulations of attacks, but clearly has limitations. The key question is whether we can devise a simple way of anchoring feature-space attacks in the application domain to allow us to meaningfully and minimally constrain abstract attacks to reflect some of the constraints that real attacks face. Next, we propose a refinement of the feature-space model that aims to do just that.

Specifically, we introduce the idea of *conserved features*, which we define to be *features, the unilateral modification of which compromises malicious functionality*. We develop this idea specifically for *binary features*, as this notion is particularly crisp in such a case (e.g., such features tend to correspond to the existence of particular objects in PDF).

Next, we present three major findings. First, conserved features do exist in all three of our classifiers over the binary feature space, and can be effectively identified (see our algorithm for identifying conserved features in Appendix A). Second, conserved features cannot be recovered using statistical feature reduction (in our case, sparse regularization), and feature reduction methods do not lead to robust classifiers. The reason is that conservation is connected to the relationship between features and malicious functionality, rather than statistical properties of non-evasion data; for example, features which are strongly correlated with malicious behavior are often a consequence of attacker “laziness” (such as whether a PDF file has an author), and are easy for attackers to change. Third, we demonstrate that the limitations of feature-space robust ML can be substantially alleviated by incorporating conserved features as attack invariants in the feature-space evasion model.

To develop intuition about the nature of conserved features, consider SL2013, which employs structural paths as features to discriminate between malicious and benign PDFs. On the one hand, the structural paths like `/Type` are unessential to preserve malicious behaviors, and we do not expect them to be conserved. On the other hand, as the shellcode which triggers malicious functionality is embedded in certain PDF objects, those corresponding structural paths are likely to be conserved in each variant crafted from the same malicious seed (e.g., `/OpenAction/JS`). In addition, structural paths that facilitate embedded script in PDF files also can be conserved features as removing them can break the script (e.g., `/Names` and `/Pages`). This further illustrates that conserved features are not necessarily optimal for statistically distinguishing benign and malicious instances (indeed, these may be common to both); rather, they serve to anchor the feature-

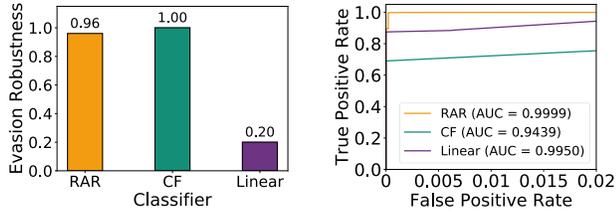

Figure 6: Classifying with conserved features: comparing evasion robustness (left) and ROC curves (right).

space attack model in the domain by connecting features to malicious functionality.

## 6.1 Classifying Using Only Conserved Features

We begin by exploring the effectiveness of using *only* conserved features for classification. We identified 8 conserved features for SL2013 (out of  $\sim 6000$ ), 7 for Hidost (out of  $\sim 1000$ ), and 4 for PDFRate-B (out of 135); these are detailed in Table 3 of the appendix, while our algorithm for identifying conserved features is presented in Appendix A.

We start by considering four natural questions pertaining to conserved features: 1) are they sufficient to make a classifier robust to evasions, 2) do they effectively discriminate between benign and malicious instances, 3) can they be identified using standard statistical methods (such as sparse regularization), and 4) are they just detecting the presence of JavaScript in PDF?

We explore these for SL2013. Specifically, we trained a classifier using *only* the 8 conserved features (*CF* henceforth). As we can see in Figure 6 (left), this classifier is 100% robust to EvadeML attacks, appearing to resolve the first question. However, we emphasize that conserved features alone need not capture the full spectrum of adversarial behavior and constraints. Indeed, in Section 7 we show that classifiers based solely on conserved features can also be evaded, particularly if attacks are *specifically designed to evade them*. Rather, as we show presently, they provide a *sufficient anchoring* in the problem domain for feature-space attack models to succeed.

To address question (2), consider Figure 6 (right): clearly, if we desire a low false positive rate, using only conserved features for classification yields subpar performance on non-adversarial data. To address the third question, we learn a linear SVM classifier for SL2013 with  $l_1$  regularization (henceforth, *Linear*) where we empirically adjust the SVM parameter  $C$  to perform feature reduction until the number of the features is also 8; we find that only 3 of these are conserved features (see Appendix A.6 for a more detailed analysis of the relationship between statistically useful and conserved features). As we can see in Figure 6 (left), this classifier exhibits poor robustness; thus, statistical methods are insufficient to

identify good conserved features.

To address the fourth question, we create a classifier using only one boolean feature which identifies the presence of JavaScript in a PDF file (henceforth, we refer to this feature as *JS*). We find that this classifier is also robust to EvadeML. On non-adversarial data, JS achieves FPR of 0.04 and FNR of 0.14 (in other words, 4% of the benign files in the non-adversarial dataset use JavaScript, while 14% of malicious instances use alternative attacks to Javascript).<sup>4</sup> To create an apples-to-apples comparison with the CF classifier, we empirically adjust the classification threshold of CF until we get the same FPR with JS. The resulting CF classifier exhibits FNR of 0.11, considerably better than JS. Nevertheless, it is clear that using either CF (only conserved features), or only JS, is impractical, since both FNR and FPR of these are quite high. Moreover, as we show in Section 7, classifiers based only on conserved features can be defeated by other realizable attacks. Next, we show that identification of conserved features is nevertheless crucial in creating highly effective feature-space attack models.

## 6.2 Feature-Space Model with Conserved Features

As discussed above, the feature-space evasion model in Equation (2) may not sufficiently boost ML robustness. Since conserved features allow us to minimally tie the abstract feature-space representation to malicious functionality, we offer a natural modification of the model in Equation (2), imposing the constraint that conserved features cannot be modified by the attacker. We formally capture this in the new optimization problem in Equation (3), where  $S$  is the set of conserved features:

$$\begin{aligned} & \underset{x}{\text{minimize}} && Q(x) = f(x) + \lambda c(x_M, x), \\ & \text{subject to} && x_i = x_{M,i}, \forall i \in S. \end{aligned} \quad (3)$$

Other than this modification, we use the same *Coordinate Greedy* algorithm with random restarts as before to compute adversarial examples. We adopt the evasion model in Equation (3) to retrain the target classifier using the retraining procedure from Section 4. We denote the classifier obtained by the retraining procedure using a feature-space model grounded by conserved features by *CFR*. We also study the effectiveness of our automated procedure for identifying conserved features as compared to using a subset that only considers Javascript features (we can think of these as expert-identified conserved features, as this is what an expert would naturally consider). To this end, we repeat the procedure above by replacing the conserved feature set  $S$  in Eq. 3 with a subset that involves Javascript. The classifier resulting from such restricted adver-

<sup>4</sup>We observe similar results for 5,000 benign PDFs obtained by using Google web searches [37], where 3% of benign files use Javascript.

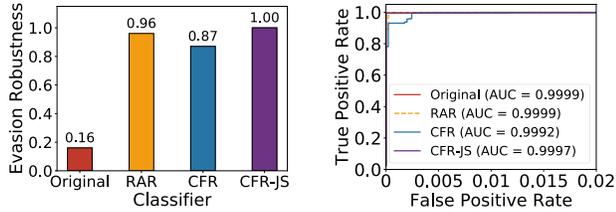

Figure 7: Evasion robustness (left) and performance on non-adversarial data (right) of different variants of SL2013.

sarial retraining with “expert”-identified conserved features is termed *CFR-JS*.

### 6.2.1 SL2013

We now evaluate the robustness and effectiveness of the feature space retraining approach, which uses conserved features. We set the parameter  $\lambda = 0.005$  as before. The robustness results are presented in Figure 7 (left). Observe that *CFR* now significantly improves robustness of the original classifier, with evasion robustness rising from 16% to 87%. Moreover, *CFR-JS* achieves a 100% evasion robustness against EvadeML. These results demonstrate that by leveraging the conserved features, the feature-space evasion models are now quite effective as a means to boost evasion robustness of SL2013.

In Figure 7 (right) we evaluate the quality of these classifiers on non-adversarial test data in terms of ROC curves. In all cases, be it original, RAR, CFR, and CFR-JS, AUC is  $> 99.9\%$ , although we can see a slight degradation of CFR for extremely low false positive rates compared to the others. It is noteworthy that CFR performs much better than FSR (robust ML using a standard feature-space approach, recall Figure 1 (right)).

### 6.2.2 Hidost

Next, we evaluate the effectiveness of CFR for Hidost. The results are shown in Figure 8 (left) and are largely consistent with SL2013. In particular, CFR boosts evasion robustness from 2% to 100% (slightly better than RAR), well above conventional FSR (recall Figure 3 (left)). In contrast, CFR-JS only boosts robustness to 53%, showing that our algorithmic approach can in some cases offer a considerable advantage to expert-chosen conserved features.

Evaluating the performance of CFR and CFR-JS on non-adversarial test data in terms of ROC curves in Figure 8 (right), we find that the CFR classifier can achieve  $\sim 99.8\%$  AUC. This is somewhat worse than RAR, particularly for very low false positive rates, but better than CFR-JS—again, in this case using the full batch of conserved features exhibits a significant advantage over solely looking for Javascript.

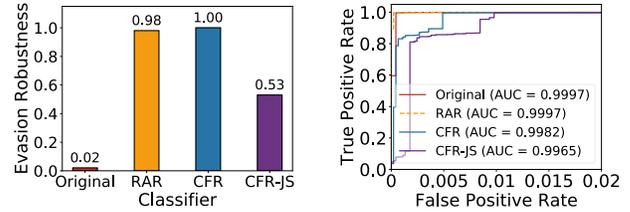

Figure 8: Evasion robustness (left) and performance on non-adversarial data (right) of different variants of Hidost.

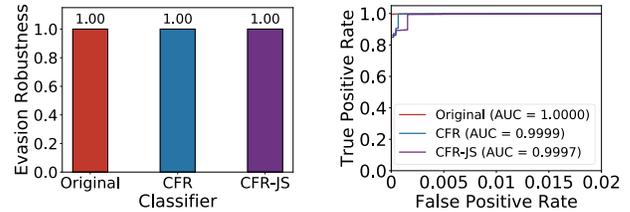

Figure 9: Evasion robustness (left) and performance on non-adversarial data (right) of different variants of PDFRate-B.

### 6.2.3 Binarized PDFRate

Finally, we evaluate the effectiveness of the CFR variants of PDFRate-B. We observe that both the *CFR* and *CFR-JS* classifiers in the PDFRate-B family achieve 100% evasion robustness against EvadeML (Figure 9 (left)), just as the RAR and FSR counterparts had.

However, a close look at Figure 9 (right) demonstrates that CFR and CFR-JS achieve far better performance on non-adversarial data, with  $>99.9\%$  AUC, where improvements are particularly significant for small false positive rates compared to FSR (recall Figure 5 (right)). Moreover, in this experiment, CFR achieves slightly higher TPR than CFR-JS for low FPR regions (below 0.003). The main takeaway here is that although the feature-space approach already yields high robustness in this setting, introducing conserved features significantly mitigates its degradation in performance on non-adversarial data.

## 7 Additional Realizable Evasion Attacks

So far we used EvadeML as the primary realizable attack in our experiments. This choice is defensible, as EvadeML explores a significantly larger attack space than many other evasion methods (e.g., Mimicry [37]), allowing deletions and swaps, in addition to insertions. Nevertheless, it is natural to wonder whether classifiers robust to EvadeML remain robust to other classes of evasion attacks. A particularly intriguing question is how the classifiers hardened against EvadeML fare in comparison with classifiers hardened against feature-space models, when faced with different realizable attacks.

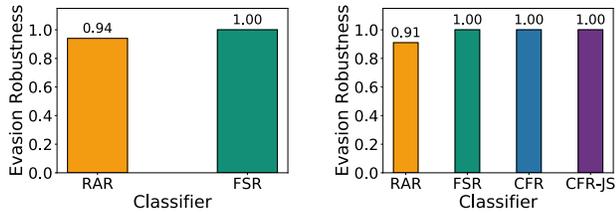

Figure 10: Robustness to Mimicry attack. Left: PDFRate-R (note that our notion of CFR is not applicable here). Right: PDFRate-B.

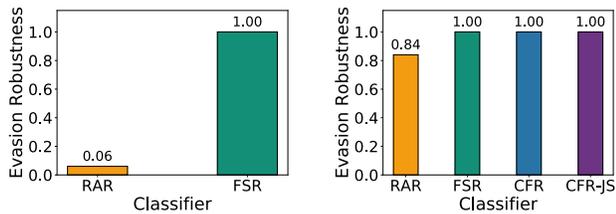

Figure 11: Robustness to Mimicry+ attack. Left: PDFRate-R (note that our notion of CFR is not applicable here). Right: PDFRate-B.

To answer these questions, we consider *five* additional realizable attacks: *Mimicry* [37], which was one of the first realizable attacks on PDF malware detectors, *Mimicry+*, an enhanced variant of *Mimicry*, *MalGAN* [19], which uses Generative Adversarial Networks (GANs) to create evasion attacks (but only targets binary classifiers), *Reverse Mimicry* [26], which inserts malicious payloads into target benign files, and a new custom attack aimed at defeating PDFRate-B conserved features. The *Mimicry/Mimicry+* attacks are designed specifically for PDFRate, and cannot be usefully applied to SL2013 or Hidost, whereas the *Reverse Mimicry* attack and our custom attack require *zero knowledge* of target classifiers.

## 7.1 Mimicry and Mimicry+ Attacks

We start by considering the *Mimicry* and *Mimicry+* attacks for both real-valued and binarized variants of PDFRate, with the same 100 malicious seeds employed in Section 5 and 6 as attack files.

The results are shown in Figures 10 and 11, and offer two noteworthy findings. First, as can be seen in Figure 11, RAR classifiers (hardened specifically against EvadeML, recall that the original PDFRate-B classifier is equivalent to RAR) can be quite vulnerable to the *Mimicry+* attack, whereas both FSR and CFR classifiers remain robust. Second, *Mimicry+* is indeed a much stronger attack than *Mimicry*: the original *Mimicry* fails to significantly degrade RAR performance, whereas *Mimicry+* largely evades the RAR variant of PDFRate-R, and is somewhat more potent against PDFRate-B

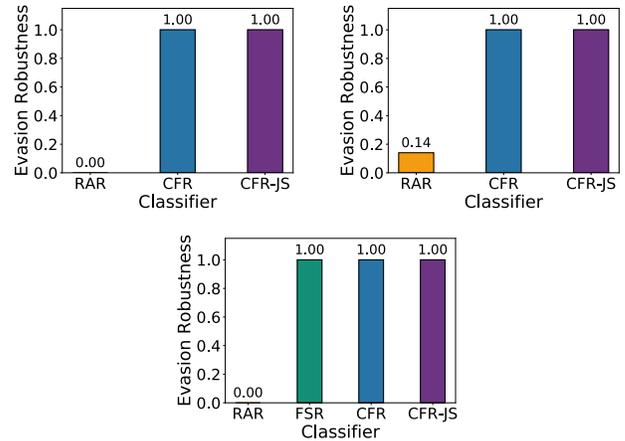

Figure 12: Robustness to MalGAN attack. SL2013 (top left), Hidost (top right), PDFRate-B (bottom).

than *Mimicry*. This demonstrates that besides its mathematical elegance, the abstract feature-space evasion models, once appropriately anchored to the domain, are rather generally robust to evasion attacks.

## 7.2 MalGAN Attack

Next, we consider the *MalGAN* attack on the three classifiers over binary feature space we have previously studied: SL2013, Hidost, and PDFRate-B, with RAR and FSR/CFR versions that have been shown robust to EvadeML.

The results, shown in Figure 12, demonstrate that despite EvadeML being a powerful attack, the RAR approaches which use it for hardening (with resulting classifiers no longer very vulnerable to EvadeML) are *highly* vulnerable to *MalGAN*, with evasion robustness of 0% in most cases. In contrast, CFR models which use conserved features remain highly robust (100% in all cases), just as we had observed earlier.

## 7.3 Reverse Mimicry Attack

Next, we employ the *Reverse Mimicry* attack on the EvadeML-robust variants of all the classifier types (SL2013, Hidost, PDFRate-R, and PDFRate-B).

Figure 13 presents the results, which are revealing in several ways. First, we again observe that RAR (hardened specifically against EvadeML) is roundly defeated in most cases. Second, consider the robustness results for the classifier using only the conserved features (CF), we can see that reverse mimicry succeeds in defeating conserved features for a non-trivial proportion of instances. It does so by including Javascript tags in structural paths that are not used as features by SL2013/Hidost (since these classifiers only consider commonly occurring sets of structural paths). Thus, this attack reveals an important vulnerability in the feature extraction

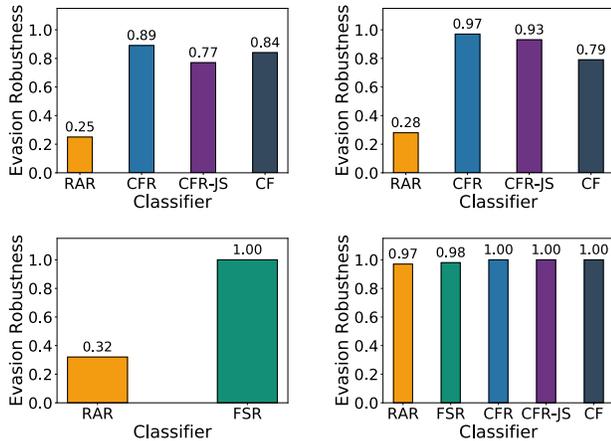

Figure 13: Robustness to Reverse Mimicry attack. SL2013 (top left), Hidost (top right), PDFRate-R (bottom left), PDFRate-B (bottom right). Note that our notions of CFR and CF for PDFRate-R is not applicable here.

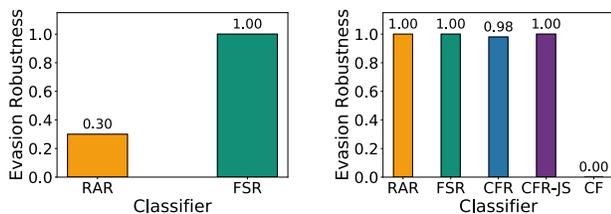

Figure 14: Robustness to the custom attack. Left: PDFRate-R (note that our notions of CFR and CF are not applicable here). Right: PDFRate-B.

approach employed by these classifiers; indeed, it suggests that structure-based classifiers may be *inherently* difficult to harden. Remarkably, CFR remains more robust than CF despite these vulnerabilities. The case of Hidost is particularly stark: CFR is nearly 20% more robust than CF!

## 7.4 The Custom Attack

Our final attack specifically targets a feature extraction bug in the Mimicus implementation of PDFRate in order to defeat the corresponding CF classifier.

The results are shown in Figure 14. We find that after this attack, CF robustness is 0. We also observe that the robustness of RAR classifier for PDFRate-R also drops, although to 0.3 rather than 0. Significantly, the FSR classifiers for both PDFRate-R and PDFRate-B remain 100% robust, and the CFR variant of PDFRate-B has nearly perfect robustness (0.98) against this attack. Our latter observation is particularly remarkable: although the conserved features are roundly defeated by this attack, the use of these as a part of a holis-

tic retraining approach yields a classifier that remains robust. Thus, not only is it possible to construct a robust malware classifier without unduly relying on conserved features, but we can accomplish this through iterative retraining in feature space.

## 8 Related Work

Below we briefly describe some of the related literature on adversarial evasion or adversarial example attacks and defenses; we refer readers to Vorobeychik and Kantarcioglu [40] for a broader and more in-depth treatment of the subject of ML attacks and defenses.

**Evasion and Adversarial Example Attacks:** An early realizable evasion attack on machine learning was devised by Fogla et al. [11, 12], who developed an attack on anomaly-based intrusion detection systems. Šrndic and Laskov [37] present a case study of an evasion attack on a state-of-the-art PDF malware classifier, PDFRate. Xu et al. [44] propose EvadeML, a fully realizable attack on PDF malware classifiers which generates evasion instances by using genetic programming to modify PDF source directly, using a sandbox to ensure that malicious functionality is preserved. Grosse et al. [16] develop a method for generating evasion attacks against a deep learning-based Android malware classifier, using a gradient-based approach which is also a form of iterative improvement heuristics, but chooses the best coordinate to improve in each iteration as evaluated by the gradient, rather than random coordinate as in our case. Their approach likely requires fewer steps than coordinate greedy, but since we run coordinate greedy until convergence, this difference isn't important in our study. Moreover, we also optimize among several local optima through random restarts, which is likely to obtain better evasion solutions (Grosse et al. [16] stop as soon as an evasion is found, rather than trying to identify the most benign looking malware). This particular attack can be viewed as realizable, even though it wasn't implemented and evaluated in actual malware, since the attack space is significantly restricted to only add features that do not interfere with others already present. Similarly, MalGAN, an evasion attack based on generative adversarial networks developed by Hu and Tan [19], only adds features from benign to malicious malware, and we treat it as a realizable attack (since it's not difficult to implement).

In addition to classifier evasion methods which change the actual malicious instances (or are relatively direct to implement as such), a number of techniques have sprouted for modeling adversarial examples in feature space [1–4, 7, 9, 15, 21, 21–24, 28, 41, 45]. Moreover, a series of efforts explore evasion in the context of image classification by deep neural networks [15, 20, 31, 33], although Gilmer et al. [13] question the common threat models used in these works. Several recent approaches attempt to generate adversarial examples against computer vision systems in physical space, such as

adding stickers to a stop sign to cause misclassification, or wearing printed glass frames to fool face recognition, and are therefore somewhat analogous to our notion of realizable attacks [10, 33].

**Evasion-Robust Classification:** Dalvi et al. [9] presented the first approach for evasion-robust classification. A series of approaches formulate robust classification as minimizing maximum loss (i.e., following a robust optimization paradigm), where maximization is attributed to the evading attacker aiming to maximize the learner’s loss through small feature-space transformations [25, 32, 39, 42, 46]. A number of alternative methods for designing classifiers consider the interaction as a non-zero-sum game [5, 6, 21–23]. Finally, a series of iterative retraining procedures have been proposed, both for general adversarial evasion [21, 23], and specifically for deep learning methods for vision [15, 20, 25] (note that Madry et al. [25] fall into both robust optimization and retraining buckets, since their approach is equivalent to retraining if stochastic gradient descent simply continues by processing adversarial examples as they are added). These diverse efforts share one common property: attack models that they leverage use feature-space manipulations, which are only a proxy for realizable attacks on ML.

## 9 Discussion and Conclusion

We undertook an extensive exploration of the extent to which robust ML that uses the conventional feature-space models of evasion attacks remains robust to “real” attacks that can be implemented in actual malware and preserve malicious functionality (what we call realizable attacks). Our first intriguing observation is that defense based on feature-space models can fail to achieve satisfactory robustness. This in itself raises some doubts about the nearly universal focus on such models as a means for ML defense, and suggests that practical usefulness of such approaches cannot be taken for granted. However, we also show that changing the nature of the feature space can make a difference: robust ML with feature-space models is quite robust in content-based detection (which uses content, rather than structural paths, as features). Additionally, we presented a refined version of the feature-space model that makes use of conserved features (which we can identify automatically, as shown in the Appendix), and showed that where feature-space defense previously failed, it now succeeds. Our final finding may well be the most intriguing: feature-space approaches exhibit generalized robustness, in that the resulting robust ML (after appropriate refinement using conserved features) exhibits robustness to multiple realizable attacks. This contrasts with defense that is hardened using a *specific* realizable attack—even one quite powerful on the surface (EvadeML)—which can fail dramatically when faced with a different attack. These findings demonstrate the power of effective mathematical abstractions in security.

It is natural to wonder how our approach and results are

applied to other domains. In computer vision, the analog of realizable malware attacks are physical attacks, whereby the physical environment is modified, rather than the digital object, such as an image. Here, the corresponding foundational question is whether common robust ML methods based on small- $l_p$  attacks successfully protect against physical attacks. The notion of conserved features can also be seen as more generally applicable. For example, in a bag-of-words representation for spam filtering, these could correspond to the existence of URL or file attachments, and in SQL injection attacks, these may refer to the existence of specific SQL commands, such as `Select`.

The main limitation of our study is in the specific choices we had to make to ensure that it is tractable. We chose a particular defensive paradigm—iterative retraining. As we have argued, it is the only paradigm that can fit every case that we investigate; for example, there is no other general approach for learning a robust SVM with non-linear kernels. However, it is possible that approaches based on robust optimization, if they were developed, can improve performance by taking advantage of the special structure of this problem. We implemented a particular class of feature-space attacks, using  $l_2$  norm to measure the attacker’s cost of feature manipulations, and stochastic local search to compute evasions. It is possible that better attack algorithms for generating attacks over binary domains will be developed, and, indeed, some alternatives exist. However, prior work suggests that this approach yields attacks that are close to optimal [23], with the use of random restarts playing a crucial role. Finally, our study was specific to PDF malware detection. However, our framework is quite general, and could be used in the future to consider other similar questions, such as the effectiveness of robust deep learning against physical attacks. Several additional limitations offer further opportunities for future work. One example is the fact that we only define conserved features when these are binary; it may be that finding meaningful conserved features in continuous feature spaces is inherently more difficult. Another issue is the surprising finding that sufficient anchoring of feature-space defense in the domain using conserved features allows us to achieve robustness, *even when conserved features can be circumvented*. It may be that conserved features are ultimately only a part of the solution, and only help if they adequately capture the attack surface in the abstract feature space. The extent to which small variations in the set of identified conserved features matters is also an open question: our evidence is mixed, with “expert”-defined features usually, but not always, sufficient for robustness.

## Appendix

### A Identifying Conserved Features

We now describe a systematic automated procedure for identifying these. We first introduce how to identify conserved features of SL2013, and then describe how to generalize the approach to extract conserved features of Hidost.

The key to identifying the conserved features of a malicious PDF is to discriminate them from non-conserved ones. Since merely applying statistical approaches on training data is insufficient to discriminate between these two classes of features, as demonstrated above, we need a qualitatively different approach which relies on the nature of evasions (as implemented in EvadeML) and the sandbox (which determines whether malicious functionality is preserved) to identify features that are conserved.

We use a modified version of pdfwr [27]<sup>5</sup> to parse the objects of PDF file and repack them to produce a new PDF file. We use Cuckoo [17] as the sandbox to evaluate malicious functionality. In the discussion below, we define  $x_i$  to be the malicious file,  $S_i$  the conserved feature set of  $x_i$ , and  $O_i$  the set of its non-conserved features. Initially,  $S_i = O_i = \emptyset$ .

At the high level, our first step is to sequentially delete each object of a malicious file and eliminate non-conserved features by evaluating the existence of a malware signature in a sandbox for each resulting PDF, which provides a preliminary set of conserved features. Then, we replace the object of each corresponding structural path in the resulting preliminary set with an external benign object and assess the corresponding functionality, which allows us to further prune non-conserved features. Next, we describe these procedures in detail.

#### A.1 Structural Path Deletion

In the first step, we filter out non-conserved features by deleting each object and its corresponding structural path, and then checking whether this eliminates malicious functionality (and should therefore be conserved). First, we obtain all the structural paths (objects) by parsing a PDF file. These objects are organized as a tree-topology and are sequentially deleted. Each time an object is removed, we produce a resulting PDF file by repacking the remaining objects. Then, we employ the sandbox to detect malicious functionality of the PDF after the object deletion. If any malware signature is captured, the corresponding structural path of the object is deleted as a non-conserved feature, and added to  $O_i$ . On the other hand, if no malware signature is detected, the corresponding feature is added in  $S_i$  as a *possibly* conserved feature.

One important challenge in this process is that features are not necessarily independent. Thus, in addition to identifying  $S_i$  and  $O_i$ , we explore *interdependence* between features by

<sup>5</sup>The modified version is available at <https://github.com/mzweilin/pdfwr>.

deleting objects. As the logic structure of a PDF file is with a tree-topology, the presence of some structural path depends on the presence of other structural paths whose object refers to the object of the prior one. We define that a structural path is a dependent of another if unilateral deleting the object associated with the latter causes a flip from 1 to 0 on the feature value of the former. For any feature  $j$  of  $x_i$ , we denote the set of features that depend on  $j$  by  $D_i^j$ . Note that for a given structural path (feature), there could be multiple corresponding PDF objects. In such a case, these objects are deleted simultaneously, so as the corresponding feature value is shifted from 1 to 0.

#### A.2 Structural Path Replacement

In the second step, we subtract the remaining non-conserved features in the preliminary  $S_i$  and move them to  $O_i$ . Similar to the prior step, we first obtain all the structural paths and objects of the malicious PDF file. Then for each object of the PDF that is in  $S_i$ , we replace it with an external object from a benign PDF file and produce the resulting PDF, which is further evaluated in the sandbox. If the sandbox detects any malware signature, then the corresponding structural path of the object replaced is moved from  $S_i$  to  $O_i$ . Otherwise, the structural path is a conserved feature since both deletion and replacement of the corresponding object removes the malicious functionality of the PDF file. Note that in the case of multiple corresponding and identical objects of a structural path, all of these objects are replaced simultaneously.

After structural path deletion and replacement, for each malicious PDF file  $x_i$ , we can get its conserved feature set  $S_i$ , non-conserved feature set  $O_i$ , and dependent feature set  $D_j$  for any feature  $j \in S_i \cup O_i$ , which could be further leveraged to design evasion-robust classifiers.

#### A.3 Obtaining a Uniform Conserved Feature Set

The systematic approach discussed above provides a conserved feature set for each malicious seed to retrain a classifier. Our goal, however, is to identify a single set of conserved features which is *independent* of the specific malicious PDF seed file. We now develop an approach for transforming a collection of  $S_i$ ,  $O_i$ , and  $D_i^j$  for a set of malicious seeds  $i$  into a *uniform* set of conserved features.

Obtaining a uniform set of conserved features faces two challenges: 1) minimizing conflicts among different conserved features, as a conserved feature for one malicious instance could be a non-conserved feature for another, and 2) abiding by feature interdependence if a conserved feature should be further eliminated.

To address these challenges, we propose a *Forward Elimination* algorithm to compute the uniform conserved feature

**Algorithm 1** Forward Elimination for uniform conserved feature set.

**Input:**

The set of conserved features for  $x_i (i \in [1, n])$ ,  $S_i$ ;  
The set of non-conserved features for  $x_i (i \in [1, n])$ ,  $O_i$ ;  
The set of dependent features for  $j \in S_i \cup O_i$ ,  $D_i^j$ ;

**Output:**

The uniform conserved feature set for  $\{x_1, x_2, \dots, x_n\}$ ,  $S$ ;

```

1:  $S \leftarrow \bigcup_{i=1}^n S_i$ ;
2:  $S' \leftarrow S$ ;
3:  $Q \leftarrow \emptyset$ ;
4:  $D^j = \bigcup_{i=1}^n D_i^j$ ;
5: for each  $j \in S'$  do
6:   if  $j \notin Q$  then
7:     if  $\sum_{i=1}^n \mathbb{1}_{j \in O_i} \geq \beta \cdot \sum_{i=1}^n \mathbb{1}_{j \in S_i}$  then
8:        $S \leftarrow S \setminus (\{j\} \cup D^j)$ ;
9:        $Q \leftarrow Q \cup (\{j\} \cup D^j)$ ;
10:    end if

set for a set of malicious seeds  $\{x_1, x_2, \dots, x_n\}$ , given the conserved feature sets, non-conserved feature sets and dependent sets for each seed. As Algorithm 1 shows, we first obtain a union of the conserved feature sets. Then, we explore the contradiction of each feature in the union with the others, by comparing the total number of the feature being selected as a non-conserved feature and conserved feature. If the former one is greater than  $\beta$  times the latter one, then this feature, together with its dependents, are eliminated from the union. Otherwise, the feature is added to the uniform feature set. We use  $\beta$  as a parameter to adjust the balance between conserved and non-conserved features. Typically,  $\beta > 1$  as we are inclined to preserve malicious functionality associated with a conserved feature, even it could be a non-conserved feature of another PDF file. We set  $\beta = 3$  in our experiments.

#### A.4 Identifying Conserved Features for Other Classifiers

Once we obtain conserved features of SL2013 for each malicious seeds, we can employ these features to identify conserved features for other classifiers using binary features. As our approach relies on the existence of malicious functionality and corresponding features, such a relation is not obvious for real-valued features; we therefore leave the question of how to define and identify conserved features in real space for future work.

**Hidost** Hidost and SL2013 are similar in nature in such a way that they employ structural paths as features. The only difference is that Hidost consolidates features of SL2013 as described in Section 4. Therefore, once the conserved fea-

tures of SL2013 are identified, we can simply apply the *PDF structural path consolidation rules* described in Srndic and Laskov [38] to transform these features to the corresponding conserved features for Hidost.

**Binarized PDFRate** We identify the conserved features for PDFRate-B by using the conserved feature set  $S_i$  of each seed  $x_i$ . For each  $x_i$ , we generate  $|S_i|$  PDF files, each of which corresponds to the PDF file when an element (structural path) in  $S_i$  is deleted. We then compare PDFRate-B features of these PDFs to the original  $x_i$ . If any feature value of  $x_i$  is flipped from 1 to 0, then this feature will be added in the conserved feature set of  $x_i$  for PDFRate-B. Afterward, we use Algorithm 1 to obtain the uniform conserved feature set. This approach can in fact be used for arbitrary PDF malware detectors over binary features (leveraging conserved structural paths identified using SL2013).

#### A.5 Conserved Features

Table 3 presents the full list of conserved features we identified for each classifier.

#### A.6 Conserved vs. Regularized Features

In our experiments, we empirically adjust the SVM parameter  $C$  to study the overlap between *conserved features* and those selected by  $l_1$  regularization. We first adjust  $C$  to perform feature reduction until the number of features is identical to the number of conserved features. In this case, sparse versions of both SL2013 and Hidost include only 3 of the conserved features, while sparse PDFRate-B includes only 1. In another experiment, we adjusted  $C$  until all conserved features were selected. In this case, SL2013 requires 510 features, Hidost needs 154, and PDFRate-B needs 83.

## Abstract

Malware detection is a popular application of Machine Learning for Information Security (ML-Sec), in which an ML classifier is trained to predict whether a given file is malware or benignware. Parameters of this classifier are typically optimized such that outputs from the model over a set of input samples most closely match the samples true malicious/benign (1/0) target labels. However, there are often a number of other sources of contextual metadata for each malware sample, beyond an aggregate malicious/benign label, including multiple labeling sources and malware type information (e.g. *ransomware*, *trojan*, etc.), which we can feed to the classifier as auxiliary prediction targets. In this work, we fit deep neural networks to multiple additional targets derived from metadata in a threat intelligence feed for Portable Executable (PE) malware and benignware, including a multi-source malicious/benign loss, a count loss on multi-source detections, and a semantic malware attribute tag loss. We find that incorporating multiple auxiliary loss terms yields a marked improvement in performance on the main detection task. We also demonstrate that these gains likely stem from a more informed neural network representation and are not due to a regularization artifact of multi-target learning. Our auxiliary loss architecture yields a significant reduction in detection error rate (false negatives) of 42.6% at a false positive rate (FPR) of  $10^{-3}$  when compared to a similar model with only one target, and a decrease of 53.8% at  $10^{-5}$  FPR.

## 1 Introduction

Machine learning (ML) for computer security (ML-Sec) has proven to be a powerful tool for malware detection. ML models are now integral parts of commercial anti-malware engines and multiple vendors in the industry have dedicated ML-Sec teams. For the malware detection problem, these

models are typically tuned to predict a binary label (malicious or benign) using features extracted from sample files. Unlike signature engines, where the aim is to reactively blacklist/whitelist malicious/benign samples that hard-match manually-defined patterns (signatures), ML engines employ numerical optimization on parameters of highly parameterized models that aim to learn more general concepts of *malware* and *benignware*. This allows some degree of proactive detection of previously unseen malware samples that is not typically provided by signature-only engines.

Frequently, malware classification is framed as a binary classification task using a simple binary cross-entropy or two-class softmax loss function. However, there often exist substantial metadata available at training time that contain more information about each input sample than just an aggregate label of whether it is malicious or benign. Such metadata might include malicious/benign labels from multiple sources (e.g., from various security vendors), malware family information, file attributes, temporal information, geographical location information, counts of affected endpoints, and associated tags. In many cases this metadata will not be available when the model is deployed, and so in general it is difficult to include this data as features in the model (although see Vapnik et al. [28, 29] for one approach to doing so with Support Vector Machines).

It is a popular practice in the domain of malware analysis to derive binary malicious/benign labels based on a heuristic combination of multiple detection sources for a given file, and then use these noisy labels for training ML models [9]. However, there is nothing that precludes training a classifier to predict each of these source labels simultaneously optimizing classifier parameters over these predictions + labels. In fact, one might argue intuitively that guiding a model to develop representations capable of predicting multiple targets simultaneously may have a smoothing or regularizing effect conducive to generalization, particularly if the auxiliary targets are related to the main target of interest. These auxiliary targets can be ignored during test time if they are ancillary to the task at hand (and in many cases the extra

\* Equal contribution.

Contact: <firstname>.<lastname>@sophos.com

weights required to produce them can be removed from the model prior to deployment), but nevertheless, there is much reason to believe that forcing the model to fit multiple targets simultaneously can improve performance on the key output of interest. In this work, we take advantage of multi-target learning [2] by exploring the use of metadata from threat intelligence feeds as auxiliary targets for model training.

Research in other domains of applied machine learning supports this intuition [14, 19, 12, 31, 1, 22], however outside of the work of Huang et al. [11], multi-target learning has not been widely applied in anti-malware literature. In this paper, we present a wide-ranging study applying auxiliary loss functions to anti-malware classifiers. In contrast to [11], which studies the addition of a single auxiliary label for a fundamentally different task, i.e., malware family classification – we study both the addition of multiple label sources for the same task and multiple label sources for multiple separate tasks. Also, in contrast to [11], we do not presume the presence of all labels from all sources, and introduce a per-sample weighting scheme on each loss term to accommodate missing labels in the metadata. We further explore the use of multi-objective training as a way to expand the number of trainable samples in cases where the aggregate malicious/benign label is unclear, and where those samples would otherwise be excluded from purely binary training.

Having established for which loss types and in which contexts auxiliary loss optimization works well, we then explore *why it works well*, via experiments designed to test whether performance gains are a result of a regularization effect from multi-objective training or information from the content of the target labels that the network has learned to correlate.

In summary, this paper makes the following contributions:

- A demonstration that including auxiliary losses yields improved performance on the main task. When all of our auxiliary loss terms are included, we see a reduction of 53.8% in detection error (false negative) rate at  $10^{-5}$  false positive rate (FPR) and a 42.6% reduction in detection error rate at  $10^{-3}$  FPR compared to our baseline model. We also see a consistently better and lower-variance ROC curve across all false positive rates.
- A breakdown of performance improvements from different auxiliary loss types. We find that an auxiliary Poisson loss on detection counts tends to yield improved detection rates at higher FPR areas ( $\geq 10^{-3}$ ) of the ROC curve, while multiple binary auxiliary losses tend to yield improved detection performance in lower FPR areas of the ROC curve ( $< 10^{-3}$ ). When combined we see a net improvement across the entire ROC curve over using any single auxiliary loss type.
- An investigation into the mechanism by which multi-objective optimization yields enhanced performance, including experiments to assess possible regularization effects.

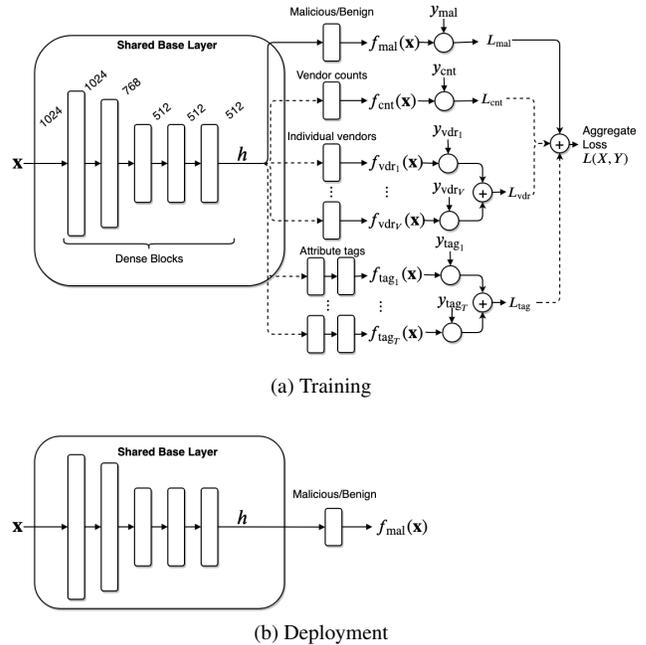

Figure 1: Schematic overview of our neural network architecture. (a) During training multiple output layers with corresponding loss functions are optionally connected to a common base topology consisting of five dense blocks (see Section 3) of sizes 1024, 768, 512, 512, and 512. This base, connected to our main malicious/benign output (solid line in the figure) with a loss on the aggregate label, constitutes our baseline architecture. Auxiliary outputs and their respective losses are represented as dashed lines. The auxiliary losses fall into three types: count loss, multi-label vendor loss, and multi-label attribute tag loss. The formulation of each of these auxiliary loss types is explained in Section 3. (b) At deployment time, these auxiliary tags outputs are removed and we predict only the main label.

We see our auxiliary loss approach as specifically useful for both endpoint and cloud deployed models in cases when the auxiliary information cannot be directly used as input into the model at prediction time, but can be collected for a training dataset. This could be due to high cost, performance issues, latency concerns, or a multitude of other constraints during prediction time. For example, it is not feasible to scan every new file executed on an endpoint via a threat intelligence feed, because of prohibitive licensing fees, endpoint latency and bandwidth limitations, as well as customer privacy concerns. However, procuring reports from such a feed for large training sets might be feasible offline.

The remainder of this paper is laid out as follows: First, in Section 2 we discuss some of the metadata available for use as auxiliary targets, and feature extraction methods for portable executable (PE) files. We then provide details on how we converted the available metadata into auxiliary tar-

gets and losses, as well as how the individual losses are weighted and combined on a per-sample basis in Section 3. We finish that Section with a description of how our dataset was collected and provide summary statistics. In Section 4 we describe our experimental evaluations across a number of combinations of auxiliary targets, and demonstrate the impact of fitting these targets on the performance of the main malware detection task. Section 5 presents discussion of our results, as well as a set of experiments on synthetic targets to explore potential explanations for the observed improvements. Section 6 presents related work and Section 7 concludes.

## 2 ML-Sec Detection Pipelines: From Single Objective to Multi-Objective

In the following, we describe a simplified ML-Sec pipeline for training a malicious file classifier, and propose a simple extension that allows the use of metadata available during training (but not at test time) and improves performance on the classification task.

ML-Sec detection pipelines use powerful machine learning models that require many labeled malicious and benign samples to train. Data is typically gathered from several sources, including deployed anti-malware products and vendor aggregation services, which run uploaded samples through vendor products and provide reports containing per-vendor detections and metadata. The exact nature of the metadata varies, but typically, malicious and benign scores are provided for each of  $M$  individual samples on a per-vendor basis, such that, given  $V$  vendors, between 0 and  $V$  of them will designate a sample malicious. For a given sample, some vendors may choose not to answer, resulting in a missing label for that vendor. Furthermore, many vendors also provide a detection name (or malware family name) when they issue a detection for a given file. Additional information may also be available, but crucially, the following metadata are presumed present for the models presented in this paper: i) per-vendor labels for each sample, either malicious/benign (mapped to binary 1/0, respectively) or NULL; ii) textual per-vendor labels on the sample describing the family and variant of the malware (an empty string if benign or NULL); and iii) time at which the sample was first seen.

Using the individual vendor detections, an aggregate label can be derived either by a voting mechanism or by thresholding the net number of vendors that identify a given sample as malicious. The use of aggregated anti-malware vendor detections as a noisy labeling source presumes that the vendor diagnoses are generally accurate. While this is not necessarily a valid assumption, e.g., for novel malware and benignware, this is typically accounted for by using samples and metadata that are slightly dated so that vendors can correct their respective mistakes (e.g., by blacklisting samples

in their signature databases).

Each malware/benignware sample must also be converted to a numerical vector to be able to train a classifier, a process called *feature extraction*. In this work we focus on static malware detection, meaning that we assume only access to the binary file, as opposed to dynamic detection, in which the features used predominantly come from the execution of the file. The feature extraction mechanism varies depending on the format type at hand, but consists of some numerical transformation that preserves aggregate and fine-grained information throughout each sample, for example, the feature extraction proposed by Saxe et al. [25] – which we use in this work – uses windowed byte statistics, 2D histograms of delimited string hash vs. length, and histograms of hashes of PE-format specific metadata – e.g., imports from the import address table (IAT).

Given extracted features and derived labels, a classifier is then trained, tuning parameters to minimize misclassification as measured by some loss criterion, which under the constraints of a statistical noise model measures the deviation of predictions from their ground truth. For both neural networks and ensemble methods a logistic sigmoid is commonly used to constrain predictions to a  $[0,1]$  range, and a cross-entropy loss between predictions and labels is used as the minimization criterion under a Bernoulli noise model per-label.

While the prior description roughly characterizes ML-Sec pipelines discussed in literature to date, note that much information in the metadata, which is often not used to determine the sample label but *is* correlated to the aggregate classification, is not used in training, e.g., the individual vendor classifications, the combined number of detections across all vendors, and information related to malware type that could be derived from the detection names. In this work, we augment a deep neural network malicious/benign classifier with additional output predictions of vendor counts, individual vendor labels, and/or attribute tags. These separate prediction arms were given their own loss functions which we jointly minimized through backpropagation. The difference between a conventional malware detection pipeline and our model can be visualized by considering Figure 1 in the absence and presence of auxiliary outputs (and their associated losses) connected by the dashed lines. In the next section, we shall explore the precise formulation and implementation of these different loss functions.

## 3 Implementation Details

In this section we describe our implementation of the experiments sketched above. We first introduce our model immediately below, followed by the various loss functions – denoted by  $L_{\text{loss type}}(X, Y)$  for some input features  $X$  and targets  $Y$  – associated with the various outputs of the model, as well as how the labels  $Y$  representing the targets of these outputs are

constructed. Finally we discuss how our data set of  $M$  samples associated with  $V$  vendor targets is collected. We use the same feature representation as well as the same general model class and topology for all experiments. Each portable executable file is converted into a feature vector as described in [25].

The base for our model (see Figure 1) is a feedforward neural network incorporating multiple blocks composed of Dropout [27], a dense layer, batch normalization [13], and an exponential linear unit (ELU) activation [7]. The core of the model contains five such blocks with 1024, 768, 512, 512, and 512 hidden units, respectively. This base topology applies the function  $f(\cdot)$  to the input vector to produce an intermediate 512 dimensional representation of the input file  $\mathbf{h} = f(\mathbf{x})$ . We then append to this model an additional block, consisting of one or more dense layers and activation functions, for each output of the model. We denote the composition of our base topology and our target-specific final dense layers and activations applied to features  $\mathbf{x}$  by  $f_{\text{target}}(\mathbf{x})$ . The output for the main malware/benign prediction task –  $f_{\text{mal}}(\mathbf{x})$  – is always present and consists of a single dense layer followed by a sigmoid activation on top of the base shared network that aims to estimate the probability of the input sample being malicious. A network architecture with only this malware/benign output serves as the baseline for our evaluations. To this baseline model we add auxiliary outputs with similar structure as described above: one fully connected layer (two for the *tag* prediction task in Section 3.4) which produces some task-specific number of outputs (a single output, with the exception of the restricted generalized Poisson distribution output, which uses two) and some task-specific activation described in the associated sections below.

Except where noted otherwise, all multi-task losses were produced by computing the sum, across all tasks, of the per-task loss multiplied by a task-specific weight (1.0 for the malware/benign task and 0.1 for all other tasks; see Section 4). Training was standardized at 10 epochs; for all experiments we used a training set of 9 million samples and a test set of approximately 7 million samples. Additional details about the training and test data are reported in Section 3.6. Additionally, we used a validation set of 100,000 samples to ensure that each network had converged to an approximate minimum on validation loss after 10 epochs. All of our models were implemented in Keras [6] and optimized using the Adam optimizer [15] with Keras’s default parameters.

### 3.1 Malware Loss

As explained in Section 2, for the task of predicting if a given binary file, represented by its features  $\mathbf{x}^{(i)}$ , is malicious or benign we used a binary cross-entropy loss between the malware/benign output of the network  $\hat{y}^{(i)} = f_{\text{mal}}(\mathbf{x}^{(i)})$  and the malicious label  $y^{(i)}$ . This results in the following loss for a dataset with  $M$  samples:

$$\begin{aligned} L_{\text{mal}}(X, Y) &= \frac{1}{M} \sum_{i=1}^M \ell_{\text{mal}}(f_{\text{mal}}(\mathbf{x}^{(i)}), y^{(i)}) \\ &= -\frac{1}{M} \sum_{i=1}^M y^{(i)} \log(\hat{y}^{(i)}) + (1 - y^{(i)}) \log(1 - \hat{y}^{(i)}). \end{aligned} \quad (1)$$

In this paper, we use a “1-/5+” criterion for labeling a given file as malicious or benign: if a file has one or fewer vendors reporting it as malicious, we label the file as ‘benign’ and use a weight of 1.0 for the malware loss for that sample. Similarly, if a sample has five or more vendors reporting it as malicious, we label the file as ‘malicious’ and use a weight of 1.0 for the malware loss for that sample.

### 3.2 Vendor Count Loss

To more finely distinguish between positive results, we investigate the use of the total number of ‘malicious’ reports for a given sample from the vendor aggregation service as an additional target; the rationale being that a sample with a higher number of malicious vendor reports should, all things being equal, be more likely to be malicious. In order to properly model this target, we require a suitable noise model for count data. A popular candidate is a Poisson noise model, parameterized by a single parameter  $\mu$ , which assumes that counts follow a Poisson process, where  $\mu$  is the mean and variance of the Poisson distribution. The probability of an observation of  $y$  counts conditional on  $\mu$  is

$$P(y|\mu) = \mu^y e^{-\mu} / y!. \quad (2)$$

In our problem, as we expect the mean number of positive results for a given sample to be related to the file itself, we attempt to learn to *estimate*  $\mu$  conditional on each sample  $\mathbf{x}^{(i)}$  in such a way that the likelihood of  $y^{(i)}|\mu^{(i)}$  is maximized (or, equivalently, the negative log-likelihood is minimized). Denote the output of the neural network with which we are attempting to estimate the mean count of vendor positives for sample  $i$  as  $f_{\text{cnt}}(\mathbf{x}^{(i)})$ . Note that under a non-distributional loss, this would be denoted by  $\hat{y}^{(i)}$ , however since we are fitting a parameter of a distribution, and not the sample label  $y$  directly, we use different notation in this section. By taking some appropriate activation function  $a(\cdot)$  that maps  $f_{\text{cnt}}(\mathbf{x}^{(i)})$  to the non-negative real numbers, we can write  $\mu^{(i)} = a(f_{\text{cnt}}(\mathbf{x}^{(i)}))$ . Consistent with generalized linear model (GLM) literature [18], we use an exponential activation for  $a$ , though one could equally well employ some other transformation with the correct output range, for instance the ReLU function.

Letting  $y^{(i)}$  here denote the actual number of vendors that recognized sample  $\mathbf{x}^{(i)}$  as malicious, the corresponding negative log-likelihood loss over the dataset is

$$\begin{aligned}
L_p(X, Y) &= \frac{1}{M} \sum_{i=1}^M \ell_p \left( a \left( f_{\text{cnt}}(\mathbf{x}^{(i)}) \right), y^{(i)} \right) \\
&= \frac{1}{M} \sum_{i=1}^M \mu^{(i)} - y^{(i)} \log(\mu^{(i)}) + \log(y^{(i)}!), \quad (3)
\end{aligned}$$

which we will refer to as the *Poisson* or *vendor count* loss. In practice, we ignore the  $\log(y^{(i)})!$  term when minimizing this loss since it does not depend on the parameters of the network.

A Poisson loss is more intuitive for dealing with count data than other common loss functions, even for count data not generated by a Poisson process. This is partly due to the discrete nature of the distribution and partly because the assumption of increased variance with predicted mean is more accurate than a homoscedastic – i.e., constant variance – noise model.

While the assumption of increasing variance with predicted count value seems reasonable, it is very unlikely that vendor counts perfectly follow a Poisson process – where the mean *is* the variance – due to correlations between vendors, which might occur from modeling choice and licensing/OEM between vendor products. The variance might increase at a higher or lower rate than the count and might not even be directly proportional to or increase monotonically with the count. Therefore, we also implemented a Restricted Generalized Poisson distribution [10] – a slightly more intricate noise model that accommodates dispersion in the variance of vendor counts. Given dispersion parameter  $\alpha$ , the Restricted Generalized Poisson distribution has a probability mass function (pmf):

$$P(y|\alpha, \mu) = \left( \frac{\mu}{1 + \alpha\mu} \right)^y (1 + \alpha y)^{y-1} \exp\left( \frac{-\mu(1 + \alpha y)}{1 + \alpha\mu} \right) / y!. \quad (4)$$

When  $\alpha = 0$ , this reduces to Eq. 2.  $\alpha > 0$  accounts for over-dispersion, while  $\alpha < 0$  accounts for under-dispersion. Note that in our use case  $\alpha$ , like  $\mu$ , is estimated by the neural network and conditioned on the feature vector, allowing varying dispersion per-sample. Given the density function in Eq. 4, the resultant log-likelihood loss for a dataset with  $M$  samples is defined as:

$$\begin{aligned}
L_{\text{gp}}(X, Y) &= -\frac{1}{M} \sum_{i=1}^M \left[ y^{(i)} (\log \mu^{(i)} - \log(1 + \alpha^{(i)} \mu^{(i)})) \right. \\
&\quad + (y^{(i)} - 1) \log(1 + \alpha^{(i)} y^{(i)}) \\
&\quad \left. - \frac{\mu^{(i)}(1 + \alpha^{(i)} y^{(i)})}{1 + \alpha^{(i)} \mu^{(i)}} + \log(y^{(i)}!) \right], \quad (5)
\end{aligned}$$

where  $\alpha^{(i)}$  and  $\mu^{(i)}$  are obtained as transformed outputs of the neural network in a similar fashion as we obtain  $\mu^{(i)}$  for

the Poisson loss. In practice, as for the Poisson loss, we dropped the term related to  $y!$  since it does not affect the optimization of the network parameters.

Note also that restrictions must be placed on the negative value of the  $\alpha^{(i)}$  term to keep the arguments of the logarithm positive. For numerical convenience, we used an exponential activation over the dense layer for our  $\alpha^{(i)}$  estimator, which accommodates over-dispersion but not under-dispersion. Results from experiments comparing the use of Poisson and Generalized Poisson auxiliary losses are presented in Section 4.1.

While the Poisson distribution is a widely used model for count data, other discrete probability distributions could also be used to model the count of vendor positive results. During early experimentation we also examined the binomial, geometric, and negative binomial distributions as models for vendor counts, but found that they produced unsatisfactory results and so do not discuss them further.

### 3.3 Per-Vendor Malware Loss

The aggregation service from which we collected our data sets contains a breakout of individual vendor results per sample. We identified a subset  $\mathcal{V} = \{v_1, \dots, v_V\}$  of 9 vendors that each produced a result for (nearly) every sample in our data. Each vendor result was added as a target in addition to the malware target by adding an extra fully connected layer per vendor followed by a sigmoid activation function to the end of the shared architecture. We employed a binary cross-entropy loss per vendor during training. Note that this differs from the vendor count loss presented above in that each high-coverage vendor is used as an individual binary target, rather than being aggregated into a count. The aggregate *vendors* loss  $L_{\text{vdr}}$  for the  $V = 9$  selected vendors is simply the sum of the individual vendor losses:

$$\begin{aligned}
L_{\text{vdr}}(X, Y) &= \frac{1}{M} \sum_{i=1}^M \sum_{j=1}^V \ell_{\text{vdr}} \left( f_{\text{vdr}_j}(\mathbf{x}^{(i)}), y_{v_j}^{(i)} \right) \\
&= -\frac{1}{M} \sum_{i=1}^M \sum_{j=1}^V y_{v_j}^{(i)} \log(\hat{y}_{v_j}^{(i)}) + (1 - y_{v_j}^{(i)}) \log(1 - \hat{y}_{v_j}^{(i)}), \quad (6)
\end{aligned}$$

where  $\ell_{\text{vdr}}$  is the per-sample binary cross-entropy function and  $f_{\text{vdr}_j}(\mathbf{x}^{(i)}) = \hat{y}_{v_j}^{(i)}$  is the output of the network that is trained to predict the label  $y_{v_j}^{(i)}$  assigned by vendor  $j$  to input sample  $\mathbf{x}^{(i)}$ .

Results from experiments exploring the use of individual vendor targets in addition to malware label targets are presented in Section 4.2.

### 3.4 Malicious Tags Loss

In this experiment we attempt exploit information contained in family detection names provided by different vendors in the form of malicious tags. We define each tag as a high level description of the purpose of a given malicious sample. The tags used as auxiliary targets in our experiments are: *flooder*, *downloader*, *dropper*, *ransomware*, *crypto-miner*, *worm*, *ad-ware*, *spyware*, *packed*, *file-infector*, and *installer*.

We create these tags from a parse of individual vendor detection names, using a set of 10 vendors which from our experience provide high quality detection names. Once we have extracted the most common tokens, we filter them to keep only tokens related to well-known malware family names or tokens that could easily be associated with one or more of our tags, for example, the token *xmrig* – even though it is not a malware family – can be recognized as referring to a crypto-currency mining software and therefore can be associated with the *crypto-miner* tag. We then create a mapping from tokens to tags based on prior knowledge. We label a sample as associated with tag  $t_j$  if any of the tokens associated with  $t_j$  are present in any of the detection names assigned to the sample by the set of trusted vendors.

Annotating our dataset with these tags, allows us to define the tag prediction task as multi-label binary classification, since zero or more tags from the set of possible tags  $\mathcal{T} = \{t_1, \dots, t_T\}$  can be present at the same time for a given sample. We introduce this prediction task in order to have targets in our loss function that are not directly related to the number of vendors that recognize the sample as malicious. The vendor counts and the individual vendor labels are closely related with the definition of our main target, i.e. the malicious label, which classifies a sample as malicious if 5 or more vendors identify the sample as malware (see Section 3.1). In the case of the tag targets, this information is not present. For instance, if all the vendors recognize a given sample as coming from the *WannaCry* family in their detection names, the sample will be associated only once with the *ransomware* tag. On the converse, because of our tagging mechanism, if only one vendor considers that a given sample is malicious and classifies it as coming from the *WannaCry* family, the *ransomware* tag will be present (although our malicious label will be 0).

In order to predict these tags, we use a *multi-headed* architecture in which we add two additional layers per tag to the end of the shared base architecture, a fully connected layer of size 512-to-256, followed by a fully connected layer of size 256-to-1, followed by a sigmoid activation function, as shown in Figure 1. Each tag  $t_j$  out of the possible  $T = 11$  tags has its own loss term computed with binary cross-entropy. Like the per-vendor malware loss, the aggregate tag loss is the sum of the individual tag losses. For the dataset with  $M$  samples it becomes:

$$\begin{aligned} L_{\text{tag}}(X, Y) &= \frac{1}{M} \sum_{i=1}^M \sum_{j=1}^T \ell_{\text{tag}} \left( f_{\text{tag}_j}(\mathbf{x}^{(i)}), y_{t_j}^{(i)} \right) \\ &= -\frac{1}{M} \sum_{i=1}^M \sum_{j=1}^T y_{t_j}^{(i)} \log(\hat{y}_{t_j}^{(i)}) + (1 - y_{t_j}^{(i)}) \log(1 - \hat{y}_{t_j}^{(i)}), \end{aligned} \quad (7)$$

where  $y_{t_j}^{(i)}$  indicates if sample  $i$  is annotated with tag  $j$ , and  $\hat{y}_{t_j}^{(i)} = f_{\text{tag}_j}(\mathbf{x}^{(i)})$  is the prediction issued by the network for that value.

### 3.5 Sample Weights

While our multi-objective network has the advantage that multiple labels and loss functions serve as additional sources of information, this introduces an additional complexity: given many (potentially missing) labels for each sample, we cannot rely on having all labels for a large quantity of the samples. Moreover, this problem gets worse as more labels are added. To address this, we incorporated per-sample weights, depending on the presence and absence of each label. For labels that are missing, we assign them to a default value and then set the associated weights to zero in the loss computation so a sample with a missing target label will not add to the loss computation for that target. Though this introduces slight implementation overhead, it allows us to train our network, even in the presence of partially labeled samples (e.g., when a vendor decides not to answer).

### 3.6 Dataset

We collected two datasets of PE files and associated metadata from a threat intelligence feed: a set for training/validation and a test set. For the training/validation set, we pulled 20M PE files and associated metadata, randomly sub-selecting over a year – from September 6, 2017 to September 6, 2018. For the test set, we pulled files from October 6, 2018 to December 6, 2018. Note also that we indexed files based on unique SHA for first seen time, so every PE in the test set comes temporally after the ones in the training set. We do not use a randomized cross-validation training/test split as is common in other fields, because that would allow the set on which the classifier was trained to contain files “from the future”, leading to spuriously optimistic results. The reason for the one month gap between the end of the training/validation set and the start of the test set is to simulate a realistic worst-case deployment scenario where the detection model of interest is updated on a monthly basis. All files used in the following experiments – both malicious and benign – were obtained from the threat intelligence feed.

We then extracted 1024-element feature vectors for all those files using feature type described in [25] and derived

an aggregate malicious/benign label using a 1-/5+ criterion as described above. Invalid PE files were discarded.

Of the valid PE files from which we were able to extract features we further subsampled our training dataset to 9,000,000 training samples, with 7,188,150 (79.87%) malicious and 1,587,035 (17.63%) benign. The remaining 224,815 (2.5%) are *gray* samples, without a benign or malicious label, i.e., samples where the total number of vendor detections is between 2 and 4 and thus do not meet our 1-/5+ labeling criterion. Our validation set was also randomly subsampled from the same period as the training data and used to monitor convergence during training. It consisted of 100,000 samples; of these, 17,620 were benign (17.62%), 79,819 were malicious (79.82%), and 2,561 were gray (2.56%). Our test set exhibited similar statistics, with 7,656,573 total samples, 1,606,787 benign (21.8%), 5,762,064 malicious (78.2%), and 287,722 gray (3.76%). Further statistics for the distribution of vendor counts and tags in our datasets are presented in Appendix A.1.

The ratios of malicious to benign data in our training, test, and validation sets are comparable, with malicious samples more prevalent than benign samples. Note that this class balance differs substantially from a real-world deployment scenario, where malware is rarely seen. Increasing the prevalence of this low-occurrence class when training on unbalanced data sets is commonly done to avoid overfitting [3] (we have also observed this in practice), and using a data set with a higher proportion of malicious samples assuming a sufficient number of benign samples – may lead to a more precise decision boundary, and better overall performance as measured by the full ROC curve. Further, when using our malicious tags loss, a greater diversity in malware can yield a more diverse tag set to learn from during training.

Note that ROC curves, which we use as performance measures in Sections 4 and 5, are independent of class ratio in the test set (unlike accuracy), since false positive rate (FPR) values depend only on the benign data, and true positive rate (TPR) values depend only on malware. We also focus on improvements in detection at the very low FPR of 0.1% or below, where we see the most dramatic improvements, since several publications by anti-virus vendors [25, 30] and our experience suggest that 0.1% or lower is indeed a practical FPR target for most deployment scenarios. Our model outputs can also be easily (without retraining) rescaled to the desired deployment class ratio, based on the provided ROC curve and/or standard calibration methods, e.g., fitting a weighted isotonic regressor on scores from the validation set with each score contribution weighted according to its ground truth label to correct the class balance discrepancy between the validation set and the expected deployment setting, then using that regressor to calibrate scores during test/deployment.

## 4 Experimental Evaluation

In this section, we apply the auxiliary losses presented in Section 3, first individually, each loss in conjunction with a main malicious/benign loss, and then simultaneously in one combined model. We then compare to a baseline model, finding that each loss term yields an improvement, either in Receiver Operating Characteristic (ROC) net area under the curve (AUC) or in terms of detection performance at low false positive rates (FPR). We note that none of the auxiliary losses we present below harmed classification relative to the baseline model; at worst, our loss-augmented models had equivalent performance to the baseline model with respect to AUC and low-FPR ROC performance on the aggregate malicious/benign label. Each model used a loss weight of 1.0 on the aggregate malicious/benign loss and 0.1 on each auxiliary loss, i.e. when we add  $K$  targets to the main loss, the final loss that gets backpropagated through the model becomes

$$L(X, Y) = L_{\text{mal}}(X, Y) + 0.1 \sum_{k=1}^K L_k(X, Y). \quad (8)$$

Results are depicted in graphical form in Figure 2 and in tabular form in Table 1.

As the training process for deep neural networks has some degree of intrinsic randomness, which can result in variations in their performance, we report our results in terms of both the mean and standard deviation for the test statistics of interest across five runs. Each model was trained five times, each time with a different random initialization and different randomization over minibatches, and all other parameters (optimizer and learning rate, training data, model structure, number of epochs, etc.) held identical. We compute the test statistic of interest (e.g. the detection rate at a false positive rate of  $10^{-3}$ ) for each model, and then compute the average and standard deviation of those results. Notice that the ROC curves in Figure 2 are plotted on a logarithmic scale for visibility, since the baseline performance is already quite high and significant marginal improvements are difficult to discern. For this reason, we also include relative reductions in mean true positive detection error (the rate at which the model fails to detect malware samples – or false negative rate – averaged over the five model results) and in standard deviation from the baseline for our best model in Table 1, and for all models in Table C.1 in the appendix.

### 4.1 Vendor Count Loss

We employed the same base PE model topology as for our other experiments, with a primary malicious/benign binary cross-entropy loss, and an auxiliary count loss. We experimented with two different loss functions for the count loss – a Poisson loss and a Restricted Generalized Poisson loss

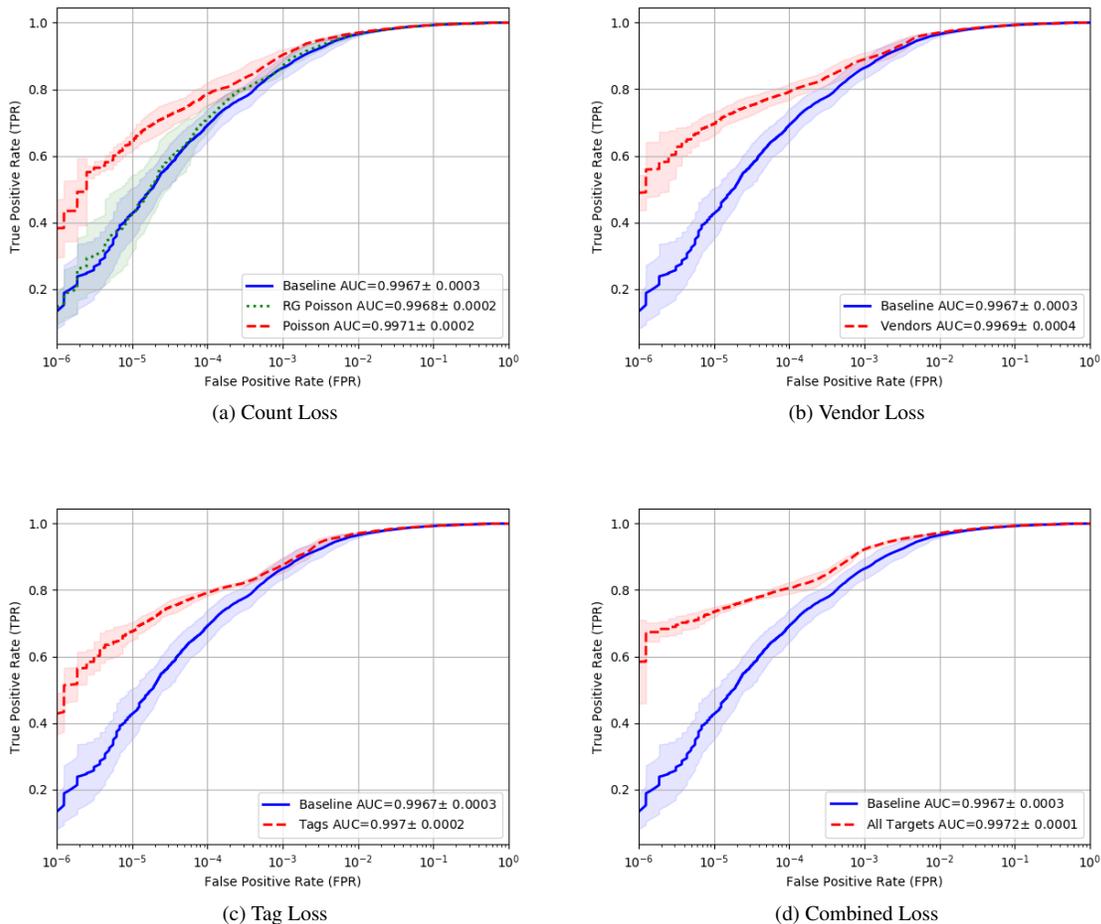

Figure 2: ROC curves and AUC statistics for count, vendor, and tag experiments compared to our baseline. Lines represent the mean TPR at a given FPR, while shaded regions represent  $\pm 1$  standard deviation. Statistics were computed over 5 training runs, each with random parameter initialization. (a) *Count loss*. Our baseline model (blue solid line) is shown compared to a model employing a Poisson auxiliary loss (red dashed line), and a dispersed Poisson auxiliary loss (green dotted line). (b) Auxiliary loss on multiple vendors malicious/benign labels (red dashed line) and baseline (blue solid line). (c) Auxiliary loss on semantic attribute tags (red dashed line) and baseline (blue solid line). (d) Our combined model (red dashed line) and baseline (blue solid line). The combined model utilizes an aggregate malicious/benign loss with an auxiliary Poisson count loss, a multi-vendor malicious/benign loss, and a malware attribute tag loss.

(equations 3 and 5 respectively). For the Poisson loss, we used an exponential activation over a dense layer atop the base to estimate  $\mu^{(i)}$ . For the Restricted Generalized Poisson (RG-Poisson) loss, we followed a similar pattern using two separate dense layers with exponential activations on top; one for the  $\mu^{(i)}$  parameter and another for the  $\alpha^{(i)}$  parameter. The choice of an exponential activation is consistent with statistics literature on Generalized Linear Models (GLMs) [18].

Results on the malware detection task using Poisson and RG-Poisson losses as an auxiliary loss function are shown in Figure 2a. When compared to a baseline using no auxil-

iary loss, we see a statistically significant improvement with the Poisson loss function in both AUC and ROC curve, particularly in low false positive rate (FPR) regions. The RG-Poisson loss, by contrast, yields no statistically significant gains over the baseline in terms of AUC, nor does it appear to yield statistically significant gains at any point along the ROC curve.

This suggests that the RG-Poisson loss model is ill-fit, which could stem from a variety of issues. First, if counts are under-dispersed, an over-dispersed Poisson loss could be an inappropriate model. Under-dispersion could occur if certain vendors disproportionately trigger simultaneously or be-

	FPR				
	$10^{-5}$	$10^{-4}$	$10^{-3}$	$10^{-2}$	$10^{-1}$
TPR Baseline	0.427 ± 0.076	0.692 ± 0.049	0.864 ± 0.031	0.965 ± 0.007	0.9928 ± 0.0007

Table 1: Top: Mean and standard deviation true positive rates (TPRs) for the different experiments in Section 4 at false positive rates (FPRs) of interest. Results were aggregated over five training runs with different weight initializations and minibatch orderings. Best results consistently occurred when using all auxiliary losses and are shown in bold. Bottom: Percentage reduction in missed true positive detections and percentage reductions in ROC curve standard deviation resulting from the best model (All Targets) compared to the baseline across various FPRs. State-of-the-art results are shown in **bold**.

cause counts are inherently bounded by the net number of vendors. Second, a Poisson model, even with added dispersion parameters, is an ill-posed model of count data, but removing the dispersion parameter removes a dimension in the parameter space to over-fit on. Inspecting the dispersion parameters predicted by the RG-Poisson model, we noted that they were relatively large, which supports the latter hypothesis. We also noticed that the RG-Poisson model converged significantly faster than the Poisson model in terms of malware detection loss.

## 4.2 Modeling Individual Vendor Responses

Incorporating an auxiliary multi-label binary cross-entropy loss across vendors (cf. Section 3.3) in conjunction with the main malicious/benign loss yields a similar increase in the TPR at low FPR regions of the ROC curve (see Figure 2b) to the Poisson experiment. Though we do not see a significant increase in AUC, since the improvement is integrated across an extremely narrow range of FPRs, this improvement in TPR at lower FPRs may still be operationally significant, and does indicate an improvement in the model.

## 4.3 Incorporating Tags as Targets

In this experiment we extend the architecture of our base network to predict, not only the malware/benign label, but also the set of 11 tags defined in Section 3.4. For this, we add two fully connected layers per tag to the end of the base architecture (see Section 3.4) which serve to identify each tag from the shared representation. Each of these tag-specialized layers predicts a binary output corresponding to presence/absence of the tag and has an associated binary cross-entropy loss that gets added to the other tag losses and the main malicious/benign loss. The overall loss for this experiment is a sum containing one term per tag, weighted by

a loss weight of 0.1 (as mentioned at the beginning of this section), and one term for the loss incurred on the main task.

The result of this experiment is represented via the ROC curves of Figure 2c. Similar to section 4.2 we see no statistical difference in the AUC values with respect to the baseline, but we do observe substantial statistical improvement in the predictions of the model in low FPR regions, particularly for FPR values lower than  $10^{-3}$ . Furthermore, we also witness a substantial decrease in the variance of the ROC curve.

## 4.4 Combined Model

Finally, we extend our model to predict all auxiliary targets in conjunction with the aggregate label, with a net loss term containing a combination of all auxiliary losses used in previous experiments. The final loss function for the experiment is the sum of all the individual losses where the malware/benign loss has a weight of 1.0 while the rest of the losses have a weight of 0.1.

The resulting ROC curve and AUC are shown in Figure 2d. The AUC of  $0.9972 \pm 0.0001$  is the highest obtained across all the experiments conducted in this study. Moreover, in contrast to utilizing any single auxiliary loss, we see a noticeable improvement in the ROC curve not only in very low FPR regions, but also at  $10^{-3}$  FPR. Additionally, variance is consistently lower across a range of low-FPR values for this combined model than for our baseline or any previous models. An exception is near  $10^{-6}$  FPR where measuring variance is an ill-posed problem because even with a test dataset of over 7M samples, detecting or misdetecting even one or two of them can significantly affect detection rate.

In order to account for the effect of gray samples in the evaluation of our detection model, we re-scanned a subset of those at a later point in time, giving the AV community time to update their detection rules, and evaluated the prediction issued by the model. Even though it is naturally harder to

determine maliciousness of these samples (otherwise they would not initially have been categorized as gray), we find that our model predicts the correct labels for more than 77% of them. A more in depth analysis of grey samples is deferred to Appendix B.

## 5 Discussion

In this section, we examine the effects of different types of auxiliary loss functions on main task ROC curve. We then perform a sanity check to establish whether our performance increases result from additional information added to our neural networks by the auxiliary loss functions or are the artifact of some regularization effect.

### 5.1 Modes of Improvement

Examining the plots in Figure 2, we see three different types of improvement that result from our auxiliary losses:

1. A bump in TPR at low FPR ( $< 10^{-3}$ ).
2. A net increase in AUC and a small bump in performance at higher FPRs ( $\geq 10^{-3}$ ).
3. A reduction in variance.

Improvement 1 is particularly pronounced in the plots due to the logarithmic scale, but it does not substantially contribute to net AUC due to the narrow FPR range. However, this low-FPR part of the ROC is important from an operational perspective when deploying a malware detection model in practice. Substantially higher TPRs at low FPR could allow for novel use cases in an operational scenario. Notice that this effect is more pronounced for auxiliary losses containing multi-objective binary labels (Figs. 2b, 2c, and 2d) than for the Poisson loss, suggesting that it occurs most prominently when employing our multi-objective binary label losses. Let us consider why a multi-objective binary loss might cause such an effect to occur: At low FPRs, we see high thresholds on the detection score from the main output of the network. To surpass this threshold and register as a detection, the main sigmoid output must be very close to 1.0, i.e., very high response. Under a latent correlation with the main output, a high-response hit for an auxiliary target label could also boost the response for the main detector output, while a baseline model without this information might wrongly classify the sample as benign. We hypothesize that improvement 1 occurs from having many objectives simultaneously and thereby increasing chances for a high-response target hit. The loss type may or may not be incidental, which is consistent with its noticeable but less pronounced presence under a single-objective Poisson auxiliary loss (Figure 2a).

Improvement 2 likely stems from improvements in detection rate that we see around  $10^{-3}$  FPR and higher. Notice that these effects are more pronounced in Figs. 2a and 2d, are somewhat noticeable in Figure 2b, and are not noticeable in

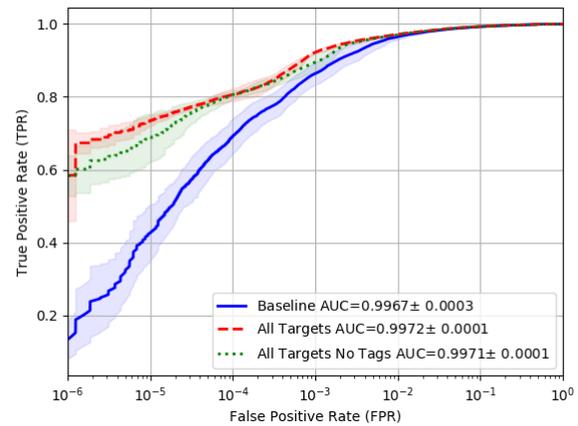

Figure 3: When we remove the attribute tags loss (green dotted line) we get a similar shaped ROC curve with similar ROC compared to using all losses (red dashed line), but with slightly higher variance in the ROC. This supports our hypotheses about effects of different loss functions on the shape of the ROC curve. The baseline is shown as a blue solid line for comparison.

Figure 2c, consistent with the resultant AUCs. This suggests that the effect occurs most prominently in the presence of an auxiliary count loss. We postulate that this occurs because our aggregate detection label is derived by *thresholding* the net number of vendor detections for each sample but doing so removes a notional view of confidence that a sample is malicious. Alternatively stated, thresholding removes information on the difficulty of classifying a malicious sample or the extent of “maliciousness” that the number of detection counts provides. Bear in mind that some detectors are better at detecting different types of malware than others, so more detections suggest a *more malicious* file, e.g., with more malware components, or a more widely blacklisted file (higher confidence). Providing information on the number of counts in an auxiliary loss function may therefore provide the classifier more principled information on how to order detection scores, thus allowing for more effective thresholding and a better ROC curve.

Improvement 3 occurs across all loss types, particularly in low FPR ranges, with the exception of *very low* FPRs (e.g.,  $10^{-6}$ ), where accurately measuring mean and variance is an ill-posed problem due to the size of the dataset (cf. section 4.4). Comparing the ROC plots in Figure 2, the reduction in variance appears more pronounced as the number of losses increases. Intuitively, this is not a surprising result since adding objectives/tasks imposes constraints the allowable weight space – while many choices of weights might allow a network to perform a single task well only a subset of these choices will work well for all tasks simultaneously.

Thus, assuming equivalent base topology, we expect a network that is able to perform at least as well on multiple tasks as many single-task networks to exhibit lower variance.

Combining all losses seems to accentuate all improvements (1-3) with predictable modes which we attribute to our various loss types (Figure 2d) – higher detection rate at low FPR brought about primarily by multi-objective binary losses, a net AUC increase and a detection bump at  $10^{-3}$  FPR brought about by the count loss, and a reduced variance brought about by many loss functions. To convince ourselves that this is not a coincidence, we also trained a network using only Poisson and vendor auxiliary losses but no attribute tags (cf. Figure 3). As expected, we see that this curve exhibits similar general shape and AUC characteristics that occur when training with all loss terms, but the variance appears slightly increased.

In the variance reduction sense, we can view our auxiliary losses as regularizers. This raises a question: are improvements 1 and 2 actually occurring for the reasons that we hypothesize or are they merely naive result of regularization?

## 5.2 Representation or Regularization?

While the introduction of some kinds of auxiliary targets appears to improve the model’s performance on the main task, it is less clear why this is the case. The reduction in variance produced by the addition of extra targets suggests one potential alternative explanation for the observed improvement: rather than inducing a more discriminative representation in the hidden layers of the network, the additional targets may be acting as constraints on the network, reducing the space of viable weights for the final trained network, and thus acting as a form of additional regularization. Alternatively, the addition of extra targets may simply be accelerating training by amplifying the gradient; while this seems unlikely given our use of a validation set to monitor approximate convergence, we nevertheless also investigate this possibility.

To evaluate these hypotheses, we constructed three additional targets (and associated loss functions) that provided uninformative targets to the model: i) a pseudo-random target that is approximately independent of either the input features or the malware/benign label; ii) an additional copy of the main malware target transformed to act as a regression target; and iii) an extra copy of the main malware target.

The random target approach attempts to directly evaluate whether or not an additional pseudo-random target might improve network performance by ‘using up’ excess capacity that might otherwise lead to overfitting. We generate pseudo-random labels for each sample based off of the parity of a hash of the file contents. While this value is effectively random and independent of the actual malware/benignware label of the file, the use of a hash value ensures that a given sample will always produce the same pseudo-random target. This target is fit via standard binary cross-entropy loss

against a sigmoid output,

$$L_{\text{rnd}}(X, Y) = -\frac{1}{M} \sum_{i=1}^M y^{(i)} \log f_{\text{rnd}}(\mathbf{x}^{(i)}) + (1 - y^{(i)}) \log (1 - f_{\text{rnd}}(\mathbf{x}^{(i)})), \quad (9)$$

where  $f_{\text{rnd}}(\mathbf{x}^{(i)})$  is the output of the network which is being fit to the random target  $y^{(i)}$ .

In contrast, the duplicated regression target evaluates whether further constraining the weights *without* requiring excess capacity to model additional independent targets has an effect on the performance on the main task. The model is forced to adopt an internal representation that can satisfy two different loss functions for perfectly correlated targets, thus inducing a constraint that does not add additional information. To do this, we convert our binary labels (taking on values of 0 and 1 for benign and malware, respectively) to -10 and 10, and add them as additional *regression* targets fit via mean squared error (MSE). Taking  $y^{(i)}$  as the  $i^{\text{th}}$  binary target and  $f_{\text{MSE}}(\mathbf{x}^{(i)})$  as the regression output of the network, we can express the MSE loss as:

$$L_{\text{mse}}(X, Y) = \sum_{i=1}^M \left( f_{\text{mse}}(\mathbf{x}^{(i)}) - 20(y^{(i)} - 0.5) \right)^2. \quad (10)$$

Finally, in the case of the duplicated target, the model effectively receives a larger gradient due to a duplication of the loss. The loss for this label uses the same cross-entropy loss as for the main target, obtained by substituting  $f_{\text{dup}}(\mathbf{x}^{(i)})$  for  $f_{\text{mal}}(\mathbf{x}^{(i)})$  in equation 1 as the additional model output that is fit to the duplicated target. Note that we performed two variants of the duplicated target experiment: one in which both the dense layer prior to the main malware target and the dense layer prior to the duplicated target were trainable, and one in which the dense layer for the duplicate target was frozen at its initialization values to avoid the trivial solution where the pre-activation layer for both the main and duplicate target were identical. In both cases, the results were equivalent; only results for the trainable case are shown.

Both  $f_{\text{rnd}}$  and  $f_{\text{dup}}$  are obtained by applying a dense layer followed by a sigmoid activation function to the intermediate output of the input sample from the shared base layer ( $\mathbf{h}$  in Figure 1), while  $f_{\text{mse}}(\mathbf{x}^{(i)})$  is obtained by passing the intermediate representation of the input sample  $\mathbf{h}$  through a fully connected layer with no output non-linearity.

Results of all three experiments are shown in Figure 4. In no case did the performance of the model on the main task improve statistically significantly over the baseline. This suggests that auxiliary tasks must encode relevant information to improve the model’s performance on the main task. For each of the three auxiliary loss types in Figure 4, there is

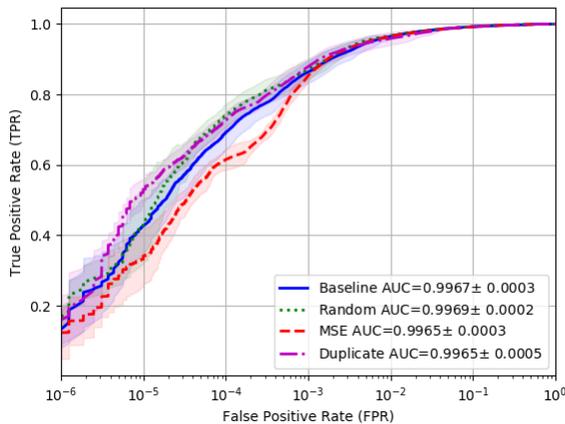

Figure 4: ROC curves comparing classification capabilities of models on the malware target when either random (green dotted line), regression (red dashed line), or duplicated targets (magenta dashed and dotted line) are added as auxiliary losses. Note that with the exception of the regression loss – which appears to harm performance – there is little discernible difference between the remaining ROC curves. The baseline is shown as a blue solid line for comparison.

no additional information provided by the auxiliary targets: the random target is completely uncorrelated from any information in the file (and indeed the final layer is ultimately dominated by the bias weights and produces a constant output of 0.5 regardless of the inputs to the layer), while the duplicated and MSE layers are perfectly correlated with the final target. In either case, there is no incentive for the network to develop a richer representation in layers closer to the input; the final layer alone is sufficient given an adequate representation in the core of the model.

## 6 Related Work

Applications of ML to computer security date back to the 1990’s [21], but large-scale commercial deployments of deep neural networks (DNNs) that have led to transformative performance gains are a more recent phenomenon. Several works from the ML-Sec community have leveraged DNNs for statically detecting malicious content across a variety of different formats and file types [25, 26, 23]. However, these works predominantly focus on applying regularized cross-entropy loss functions between single network outputs and malicious/benign labels per-sample, leaving the potential of multiple-objective optimization largely untapped.

A notable exception, which we build upon in this work, is [11], in which Huang et al. add a multiclass label for Microsoft’s malware families to their classification model using a categorical cross-entropy loss function atop a softmax

output as an auxiliary objective. They observed that adding targets in this fashion increased performance both on the detection task and on the malware family classification task. Our work builds upon theirs in several respects. First, while their work used 4000-dimensional dynamic features derived from Windows API calls, we extend multi-target approaches to lower-dimensional static features on a larger data set. In this respect, our work pioneers a more scalable approach, but lacks the advantages of dynamic features that their approach provides. Second, we demonstrate that improvements from multi-target learning also occur using far more targets, and we introduce heterogeneous loss functions, i.e., binary cross-entropy and Poisson, whereas their work employs only two categorical cross-entropy losses. Finally, our work introduces loss-weighting to account for potentially missing labels, which may not be problematic for only two targets but become more prevalent with additional targets.

Despite the lack of attention from the ML-Sec community, multi-target learning has been applied to other areas of ML for a long time. The work of Abu-Mostafa [2] predates most explicit references to multi-task learning by introducing the concept of *hints*, in which known invariances of a solution (e.g., translation invariance, invariance under negation) can be incorporated into network structure and used to generate additional training samples by applying the invariant operation to the existing samples, or – most relevant to our work – used as an additional target by enforcing that samples modified by an invariant function should be *both* correctly classified *and* explicitly classified identically. Caruna [5] first introduced multi-task learning in neural networks as a “source of inductive bias” (also reframed as inductive transfer in [4]), in which more difficult tasks could be combined in order to exploit similarities between tasks that could serve as complementary signals during training. While his work predates the general availability of modern GPUs, and thus the models and tasks he examines are fairly simple, Caruna nevertheless demonstrates that jointly learning related tasks produces better generalization on a task-by-task basis than learning them individually. It is interesting to note that in [5] he also demonstrated that learning multiple copies of the same task can also lead to a modest improvement in performance (which we did not observe in this work, possibly due to the larger scale and complexity of our task).

Kumar and Duame [17] consider a refinement on the basic multi-task learning approach that leads to clustering related tasks, in an effort to mitigate the potential of *negative transfer* in which unrelated tasks degrade performance on the target task. Similarly, the work of Rudd et al. [22] explores the use of domain-adaptive weighting of tasks during the training process.

Multi-target learning has been applied to extremely complex image classification tasks, including predicting characters and ngrams within unconstrained images of text [14], joint facial landmark localization and detection [19], image

tagging and retrieval [12, 31], and attribute prediction [1, 22] where a common auxiliary task is to challenge the network to classify additional attributes of the image, such as manner of dress for full-body images of people or facial attributes (e.g., smiling, narrow eyes, race, gender). While a range of neural network structures are possible, common exemplars include largely independent networks with a limited number of shared weights (e.g., [1]), a single network with minimal separation between tasks (e.g., [22]), or a number of parallel single-task classifiers in which the weights are constrained to be similar to each other. A more complex approach may be found in [24], in which the sharing between tasks is learned automatically in an online fashion.

Other, more distantly connected domains of ML research reinforce the intuition that learning on disparate tasks can improve model performance. Work in semi-supervised learning, such as [16] and [20], has shown the value of additional reconstruction and denoising tasks to learn representations valuable for a core classification model, both through regularization and through access to a larger dataset than is available with labels. The widespread success of transfer learning is also a testament to the value of training a single model on nominally distinct tasks. BERT [8], a recent example from the Natural Language Processing literature, shows strong performance gains from pre-training a model on masked-word prediction and predictions of whether two sentences appear in sequence, even when the true task of interest is quite distinct (e.g. question answering, translation).

Multi-view learning (see [32] for a survey) is a related approach in which multiple inputs are trained to a single target. This approach also arguably leads to the same general mechanism for improvement: the model is forced to learn relationships between sets of features that improve the performance using any particular set. While this approach often requires all sets of features to be available at test time, there are other approaches, such as [28], that relax this constraint.

## 7 Conclusion

In this paper, we have demonstrated the effectiveness of auxiliary losses for malware classification. We have also provided experimental evidence which suggests that performance gains result from an improved and more informative representation, not merely a regularization artifact. This is consistent with our observation that improvements occur as additional auxiliary losses and different loss types are added. We also note that different loss types have different effects on the ROC; multi-label vendor and semantic attribute tag losses have greatest effect at low false positive rates ( $\leq 10^{-3}$ ), while Poisson counts have a substantial net impact on AUC, the bulk of which stems from detection boosts at higher FPR.

While we experimented on PE malware in this paper, our auxiliary loss technique could be applied to many other prob-

lems in the ML-Sec community, including utilizing a label on format/file type for format-agnostic features (e.g., office document type in [23]) or file type under a given format, for example APKs and JARs both share an underlying ZIP format; a zip-archive malware detector could use tags on the file type for auxiliary targets. Additionally, tags on topics and classifications of embedded URLs could serve as auxiliary targets when classifying emails or websites.

One open question is whether or not multiple auxiliary losses improve each others' performances as well as the main task's. If the multiple outputs of operational interest (such as the tagging output) can be trained simultaneously while also increasing (or at least not decreasing) their joint accuracy, this could lead to models that are both more compact and more accurate than individually deployed ones. In addition to potential accuracy gains, this has significant potential operational benefits, particularly when it comes to model deployment and updates. We defer a more complete evaluation of this question to future work.

While this work has focused on applying auxiliary losses in the context of deep neural networks, there is nothing mathematically that precludes using them in conjunction with a number of other classifier types. Notably, gradient boosted classifier ensembles, which are also popular in the ML-Sec community could take very similar auxiliary loss functions even though the structure of these classifiers is much different. We encourage the ML-Sec research community to implement multi-objective ensemble classifiers and compare with our results. Our choice of deep neural networks for this paper is infrastructural more than anything else; while several deep learning platforms, including PyTorch, Keras, and Tensorflow among others easily support multiple objectives and custom loss functions, popular boosting frameworks such as lightGBM and XGBoost have yet to implement this functionality.

The analyses conducted herein used metadata that can naturally be transformed into a label source and impart additional information to the classifier with no extra data collection burden on behalf of the threat intelligence feed. Moreover, our auxiliary loss technique does not change the underlying feature space representation. Other types of metadata, e.g., the file path of the malicious binary or URLs extracted from within the binary might be more useful in a multi-view context, serving as input to the classifier, but this approach raises challenges associated with missing data that our loss weighting scheme trivially addresses. Perhaps our weighting scheme could even be extended, e.g., by weighting each sample's loss contribution according to certainty/uncertainty in that sample's label, or re-balancing the per-task loss according to the expected frequency of the label in the target distribution. This could open up novel applications, e.g., detectors customized to a particular user endpoints and remove sampling biases inherent to multi-task data.

## 8 Acknowledgments

## A Dataset Statistics

### A.1 Vendor Counts Distribution

To better characterize the distribution of the Vendor Counts auxiliary target for our Poisson loss experiment, we plot a histogram representing the distribution of the number of vendor convictions in Figure A.1. The  $x$ -axis depicts the number of vendors that identify a given sample as malicious, while the  $y$ -axis represents the number of samples for which that number of detections was observed in our training dataset (note the logarithmic scale). The statistics of the test and validation datasets are similar and not shown here due to space considerations.

We note that there is a peak at zero detections, accounting for the majority of the benign files. Most of the samples considered malicious by our labeling scheme have more than 20 individual detections out of 67 total vendors considered, with a peak around 57 detections.

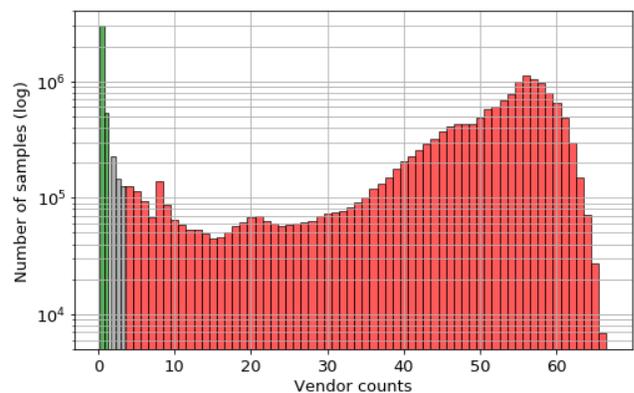

Figure A.1: Histogram of vendor detections per file. Files with zero or one detections (green bars) are considered benign under our labeling scheme, samples with two, three or four vendor detections (gray bars) are considered gray files, and files with more than four detections (red bars) are considered malicious.

### A.2 Individual Vendor Responses

Table A.1 summarizes the number of samples identified as malware, benign and number of missing samples per vendor for the nine vendors used to compute the auxiliary per-vendor malware loss. In Figure A.2 we plot the pairwise similarity of the predictions between vendors. The value in the  $j, k$  position of the matrix is the fraction of samples for which the predictions of vendor  $j$  are equal to the predictions for vendor  $k$ . Even though the predictions by each vendor are created in a quasi independent manner, they tend to agree for most of the samples. The diagonal elements of the matrix

indicate the fraction of samples for which we have a classification by the vendor (fraction of non-missing values).

	Malware	Benign	None
v1	13,752,004 (69%)	6,110,180 (31%)	20,979 (<1%)
v2	14,751,413 (74%)	5,122,728 (26%)	9,022 (<1%)
v3	14,084,689 (71%)	5,713,116 (29%)	85,358 (<1%)
v4	14,438,043 (73%)	5,239,896 (26%)	205,224 (1 %)
v5	13,778,367 (69%)	5,922,859 (30%)	181,937 (1 %)
v6	15,065,196 (76%)	4,704,695 (24%)	113,272 (1 %)
v7	14,935,624 (75%)	4,927,436 (25%)	20,103 (<1%)
v8	12,704,512 (64%)	7,009,855 (35%)	168,796 (1 %)
v9	14,234,545 (72%)	5,613,604 (28%)	35,014 (<1%)

Table A.1: Individual vendor counts for files in the training set identified as malicious, benign, or missing value for the set of nine vendors used in the per-vendor malware loss 3.3.

### A.3 Semantic Tags Distribution

In this section we analyze the distribution of the semantic tags over three sets of samples: i) samples in the training set; ii) samples in the test set; and iii) those which the baseline model classifies incorrectly but our model trained with all targets classifies correctly either as malicious or benign samples. The percentages in Table A.2 represent the number of samples in each set labeled with a given tag. The total number of samples in the test set for which the improved model makes correct conviction classification but the baseline model fails is 665,944. The binarization of the predictions for the baseline and the final model was done such that each would have a FPR of  $10^{-3}$  in the test set. As shown below, those samples with the *adware* tag are the ones that most benefit from the addition of auxiliary losses during training, however we also see notable improvements on *packed* samples, *spyware*, and *droppers*.

## B Gray Samples Evaluation

In Section 3.6 we observed that 2.5% of the samples in our training set, and 3.7% of the samples in our test set are considered gray samples by our labeling function. While training this is not necessarily an issue since we can assign a weight of zero for those samples in their malware/benign label as noted in Section 3.5. For the evaluation of the detection algorithms though, the performance on those becomes more relevant. To evaluate how our proposed detection model performs on those samples we re-scanned a random selection of 10,000 gray samples in the test set 5 months later than the original collection. From these, 5,000 were predicted by the model as benign and 5,000 as malicious. We expect, after this time-lag, that, with updated detection

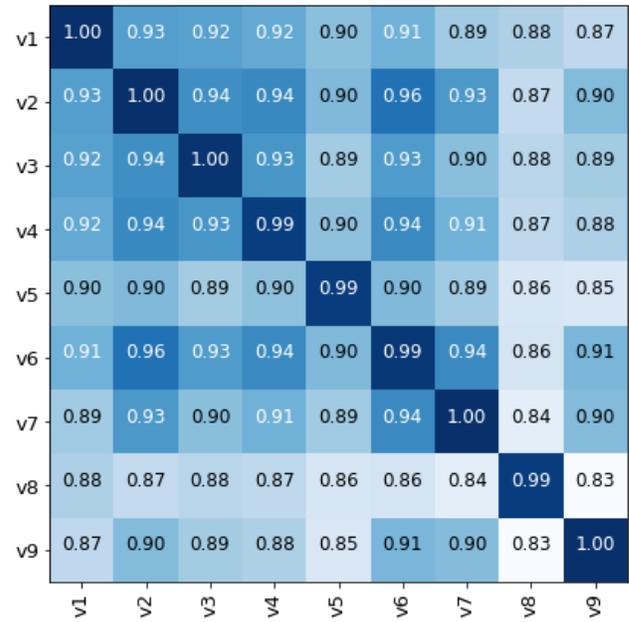

Figure A.2: Vendor predictions similarity matrix. Each entry in the matrix represents the percentage of samples that are the same for any two vendors. The elements in the diagonal of the matrix represent the percentage of the samples for predictions from the vendor are present (i.e., not missing). Note that diagonal values of less than 1.0 are due to missing labels (compare to the final column of table A.1), which we treat as disagreeing with *any* label.

	Train Set	Test Set	Improvement over baseline
adware	21 %	18%	41 %
crypto-miner	7 %	2%	1 %
downloader	25 %	18%	11 %
dropper	29 %	22%	17 %
file-infector	19 %	12%	9 %
flooder	1 %	1%	<1%
installer	7 %	1 %	5 %
packed	34 %	25%	19 %
ransomware	5 %	6%	1 %
spyware	40 %	25%	18 %

Table A.2: Tag statistics for three sets of interest: train set; test set; and the set of samples for which the full model classifies correctly but the baseline model fails.

rules from the AV community, that samples originally labeled as “gray” that are effectively malicious will accrue additional detections and samples originally labeled as “gray” that are effectively benign will accrue fewer detections as vendors have re-written their rules to suppress false positives

and recognize false negatives. Thus, the gray sample labels will tend to converge to either malicious or benign under our 1-/5+ criterion. Out of these 10,000 rescans, we were able to label 5,653 gray samples: 3,877 (68.6%) as malicious and 1,776 (31.4%) as benign.

In Figure B.1 we plot the ROC curve for the predictions on the re-scanned samples for our final model trained with all targets, which achieves an AUC of 0.84. Even though the AUC is much lower than the one obtained on our test set, our model trained with knowledge from 5 months earlier (after the first collection) still correctly predicts more than 77% of the samples correctly. We measure this by binarizing the predictions using a threshold that would achieve an FPR of  $10^{-3}$  on the original test set. Furthermore we note that the samples we are evaluating on in this case are more difficult or even ambiguous in nature, to the point that at the original collection time there was not consensus across the AV community.

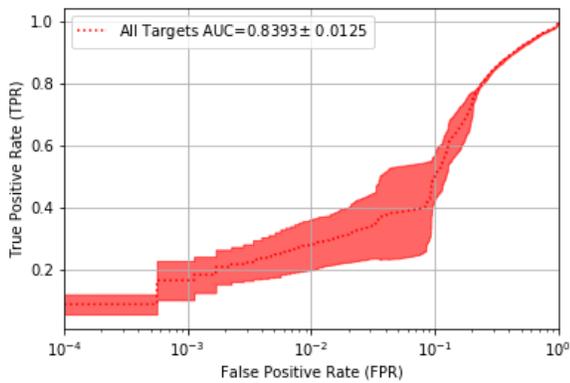

Figure B.1: Mean and standard deviation ROC curve over rescanned samples.

## C Relative Improvements

In Table C.1 we present the relative percentage reduction both in true positive detection error and standard deviation with respect to the baseline model trained only using the malware/benign target for various values of false positive rates.

	FPR				
	$10^{-5}$	$10^{-4}$	$10^{-3}$	$10^{-2}$	$10^{-1}$
Poisson	38.05, 61.84	30.19, 30.61	28.68, 48.39	14.29, <b>85.71</b>	5.56, <b>97.14</b>
RG Poisson	0.00, -52.63	6.17, 16.33	4.41, 48.39	2.86, 57.14	2.78, 95.71
Vendors	47.12, 55.26	32.47, 51.02	18.38, 35.48	14.29, 42.86	0.00, 80.00
Tags	43.63, 64.47	32.47, <b>81.63</b>	8.09, 29.03	17.14, 42.86	5.56, 88.57
All Targets	<b>53.75, 81.58</b>	<b>37.01</b> , 65.31	<b>42.65, 87.10</b>	<b>20.00</b> , 57.14	<b>8.33</b> , 94.29

Table C.1: Relative percentage reductions in true positive detection error and standard deviation compared to the baseline model (displayed as *detection error reduction*, *standard deviation reduction*) at different false positive rates (FPRs) for the different experiments in Section 4. Results were evaluated over five different weight initializations and minibatch orderings. Best detection error reduction consistently occurred when using all auxiliary losses. Best results are shown in **bold**.

# Why Do Adversarial Attacks Transfer? Explaining Transferability of Evasion and Poisoning Attacks

## Abstract

Transferability captures the ability of an attack against a machine-learning model to be effective against a different, potentially unknown, model. Empirical evidence for transferability has been shown in previous work, but the underlying reasons why an attack transfers or not are not yet well understood. In this paper, we present a comprehensive analysis aimed to investigate the transferability of both test-time evasion and training-time poisoning attacks. We provide a unifying optimization framework for evasion and poisoning attacks, and a formal definition of transferability of such attacks. We highlight two main factors contributing to attack transferability: the *intrinsic adversarial vulnerability* of the target model, and the *complexity* of the surrogate model used to optimize the attack. Based on these insights, we define three metrics that impact an attack's transferability. Interestingly, our results derived from theoretical analysis hold for both evasion and poisoning attacks, and are confirmed experimentally using a wide range of linear and non-linear classifiers and datasets.

## 1 Introduction

The wide adoption of machine learning (ML) and deep learning algorithms in many critical applications introduces strong incentives for motivated adversaries to manipulate the results and models generated by these algorithms. Attacks against machine learning systems can happen during multiple stages in the learning pipeline. For instance, in many settings training data is collected online and thus can not be fully trusted. In *poisoning availability attacks*, the attacker controls a certain amount of training data, thus influencing the trained model and ultimately the predictions at testing time on most points in testing set [4, 18, 20, 28–30, 34, 36, 41, 48]. *Poisoning integrity attacks* have the goal of modifying predictions on a few targeted points by manipulating the training process [20, 41]. On the other hand, *evasion attacks* involve small manipulations of testing data points that results in misprediction at testing time on those points [3, 8, 10, 14, 32, 38, 42, 45, 49].

Creating poisoning and evasion attack points is not a trivial task, particularly when many online services avoid disclosing information about their machine learning algorithms. As a result, attackers are forced to craft their attacks in *black-box* settings, against a surrogate model instead of the real model used by the service, hoping that the attack will be effective on the real model. The *transferability* property of an attack is satisfied when an attack developed for a particular machine learning model (i.e., a surrogate model) is also effective against the target model. Attack transferability was observed in early studies on adversarial examples [14, 42] and has gained a lot more interest in recent years with the advancement of machine learning cloud services. Previous work has reported empirical findings about the transferability of evasion attacks [3, 13, 14, 21, 26, 32, 33, 42, 43, 47] and, only recently, also on the transferability of poisoning integrity attacks [41]. In spite of these efforts, the question of *when and why do adversarial points transfer* remains largely unanswered.

In this paper we present the first comprehensive evaluation of transferability of evasion and poisoning availability attacks, understanding the factors contributing to transferability of both attacks. In particular, we consider attacks crafted with gradient-based optimization techniques (e.g., [4, 8, 23]), a popular and successful mechanism used to create attack data points. We unify for the first time evasion and poisoning attacks into an optimization framework that can be instantiated for a range of threat models and adversarial constraints. We provide a formal definition of transferability and show that, under linearization of the loss function computed under attack, several main factors impact transferability: the *intrinsic adversarial vulnerability* of the target model, the *complexity* of the surrogate model used to optimize the attacks, and its alignment with the target model. Furthermore, we derive a new poisoning attack for logistic regression, and perform a comprehensive evaluation of both evasion and poisoning attacks on multiple datasets, confirming our theoretical analysis.

In more detail, the contributions of our work are:

**Optimization framework for evasion and poisoning attacks.** We introduce a unifying framework based on gradient-

descent optimization that encompasses both evasion and poisoning attacks. Our framework supports threat models with different adversarial goals (integrity and availability), amount of knowledge available to the adversary (white-box and black-box), as well as different adversarial capabilities (causative or exploratory). Our framework generalizes existing attacks proposed by previous work for evasion [3, 8, 14, 23, 42] and poisoning [4, 18, 20, 24, 27, 48]. Under our framework, we derive a novel gradient-based poisoning availability attack against logistic regression. We remark here that poisoning attacks are more difficult to derive than evasion ones, as they require computing hypergradients from a bilevel optimization problem, to capture the dependency on how the machine-learning model changes while the training poisoning points are modified [4, 18, 20, 24, 27, 48].

**Transferability definition and theoretical bound.** We give a formal definition of transferability of evasion and poisoning attacks, and an upper bound on a transfer attack’s success. This allows us to derive three metrics connected to *model complexity*. Our formal definition unveils that transferability depends on: (1) the size of input gradients of the target classifier; (2) how well the gradients of the surrogate and target models align; and (3) the variance of the loss landscape optimized to generate the attack points.

**Comprehensive experimental evaluation of transferability.** We consider a wide range of classifiers, including logistic regression, SVMs with both linear and RBF kernels, ridge regression, random forests, and deep neural networks (both feed-forward and convolutional neural networks), all with different hyperparameter settings to reflect different model complexities. We evaluate the transferability of our attacks on three datasets related to different applications: handwritten digit recognition (MNIST), Android malware detection (DREBIN), and face recognition (LFW). We confirm our theoretical analysis for both evasion and poisoning attacks.

**Insights into transferability.** We demonstrate that attack transferability depends strongly on the *complexity* of the target model, i.e., on its inherent vulnerability. This confirms that reducing the size of input gradients, e.g., via regularization, may allow us to learn more robust classifiers not only against evasion [22, 35, 39, 44] but also against poisoning availability attacks. Second, transferability is also impacted by the surrogate model’s alignment with the target model. Surrogates with better alignments to their targets (in terms of the angle between their gradients) are more successful at transferring the attack points. Third, surrogate loss functions that are stabler and have lower variance tend to facilitate gradient-based optimization attacks to find better local optima (see Figure 1). As less complex models exhibit a lower variance of their loss function, they typically result in better surrogates.

**Organization.** We discuss background on threat modeling against machine learning in Section 2. We introduce our unifying optimization framework for evasion and poisoning attacks,

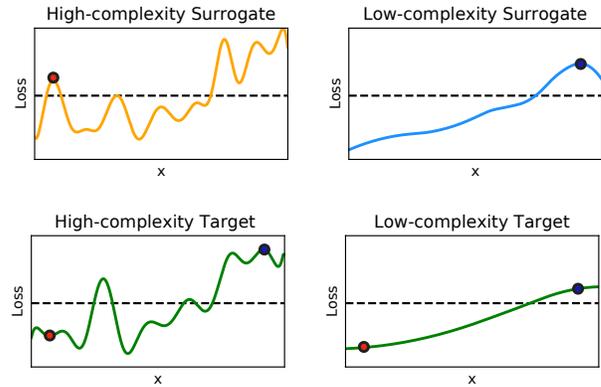

Figure 1: Conceptual representation of transferability. We show the loss function of the attack objective as a function of a single feature  $x$ . The top row includes 2 surrogate models (*high* and *low* complexity), while the bottom row includes both models as targets. The adversarial samples are represented as red dots for the high-complexity surrogate and as blue dots for the low-complexity surrogate. If the adversarial sample loss is below a certain threshold (i.e., the black horizontal line), the point is correctly classified, otherwise it is misclassified. The adversarial point computed against the high-complexity model (top left) lays in a local optimum due to the irregularity of the objective. This point is not effective even against the same classifier trained on a different dataset (bottom left) due to the variance of the high-complexity classifier. The adversarial point computed against the low complexity model (top right), instead, succeeds against both low and high-complexity targets (left and right bottom, respectively).

as well as the poisoning attack for logistic regression in Section 3. We then formally define transferability for both evasion and poisoning attacks, and show its approximate connection with the input gradients used to craft the corresponding attack samples (Section 4). Experiments are reported in Section 5, highlighting connections among regularization hyperparameters, the size of input gradients, and transferability of attacks, on different case studies involving handwritten digit recognition, Android malware detection, and face recognition. We discuss related work in Section 6 and conclude in Section 7.

## 2 Background and Threat Model

Supervised learning includes: (1) a training phase in which training data is given as input to a learning algorithm, resulting in a trained ML model; (2) a testing phase in which the model is applied to new data and a prediction is generated. In this paper, we consider a range of adversarial models against machine learning classifiers at both training and testing time. Attackers are defined by: (i) their goal or objective in attacking the system; (ii) their knowledge of the system; (iii) their capabilities in influencing the system through manipulation

of the input data. Before we detail each of these, we introduce our notation, and point out that the threat model and attacks considered in this work are suited to binary classification, but can be extended to multi-class settings.

**Notation.** We denote the sample and label spaces with  $\mathcal{X}$  and  $\mathcal{Y} \in \{-1, +1\}$ , respectively, and the training data with  $\mathcal{D} = (\mathbf{x}_i, y_i)_{i=1}^n$ , where  $n$  is the training set size. We use  $L(\mathcal{D}, \mathbf{w})$  to denote the *loss* incurred by classifier  $f: \mathcal{X} \mapsto \mathcal{Y}$  (parameterized by  $\mathbf{w}$ ) on  $\mathcal{D}$ . Typically, this is computed by averaging a loss function  $\ell(y, \mathbf{x}, \mathbf{w})$  computed on each data point, i.e.,  $L(\mathcal{D}, \mathbf{w}) = \frac{1}{n} \sum_{i=1}^n \ell(y_i, \mathbf{x}_i, \mathbf{w})$ . We assume that the classifier  $f$  is learned by minimizing an objective function  $\mathcal{L}(\mathcal{D}, \mathbf{w})$  on the training data. Typically, this is an estimate of the generalization error, obtained by the sum of the empirical loss  $L$  on training data  $\mathcal{D}$  and a regularization term.

## 2.1 Threat Model: Attacker’s Goal

We define the attacker’s goal based on the desired security violation. In particular, the attacker may aim to cause either an *integrity* violation, to evade detection without compromising normal system operation; or an *availability* violation, to compromise the normal system functionalities available to legitimate users.

## 2.2 Threat Model: Attacker’s Knowledge

We characterize the attacker’s knowledge  $\kappa$  as a tuple in an abstract knowledge space  $\mathcal{K}$  consisting of four main dimensions, respectively representing knowledge of: (*k.i*) the training data  $\mathcal{D}$ ; (*k.ii*) the feature set  $\mathcal{X}$ ; (*k.iii*) the learning algorithm  $f$ , along with the objective function  $\mathcal{L}$  minimized during training; and (*k.iv*) the parameters  $\mathbf{w}$  learned after training the model. This categorization enables the definition of many different kinds of attacks, ranging from *white-box* attacks with full knowledge of the target classifier to *black-box* attacks in which the attacker has limited information about the target system.

**White-Box Attacks.** We assume here that the attacker has full knowledge of the target classifier, i.e.,  $\kappa = (\mathcal{D}, \mathcal{X}, f, \mathbf{w})$ . This setting allows one to perform a worst-case evaluation of the security of machine-learning algorithms, providing empirical upper bounds on the performance degradation that may be incurred by the system under attack.

**Black-Box Attacks.** We assume here that the input feature representation  $\mathcal{X}$  is known. For images, this means that we do consider pixels as the input features, consistently with other recent work on black-box attacks against machine learning [32, 33]. At the same time, the training data  $\mathcal{D}$  and the type of classifier  $f$  are not known to the attacker. We consider the most realistic attack model in which the attacker does not have querying access to the classifier.

The attacker can collect a surrogate dataset  $\hat{\mathcal{D}}$ , ideally sampled from the same underlying data distribution as  $\mathcal{D}$ , and

train a *surrogate model*  $\hat{f}$  on such data to approximate the target function  $f$ . Then, the attacker can craft the attacks against  $\hat{f}$ , and then check whether they successfully *transfer* to the target classifier  $f$ . By denoting limited knowledge of a given component with the *hat* symbol, such black-box attacks can be denoted with  $\hat{\kappa} = (\hat{\mathcal{D}}, \mathcal{X}, \hat{f}, \hat{\mathbf{w}})$ .

## 2.3 Threat Model: Attacker’s Capability

This attack characteristic defines how the attacker can influence the system, and how data can be manipulated based on application-specific constraints. If the attacker can manipulate both training and test data, the attack is said to be *causative*. It is instead referred to as *exploratory*, if the attacker can only manipulate test data. These scenarios are more commonly known as *poisoning* [4, 18, 24, 27, 48] and *evasion* [3, 8, 14, 42].

Another aspect related to the attacker’s capability depends on the presence of application-specific constraints on data manipulation; e.g., to evade malware detection, malicious code has to be modified without compromising its intrusive functionality. This may be done against systems leveraging static code analysis, by injecting instructions that will never be executed [11, 15, 45]. These constraints can be generally accounted for in the definition of the optimal attack strategy by assuming that the initial attack sample  $\mathbf{x}$  can only be modified according to a space of possible modifications  $\Phi(\mathbf{x})$ .

## 3 Optimization Framework for Gradient-based Attacks

We introduce here a general optimization framework that encompasses both evasion and poisoning attacks. Gradient-based attacks have been considered for evasion (e.g., [3, 8, 14, 23, 42]) and poisoning (e.g., [4, 18, 24, 27]). Our optimization framework not only unifies existing evasion and poisoning attacks, but it also enables the design of new attacks. After defining our general formulation, we instantiate it for evasion and poisoning attacks, and use it to derive a new poisoning availability attack for logistic regression.

### 3.1 Gradient-based Optimization Algorithm

Given the attacker’s knowledge  $\kappa \in \mathcal{K}$  and an attack sample  $\mathbf{x}' \in \Phi(\mathbf{x})$  along with its label  $y$ , the attacker’s goal can be defined in terms of an objective function  $\mathcal{A}(\mathbf{x}', y, \kappa) \in \mathbb{R}$  (e.g., a loss function) which measures how effective the attack sample  $\mathbf{x}'$  is. The optimal attack strategy can be thus given as:

$$\mathbf{x}^* \in \arg \max_{\mathbf{x}' \in \Phi(\mathbf{x})} \mathcal{A}(\mathbf{x}', y, \kappa). \quad (1)$$

Note that, for the sake of clarity, we consider here the optimization of a single attack sample, but this formulation can be easily extended to account for multiple attack points. In

---

**Algorithm 1** Gradient-based Evasion and Poisoning Attacks

**Input:**  $\mathbf{x}, y$ : the input sample and its label;  $\mathcal{A}(\mathbf{x}, y, \kappa)$ : the attacker’s objective;  $\kappa = (\mathcal{D}, \mathcal{X}, f, \mathbf{w})$ : the attacker’s knowledge parameter vector;  $\Phi(\mathbf{x})$ : the feasible set of manipulations that can be made on  $\mathbf{x}$ ;  $t > 0$ : a small number.

**Output:**  $\mathbf{x}'$ : the adversarial example.

- 1: Initialize the attack sample:  $\mathbf{x}' \leftarrow \mathbf{x}$
  - 2: **repeat**
  - 3:   Store attack from previous iteration:  $\mathbf{x} \leftarrow \mathbf{x}'$
  - 4:   Update step:  $\mathbf{x}' \leftarrow \Pi_{\Phi}(\mathbf{x} + \eta \nabla_{\mathbf{x}} \mathcal{A}(\mathbf{x}, y, \kappa))$ , where the step size  $\eta$  is chosen with line search (bisection method), and  $\Pi_{\Phi}$  ensures projection on the feasible domain  $\Phi$ .
  - 5:   **until**  $|\mathcal{A}(\mathbf{x}', y, \kappa) - \mathcal{A}(\mathbf{x}, y, \kappa)| \leq t$
  - 6: **return**  $\mathbf{x}'$
- 

particular, as in the case of poisoning attacks, the attacker can maximize the objective by iteratively optimizing one attack point at a time [5, 48].

**Attack Algorithm.** Algorithm 1 provides a general projected gradient-ascent algorithm that can be used to solve the aforementioned problem for both evasion and poisoning attacks. It iteratively updates the attack sample along the gradient of the objective function, ensuring the resulting point to be within the feasible domain through a projection operator  $\Pi_{\Phi}$ . The gradient step size  $\eta$  is determined in each update step using a line-search algorithm based on the bisection method, which solves  $\max_{\eta} \mathcal{A}(\mathbf{x}'(\eta), y, \kappa)$ , with  $\mathbf{x}'(\eta) = \Pi_{\Phi}(\mathbf{x} + \eta \nabla_{\mathbf{x}} \mathcal{A}(\mathbf{x}, y, \kappa))$ . For the line search, in our experiments we consider a maximum of 20 iterations. This allows us to reduce the overall number of iterations required by Algorithm 1 to reach a local or global optimum. We also set the maximum number of iterations for Algorithm 1 to 1,000, but convergence (Algorithm 1, line 5) is typically reached only after a hundred iterations.

We finally remark that non-differentiable learning algorithms, like decision trees and random forests, can be attacked with more complex strategies [17, 19] or using gradient-based optimization against a differentiable surrogate learner [31, 37].

### 3.2 Evasion Attacks

In evasion attacks, the attacker manipulates test samples to have them misclassified, i.e., to evade detection by a learning algorithm. For white-box evasion, the optimization problem given in Eq. (1) can be rewritten as:

$$\max_{\mathbf{x}'} \quad \ell(y, \mathbf{x}', \mathbf{w}), \quad (2)$$

$$\text{s.t.} \quad \|\mathbf{x}' - \mathbf{x}\|_p \leq \varepsilon, \quad (3)$$

$$\mathbf{x}_{\text{lb}} \preceq \mathbf{x}' \preceq \mathbf{x}_{\text{ub}}, \quad (4)$$

where  $\|\mathbf{v}\|_p$  is the  $\ell_p$  norm of  $\mathbf{v}$ , and we assume that the classifier parameters  $\mathbf{w}$  are known. For the black-box case, it

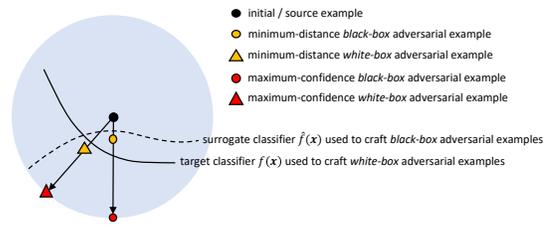

Figure 2: Conceptual representation of maximum-confidence evasion attacks (within an  $\ell_2$  ball of radius  $\varepsilon$ ) vs. minimum-distance adversarial examples. Maximum-confidence attacks tend to transfer better as they are misclassified with higher confidence (though requiring more modifications).

suffices to use the parameters  $\hat{\mathbf{w}}$  of the surrogate classifier  $\hat{f}$ . In this work we consider  $\ell(y, \mathbf{x}', \mathbf{w}) = -yf(\mathbf{x}')$ , as in [3].

The intuition here is that the attacker maximizes the loss on the adversarial sample with the original class, to cause misclassification to the opposite class. The manipulation constraints  $\Phi(\mathbf{x})$  are given in terms of: (i) a distance constraint  $\|\mathbf{x}' - \mathbf{x}\|_p \leq \varepsilon$ , which sets a bound on the maximum input perturbation between  $\mathbf{x}$  (i.e., the input sample) and the corresponding modified adversarial example  $\mathbf{x}'$ ; and (ii) a box constraint  $\mathbf{x}_{\text{lb}} \preceq \mathbf{x}' \preceq \mathbf{x}_{\text{ub}}$  (where  $\mathbf{u} \preceq \mathbf{v}$  means that each element of  $\mathbf{u}$  has to be not greater than the corresponding element in  $\mathbf{v}$ ), which bounds the values of the attack sample  $\mathbf{x}'$ .

For images, the former constraint is used to implement either *dense* or *sparse* evasion attacks [12, 25, 37]. Normally, the  $\ell_2$  and the  $\ell_\infty$  distances between pixel values are used to cause an indistinguishable image blurring effect (by slightly manipulating all pixels). Conversely, the  $\ell_1$  distance corresponds to a sparse attack in which only few pixels are significantly manipulated, yielding a salt-and-pepper noise effect on the image [12, 37]. The box constraint can be used to bound each pixel value between 0 and 255, or to ensure manipulation of only a specific region of the image. For example, if some pixels should not be manipulated, one can set the corresponding values of  $\mathbf{x}_{\text{lb}}$  and  $\mathbf{x}_{\text{ub}}$  equal to those of  $\mathbf{x}$ .

**Maximum-confidence vs. minimum-distance evasion.** Our formulation of evasion attacks aims to produce adversarial examples that are misclassified with *maximum confidence* by the classifier, within the given space of feasible modifications. This is substantially different from crafting minimum-distance adversarial examples, as formulated in [42] and in follow-up work (e.g., [33]). This difference is conceptually depicted in Fig. 2. In particular, in terms of transferability, it is now widely acknowledged that higher-confidence attacks have better chances of successfully transferring to the target classifier (and even of bypassing countermeasures based on gradient masking) [2, 8, 13]. For this reason, in this work we consider evasion attacks that aim to craft adversarial examples misclassified with *maximum* confidence.

**Initialization.** There is another factor known to improve trans-

ferability of evasion attacks, as well as their effectiveness in the white-box setting. It consists of running the attack starting from different initialization points to mitigate the problem of getting stuck in poor local optima [3, 13, 50]. In addition to starting the gradient ascent from the initial point  $\mathbf{x}$ , for non-linear classifiers we also consider starting the gradient ascent from the projection of a randomly-chosen point of the opposite class onto the feasible domain. This double-initialization strategy helps finding better local optima, through the identification of more promising paths towards evasion [13, 47, 50].

### 3.3 Poisoning Availability Attacks

Poisoning attacks consist of manipulating training data (mainly by injecting adversarial points into the training set) to either favor intrusions without affecting normal system operation, or to purposely compromise normal system operation to cause a denial of service. The former are referred to as poisoning integrity attacks, while the latter are known as poisoning availability attacks [5, 48]. Recent work has mostly addressed transferability of poisoning integrity attacks [41], including backdoor attacks [9, 16]. In this work we focus on poisoning availability attacks, as their transferability properties have not yet been widely investigated. Crafting transferable poisoning availability attacks is much more challenging than crafting transferable poisoning integrity attacks, as the latter have a much more modest goal (modifying prediction on a small set of targeted points).

As for the evasion case, we formulate poisoning in a white-box setting, given that the extension to black-box attacks is immediate through the use of surrogate learners. Poisoning is formulated as a bilevel optimization problem in which the outer optimization maximizes the attacker’s objective  $\mathcal{A}$  (typically, a loss function  $L$  computed on untainted data), while the inner optimization amounts to learning the classifier on the poisoned training data [4, 24, 48]. This can be made explicit by rewriting Eq. (1) as:

$$\max_{\mathbf{x}'} L(\mathcal{D}_{\text{val}}, \mathbf{w}^*) = \sum_{j=1}^m \ell(y_j, \mathbf{x}_j, \mathbf{w}^*) \quad (5)$$

$$\text{s.t. } \mathbf{w}^* \in \arg \min_{\mathbf{w}} \mathcal{L}(\mathcal{D}_{\text{tr}} \cup (\mathbf{x}', y), \mathbf{w}) \quad (6)$$

where  $\mathcal{D}_{\text{tr}}$  and  $\mathcal{D}_{\text{val}}$  are the training and validation datasets available to the attacker. The former, along with the poisoning point  $\mathbf{x}'$ , is used to train the learner on poisoned data, while the latter is used to evaluate its performance on untainted data, through the loss function  $L(\mathcal{D}_{\text{val}}, \mathbf{w}^*)$ . Notably, the objective function implicitly depends on  $\mathbf{x}'$  through the parameters  $\mathbf{w}^*$  of the poisoned classifier.

The attacker’s capability is limited by assuming that the attacker can inject only a small fraction  $\alpha$  of poisoning points into the training set. Thus, the attacker solves an optimization problem involving a set of poisoned data points ( $\alpha n$ ) added to the training data.

Poisoning points can be optimized via gradient-ascent procedures, as shown in Algorithm 1. The main challenge is to compute the gradient of the attacker’s objective (i.e., the validation loss) with respect to each poisoning point. In fact, this gradient has to capture the implicit dependency of the optimal parameter vector  $\mathbf{w}^*$  (learned after training) on the poisoning point being optimized, as the classification function changes while this point is updated. Provided that the attacker function is differentiable w.r.t.  $\mathbf{w}$  and  $\mathbf{x}$ , the required gradient can be computed using the chain rule [4, 5, 24, 27, 48]:

$$\nabla_{\mathbf{x}} \mathcal{A} = \nabla_{\mathbf{x}} L + \frac{\partial \mathbf{w}^*}{\partial \mathbf{x}}^{\top} \nabla_{\mathbf{w}} L, \quad (7)$$

where the term  $\frac{\partial \mathbf{w}^*}{\partial \mathbf{x}}$  captures the implicit dependency of the parameters  $\mathbf{w}$  on the poisoning point  $\mathbf{x}$ . Under some regularity conditions, this derivative can be computed by replacing the inner optimization problem with its stationarity (Karush-Kuhn-Tucker, KKT) conditions, i.e., with its implicit equation  $\nabla_{\mathbf{w}} \mathcal{L}(\mathcal{D}_{\text{tr}} \cup (\mathbf{x}', y), \mathbf{w}) = \mathbf{0}$  [24, 27].<sup>1</sup> By differentiating this expression w.r.t. the poisoning point  $\mathbf{x}$ , one yields:

$$\nabla_{\mathbf{x}} \nabla_{\mathbf{w}} \mathcal{L} + \frac{\partial \mathbf{w}^*}{\partial \mathbf{x}}^{\top} \nabla_{\mathbf{w}}^2 \mathcal{L} = \mathbf{0}. \quad (8)$$

Solving for  $\frac{\partial \mathbf{w}^*}{\partial \mathbf{x}}$ , we obtain  $\frac{\partial \mathbf{w}^*}{\partial \mathbf{x}}^{\top} = -(\nabla_{\mathbf{x}} \nabla_{\mathbf{w}} \mathcal{L})(\nabla_{\mathbf{w}}^2 \mathcal{L})^{-1}$ , which can be substituted in Eq. (7) to obtain the required gradient:

$$\nabla_{\mathbf{x}} \mathcal{A} = \nabla_{\mathbf{x}} L - (\nabla_{\mathbf{x}} \nabla_{\mathbf{w}} \mathcal{L})(\nabla_{\mathbf{w}}^2 \mathcal{L})^{-1} \nabla_{\mathbf{w}} L. \quad (9)$$

**Gradients for SVM.** Poisoning attacks against SVMs were first proposed in [4]. Here, we report a simplified expression for SVM poisoning, with  $\mathcal{L}$  corresponding to the dual SVM learning problem, and  $L$  to the hinge loss (in the outer optimization):

$$\nabla_{\mathbf{x}_c} \mathcal{A} = -\alpha_c \frac{\partial \mathbf{k}_{kc}}{\partial \mathbf{x}_c} \mathbf{y}_k + \alpha_c \begin{bmatrix} \frac{\partial \mathbf{k}_{sc}}{\partial \mathbf{x}_c} & 0 \end{bmatrix} \begin{bmatrix} \mathbf{K}_{ss} & \mathbf{1} \\ \mathbf{1}^{\top} & 0 \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{K}_{sk} \\ \mathbf{1}^{\top} \end{bmatrix} \mathbf{y}_k. \quad (10)$$

We use  $c$ ,  $s$  and  $k$  here to respectively index the attack point, the support vectors, and the validation points for which  $\ell(y, \mathbf{x}, \mathbf{w}) > 0$  (corresponding to a non-null derivative of the hinge loss). The coefficient  $\alpha_c$  is the dual variable assigned to the poisoning point by the learning algorithm, and  $\mathbf{k}$  and  $\mathbf{K}$  contain kernel values between the corresponding indexed sets of points.

**Gradients for Logistic Regression.** Logistic regression is a linear classifier that estimates the probability of the positive class using the sigmoid function. A poisoning attack against logistic regression has been derived in [24], but maximizing a different outer objective and not directly the validation loss.

<sup>1</sup>More rigorously, we should write the KKT conditions in this case as  $\nabla_{\mathbf{w}} \mathcal{L}(\mathcal{D}_{\text{tr}} \cup (\mathbf{x}', y), \mathbf{w}) \in \mathbf{0}$ , as the solution may not be unique.

One of our contributions is to compute gradients for logistic regression under our optimization framework. Using logistic loss as the attacker’s loss, the poisoning gradient for logistic regression can be computed as:

$$\nabla_{\mathbf{x}_c} \mathcal{A} = - \begin{bmatrix} \nabla_{\mathbf{x}_c} \nabla_{\theta} \mathcal{L} \\ C z_c \theta \end{bmatrix}^{\top} \begin{bmatrix} \nabla_{\theta}^2 \mathcal{L} & \mathbf{X} \mathbf{z} C \\ C \mathbf{z} \mathbf{X} & C \sum_i^n z_i \end{bmatrix}^{-1} \begin{bmatrix} \mathbf{X}(\mathbf{y} \circ \sigma - \mathbf{y}) \\ \mathbf{y}^{\top} (\sigma - 1) \end{bmatrix} C,$$

where  $\theta$  are the classifier weights (bias excluded),  $\circ$  is the element-wise product,  $\mathbf{z}$  is equal to  $\sigma(1 - \sigma)$ ,  $\sigma$  is the sigmoid of the signed discriminant function (each element of that vector is therefore:  $\sigma_i = \frac{1}{1 + \exp(-y_i f_i)}$  with  $f_i = \mathbf{x}_i \theta + b$ ), and:

$$\nabla_{\theta}^2 \mathcal{L} = C \sum_i^n \mathbf{x}_i z_i \mathbf{x}_i^{\top} + \mathbb{I}, \quad (11)$$

$$\nabla_{\mathbf{x}_c} \nabla_{\theta} \mathcal{L} = C(\mathbb{I} \circ (y_c \sigma_c - y_c) + z_c \theta \mathbf{x}_c^{\top}) \quad (12)$$

In the above equations,  $\mathbb{I}$  is the identity matrix.

## 4 Transferability Definition and Metrics

We discuss here an intriguing connection among transferability of both evasion and poisoning attacks, input gradients and model complexity, and highlight the factors impacting transferability between a surrogate and a target model. Model complexity is a measure of the capacity of a learning algorithm to fit the training data. It is typically penalized to avoid overfitting by reducing either the number of classifier parameters to be learnt or their size (e.g., via regularization) [6]. Given that complexity is essentially controlled by the hyperparameters of a given learning algorithm (e.g., the number of neurons in the hidden layers of a neural network, or the regularization hyperparameter  $C$  of an SVM), *only models that are trained using the same learning algorithm should be compared in terms of complexity*. As we will see, this is an important point to correctly interpret the results of our analysis. For notational convenience, we denote in the following the attack points as  $\mathbf{x}^* = \mathbf{x} + \hat{\delta}$ , where  $\mathbf{x}$  is the initial point and  $\hat{\delta}$  the adversarial perturbation optimized by the attack algorithm against the *surrogate* classifier, for both evasion and poisoning attacks. We start by formally defining transferability for evasion attacks, and then discuss how this definition and the corresponding metrics can be generalized to poisoning.

**Transferability of Evasion Attacks.** Given an evasion attack point  $\mathbf{x}^*$ , crafted against a surrogate learner (parameterized by  $\hat{\mathbf{w}}$ ), we define its *transferability* as the loss attained by the target classifier  $f$  (parameterized by  $\mathbf{w}$ ) on that point, i.e.,  $T = \ell(y, \mathbf{x} + \hat{\delta}, \mathbf{w})$ . This can be simplified through a linear approximation of the loss function as:

$$T = \ell(y, \mathbf{x} + \hat{\delta}, \mathbf{w}) \approx \ell(y, \mathbf{x}, \mathbf{w}) + \hat{\delta}^{\top} \nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \mathbf{w}). \quad (13)$$

This approximation may not only hold for sufficiently-small input perturbations. It may also hold for larger perturbations

if the classification function is linear or has a small curvature (e.g., if it is strongly regularized). It is not difficult to see that, for any given point  $\mathbf{x}, y$ , the evasion problem in Eqs. (2)-(3) (without considering the feature bounds in Eq. 4) can be rewritten as:

$$\hat{\delta} \in \arg \max_{\|\hat{\delta}\|_p \leq \varepsilon} \ell(y, \mathbf{x} + \hat{\delta}, \hat{\mathbf{w}}). \quad (14)$$

Under the same linear approximation, this corresponds to the maximization of an inner product over an  $\varepsilon$ -sized ball:

$$\max_{\|\hat{\delta}\|_p \leq \varepsilon} \hat{\delta}^{\top} \nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}}) = \varepsilon \|\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}})\|_q, \quad (15)$$

where  $\ell_q$  is the dual norm of  $\ell_p$ .

The above problem is maximized as follows:

1. For  $p = 2$ , the maximum is  $\hat{\delta} = \varepsilon \frac{\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}})}{\|\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}})\|_2}$ ;
2. For  $p = \infty$ , the maximum is  $\hat{\delta} \in \varepsilon \cdot \text{sign}\{\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}})\}$ ;
3. For  $p = 1$ , the maximum is achieved by setting the values of  $\hat{\delta}$  that correspond to the maximum absolute values of  $\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \hat{\mathbf{w}})$  to their sign, i.e.,  $\pm 1$ , and 0 otherwise.

Substituting the optimal value of  $\hat{\delta}$  into Eq. (13), we can compute the loss increment  $\Delta \ell = \hat{\delta}^{\top} \nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \mathbf{w})$  under a transfer attack in closed form; e.g., for  $p = 2$ , it is given as:

$$\Delta \ell = \varepsilon \frac{\nabla_{\mathbf{x}} \hat{\ell}^{\top}}{\|\nabla_{\mathbf{x}} \hat{\ell}\|_2} \nabla_{\mathbf{x}} \ell \leq \varepsilon \|\nabla_{\mathbf{x}} \ell\|_2, \quad (16)$$

where, for compactness, we use  $\hat{\ell} = \ell(y, \mathbf{x}, \hat{\mathbf{w}})$  and  $\ell = \ell(y, \mathbf{x}, \mathbf{w})$ . In this equation, the left-hand side is the increase in the loss function in the black-box case, while the right-hand side corresponds to the white-box case. The upper bound is obtained when the surrogate classifier  $\hat{\mathbf{w}}$  is equal to the target  $\mathbf{w}$  (white-box attacks). Similar results hold for  $p = 1$  and  $p = \infty$  (using the dual norm in the right-hand side).

**Intriguing Connections and Transferability Metrics.** The above findings reveal some interesting connections among transferability of attacks, model complexity (controlled by the classifier hyperparameters) and input gradients, as detailed below, and allow us to define simple and computationally-efficient transferability metrics.

(1) *Size of Input Gradients.* The first interesting observation is that transferability depends on the size of the gradient of the loss  $\ell$  computed using the *target* classifier, regardless of the surrogate: the larger this gradient is, the larger the attack impact may be. This is inferred from the upper bound in Eq. (16). We define the corresponding metric  $S(\mathbf{x}, y)$  as:

$$S(\mathbf{x}, y) = \|\nabla_{\mathbf{x}} \ell(y, \mathbf{x}, \mathbf{w})\|_q, \quad (17)$$

where  $q$  is the dual of the perturbation norm.

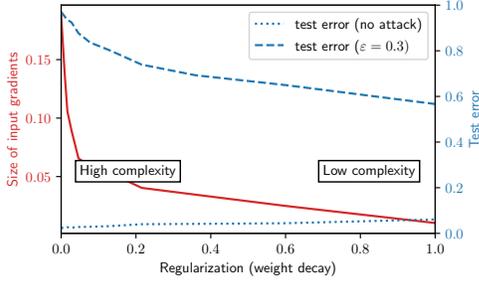

Figure 3: Size of input gradients (averaged on the test set) and test error (in the absence and presence of evasion attacks) against regularization (controlled via weight decay) for a neural network trained on MNIST89 (see Sect. 5.1.1). Note how the size of input gradients and the test error under attack decrease as regularization (complexity) increases (decreases).

The size of the input gradient also depends on the complexity of the given model, controlled, e.g., by its regularization hyperparameter. Less complex, strongly-regularized classifiers tend to have smaller input gradients, i.e., they learn smoother functions that are more robust to attacks, and vice-versa. Notably, this holds for both evasion and poisoning attacks (e.g., the poisoning gradient in Eq. 10 is proportional to  $\alpha_c$ , which is larger when the model is weakly regularized). In Fig. 3 we report an example showing how increasing regularization (i.e., decreasing complexity) for a neural network trained on MNIST89 (see Sect. 5.1.1), by controlling its *weight decay*, reduces the average size of its input gradients, improving adversarial robustness to evasion. It is however worth remarking that, since complexity is a model-dependent characteristic, the size of input gradients cannot be directly compared across different learning algorithms; e.g., if a linear SVM exhibits larger input gradients than a neural network, we cannot conclude that the former will be more vulnerable.

Another interesting observation is that, if a classifier has large input gradients (e.g., due to high-dimensionality of the input space and low level of regularization), for an attack to succeed it may suffice to apply only tiny, *imperceptible* perturbations. As we will see in the experimental section, this explains why adversarial examples against deep neural networks can often only be slightly perturbed to mislead detection, while when attacking less complex classifiers in low dimensions, modifications become more evident.

(2) *Gradient Alignment*. The second relevant impact factor on transferability is based on the alignment of the input gradients of the loss function computed using the target and the surrogate learners. If we compare the increase in the loss function in the black-box case (the left-hand side of Eq. 16) against that corresponding to white-box attacks (the right-hand side), we find that the relative increase in loss, at least for  $\ell_2$  perturbations, is given by the following value:

$$R(\mathbf{x}, y) = \frac{\nabla_{\mathbf{x}} \hat{\ell}^\top \nabla_{\mathbf{x}} \ell}{\|\nabla_{\mathbf{x}} \hat{\ell}\|_2 \|\nabla_{\mathbf{x}} \ell\|_2}. \quad (18)$$

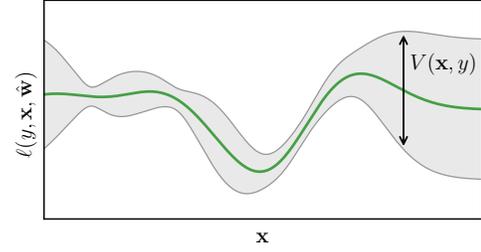

Figure 4: Conceptual representation of the variability of the loss landscape. The green line represents the expected loss with respect to different training sets used to learn the surrogate model, while the gray area represents the variance of the loss landscape. If the variance is too large, local optima may change, and the attack may not successfully transfer.

Interestingly, this is exactly the cosine of the angle between the gradient of the loss of the surrogate and that of the target classifier. This is a novel finding which explains why the cosine angle metric between the target and surrogate gradients can well characterize the transferability of attacks, confirming empirical results from previous work [21]. For other kinds of perturbation, this definition slightly changes, but gradient alignment can be similarly evaluated. Differently from the gradient size  $S$ , gradient alignment is a pairwise metric, allowing comparisons across different surrogate models; e.g., if a surrogate SVM is better aligned with the target model than another surrogate, we can expect that attacks targeting the surrogate SVM will transfer better.

(3) *Variability of the Loss Landscape*. We define here another useful metric to characterize attack transferability. The idea is to measure the variability of the loss function  $\hat{\ell}$  when the training set used to learn the surrogate model changes, even though it is sampled from the same underlying distribution. The reason is that the loss  $\hat{\ell}$  is exactly the objective function  $\mathcal{A}$  optimized by the attacker to craft evasion attacks (Eq. 1). Accordingly, if this loss landscape changes dramatically even when simply resampling the surrogate training set (which may happen, e.g., for surrogate models exhibiting a large error variance, like neural networks and decision trees), it is very likely that the local optima of the corresponding optimization problem will change, and this may in turn imply that the attacks will not transfer correctly to the target learner.

We define the variability of the loss landscape simply as the *variance* of the loss, estimated at a given attack point  $\mathbf{x}, y$ :

$$V(\mathbf{x}, y) = \mathbb{E}_{\mathcal{D}}\{\ell(y, \mathbf{x}, \hat{\mathbf{w}})^2\} - \mathbb{E}_{\mathcal{D}}\{\ell(y, \mathbf{x}, \hat{\mathbf{w}})\}^2, \quad (19)$$

where  $\mathbb{E}_{\mathcal{D}}$  is the expectation taken with respect to different (surrogate) training sets. This is very similar to what is typically done to estimate the variance of classifiers' predictions. This notion is clarified also in Fig. 4. As for the size of input gradients  $S$ , also the loss variance  $V$  should only be compared across models trained with the same learning algorithm.

The transferability metrics  $S$ ,  $R$  and  $V$  defined so far depend on the initial attack point  $\mathbf{x}$  and its label  $y$ . In our experiments, we will compute their mean values by averaging on different initial attack points.

**Transferability of Poisoning Attacks.** For poisoning attacks, we can essentially follow the same derivation discussed before. Instead of defining transferability in terms of the loss attained on the modified test point, we define it in terms of the validation loss attained by the target classifier under the influence of the poisoning points. This loss function can be linearized as done in the previous case, yielding:  $T \cong L(\mathcal{D}, \mathbf{w}) + \hat{\delta}^\top \nabla_{\mathbf{x}} L(\mathcal{D}, \mathbf{w})$ , where  $\mathcal{D}$  are the untainted validation points, and  $\hat{\delta}$  is the perturbation applied to the initial poisoning point  $\mathbf{x}$  against the surrogate classifier. Recall that  $L$  depends on the poisoning point through the classifier parameters  $\mathbf{w}$ , and that the gradient  $\nabla_{\mathbf{x}} L(\mathcal{D}, \mathbf{w})$  here is equivalent to the generic one reported in Eq. (9). It is then clear that the perturbation  $\hat{\delta}$  maximizes the (linearized) loss when it is best aligned with its derivative  $\nabla_{\mathbf{x}} L(\mathcal{D}, \mathbf{w})$ , according to the constraint used, as in the previous case. The three transferability metrics defined before can also be used for poisoning attacks provided that we simply replace the evasion loss  $\ell(y, \mathbf{x}, \mathbf{w})$  with the validation loss  $L(\mathcal{D}, \mathbf{w})$ .

## 5 Experimental Analysis

In this section, we evaluate the transferability of both evasion and poisoning attacks across a range of ML models. We highlight some interesting findings about transferability, based on the three metrics developed in Sect. 4. In particular, we analyze attack transferability in terms of its connection to the size of the input gradients of the loss function, the gradient alignment between surrogate and target classifiers, and the variability of the loss function optimized to craft the attack points. We provide recommendations on how to choose the most effective surrogate models to craft transferable attacks in the black-box setting.

### 5.1 Transferability of Evasion Attacks

We start by reporting our experiments on evasion attacks. We consider here two distinct case studies, involving handwritten digit recognition and Android malware detection.

#### 5.1.1 Handwritten Digit Recognition

The MNIST89 data includes the MNIST handwritten digits from classes 8 and 9. Each digit image consists of 784 pixels ranging from 0 to 255, normalized in  $[0, 1]$  by dividing such values by 255. We run 10 independent repetitions to average the results on different training-test splits. In each repetition, we run white-box and black-box attacks, using 5,900 samples to train the target classifier, 5,900 distinct samples to train the surrogate classifier (without even relabeling the surrogate data

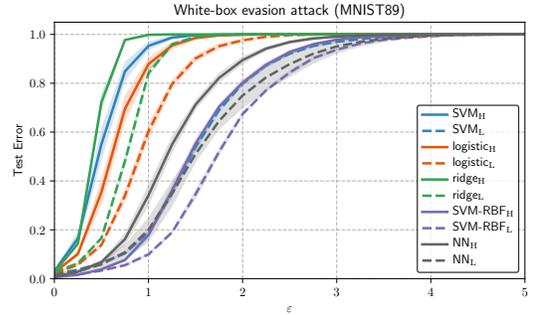

Figure 5: White-box evasion attacks on MNIST89. Test error against increasing maximum perturbation  $\epsilon$ .

with labels predicted by the target classifier; i.e., we do not perform any query on the target), and 1,000 test samples. We modified test digits in both classes using Algorithm 1 under the  $\ell_2$  distance constraint  $\|\mathbf{x} - \mathbf{x}'\|_2 \leq \epsilon$ , with  $\epsilon \in [0, 5]$ .

For each of the following learning algorithms, we train a high-complexity (H) and a low-complexity (L) model, by changing its hyperparameters: (i) SVMs with linear kernel (SVM<sub>H</sub> with  $C = 100$  and SVM<sub>L</sub> with  $C = 0.01$ ); (ii) SVMs with RBF kernel (SVM-RBF<sub>H</sub> with  $C = 100$  and SVM-RBF<sub>L</sub> with  $C = 1$ , both with  $\gamma = 0.01$ ); (iii) logistic classifiers (logistic<sub>H</sub> with  $C = 10$  and logistic<sub>L</sub> with  $C = 1$ ); (iv) ridge classifiers (ridge<sub>H</sub> with  $\alpha = 1$  and ridge<sub>L</sub> with  $\alpha = 10$ );<sup>2</sup> (v) fully-connected neural networks with two hidden layers including 50 neurons each, and ReLU activations (NN<sub>H</sub> with no regularization, i.e., weight decay set to 0, and NN<sub>L</sub> with weight decay set to 0.01), trained via cross-entropy loss minimization; and (vi) random forests consisting of 30 trees (RF<sub>H</sub> with no limit on the depth of the trees and RF<sub>L</sub> with a maximum depth of 8). These configurations are chosen to evaluate the robustness of classifiers that exhibit similar test accuracies but different levels of complexity.

**How does model complexity impact evasion attack success in the white-box setting?** The results for white-box evasion attacks are reported for all classifiers that fall under our framework and can be tested for evasion with gradient-based attacks (SVM, Logistic, Ridge, and NN). This excludes random forests, as they are not differentiable. We report the complete *security evaluation curves* [5] in Fig. 5, showing the mean test error (over 10 runs) against an increasing maximum admissible distortion  $\epsilon$ . In Fig. 6a we report the mean test error at  $\epsilon = 1$  for each target model against the size of its input gradients ( $S$ , averaged on the test samples and on the 10 runs).

The results show that, for each learning algorithm, the low-complexity model has smaller input gradients, and it is less vulnerable to evasion than its high-complexity counterpart, confirming our theoretical analysis. This is also confirmed by the  $p$ -values reported in Table 1 (first column), obtained by

<sup>2</sup>Recall that the level of regularization increases as  $\alpha$  increases, and as  $C$  decreases.

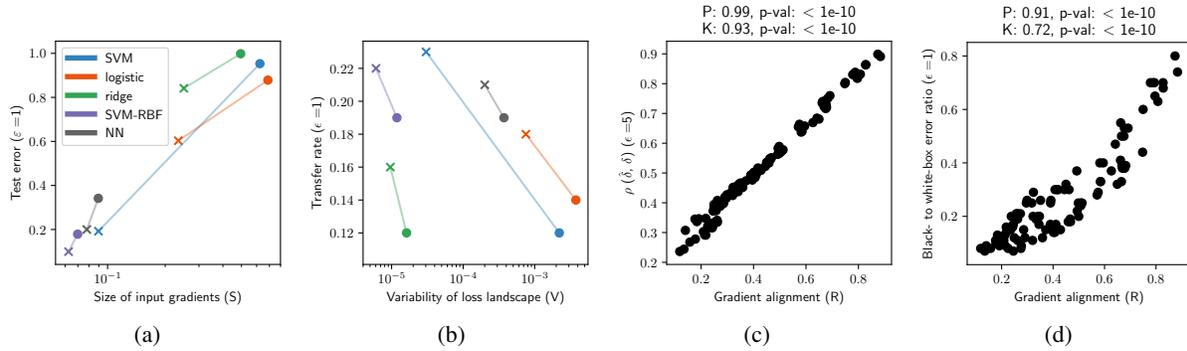

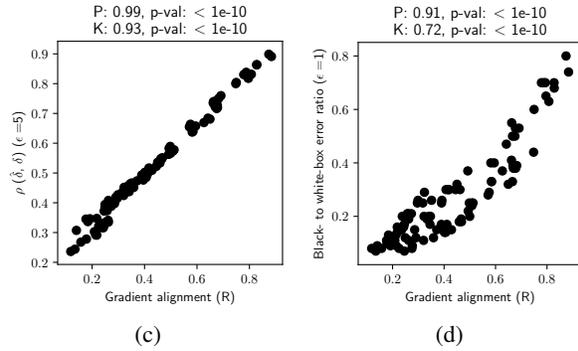

Figure 6: Evaluation of our metrics for evasion attacks on MNIST89. (a) Test error under attack vs average size of input gradients ( $S$ ) for low- (denoted with ‘ $\times$ ’) and high-complexity (denoted with ‘ $\circ$ ’) classifiers. (b) Average transfer rate vs variability of loss landscape ( $V$ ). (c) Pearson correlation coefficient  $\rho(\hat{\delta}, \delta)$  between black-box ( $\hat{\delta}$ ) and white-box ( $\delta$ ) perturbations (values in Fig. 8, right) vs gradient alignment ( $R$ , values in Fig. 8, left) for each target-surrogate pair. Pearson ( $P$ ) and Kendall ( $K$ ) correlations between  $\rho$  and  $R$  are also reported along with the  $p$ -values obtained from a permutation test to assess statistical significance.

	Evasion				Poisoning			
	MNIST89		DREBIN		MNIST89		LFW	
	$\epsilon = 1$	$\epsilon = 1$	$\epsilon = 5$	$\epsilon = 30$	5%	20%	5%	20%
SVM	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	0.75
logistic	<1e-2	<1e-2	<1e-2	0.02	<1e-2	<1e-2	0.10	0.21
ridge	<1e-2	<1e-2	<1e-2	<1e-2	0.02	<1e-2	0.02	0.75
SVM-RBF	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	<1e-2	0.11
NN	<1e-2	<1e-2	<1e-2	0.02				

Table 1: Statistical significance of our results. For each attack, dataset and learning algorithm, we report the  $p$ -values of two two-sided binomial tests, to respectively reject the null hypothesis that: (i) for white-box attacks, the test errors of the high- and low-complexity target follow the same distribution; and (ii) for black-box attacks, the transfer rates of the high- and low-complexity surrogate follow the same distribution. Each test is based on 10 samples, obtained by comparing the error of the high- and low-complexity models for each learning algorithm in each repetition. In the first (second) case, success corresponds to a larger test (transfer) error for the high-complexity target (low-complexity surrogate).

running a binomial test for each learning algorithm to compare the white-box test error of the corresponding high- and low-complexity models. All the  $p$ -values are smaller than 0.05, which confirms 95% statistical significance. Recall that these results hold only when comparing models trained using the same learning algorithm. This means that we can compare, e.g., the  $S$  value of  $SVM_H$  against  $SVM_L$ , but not that of  $SVM_H$  against  $logistic_H$ . In fact, even though  $logistic_H$  exhibits the largest  $S$  value, it is not the most vulnerable classifier. Another interesting finding is that nonlinear classifiers tend to be less vulnerable than linear ones.

**How do evasion attacks transfer between models in black-box settings?** In Fig. 7 we report the results for black-box evasion attacks, in which the attacks against surrogate models (in rows) are transferred to the target models (in columns).

The top row shows results for surrogates trained using only 20% of the surrogate training data, while in the bottom row surrogates are trained using all surrogate data, i.e., a training set of the same size as that of the target. The three columns report results for  $\epsilon \in \{1, 2, 5\}$ .

It can be noted that lower-complexity models (with stronger regularization) provide better surrogate models, on average. In particular, this can be seen best in the middle column for medium level of perturbation, in which the lower-complexity models ( $SVM_L$ ,  $logistic_L$ ,  $ridge_L$ , and  $SVM-RBF_L$ ) provide on average higher error when transferred to other models. The reason is that they learn smoother and stabler functions, that are capable of better approximating the target function. Surprisingly, this holds also when using only 20% of training data, as the black-box attacks relying on such low-complexity models still transfer with similar test errors. This means that most classifiers can be attacked in this black-box setting with almost no knowledge of the model, no query access, but provided that one can get a small amount of data similar to that used to train the target model.

These findings are also confirmed by looking at the variability of the loss landscape, computed as discussed in Sect. 4 (by considering 10 different training sets), and reported against the average transfer rate of each surrogate model in Fig. 6b. It is clear from that plot that higher-variance classifiers are less effective as surrogates than their less-complex counterparts, as the former tend to provide worse, unstable approximations of the target classifier. To confirm the statistical significance of this result, for each learning algorithm we also compare the mean transfer errors of high- and low-complexity surrogates with a binomial test whose  $p$ -values (always lower than 0.05) are reported in Table 1 (second column).

Another interesting, related observation is that the adversarial examples computed against lower-complexity surrogates have to be perturbed more to evade (see Fig. 9), whereas the perturbation of the ones computed against complex models

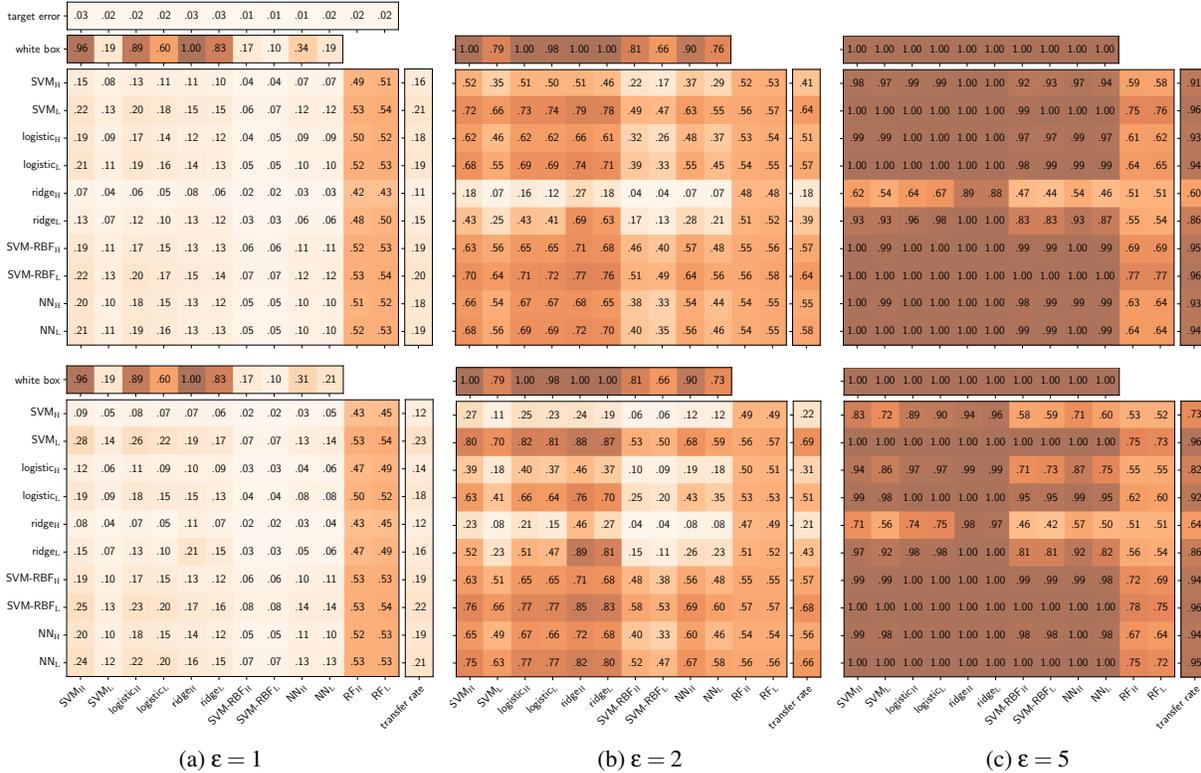

Figure 7: Black-box (transfer) evasion attacks on MNIST89. Each cell contains the test error of the target classifier (in columns) computed on the attack samples crafted against the surrogate (in rows). Matrices in the top (bottom) row correspond to attacks crafted against surrogate models trained with 20% (100%) of the surrogate training data, for  $\epsilon \in \{1, 2, 5\}$ . The test error of each target classifier in the absence of attack (target error) and under (white-box) attack are also reported for comparison, along with the mean transfer rate of each surrogate across targets. Darker colors mean higher test error, i.e., better transferability.

can be smaller. This is again due to the instability induced by high-complexity models into the loss function optimized to craft evasion attacks, whose sudden changes cause the presence of closer local optima to the initial attack point.

*On the vulnerability of random forests.* A noteworthy finding is that random forests can be effectively attacked at small perturbation levels using most other models (see last two columns in Fig. 7). We looked at the learned trees and discovered that trees often are susceptible to small changes. In one example, a node of the tree checked if a particular feature value was above 0.002, and classified samples as digit 8 if that condition holds (and digit 9 otherwise). The attack modified that feature from 0 to 0.028, causing it to be immediately misclassified. This vulnerability is intrinsic in the selection process of the threshold values used by these decision trees to split each node. The threshold values are selected among the existing values in the dataset (to correctly handle categorical attributes). Therefore, for pixels which are highly discriminant (e.g., mostly black for one class and white for the other), the threshold will be either very close to one extreme or the other, making it easy to subvert the prediction by a small change. Since  $\ell_2$ -norm attacks change almost all feature values, with high probability the attack modifies at least one feature on

every path of the tree, causing misclassification.

### Is gradient alignment an effective transferability metric?

In Fig. 8, we report on the left the gradient alignment computed between surrogate and target models, and on the right the Pearson correlation coefficient  $\rho(\hat{\delta}, \delta)$  between the perturbation optimized against the surrogate (i.e., the black-box perturbation  $\hat{\delta}$ ) and that optimized against the target (i.e., the white-box perturbation  $\delta$ ). We observe immediately that gradient alignment provides an accurate measure of transferability: the higher the cosine similarity, the higher the correlation (meaning that the adversarial examples crafted against the two models are similar). We correlate these two measures in Fig. 6c, and show that such correlation is statistically significant for both Pearson and Kendall coefficients. In Fig. 6d we also correlate gradient alignment with the ratio between the test error of the target model in the black- and white-box setting (extrapolated from the matrix corresponding to  $\epsilon = 1$  in the bottom row of Fig. 7), as suggested by our theoretical derivation. The corresponding permutation tests confirm statistical significance. We finally remark that gradient alignment is extremely fast to evaluate, as it does not require simulating any attack, but it is only a relative measure of the attack trans-

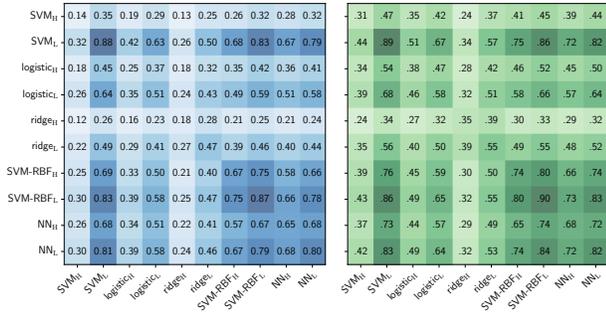

Figure 8: Gradient alignment and perturbation correlation for evasion attacks on MNIST89. *Left*: Gradient alignment  $R$  (Eq. 18) between surrogate (rows) and target (columns) classifiers, averaged on the unmodified test samples. *Right*: Pearson correlation coefficient  $\rho(\delta, \hat{\delta})$  between white-box and black-box perturbations for  $\epsilon = 5$ .

ferability, as the latter also depends on the complexity of the target model; i.e., on the size of its input gradients.

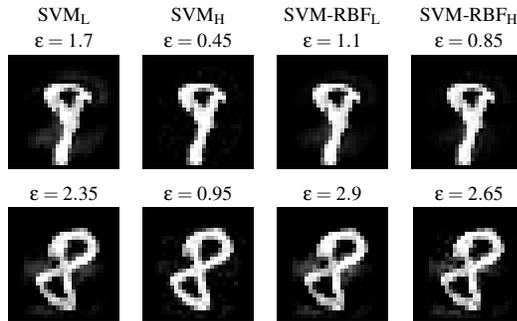

Figure 9: Digit images crafted to evade linear and RBF SVMs. The values of  $\epsilon$  reported here correspond to the minimum perturbation required to evade detection. Larger perturbations are required to mislead low-complexity classifiers (L), while smaller ones suffice to evade high-complexity classifiers (H).

### 5.1.2 Android Malware Detection

The Drebin data [1] consists of around 120,000 legitimate and around 5000 malicious Android applications, labeled using the VirusTotal service. A sample is labeled as malicious (or positive,  $y = +1$ ) if it is classified as such from at least five out of ten anti-virus scanners, while it is flagged as legitimate (or negative,  $y = -1$ ) otherwise. The structure and the source code of each application is encoded as a *sparse* feature vector consisting of around a million binary features denoting the presence or absence of permissions, suspicious URLs and other relevant information that can be extracted by statically analyzing Android applications. Since we are working with sparse binary features, we use the  $\ell_1$  norm for the attack.

We use 30,000 samples to learn surrogate and target classifiers, and the remaining 66,944 samples for testing. The

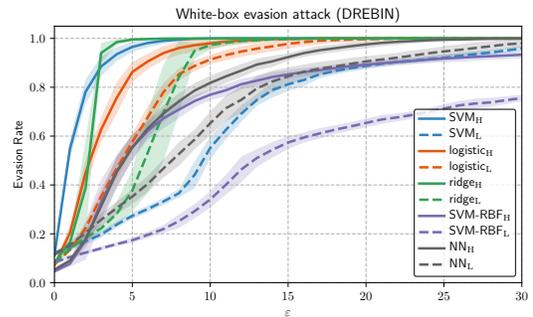

Figure 10: White-box evasion attacks on DREBIN. Evasion rate against increasing maximum perturbation  $\epsilon$ .

classifiers and their hyperparameters are the same used for MNIST89, apart from (i) the number of hidden neurons for  $NN_H$  and  $NN_L$ , set to 200, (ii) the weight decay of  $NN_L$ , set to 0.005; and (iii) the maximum depth of  $RF_L$ , set to 59.

We perform feature selection to retain those 5,000 features which maximize information gain, i.e.,  $|p(x_k = 1|y = +1) - p(x_k = 1|y = -1)|$ , where  $x_k$  is the  $k^{\text{th}}$  feature. While this feature selection process does not significantly affect the detection rate (which is only reduced by 2%, on average, at 0.5% false alarm rate), it drastically reduces the computational complexity of classification.

In each experiment, we run white-box and black-box evasion attacks on 1,000 distinct malware samples (randomly selected from the test data) against an increasing number of modified features in each malware  $\epsilon \in \{0, 1, 2, \dots, 30\}$ . This is achieved by imposing the  $\ell_1$  constraint  $\|\mathbf{x}' - \mathbf{x}\|_1 \leq \epsilon$ . As in previous work, we further restrict the attacker to only *inject* features into each malware sample, to avoid compromising its intrusive functionality [3, 11].

To evaluate the impact of the aforementioned evasion attack, we measure the evasion rate (i.e., the fraction of malware samples misclassified as legitimate) at 0.5% false alarm rate (i.e., when only 0.5% of the legitimate samples are misclassified as malware). As in the previous experiment, we report the complete *security evaluation curve* for the white-box attack case, whereas we report only the value of test error for the black-box case. The results, reported in Figs. 10, 11, 12, and 13, along with the statistical tests in Table 1 (third and fourth columns) confirm the main findings of the previous experiments. One significant difference is that random forests are much more robust in this case. The reason is that the  $\ell_1$ -norm attack (differently from the  $\ell_2$ ) only changes a small number of features, and thus the probability that it will change features in all the ensemble trees is very low.

### 5.2 Transferability of Poisoning Attacks

For poisoning attacks, we report experiments on handwritten digits and face recognition.

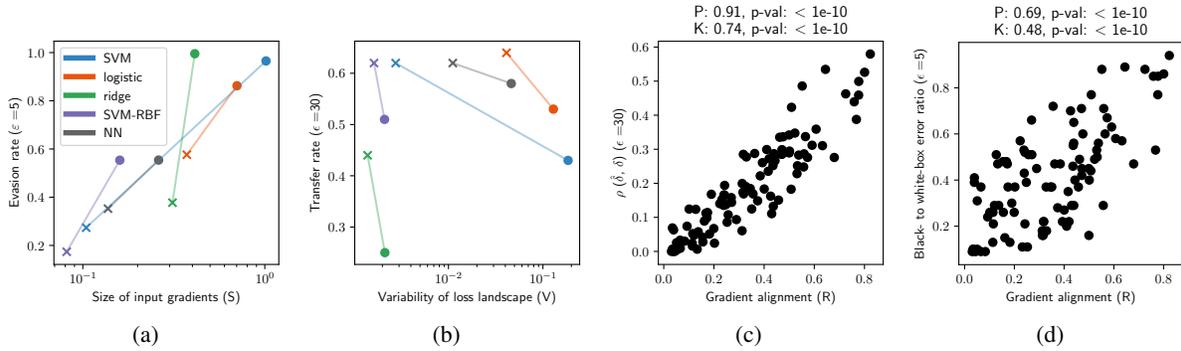

Figure 11: Evaluation of our metrics for evasion attacks on DREBIN. See the caption of Fig. 6 for further details.

### 5.2.1 Handwritten Digit Recognition

We apply our optimization framework to poison SVM, logistic, and ridge classifiers in the white-box setting. Designing efficient poisoning availability attacks against neural networks is still an open problem due to the complexity of the bilevel optimization and the non-convexity of the inner learning problem. Previous work has mainly considered integrity poisoning attacks against neural networks [5, 20, 41], and it is believed that neural networks are much more resilient to poisoning availability attacks due to their memorization capability. Poisoning random forests is not feasible with gradient-based attacks, and we are not aware of any existing attacks for this ensemble method. We thus consider as surrogate learners: (i) linear SVMs with  $C = 0.01$  (SVM<sub>L</sub>) and  $C = 100$  (SVM<sub>H</sub>); (ii) logistic classifiers with  $C = 0.01$  (logistic<sub>L</sub>) and  $C = 10$  (logistic<sub>H</sub>); (iii) ridge classifiers with  $\alpha = 100$  (ridge<sub>L</sub>) and  $\alpha = 10$  (ridge<sub>H</sub>); and (iv) SVMs with RBF kernel with  $\gamma = 0.01$  and  $C = 1$  (SVM-RBF<sub>L</sub>) and  $C = 100$  (SVM-RBF<sub>H</sub>). We additionally consider as target classifiers: (i) random forests with 100 base trees, each with a maximum depth of 6 for RF<sub>L</sub>, and with no limit on the maximum depth for RF<sub>H</sub>; (ii) feed-forward neural networks with two hidden layers of 200 neurons each and ReLU activations, trained via cross-entropy loss minimization with different regularization (NN<sub>L</sub> with weight decay 0.01 and NN<sub>H</sub> with no decay); and (iii) the Convolutional Neural Network (CNN) used in [7].

We consider 500 training samples, 1,000 validation samples to compute the attack, and a separate set of 1,000 test samples to evaluate the error. The test error is computed against an increasing number of poisoning points into the training set, from 0% to 20% (corresponding to 125 poisoning points). The reported results are averaged on 10 independent, randomly-drawn data splits.

**How does model complexity impact poisoning attack success in the white-box setting?** The results for white-box poisoning are reported in Fig. 14. Similarly to the evasion case, high-complexity models (with larger input gradients, as shown in Fig. 15a) are more vulnerable to poisoning attacks than their low-complexity counterparts (i.e., given that the same

learning algorithm is used). This is also confirmed by the statistical tests in the fifth column of Table 1. Therefore, model complexity plays a large role in a model’s robustness also against poisoning attacks, confirming our analysis.

**How do poisoning attacks transfer between models in black-box settings?** The results for black-box poisoning are reported in Fig. 16. For poisoning attacks, the best surrogates are those matching the complexity of the target, as they tend to be better aligned and to share similar local optima, except for low-complexity logistic and ridge surrogates, which seem to transfer better to linear classifiers. This is also witnessed by gradient alignment in Fig. 17, which is again not only correlated to the similarity between black- and white-box perturbations (Fig. 15c), but also to the ratio between the black- and white-box test errors (Fig. 15d). Interestingly, these error ratios are larger than one in some cases, meaning that attacking a surrogate model can be more effective than running a white-box attack against the target. A similar phenomenon has been observed for evasion attacks [33], and it is due to the fact that optimizing attacks against a *smoother* surrogate may find better local optima of the target function (e.g., by overcoming gradient obfuscation [2]). According to our findings, for poisoning attacks, reducing the variability of the loss landscape (V) of the surrogate model is less important than finding a good alignment between the surrogate and the target. In fact, from Fig. 15b it is evident that increasing V is even beneficial for SVM-based surrogates (and all these results are statistically significant according to the  $p$ -values in the sixth column of Table 1). A visual inspection of the poisoning digits in Fig. 18 reveals that the poisoning points crafted against high-complexity classifiers are only minimally perturbed, while the ones computed against low-complexity classifiers exhibit larger, visible perturbations. This is again due to the presence of closer local optima in the former case. Finally, a surprising result is that RFs are quite robust to poisoning, as well as NNs when attacked with low-complexity linear surrogates. The reason may be that these target classifiers have a large capacity, and can thus fit *outlying* samples (like the digits crafted against low-complexity classifiers in Fig. 18) without affecting the classification of the other training samples.

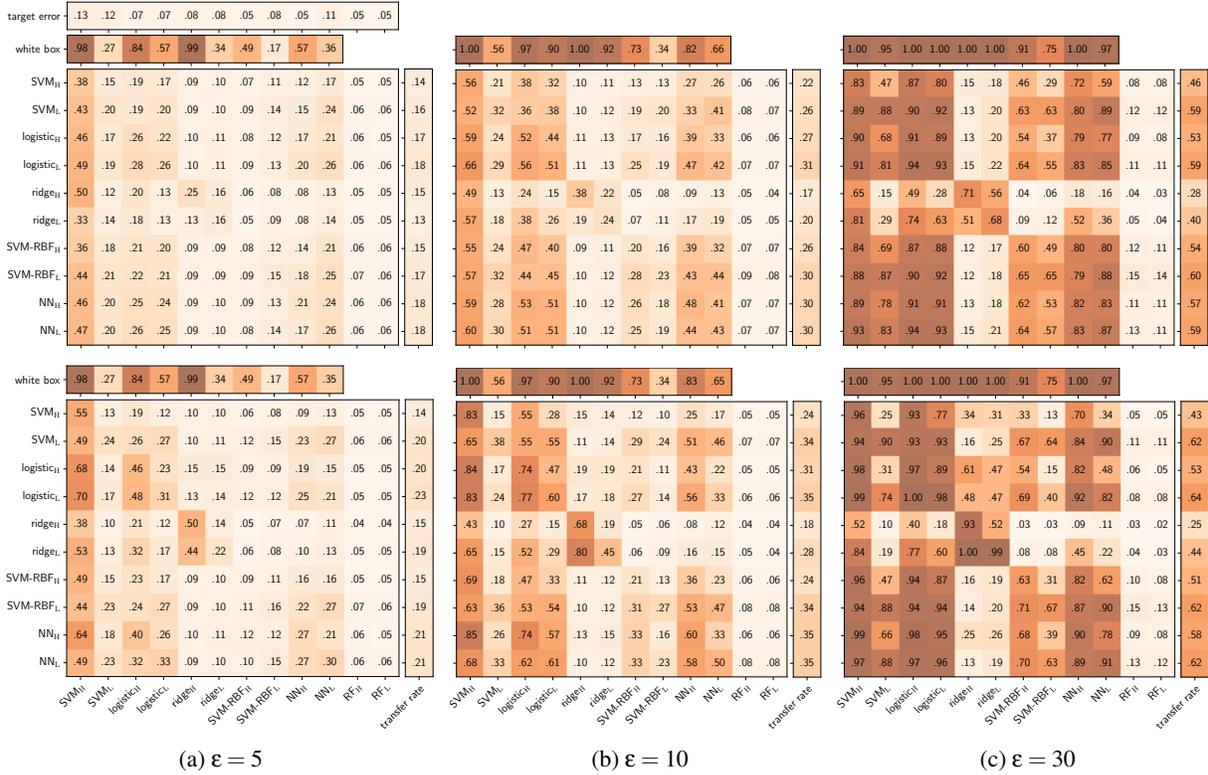

Figure 12: Black-box (transfer) evasion attacks on DREBIN. See the caption of Fig. 7 for further details.

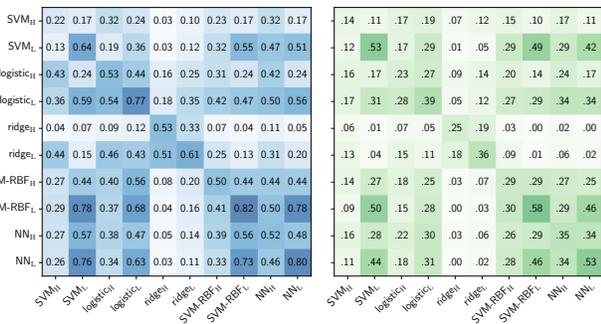

Figure 13: Gradient alignment and perturbation correlation (at  $\epsilon = 30$ ) for evasion attacks on DREBIN. See the caption of Fig. 8 for further details.

## 5.2.2 Face Recognition

The Labeled Face on the Wild (LFW) dataset consists of faces of famous peoples collected on Internet. We considered the six identities with the largest number of images in the dataset. We considered the person with most images as positive class, and all the others as negative. Our dataset consists of 530 positive and 758 negative images. The classifiers and their hyperparameters are the same used for MNIST89, except that we set: (i)  $C = 0.1$  for logistic<sub>L</sub>, (ii)  $\alpha = 1$  for ridge<sub>H</sub>, (iii)  $\gamma = 0.001, C = 10$  for SVM-RBF<sub>L</sub>, (iv)  $\gamma = 0.001, C = 1000$

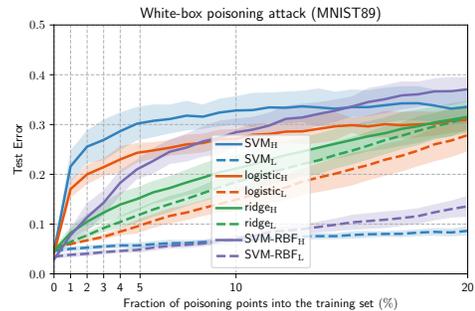

Figure 14: White-box poisoning attacks on MNIST89. Test error against an increasing fraction of poisoning points.

for SVM-RBF<sub>H</sub>, and (v) weight decay to 0.001 for NN<sub>L</sub>. We run 10 repetitions with 300 samples in each training, validation and test set. The results are shown in Figs 19, 20, 21 and 22, confirming the main findings discussed for poisoning attacks on MNIST89. Statistical tests for significance are reported in Table 1 (seventh and eighth columns). In this case, there is not a significant distinction between the mean transfer rates of high- and low-complexity surrogates, probably due to the reduced size of the training sets used. Finally, in Fig. 23 we report examples of perturbed faces against surrogates with different complexities, confirming again that larger perturbations are required to attack lower-complexity models.

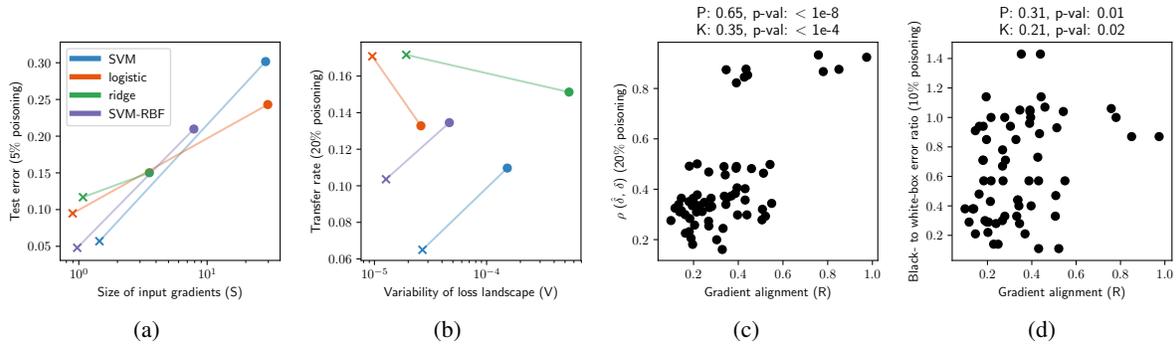

Figure 15: Evaluation of our metrics for poisoning attacks on MNIST89. See the caption of Fig. 6 for further details.

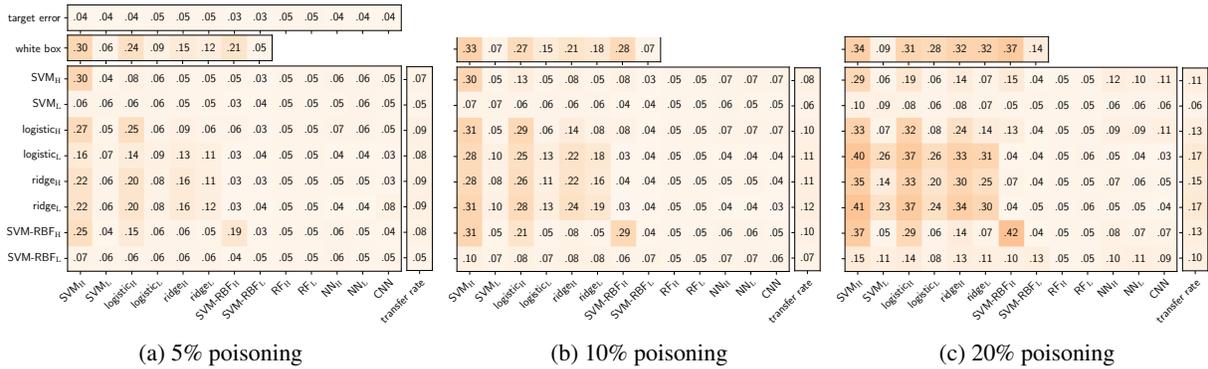

Figure 16: Black-box (transfer) poisoning attacks on MNIST89. See the caption of Fig. 7 for further details.

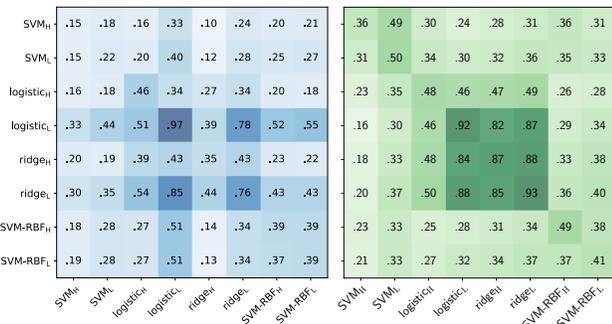

Figure 17: Gradient alignment and perturbation correlation (at 20% poisoning) for poisoning attacks on MNIST89. See the caption of Fig. 8 for further details.

### 5.3 Summary of Transferability Evaluation

We summarize the results of transferability for evasion and poisoning attacks below.

(1) **Size of input gradients.** Low-complexity target classifiers are less vulnerable to evasion and poisoning attacks than high-complexity target classifiers trained with the same learning algorithm, due to the reduced size of their input gradients. In general, nonlinear models are more robust than linear models to both types of attacks.

(2) **Gradient alignment.** Gradient alignment is correlated

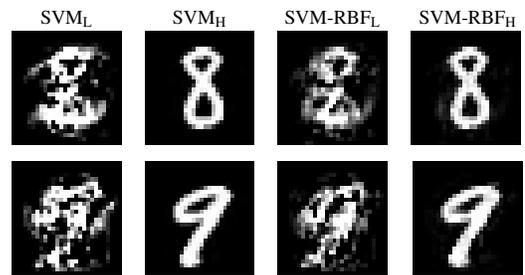

Figure 18: Poisoning digits crafted against linear and RBF SVMs. Larger perturbations are required to have significant impact on low-complexity classifiers (*L*), while minimal changes are very effective on high-complexity SVMs (*H*).

with transferability. Even though it cannot be directly measured in black-box scenarios, some useful guidelines can be derived from our analysis. For evasion attacks, low-complexity surrogate classifiers provide stabler gradients which are better aligned, on average, with those of the target models; thus, it is generally preferable to use strongly-regularized surrogates. For poisoning attacks, instead, gradient alignment tends to improve when the surrogate matches the complexity (regularization) of the target (which may be estimated using techniques from [46]).

(3) **Variability of the loss landscape.** Low-complexity surro-

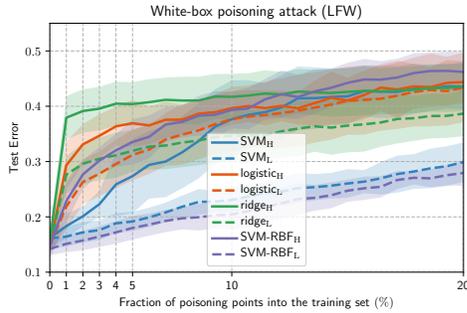

Figure 19: White-box poisoning attacks on LFW. Test error against an increasing fraction of poisoning points.

gate classifiers provide loss landscapes with lower variability than high-complexity surrogate classifiers trained with the same learning algorithm, especially for evasion attacks. This results in better transferability.

To summarize, for evasion attacks, decreasing complexity of the surrogate model by properly adjusting the hyperparameters of its learning algorithm provides adversarial examples that transfer better to a range of models. For poisoning attacks, the best surrogates are generally models with similar levels of regularization as the target model. The reason is that the poisoning objective function is relatively stable (i.e., it has low variance) for most classifiers, and gradient alignment between surrogate and target becomes a more important factor.

Understanding attack transferability has two main implications. First, even when attackers do not know the target classifier, our findings suggest that low-complexity surrogates have a better chance of transferring to other models. Our recommendation to performing black-box evasion attacks is to choose surrogates with low complexity (e.g., by using strong regularization and reducing model variance). To perform poisoning attacks, our recommendation is to acquire additional information about the level of regularization of the target and train a surrogate model with a similar level of regularization. Second, our analysis also provides recommendations to defenders on how to design more robust models against evasion and poisoning attacks. In particular, lower-complexity models tend to have more resilience compared to more complex models. Of course, we need to take into account the bias-variance trade-off and choose models that still perform relatively well on the original prediction tasks.

## 6 Related Work

**Transferability for evasion attacks.** Transferability of evasion attacks has been studied in previous work, e.g., [3, 13, 14, 21, 26, 32, 33, 42, 43, 47]. Biggio et al. [3] have been the first to consider evasion attacks against surrogate models in a limited-knowledge scenario. Goodfellow et al. [14], Tramer et al. [43], and Moosavi et al. [26] have made the observation that different models might learn intersecting decision bound-

aries in both benign and adversarial dimensions and in that case adversarial examples transfer better. Tramer et al. have also performed a detailed study of transferability of model-agnostic perturbations that depend only on the training data, noting that adversarial examples crafted against linear models can transfer to higher-order models. We answer some of the open questions they posed about factors contributing to attack transferability. Liu et al. [21] have empirically observed the gradient alignment between models with transferable adversarial examples. Papernot et al. [32, 33] have observed that adversarial examples transfer across a range of models, including logistic regression, SVMs and neural networks, without providing a clear explanation of the phenomenon. Prior work has also investigated the role of input gradients and Jacobians. Some authors have proposed to decrease the magnitude of input gradients during training to defend against evasion attacks [22, 35] or improve classification accuracy [40, 44]. In [35, 39], the magnitude of input gradients has been identified as a cause for vulnerability to evasion attacks. A number of papers have shown that transferability of adversarial examples is increased by averaging the gradients computed for ensembles of models [13, 21, 43, 47]. We highlight that we obtain similar effect by attacking a strongly-regularized surrogate model with a smoother and stabler decision boundary (resulting in a lower-variance model). The advantage of our approach is to reduce the computational complexity compared to attacking classifier ensembles. Through our formalization, we shed light on the most important factors for transferability. In particular, we identify a set of conditions that explain transferability including the gradient alignment between the surrogate and targeted models, and the size of the input gradients of the target model, connected to model complexity. We demonstrate that adversarial examples crafted against lower-variance models (e.g., those that are strongly regularized) tend to transfer better across a range of models.

**Transferability for poisoning attacks.** There is very little work on the transferability of poisoning availability attacks, except for a preliminary investigation in [27]. That work indicates that poisoning examples are transferable among very simple network architectures (logistic regression, MLP, and Adaline). Transferability of targeted poisoning attacks has been addressed recently in [41]. We are the first to study in depth transferability of poisoning availability attacks.

## 7 Conclusions

We have conducted an analysis of the transferability of evasion and poisoning attacks under a unified optimization framework. Our theoretical transferability formalization sheds light on various factors impacting the transfer success rates. In particular, we have defined three metrics that impact the transferability of an attack, including the complexity of the target model, the gradient alignment between the surrogate and

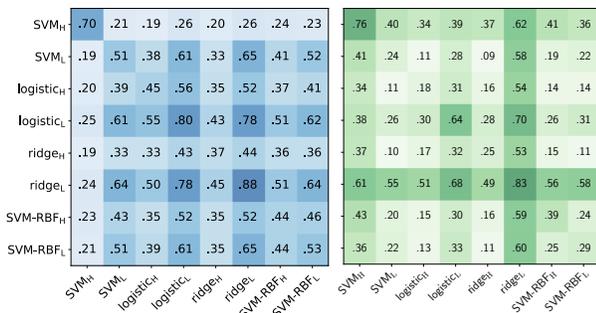

Figure 22: Gradient alignment and perturbation correlation (at 20% poisoning) for poisoning attacks on LFW. See the caption of Fig. 8 for further details.

target models, and the variance of the attacker optimization objective. The lesson to system designers is to evaluate their classifiers against these criteria and select lower-complexity, stronger regularized models that tend to provide higher robustness to both evasion and poisoning. Interesting avenues for future work include extending our analysis to multi-class classification settings, and considering a range of gray-box models in which attackers might have additional knowledge of the machine learning system (as in [41]). Application-dependent scenarios such as cyber security might provide additional constraints on threat models and attack scenarios and could impact transferability in interesting ways.

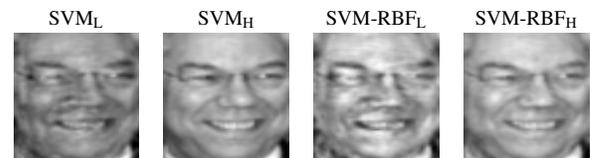

Figure 23: Adversarial examples crafted against linear and RBF SVMs. Larger perturbations are required to have significant impact on low-complexity classifiers ( $L$ ), while minimal changes are very effective on high-complexity SVMs ( $H$ ).

### Abstract

Stack Overflow is the most popular discussion platform for software developers. However, recent research identified a large amount of insecure encryption code in production systems that has been inspired by examples given on Stack Overflow. By copying and pasting functional code, developers introduced exploitable software vulnerabilities into security-sensitive high-profile applications installed by millions of users every day.

Proposed mitigations of this problem suffer from usability flaws and push developers to continue shopping for code examples on Stack Overflow once again. This motivates us to fight the proliferation of insecure code directly at the root before it even reaches the clipboard. By viewing Stack Overflow as a market, implementation of cryptography becomes a decision-making problem. In this context, our goal is to simplify the selection of helpful and secure examples. More specifically, we focus on supporting software developers in making better decisions on Stack Overflow by applying nudges, a concept borrowed from behavioral economics and psychology. This approach is motivated by one of our key findings: For 99.37% of insecure code examples on Stack Overflow, similar alternatives are available that serve the same use case and provide strong cryptography.

Our system design that modifies Stack Overflow is based on several nudges that are controlled by a deep neural network. It learns a representation for cryptographic API usage patterns and classification of their security, achieving average AUC-ROC of 0.992. With a user study, we demonstrate that nudge-based security advice significantly helps tackling the most popular and error-prone cryptographic use cases in Android.

### 1 Introduction

Informal documentation such as Stack Overflow outperforms formal documentation in effectiveness and efficiency when helping software developers implementing functional code.

The fact that 78% of software developers primarily seek help on Stack Overflow on a daily basis<sup>1</sup> underlines the usability and perceived value of community and example-driven documentation [2].

Reuse of code examples is the most frequently observed user pattern on Stack Overflow [17]. It reduces the effort for implementing a functional solution to its minimum and the functionality of the solution can immediately be tested and verified. However, when implementing encryption, its security, being a non-functional property, is difficult to verify as it necessitates profound knowledge of the underlying cryptographic concepts. Moreover, most developers are unaware of pitfalls when applying cryptography and that misuse can actually harm application security. Instead, it is often assumed that mere application of any encryption is already enough to protect private data [13, 14]. Stack Overflow users also cannot rely on the community to correctly verify the security of available code examples [9]. Security advice given by community members and moderators is mostly missing and oftentimes overlooked. This is due to only a few security experts being available as community moderators and a feedback system which is not sufficient to communicate security advice effectively. Consequently, highly insecure code examples are frequently reused in production code [17]. Exploiting these insecure samples, high-profile applications were successfully attacked, leading to theft of user credentials, credit card numbers and other private data [13].

While mainly focused on the negative impact of Stack Overflow on code security, recent research has also reported that there is a full range of code snippets providing strong security for symmetric, asymmetric and password-based encryption, as well as TLS, message digests, random number generation, and authentication [17]. However, it was previously unknown whether useful alternatives can be found for most use cases. In our work, we show that for 99.37% of insecure encryption code examples on Stack Overflow a similar secure alternative is available that serves the same use

<sup>1</sup><https://insights.stackoverflow.com/survey/2016#community>

case. So, why are they not used in a consistent fashion?

We take a new perspective and see implementation of cryptography as a decision-making problem between available secure and insecure examples on Stack Overflow. In order to assist developers in making better security decisions, we apply nudges, a concept borrowed from experimental economics and psychology to attempt altering individuals' behaviors in a predictable way without forbidding any options or significantly changing their economic incentives. Nudging interventions typically address problems associated with cognitive and behavioral biases, such as anchoring, loss aversion, framing, optimism, overconfidence, post-completion errors, and status-quo bias [5, 31]. They have been applied in the security and privacy domain in a successful fashion [4, 5, 7, 19, 22, 32]. In contrast to these approaches, which focused on systems for end-users, we translate the concept of nudges to the software developer domain by modifying the choice architecture of Stack Overflow. It nudges developers towards reusing secure code examples without interfering with their primary goals.

Our designed security nudges are controlled by a code analysis system based on deep learning. It learns general features that allow the separation of secure and insecure cryptographic usage patterns, as well as their similarity-based clustering and use-case classification. Applying this system, we can directly derive a choice architecture that is based on providing similar, secure, and use-case preserving code examples for insecure encryption code on Stack Overflow.

In summary, we make the following contributions:

- We present a deep learning-based representation learning approach of cryptographic API usage patterns that encodes their similarity, use case and security.
- Our trained security classification model which uses the learned representations achieves average AUC-ROC of 0.992 for predicting insecure usage patterns.
- We design and implement several security nudges on Stack Overflow that apply our similarity, use case and security models to help developers make better decisions when reusing encryption code examples.
- We demonstrate the effectiveness of nudge-based security advice within a user study where participants had to implement the two most popular and error-prone cryptographic use cases in Android [13, 17]: nudged participants provided significantly more secure solutions, while achieving the same level of functionality as the control group.

We proceed as follows. After reviewing related work (Section 2), we present our system design that combines deep learning-based representation learning with nudge-based security advice (Sections 3 – 6). Then, we present our model evaluation and user study (Sections 7 & 8), as well as limitations, future work, and conclusions (Sections 9 – 11).

## 2 Related Work

### 2.1 Getting Cryptography Right

Acar et al. [2] have investigated the impact of formal and informal information sources on Android application security. With a lab study, they found that developers prefer informal documentation such as Stack Overflow over official Android documentation and textbooks when implementing encryption code. Solutions based on advice from Stack Overflow provided significantly more functional – but less secure – solutions than those based on formal documentation. Work by Fischer et al. [17] showed that 30% of cryptographic code examples on Stack Overflow were insecure. Many severely vulnerable samples were reused in over 190,000 Android applications from Google Play including high-profile applications from security-sensitive categories. Moreover, they have shown that the community feedback given on Stack Overflow was not helpful in preventing reuse of insecure code.

Chen et al. studied the impact of these community dynamics on Stack Overflow in more detail [9]. Based on manual inspection of a subset of posts, they found that (on average) posts with insecure snippets garnered higher view counts and higher scores, and had more duplicates compared to posts with secure snippets. Further, they demonstrated that a sizable subset of posts from trusted users were insecure. Taken together, these works show that developers (by copying and pasting insecure code) are imposing negative externalities on millions of users who eventually bear the cost of apps harboring vulnerabilities [8].

Oliveira et al. focus on developers' misunderstandings of ambiguities in APIs (including cryptography), which may contribute to vulnerabilities in the developed code [26]. They studied the impact of personality characteristics and contextual factors (such as problem complexity), which impact developers' ability to identify such ambiguities. Likewise, Acar et al. [1] investigated whether current cryptographic API design had an impact on cryptographic misuse. They selected different cryptographic APIs; including some particularly simplified APIs in order to prevent misuse. However, while indeed improving security, these APIs produced significantly less functional solutions and oftentimes were not applicable to specific use cases at all. As a consequence, developers searched for code examples on Stack Overflow again.

Nguyen et al. [25] developed FixDroid, a static code analysis tool integrated in Android Studio which checks cryptographic code flaws and suggests quick fixes.

### 2.2 Security Nudges

Wang et al. [32] implemented privacy nudges on Facebook in order to make users consider the content and audience of their online publications more carefully, as research has

shown that users eventually regret some of their disclosure decisions. They found that a reminder nudge about the audience effectively and non-intrusively prevents unintended disclosure. Almuhimedi et al. [6] implemented an app permissions manager that sends out nudges to the user in order to raise awareness of data collected by installed apps. With the help of a user study they were able to show that 95% of the participants reassessed their permissions, while 58% of them further restricted them. Liu et al. [23] created a personalized privacy assistant that predicts personalized privacy settings based on a questionnaire. In a field study, 78.7% of the recommendations made by the assistant were adopted by users, who perceived these recommendations as usable and useful. They were further motivated to review and modify the proposed settings with daily privacy nudges.

### 2.3 Deep Learning Code

Fischer et al. [17] proposed an approach based on machine learning to predict the security score of encryption code snippets from Stack Overflow. They used *tf-idf* to generate features from source code and trained a support vector machine (SVM) using an annotated dataset of code snippets. The resulting model was able to predict the security score of code snippets with an accuracy of 0.86, with precision and recall of 0.85 and 0.75, respectively. However, security predictions were only available for the complete code snippet. It did not allow indicating and marking specific code parts within the snippet to be insecure. This lack of explainability is detrimental for security advice.

Xiaojun et al. [33] introduced neural network-based representation learning of control flow graphs (CFGs) generated from binary code. Using a Siamese network architecture they learned similar graph embeddings using *Structure2vec* [11] from similar binary functions over different platforms. These embeddings were used to detect vulnerabilities in binary blobs by applying code-similarity search. Their approach significantly outperformed the state-of-the-art [16] in both, efficiency and effectiveness, by providing shorter training times and higher area under the curve (AUC) on detecting vulnerabilities. The approach does not allow identification and description of code parts within binary functions that cause the vulnerabilities. To allow better explainability, we depend on our new approach to provide statement-level granularity. It enables identifying and classifying multiple code patterns within a single function.

Li et al. [21] developed VulDeePecker, a long short-term memory (LSTM) neural network that predicts buffer overflows and resource management error vulnerabilities of source code gadgets. Code gadgets are backward and forward slices, considering data and control flow, that are generated from arguments used in library function calls. Further, they use *word2Vec* to create embeddings for the symbolic representation of code gadgets. These embeddings

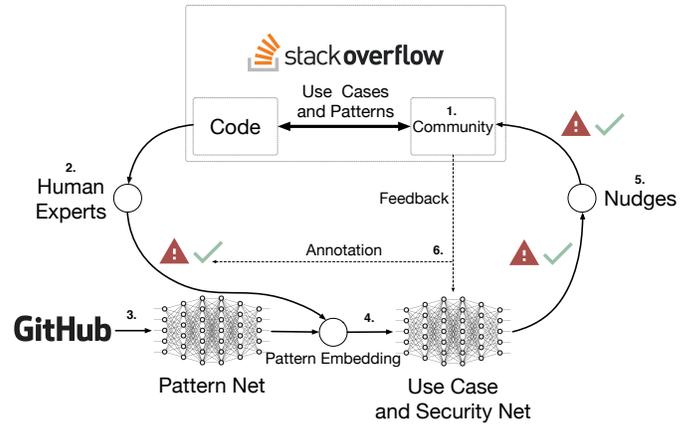

Figure 1: Learn-to-Nudge Loop Overview

are then used together with their security label to train a bi-directional LSTM. VulDeePecker outperforms several pattern-based and code similarity-based vulnerability detection systems with respect to false positive and false negative rates. However, their LSTM model has a very long training time. Our convolutional approach leverages transfer learning to achieve much faster training.

### 3 Overview

We present an overview of our system design for nudge- and deep learning-based security advice on Stack Overflow in Figure 1. It depicts a learn-to-nudge loop that represents the interaction and interference of the community behavior, classification models and proposed security nudges on Stack Overflow. The community behavior on Stack Overflow (1) triggers the loop by continuously providing and reusing code examples that introduce new use cases and patterns of cryptographic application programming interfaces (APIs). In the initial step (2), a representative subset of these code examples is extracted and annotated by human experts. The annotations provide ground truth about the use cases and security of cryptographic patterns in the given code. Then (3), a representation for these patterns is learned by an unsupervised neural network based on open source projects provided by GitHub. In combination with the given annotations, the pattern embeddings are used to train an additional model to predict their use cases and security (4). Based on these predictions, we can apply security nudges on Stack Overflow by providing security warnings, reminders, recommendations and defaults for encryption code examples (5). Further, we allow assigned security moderators<sup>2</sup> within the community to annotate unknown patterns and provide feedback to predictions of our models (6). Therefore, our system creates a

<sup>2</sup><https://stackexchange.com/about/moderators>

learn-to-nudge loop that is supposed to iteratively improve the classification models, which in turn help improving the security decisions made by the community and the security of code provided on Stack Overflow.

## 4 Nudge-Based System Design

We apply five popular nudges [30, 31] and describe their translation to security advice in this section.

**Simplification** A simplification nudge promotes building upon existing and established infrastructures and programs. We apply this nudge by integrating our system in Stack Overflow, a platform that is already used by the majority of software developers worldwide. By integrating developer tools on a platform that is already used by almost everyone, we unburden developers from installing additional tools. Moreover, it allows us to create awareness of the problem of cryptographic misuse in general.

**Warnings** A warning nudge aims at raising the user's attention in order to counteract the natural human tendency towards unrealistic optimism [5]. We apply this nudge by integrating security warnings on Stack Overflow. Whenever an insecure code example has been detected, a warning is displayed to the developer to inform about the security problem and potential risks in reusing the code sample.

**Increases in Ease and Convenience (IEC)** Research has also shown that users oftentimes discount security warnings. However, if they additionally describe available alternative options to make a less risky decision, warnings tend to be much more effective [5]. Therefore, our design combines security warnings with recommendations for similar code examples with strong cryptography. With this nudge, we make code examples with better security visible to the user. To provide an easy choice, we present the recommended code examples by displaying a list of the related posts. This aims at encouraging the user to consider the recommendations as it only demands clicking on a link.

**Reminders** Users might not engage in the expected conduct of paying attention to the warning and following the recommendations. This might be due to inertia, procrastination, competing priorities, and simple forgetfulness [5]. Oftentimes seeking functional solutions is considered as a competing priority to secure solutions [2]. Therefore, we apply a reminder nudge, which is triggered whenever the user copies an insecure code example.

**Defaults** The default nudge is the most popular and effective nudge in improving decision-making. Popular examples are automated enrollment in healthcare plans

or corporate wellness programs, or double-sided printing which can promote environmental protection [5]. We apply this nudge by up-ranking posts that only contain secure code examples in Stack Overflow search results by default.

The goal of our approach is to thoughtfully develop a new user interface (UI) design that implements the proposed nudges (see Section 6) and to test whether it improves developer behavior on Stack Overflow. Please note that we do not intend to comparatively evaluate multiple UI candidates for our design patterns to identify the most effective one. We consider this out of scope for this paper and leave this task for future work.

## 5 Neural Network-Based Learning of Cryptographic Use Cases and Security

The nudge-based system design requires algorithmic decisions about the security and similarity of code examples. In order to display security warnings, code examples have to be scanned for encryption flaws. To further recommend helpful alternatives without common encryption problems, Stack Overflow posts have to be scanned for similar examples with strong cryptography.

Due to *Simplification* (see Section 4), we already chose a platform that provides us with a large amount of secure and insecure samples that contain cryptographic API usage patterns to learn from in order to design the code analysis approach [17]. Instead of defining rule-based algorithms [12, 13, 20] that would have to be updated whenever samples with unknown patterns are added to Stack Overflow, we simplify and increase the flexibility of our system by applying deep learning to automatically learn the similarity, use-case and security features from the ever-increasing dataset of available code on Stack Overflow. Based on the learned features, our models are able to predict insecure code examples and similar but secure alternatives that serve the same use case. However, newly added code examples that provide unknown use cases and security flaws might be underrepresented in the data and therefore difficult to learn. Therefore, we apply transfer learning where we reuse already obtained knowledge that facilitates learning from a small sample set of a similar domain.

### 5.1 Cryptographic Use Cases

Stack Overflow offers a valuable source for common use cases of cryptographic APIs in Android. As developers post questions whenever they have a particular problem with an API, a collection of error-prone or difficult cryptographic problems is aggregating over time. Moreover, frequencies of similar posted questions, view counts, and scores of questions posted on Stack Overflow indicate very common and important problems developers encounter when writing

Figure 2: Example for a secure and insecure usage pattern of `new IvParameterSpec`. It shows the program dependency graph (PDG) of the 5-hop neighborhood of the seed statement  $s_1$  for the secure and insecure code example displayed in (a) and (b). Next to each node in the graph we provide the shortened signature of the related statement, highlighting a subset of its attributes we store in the feature vector. Bytecode instruction types are highlighted yellow, Java types and constants magenta.

security-related code. Therefore, Stack Overflow can be seen as a dataset of different cryptographic use cases that are frequently required in production code. Previous work identified the most popular and error-prone use cases of cryptography in Android apps [17]. The authors scanned Stack Overflow for insecure code examples that use popular cryptographic APIs, e.g. Oracle’s Java Cryptography Architecture (JCA), and detected their reuse in Android applications. We summarize the identified use cases in Table 1.

Use Case Identifier	Usage Pattern Description	API Seed Statement
Cipher	Initialization of cipher, mode and padding	<code>Cipher.getInstance</code>
Key	Generation of symmetric key	<code>new SecretKeySpec</code>
IV	Generation of initialization vector	<code>new IvParameterSpec</code>
Hash	Initialization of cryptographic hash function	<code>MessageDigest.getInstance</code>
TLS	Initialization of TLS protocol	<code>SSLContext.getInstance</code>
HNV	Setting the hostname verifier	<code>setHostnameVerifier</code>
HNVOR	Overriding the hostname verification	<code>verify</code>
TM	Overriding server certificate verification	<code>checkServerTrusted</code>

Table 1: Common cryptographic use cases in Android

## 5.2 Learning API Usage Patterns

In order to predict similarity, use case and security of encryption code, we need to learn a numerical representation of the

related patterns that can be understood by a neural network. Therefore, our first step is learning an embedding of cryptographic API usage patterns.

**Usage Pattern** As shown in Table 1, a cryptographic API element, e.g., `javax.crypto.Cipher.getInstance`, can have different usage patterns that belong to the same use case. A usage pattern consists of a particular API element, all statements it depends on, and all its dependent statements within the given code. In other words, a pattern can be seen as a subgraph of the PDG, which represents the control and data dependencies of statements. The subgraph is created by pruning the graph from anything but the forward and backward slices of the API element, as shown in Figure 2. We call this element the *seed statement*. This pruned graph can become very large and therefore might contain noise with respect to the identification of patterns. Our goal is to learn an optimal representation of usage patterns that allows accurate classification of their use cases and security. Ideally, the related subgraph is minimized to a *neighborhood* of the seed statement in the pruned PDG such that it provides enough information to solve the classification tasks.

**Neighborhood Aggregation** Our approach learns *pattern embeddings* for the  $K$ -hop neighborhood of cryptographic API elements within the PDG, as shown in Figure 2. To generate these embeddings we use the *neighborhood-aggregation* algorithm provided by *Structure2vec* [11]. This method leverages node features (e.g., instruction types of a statement node) and graph statistics (e.g., node degrees) to

inform their embeddings. It provides a convolutional method that represents a node as a function of its surrounding neighborhood. The parameter  $K$  allows us to search for a neighborhood that optimally represents usage patterns to solve given classification tasks. In other words, we learn the code representation in a way such that its features improve use case and security prediction of the code. As we will show throughout this work, this representation is very helpful for classifying cryptographic API usage patterns. We further argue that the learned pattern representation is not restricted to cryptographic APIs, as the used features are general code graph properties.

**Neighborhood Similarity** We learn pattern embeddings such that similar patterns have similar embeddings by minimizing their distance in the embedding space. Therefore, next to the neighborhood information, pattern embeddings additionally encode their similarity information. On the one hand, this allows us to apply efficient and accurate search for similar usage patterns on Stack Overflow [33]. On the other hand, we can transfer knowledge from the similarity domain to the use case and security domain. This knowledge transfer is leveraged by our use case and security classification models.

Code similarity is very helpful to predict code security. Therefore, we expect that the similarity feature of our pattern embeddings will improve the accuracy and efficiency of the security classification model. However, code similarity is oftentimes not enough for predicting security. Therefore, the main effort of our classification models lies in learning the additional unknown conditions where code similarity becomes insufficient.

To learn our embeddings, we apply a modified architecture of the graph embedding network *Gemini* [33].

### 5.3 Feature Engineering

The embedding network should learn a pattern embedding that is general enough to allow several classification tasks. This means that the embedding has to be learned from general code features or attributes, e. g., statistical and structural features [33] from each statement within the PDG representation of the code. Further, pattern embeddings should represent very small neighborhoods. As we want to minimize the neighborhood size  $K$ , patterns might consist only of a few lines of code. Therefore, considering only graph statistics as features might not be sufficient and may result in similar features for dissimilar patterns. In order to overcome these insufficiencies, we additionally combine structural and statistical with lexical and numerical features for each statement in a neighborhood.

**Structure and Statistics** We first create the PDG of the given input program using WALA<sup>3</sup>, a static analysis framework for Java. Note that WALA creates a PDG for each Java method. Then, we extract the resulting statistical and structural features for each statement. We store the bytecode instruction type of a statement using a one-hot indicator vector. Additionally, we store the count of string and numerical constants that are used by the statement. We further add structural features by storing the offspring count and node degree of a statement in the PDG [33]. Finally, we store the indexes of the statement's direct neighbors in the graph.

**Element Names and String Constants** Method and field names of APIs are strings and have to be transformed into a numerical representation first. We learn feature vectors for these tokens by training a simple unsupervised neural network to predict the Java type that defines the given method or field name. Thereby, each name is represented in a one-hot encoding vector with dimension 23,545, corresponding to the number of unique element names provided by the cryptographic APIs [17]. To learn features, we use a network architecture with one hidden layer and apply categorical cross-entropy as a loss function during training. Finally, we apply the trained model on all names and extract the neurons of the hidden layer as they can be seen as learned features necessary to solve the classification task. This way, each name obtains a unique feature vector which preserves its type information. We use the same approach for learning feature vectors for the 763 unique string constants given by the APIs.

### 5.4 Pattern Embedding Network

Many code examples on Stack Overflow typically do not provide sound programs as they mostly consist of loose code parts [17]. In contrast to complete programs, compiling these partial programs might introduce multiple types of ambiguities in the resulting PDG such that the extracted statement features  $x_u$  are not sound [10]. Whenever we generate sound and unsound features  $x_s$ ,  $x_u$  from a complete and a partial program, respectively, that provide the same usage pattern for a given seed statement, both sets of feature vectors extracted from the patterns might be different. Therefore, we need to learn a representation for patterns that preserves their similarity properties independently from the shape of the containing program. With a Siamese network architecture [33], we can learn similar pattern embeddings independently from the completeness of the code example. It learns embeddings from similar and dissimilar input pairs. We create similar input pairs by extracting sound and unsound features for the same pattern and dissimilar pairs by extracting sound and unsound features from different patterns. The

<sup>3</sup><https://github.com/wala/WALA>

---

**Algorithm 1** Neighborhood-aggregation algorithm
 

---

**Input:** PDG  $G(V, E)$  input features  $\{x_v, \forall v \in V\}$ ;

**Output:** Pattern embedding  $p_v, \forall v \in V$

- 1:  $\phi_v^0 \leftarrow 0, \forall v \in V$ ,
  - 2: **for**  $k = 1 \dots K$  **do**
  - 3:   **for**  $v \in V$  **do**
  - 4:      $\phi_{N(v)}^k \leftarrow \text{AGGREGATE}(\phi_n^{k-1}, \forall n \in N(v))$
  - 5:      $\phi_v^k \leftarrow \tanh(W_1 x_v \cdot \sigma(\phi_{N(v)}^k))$
- return**  $\{p_v = W_2 \phi_v^K, \forall v \in V\}$
- 

trained model will then generate similar embeddings independently from the completeness of the program.

The pattern embeddings are generated with *Structure2vec* as depicted in Algorithm 1. We provide the abstract description of the algorithm and refer to *Gemini*'s neural network architecture that gives information about its implementation, which we use as the basis for our approach. The update function calculates a pattern embedding  $p_v$  for each feature vector  $x_v$  of statements (i. e., nodes)  $v \in V$  in the PDG  $G(V, E)$ . An embedding  $p_v$  is generated by recursively aggregating previously generated embeddings  $\{\phi_n^{k-1}, \forall n \in N(v)\}$  of direct neighbors  $N(v)$  in the graph, combining it with the weighted feature vector  $x_v$ . Unlike *Gemini*, which outputs an aggregation of  $p_v$  to return an embedding for the complete graph, our network returns the set of pattern embeddings  $P = \{p_v, \forall v \in V\}$ .

We give an overview of the pattern embedding network in Figure 3. Here, the insecure pattern  $G(x_3, x_4, x_5, E)$  informs the embedding of its direct neighbors in each iteration step, finally informing the seed statement in iteration  $k = 2$ . After this step, the seed statement knows that it is part of an insecure pattern and its embedding preserves this information accordingly. We extract the pattern embedding  $\phi_1^K$  of the seed statement and apply weights  $W_2$ . Note, we train  $W_2$  based on classification loss of aggregated pattern similarity  $p_a$  as explained in Section 5.5. However, we use the trained model to generate and output embeddings for each individual pattern  $p_v$  in the graph (see Figure 3).

## 5.5 Training

For unsupervised training of pattern embeddings, we need to generate similar and dissimilar input pairs from data that provides ground truth. We use two different sets of PDGs that are compiled from the same source code. One set  $S$  contains the sound graph representations of the code, the other one the unsound graphs  $U$ . A sound graph  $G_s(V_s, E_s)$  in the first set is compiled from a complete program using a standard Java compiler. An unsound graph  $G_u(V_u, E_u)$  in the second set is generated by a partial compiler [10] that compiles each Java class of a program individually. Then we construct the feature vectors  $X_s = \{x_s\}_{v_s \in V_s}$  and  $X_u = \{x_u\}_{v_u \in V_u}$  for all

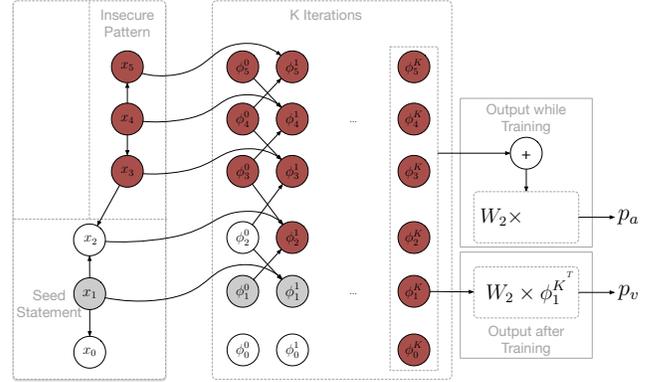

Figure 3: Pattern embedding network overview

statements  $v$  in the respective graphs.

To obtain ground truth for similar and dissimilar usage patterns we need to create similar pairs  $(\langle v_s, v_u \rangle, 1)$  and dissimilar pairs  $(\langle v_s, v_u \rangle, -1)$ . However, we do not have information about the relationship of statements in  $G_u(V_u, E_u)$  with statements  $G_s(V_s, E_s)$ , which is necessary to create these pairs. Note that source code statements do not correspond one-to-one with statements in the PDG. The compiler may divide a source code statement into multiple instructions, which may have different associated statements in the PDG. Since we use different compilers, the resulting PDG statements in  $V_s$  and  $V_u$  may look different even though they represent the same source code. Therefore, we aggregate all pattern embeddings from a method into  $p_a$  and use the resulting embedding for training. The network calculates the loss based on the cosine similarity of the aggregated pattern embedding pairs  $\{\langle p_a^s, p_a^u \rangle\}_{x_s, x_u \in X_s, X_u}$  and their given similarity label  $y \in \{-1, 1\}$ .

We downloaded 824 open source Android apps from GitHub and compiled the complete and sound graph  $G_s(V_s, E_s)$  for each method. Further, we used the partial compiler to obtain the unsound graph for each method  $G_u(V_u, E_u)$ . After creating the feature vectors  $X_s$  and  $X_u$  from the graphs, similar method pairs  $(\langle X_s, X_u \rangle, 1)$  were created by extracting  $X_s$  and  $X_u$  from the same source code, and dissimilar  $(\langle X_s, X_u \rangle, -1)$  by extracting  $X_s$  and  $X_u$  from different source code. From the 824 downloaded apps, we extracted 91,075 methods to create 157,162 input pairs in total. These pairs have been split up into the training and validation set, where 80% have been randomly allocated for training and 20% for validation. Note that the intersection of both sets is empty.

## 5.6 Learning Use Cases and Security

From a given source code example, we want to be able to predict the cryptographic use case and security of patterns within the code. We apply transfer learning by reusing the

previously learned pattern embedding that already encodes their similarity information.

Pattern embeddings are learned unsupervised and we can obtain almost arbitrarily large training datasets from open source projects. However, code examples on Stack Overflow provide a very different distribution of data [17]. Many use case and security classes are under- or overrepresented and availability of encryption code examples is limited in general. We transfer knowledge from the similarity domain to the use case and security domain in order to tackle these problems. We argue that the similarity information preserved in our pattern embeddings will be helpful for classifying their use cases and security.

## 5.7 Labeling

We extracted 10,558 code examples from Stack Overflow<sup>4</sup> by searching for code that contained at least one of the seed statements. Each code sample has been manually reviewed in order to label use case and security of the contained usage patterns. Labeling was done by two security experts individually applying the labeling rules given by [12, 13, 17]. This leads to conservative binary security labeling, which might at times be too strict. For instance, depending on the context, MD5 can be the better trade-off and secure enough. However, our approach aims at developers that are layman in cryptography and we consider binary classification preferable to encourage safe defaults.

Initially, 100 samples for each of the different seed statements have been selected randomly to apply dual control labeling. After clearing up disagreements, the remaining samples have been annotated individually to speed up the labeling. The whole process took approximately 10 man days to complete. To evaluate individual annotation accuracy, we randomly selected 200 samples from both experts and report agreement of 98.32% on given labels. We further publish the annotated dataset in order to allow verification of annotation accuracy and reproduction of our results. Please refer to Appendix C for further details on the annotation process.

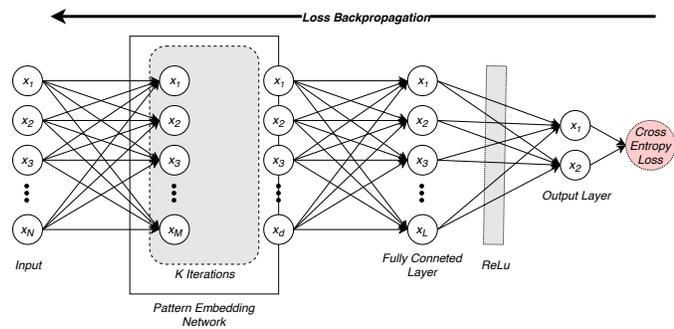

Figure 4: End-to-End Network Architecture

<sup>4</sup>I.e., from the Official Stack Overflow Data Dump.

## 5.8 End-to-end Architecture

We introduce an architecture that allows classification of different uses cases and security, while improving the pattern-embedding model in order to forward optimized code representations to the classification layer (see Figure 4).

To achieve this, we add a fully connected layer with dimension 1,024 using Rectified Linear Unit (ReLU) as the activation function on top of the pattern-embedding network. We use a softmax layer for binary and multi-class classification and trained our network to optimize cross-entropy loss. Applying transfer learning, we initialize the pattern-embedding network using the previously learned weights for pattern similarity (see Section 5.4). The end-to-end network now connects the pattern-embedding network with the classification layers. Within training, the latter backpropagates cross-entropy loss from the classification task all the way to the input of the pattern-embedding network. This allows the similarity network to adjust the pattern representation in order to better perform on the classification. Therefore, both coupled networks now generate a new pattern representation for the given classification problem in such a way that it is optimally solved.

For instance, security classification of *Cipher*, *Key* and *TM* rely on very different features. Only using the pre-trained “static” pattern embeddings might therefore be disadvantageous for some use cases. However, by dynamically customizing the pattern embedding with respect to classification loss minimization, the network learns a code representation that preserves the necessary code features to improve classification.

## 5.9 Training

The Stack Overflow dataset provides 16,539 pattern embeddings extracted from 10,558 code examples. Note that a single code example might contain several patterns, e. g. *IV*, *Key* is used to initialize *Cipher*. We test pattern embeddings generated from several models that were trained on different neighborhood sizes  $K$  and different output dimensions  $d$  for the embeddings. Thereby, we search for the optimal hyperparameter  $K$  and  $d$  to achieve the best performance on both classification tasks. We first train the network to learn the use case identifier of pattern embeddings using the complete dataset. Then, we train a different model to learn the security labels. Here, patterns with the same security label belong to the same class independently of their use case. Finally, we divide the dataset into combinations of several use case classes, testing the effect on performance of security prediction.

## 6 Security Nudges

The neural network architecture described in the previous section provides everything needed to apply the security nudges on Stack Overflow. In this section, we explain the design of each nudge including its implementation on Stack Overflow and how it applies the predictions from the similarity and classification models<sup>5</sup>.

### 6.1 Security Warnings

Whenever an insecure code example is detected, a security warning, as shown in Figure 8, which surrounds the code, is displayed to the user. The warning is triggered by the prediction result of the security model that classifies each pattern in the snippet.

The difficulties in designing effective security warnings are widely known and have been extensively investigated. We base our approach on the design patterns of Google Chrome’s security warning for insecure server communication, whose effectiveness has been comprehensively field-tested [3]. The header of the warning informs the user that a security problem has been detected in the encryption code of the sample. Note that we assume users with a very diverse background, knowledge and expertise in cryptography. Users and even experienced developers might not be aware of flawed or out-dated encryption that does not provide sufficient security. Therefore, we inform the user about the consequences that might occur when reusing insecure code examples in production code, e. g., private information might be at risk in an attack scenario.

We further provide code annotations for each seed statement in the code whose usage pattern has been classified as insecure (see Figure 2). The annotation is attached below and points at the statement. It gives further information about the statement, while additionally highlighting the consequences of reusing it. In order to select the correct annotation for the insecure statement, we apply use case prediction of the related pattern. Each use case identifier has an assigned security annotation to be displayed in the code snippet.

### 6.2 Security Recommendations

Security warnings should always offer a way out of a situation where the user seems to be unable to continue with her current action due to the warning. Whenever the user decides to follow the advice given by the warning, she would refuse to reuse the code example that was originally considered a candidate for solving her problem. In this situation, she has been thrown out of her usual user pattern as she has to restart searching for another example. Therefore, for each insecure code example, we recommend a list of similar examples, as shown in Figure 8, that serve the same use case and provide

stronger encryption. Ideally, the user would only have to click on a single link to the recommended alternative. Our nudge design pattern does not claim that the recommended code is generally secure, as it still might contain insecure patterns that are unknown to the model. However, for simplicity, we refer to code examples, which do not contain any detected insecure patterns and do contain detected secure patterns, as *secure* code examples throughout the paper.

We create this list of recommendations by applying similarity search, use case and security prediction of usage patterns in code examples. We start with predicting the use case of each insecure usage pattern.  $I_q$  contains all insecure use cases of a method  $q \in M_q$ , where  $M_q$  is the set of query methods in the snippet. We create the set  $\{I_q\}_{q \in M_q}$ , which consists of the sets of insecure use cases over all methods in the snippet. Then, we generate the set of aggregated pattern embeddings  $\{e_q\}_{q \in M_q}$ , as described in Section 5.4. Afterwards, we analogously create the set of secure use cases for all target methods  $\{S_t\}_{t \in M_t}$  where  $M_t$  is the set of methods available on Stack Overflow that only contain usage patterns our model has classified as secure. Likewise, we create the aggregated pattern embeddings  $\{e_t\}_{t \in M_t}$ . We rank  $M_t$  for given  $I_q, S_t$  and  $e_q, e_t$  based on ascending Jaccard distance  $d_J(I_q, S_t)$ , ranking pairs with the same distance using cosine similarity  $\cos(e_q, e_t)$ . We create the ranked list of recommended posts  $R$  by adding the related Stack Overflow post for each  $t$  of the top-fifty results in the ranking. Beneath the security warning, we display a scrollable list of  $R$ , as displayed in Figure 8. Each post is displayed by showing the title of the related question. When the user clicks on the title, a new browser tab opens and the web page automatically scrolls down to the recommended code example, highlighting it with a short flash animation.

Recommended examples are displayed inside a green box, annotated with a check mark and message informing the user that no common encryption problems have been found within the code. This way, we avoid declaring the code example to be secure, which would be a too strong claim. However, the statement intends to be strong enough to reach the users and make them follow the advice. Similar to warnings, we provide code annotations for each statement in the code whose usage pattern has been classified as secure.

### 6.3 Security Reminders and Defaults

We further caution the user – in addition to prompting the security warning and recommendations – by blurring out the remainder of the web page, whenever a copy event of an insecure code example is triggered.

We additionally apply a search filter which up-ranks posts that only contain secure code examples. Posts with insecure code examples are appended to the list of secure posts. The original ranking of posts within its security class is maintained. This approach lowers the risk of reusing code exam-

<sup>5</sup>We provide further example figures of our nudges in the Appendix.

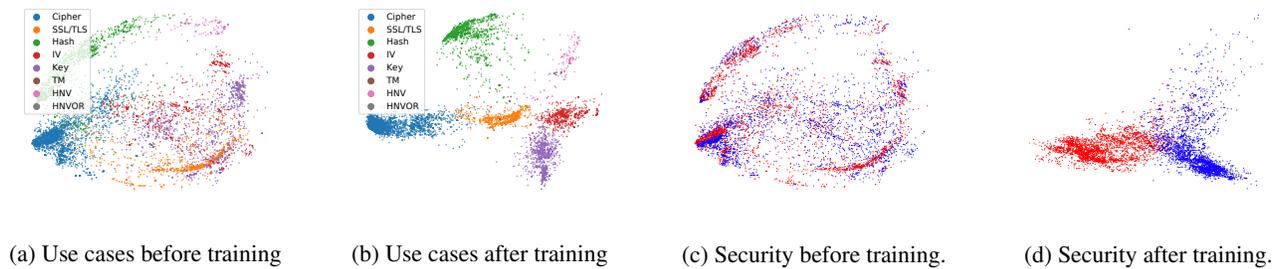

Figure 5: Visualizing the pattern embeddings of different use cases and security using PCA. Each color indicates one use case in (a) and (b), and security in (c) and (d). The legend provides the use case identifier.

ples that have been predicted to be insecure. This also means that whenever a post consists of secure and insecure samples it is ranked lower than posts with only secure samples.

## 7 Model Evaluation

### 7.1 Pattern Similarity

We evaluate the learned pattern embeddings by measuring cosine similarity for all pairs in the validation set and calculate the receiver operating characteristic curve (ROC) given the similarity label  $y \in \{-1, 1\}$  for each pair. Our approach reaches an optimal AUC of 0.978, which slightly outperforms *Gemini* with AUC of 0.971. *Gemini* was originally applied to similarity prediction of binary functions by learning embeddings for CFGs and may not be a suitable benchmark.

We observe that the model converges already after five epochs. For the remaining epochs, AUC stays around 0.978 and does not improve significantly. This allows for a very short training time, as five epochs only need 27 minutes on average on our system<sup>6</sup>. However, we choose the model with the best AUC for generating the pattern embeddings.

### 7.2 Use Case Classification

For training the use case and security models, we apply the dataset consisting of 16,539 pattern embeddings extracted from Stack Overflow split up into subsets for training (80%) and validation (20%). Note that the validation set is constructed such that none of its samples appear in the training set. Therefore, we evaluate the performance of use case prediction on unseen pattern embeddings.

**Visualization** To illustrate the transfer learning process, we plot the pattern embeddings in 2D using principal component analysis (PCA) before and after the training of the classification model. Figure 5(a) shows the complete set of pattern embeddings before training, displayed in the color of

<sup>6</sup>Intel Xeon E5-2660 v2 (“Sandy Bridge”), 20 CPU cores, 240GB memory

their use case. We observe that some use cases already build clusters in the plot, while others appear overlapping and intermixed. Therefore, we apply an additional neural network on top that leverages supervision on use cases in addition to the similarity knowledge preserved in the input embeddings. Figure 5(b) plots the pattern embeddings again after supervised training of the model. Here, we input the initial pattern embeddings into the trained model and extract the last hidden layer of the network to obtain new embeddings that preserve information about their use case. We observe that the new embeddings now create dense and separable clusters for each use case in the plot. The network has moved pattern embeddings that belong to the same use case closer together, and the resulting clusters further away from each other in the embedding space.

**Accuracy** The promising observations from the visualization of pattern embeddings are confirmed by the accuracy results of the classification model. We performed a grid search that revealed the optimal neighborhood size of  $K = 5$ . The average AUC for predicting the different use cases already achieves its optimum of 0.999 after 20 epochs. As already indicated by the PCA plots, pattern embeddings provide a very good representation of use cases as the average AUC for all classes before training (epoch zero) is already above 0.998. However, precision and recall of *IV*, *HNVOR* and *TM* start below 0.878 and have been improved up to above 0.986 within 30 epochs of training.

### 7.3 Security Classification

**Visualization** We start again with illustrating the transfer learning process for security classification by plotting pattern embeddings before and after training. Figure 5(c) displays pattern embeddings before training with their respective security score, Figure 5(d) plots the new embeddings after training. Samples that were labeled as secure are depicted in blue, insecure samples in red. When comparing Figure 5(a) and Figure 5(c), we can already observe several secure and insecure clusters within the use case clus-

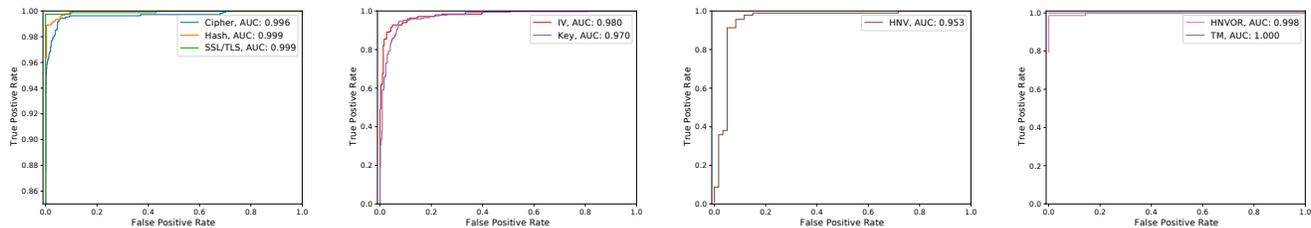

Figure 6: ROC for security classification of different use cases. The legend provides use case identifier and respective AUC.

ters, e. g., *Hash*, *Cipher* and *SSL/TLS*. However, again many secure and insecure samples appear to have a wide distribution because PCA does not plot them in dense clusters. After training the security classification model, we input the complete set of pattern embeddings and plot the last layer of the neural network for each sample in Figure 5(d) again. Now, we observe dense and separated clusters for secure and insecure samples. The network has adjusted the pattern embeddings such that samples within both security classes have been moved closer together in the embedding space. Samples with different security have been moved further away from each other, finally dividing samples into two security clusters.

**Accuracy** We trained a single model using the labeled dataset of 16,539 pattern embeddings. Thereby, a single model learns security classification for all use cases. Our grid search revealed  $K = 5$  as the optimal neighbourhood size. The model provides a good fit because training and validation loss already converge after 50 epochs. A single epoch takes 0.58 seconds on average on our system, resulting in roughly five minutes for complete training time. We plot ROC curves for security prediction for each use case class in Figure 6. We observe that the three use cases *Hash*, *Cipher* and *SSL/TLS* that provide the largest percentage of samples in the dataset achieve the best results. The model achieves very good classification accuracy with AUC values of 0.999, 0.996 and 0.999, respectively, similar to *HNVOR* and *TM*. However, performance drops marginally for *IV*, *Key* and *HNV* to 0.980, 0.970 and 0.953, respectively.

**Comparison** In Table 2, we compare our approach on security prediction on Stack Overflow with [17], where the authors use *tf-idf* to create a feature vector as a representation for the complete input snippets and to train a SVM predicting its binary security score. Our deep learning approach (marked as CNN in the table) significantly outperforms their classifier in all use cases; especially *IV*, *Key* and *HNVOR*, where security evaluation heavily relies on data and control flow. In contrast to our approach, the work by Fischer et al. [17] does not inform the learning model about these properties, but solely relies on lexical features.

Moreover, our deep learning approach allows a higher level of explainability to the user. While [17] can only report security warnings for the complete snippet, our more fine-grained approach is able to directly highlight statements in the code and provides annotations that explain the security issue. Since we learn a representation of code patterns that allows prediction of different code properties beyond security, we can provide this additional explanation, which is crucial for developer advice.

	CNN		tfidf+SVM	
	AUC-ROC	Explanation	AUC-ROC	Explanation
Cipher	0.996	SW, CA	0.960	SW
Hash	0.999	SW, CA	0.956	SW
TLS	0.999	SW, CA	0.902	SW
IV	0.980	SW, CA	0.881	SW
Key	0.970	SW, CA	0.886	SW
HNV	0.953	SW, CA	0.922	SW
HNVOR	0.998	SW, CA	0.850	SW
TM	1.000	SW, CA	0.982	SW

Table 2: Performance and explainability comparison of security prediction on Stack Overflow. SW: Provides security warnings for the complete snippet. CA: Additionally provides code annotation that explains the issue in detail.

## 7.4 Recommendations

We applied our trained models in order to evaluate whether Stack Overflow provides secure alternative code snippets, which preserve the use case and are similar to detected insecure code examples. Thereby, we extracted all methods from the complete set of 10,558 snippets, generated their aggregated embeddings and separated them into two sets. The first set contains all 6,442 distinct insecure *query* embeddings and the second one all 3,579 distinct secure *target* embeddings. We created these two sets by applying the security model and predicted the security of each pattern within a given method. Finally, we ranked the embeddings based on their Jaccard distance, applying the use case model, and cosine similarity, as described in Section 6.2. We found 6,402 (99.37%) query methods that have Jaccard distance of 0.0 to at least one target method. This means that for almost every insecure method, a secure one exist on Stack Overflow

that serves the same use case. When additionally demanding code similarity, we found 6,047 (93.86%) query methods with a cosine similarity above 0.81 and 4,805 (75.58%) query methods with a similarity above 0.9 with at least one target method.

## 8 Evaluation of Security Nudges

To evaluate the impact of our system including the security nudges on the security of programming results, we perform a laboratory user study. Thereby, participants had to solve programming tasks with the help from Stack Overflow.

### 8.1 User Study Setup

Participants were randomly assigned to one of two treatment conditions. For the nudge treatment, we provided security warnings (Figure 2a) for insecure code examples, recommendations for secure snippets (Figure 2b) and recommendations lists attached to each warning (Figure 8). Further, security reminders were enabled. In the control treatment, all security nudges on Stack Overflow were disabled.

Participants were advised to use Stack Overflow to solve the tasks. In all treatments, we restricted Stack Overflow search results to posts that contain a code example from the set of 10,558 code examples we extracted from Stack Overflow<sup>7</sup>. Further, we applied a whitelist filter to restrict access to Stack Overflow in the Chrome browser. Any requests to different domains were redirected to the Stack Overflow search page. Participants were provided with the Google Chrome browser and Eclipse pre-loaded with two Java class templates. Both class templates provided code skeletons that were intended to reduce the participants' workload and simplify the programming tasks. Using additional applications was prohibited. All tasks had to be solved within one hour. We avoided security or privacy priming during the introduction and throughout the study. Moreover, we did not name or explain any of the security nudges on Stack Overflow.

### 8.2 Tasks

All participants had to solve five programming tasks related to symmetric encryption and certificate pinning. We chose these two use cases as they provide the most error-prone cryptographic problems in Android [17].

**Symmetric Encryption** The first three tasks dealt with initializing a symmetric cipher in order to encrypt and decrypt a message. Task *Cipher*: a symmetric cipher had to be initialized by setting the algorithm, block mode and padding. The main security pitfalls in this task are choosing a weak cipher

<sup>7</sup>This aims at simplifying search for participants. All Stack Overflow posts that contain a seed statement are available during the study.

and block mode. Task *Key*: a symmetric cryptographic key had to be generated. Participants had to create a key having the correct and secure key length necessary for the previously defined cipher. It had to be generated from a secure random source and should not have been stored in plaintext. Task *IV*: an initialization vector had to be instantiated. Like key generation, this task is particularly error-prone as choosing the correct length, secure random source and storage can be challenging.

**Certificate Pinning** Within these two tasks, a SSL/TLS context had to be created to securely communicate with a specific server via HTTPS. In the end, the program should have been able to perform a successful GET request on the server, while denying connection attempts to domains that provide a different server certificate. A solution for Task *TLS* would have been to select a secure TLS version to initialize the context. Task *TM*: the server's certificate had to be added to an empty custom trust manager replacing the default manager. This way, the program would pin the server's certificate and create a secure communication channel, while rejecting attempts to any other server with a different certificate.

### 8.3 Preliminaries and Participants

We advertised the study in lectures and across various university communication channels. 30 subjects participated in the study, however, three subjects dropped out, because they misunderstood a basic participation requirement (i.e., having at least basic Java programming knowledge). Of the remaining 27 subjects, 16 were assigned to the nudge treatment, and 11 to the control treatment. While being students, our sample varied across demographics and programming skill, but none of the self-reported characteristics systematically differed across the two treatments (see Appendix A for details).

We followed well-established community principles for conducting security and privacy studies [29]. Participants were presented with a comprehensive consent form and separate study instructions on paper. Participants were compensated with 20 Euros.

After submission of the solutions, participants were asked to complete a short exit survey. We asked specific questions addressing the effectiveness of the security nudges and whether they were noticed by the participants. Also, we only asked demographic questions at this point to avoid any bias during the study. See Table 3 in the Appendix for details.

### 8.4 User Study Results

**Functional Correctness** Our system is not designed to address difficulties of programmers to deliver functionally correct code. However, it is important that using the system does not create obstacles to programmers. Participants predominantly submitted functionally correct code in both treatments

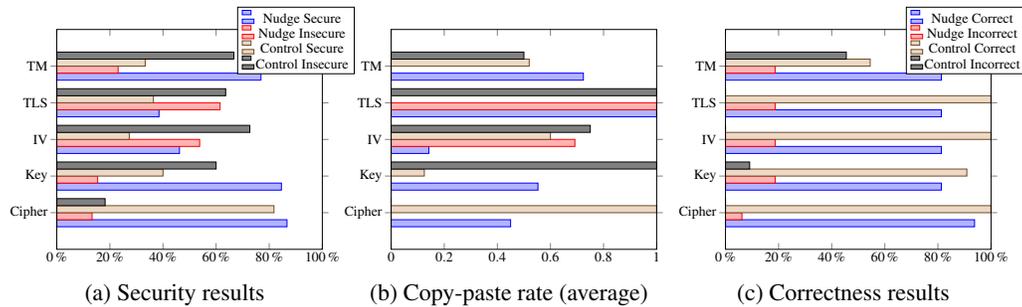

Figure 7: User study results for security, copy-paste rate and correctness of the submitted solutions across both treatments.

with some differences across tasks (cf. Figure 7c). Applying ordinal logistic regression (cf. Table 4 in the Appendix) indicates that the nudge treatment has – as anticipated – no effect on functional correctness of submitted tasks. However, non-professionals submitted significantly less functional code ( $p < 0.05$ ). *Cipher* submissions are more often functional, irrespective of the treatment ( $p < 0.05$ ).

**Security** Figure 7a shows the security results per task for both treatments. Performing ordinal logistic regression (see Table 5 in the Appendix), we show that the nudge treatment is significantly outperforming the control group in producing secure solutions (with an estimate of 1.303 and  $p < 0.01$ ; Model 4). While the main effect of the nudge treatment dominates the regression models, we can observe from Figure 7a that comparatively more secure submissions are made for *TM* and *Key*. Indeed, pairwise testing using Chi-Square tests reveals  $p < 0.001$  for both tasks. Participants from the nudge group provided 84.6% secure solutions for *Key* and 76.9% for *TM*, while 60.0% and 66.7% of the respective solutions submitted by the control group were insecure. These observations for *TM* are somewhat encouraging given previous findings: [17] have shown that reused insecure *TM* code snippets from Stack Overflow were responsible for 91% (183,268) of tested apps from Google Play being vulnerable. Only 0.002% (441) of apps contained secure *TM* code from Stack Overflow. Based on these insecure *TM* snippets, [13] were able to attack several high-profile apps extracting private data. Moreover, [27] found that only 45 out of 639,283 Android apps applied certificate pinning, while 25% of developers find certificate pinning too complex to use. [2] reported that tasks very similar to *TM* could not be solved with the help of simplified cryptographic APIs within a user study.

For *Cipher*, the nudge treatment performs very well, but only slightly better than the control treatment, as both achieved 86.7% and 81.8% secure solutions, respectively.

For *IV* and *TLS*, the nudge results are less desirable with 46.2% and 38.5% secure solutions, while performing better but not significantly ( $p < 0.077$  and  $p < 0.53$ ; Chi-Square) than the control treatment. To better understand these observations, we analyzed visited posts, copy-and-paste history

and the submitted code of participants that provided insecure solutions for these two tasks. In the case of *IV*, we found that four insecure solutions reused insecure patterns from code snippets that were falsely marked as recommended code. To encounter false predictions of the security model was *a priori* extremely unlikely. Interestingly, the remaining insecure solutions were created by users combining secure code from different correctly marked recommendations (true negatives) into insecure code. Thereby, users reused the seed statement for *IV* from one snippet and initialized it with an empty array obtained from another code snippet that did not make use of *IV* at all. In the case of *TLS*, all insecure solutions were copied from code snippets that were clearly marked as insecure.

**Copy-and-Paste Behavior** We calculated the average copy-paste rate per task for both treatments, which reports the relative frequency copied code has also been reused in a submitted solution (see Figure 7b). Importantly, in the nudge treatment, *not a single* insecure copy-and-paste event was observed for *Cipher*, *Key* and *TM*, while secure code that was copied into the clipboard was reused at a rate of 0.45, 0.55, and 0.72 on average, respectively. This goes in line with observed security outcomes depicted in Figure 7a, where more secure than insecure solutions were provided for these tasks. However, insecure copy-and-paste events were observed for *IV* and *TLS*, partly explaining the comparatively higher number of insecure solutions. In the control treatment, the copy-paste rate for insecure snippets closely follows the observed frequencies of insecure results for all tasks except *Cipher*.

**Warnings/Recommendations/Reminder** Even though all users within the nudge group saw security warnings during their journey, we observed an insecure-to-secure copy event ratio of 0.27 for both treatments indicating that warnings alone are not sufficient for preventing users from placing insecure code on the clipboard. However, the copy-paste rate measuring the relative frequency of copy to paste events (see Figure 7b) offers more nuanced results. It shows that the nudge group tends to discard insecure copies, while pasting more secure copies into their solutions. This is most likely

the result of the reminder nudge, which was triggered by insecure copy events. As a result, users dropped copied insecure samples and started looking for a secure alternative. In contrast, the copy-paste rate for control shows that copied insecure snippets were not dropped, but rather pasted into the solution. Therefore, the interaction of several nudges was responsible for improving the security decisions of the participants. In the exit survey, users also marked the relevant nudges with high average Likert score values of above 4 (on 5-point scales).

We only observed 22 events where users clicked on a proposed recommendation link as shown in the bottom part of Figure 8a. Therefore, only 10.1% of secure posts (of 219 in total) were visited following such a proposed recommendation. However, 86.6% remembered the feature during the exit survey. With 4 paste and 8 copy events (i.e., a copy-paste rate of 0.5) only a very small amount of reused secure code in the submitted solutions was directly related to this nudge. Though contributing to the improvement of code security, we can state that this nudge was surprisingly the least effective one. The average Likert score for the list of recommendations was also comparatively low with 3.2.

## 9 Limitations

The response rate during recruitment for our developer study was quite low. However, we achieved a participation count per treatment which was very similar to comparable peer-reviewed studies (e.g., [2]). However, participation may introduce self-selection bias. Therefore, we avoided any security framing during recruitment and have no reason to believe that the final group of participants was systematically different in terms of security knowledge. The study was performed within a laboratory under strict time constraints. By enforcing a time limit, we intended to create a more realistic scenario and to obtain a comparable outcome for both treatments. Participants had to solve their programming tasks using a given code editor, browser, as well as operating system which they might not have been familiar with. Most of our participants were students, while only a minority had a professional background, which may limit the generalizability of our results. Professionals performed slightly better in achieving functional solutions, but not in security across both treatments. Therefore, comparisons among both treatments remain valid.

For implementing custom trust managers in Android (see Section 8.2), current best practices suggest a declarative solution which uses a static configuration file instead of Java code.<sup>8</sup> Being able to include other formats, such as formal documentation in our recommendations would additionally allow suggesting this solution. One possible way to achieve

<sup>8</sup><https://developer.android.com/training/articles/security-config>

that is to create a link between code examples from Stack Overflow and natural language text in official documentation. I.e., we would have to extend our framework such that it embeds code examples and natural language text into the same vector space. This can be done with sequence-to-sequence models, which are usually applied for natural language translation. GitHub is currently testing a similar approach for their semantic code search engine.<sup>9</sup>

## 10 Future Work

Our recommendation approach may be subject to attacks. More specifically, in an adversarial setting, machine learning algorithms are often not robust against manipulated input data. Similar to efforts in malware obfuscation and spam filter bypassing, an attacker might be able to craft malicious code that gets mistakenly classified as secure. This way, the attacker could spread malicious code into the ecosystem on a large scale. However, a number of novel techniques have been proposed to counter the adversarial effect [18, 24, 28].

Stack Overflow provides code examples for almost each and every programming language. Since our framework learns the optimal code representation for a given classification task based on general code features, we do not see major issues in applying it to different programming languages. A language-specific compiler or a universal parser can be used to generate the PDG, which is then fed to our pattern embedding network (see Section 5.4). The representation learning of API-specific lexical features (see Section 5.3) is completely independent from the programming language and therefore straightforward.

We suggest to conduct additional UI testing as we might not have identified the optimal design, yet. Following Felt et al. [15], different security indicators such as alternative candidate icons and text have to be tested, for instance within user surveys or by repeating our developer study. Stack Overflow recently proposed a partnership program with academia that would allow to extend their developer survey and to test design tweaks on their website.<sup>10</sup>

## 11 Conclusion

In this paper, we propose an approach for deep learning security nudges that help software developers write strong encryption code. We propose a system design integrated in Stack Overflow whose components consist of several security nudges, namely *warnings*, *recommendations*, *reminders*, and *defaults* and a neural network architecture that controls these nudges by learning and predicting secure and insecure cryptographic usage patterns from community-provided

<sup>9</sup><https://githubengineering.com/towards-natural-language-semantic-code-search/>

<sup>10</sup><https://meta.stackoverflow.com/questions/377152/stack-overflow-academic-research-partnership-program>

code examples. We propose a novel approach on deep learning optimized code representations for given code classification tasks and train a classification model that is able to predict use cases and security scores of encryption code examples with an AUC-ROC of 0.999 and 0.992, respectively. Applying this model within our nudge-based system design on Stack Overflow, we performed a user study where participants had to solve the most error-prone cryptographic programming tasks reported in recent research. Our results demonstrate the effectiveness of nudges in helping software developers to make better security decisions on Stack Overflow.

### Appendix A: Additional Participant Data

Table 3 includes additional data about the 27 participants, who completed the study.

We also conducted a series of statistical tests to verify that the self-reported characteristics of the recruited participants did not systematically vary across treatments. Indeed, using the Mann-Whitney U Test, we found that participants did not differ in their reported age across treatments ( $p = 0.79$ ). Applying Fisher’s Exact Test, we also observed the absence of a statistically significant difference for country of origin ( $p = 0.809$ ), gender ( $p = 0.551$ ), level of education ( $p = 0.217$ ), security knowledge/background ( $p = 0.124$ ), and professional programming experience ( $p = 0.315$ ). Using the Mann-Whitney U Test, we did not find any statistically significant difference for years of experience with Java programming ( $p = 0.422$ ). We also did not find any reportable differences regarding participants’ awareness of encryption flaws ( $p = 0.363$ ) using Fisher’s Exact Test. The percentage of participants who had to program Java as primary activity for their work ( $p = 1$ ) or for whom writing Java code was part of their primary job in the last 5 years ( $p = 0.696$ ) also did not differ across treatments (using Fisher’s Exact Test).

### Appendix B: Detailed Regression Results

Based on the user study data and self-reported survey responses, we follow an ordinal (Logit link) regression ap-

proach, which is primarily focused on evaluating the effectiveness of the nudge treatment.

First, we report a series of four models (M1 - M4) to evaluate whether the nudge treatment significantly impacts the *functional correctness* of the submitted programs for the five different tasks (see Table 4). We iteratively add factors to the regression model to also test whether programming expertise or security expertise positively impact the outcome variable. Most importantly, as the nudge treatment is not designed to address this aspect of programming, we did *not* expect any significantly positive effect. Indeed, across all model specifications that we tested, we did not observe any significant (positive or negative) effect. Regarding the different programming tasks, we found that the Cipher task was associated with a significantly increased likelihood of being functionally correct (M2 - M4). Further, not being a security professional (as reported by the participants) significantly impacts the likelihood that functional programs were submitted in a negative fashion (M3 - M4). In contrast, a higher degree of security knowledge (as reported by the participants) did not significantly impact the results (M4).

Note that the regression statistics for tasks IV and TLS are identical as the aggregate results for functional correctness happen to be the same (see Figure 7c).

Second, we report a series of four models (M1 - M4) to evaluate whether the nudge treatment significantly impacts the *security* of the submitted programs for the five different tasks (see Table 5). For consistency, we iteratively add the same factors to the regression model to also test whether programming expertise or security expertise positively impact the outcome variable.

Most importantly, as the nudge treatment is designed to improve the security of cryptography-related programming, we did expect a significantly positive effect. Indeed, across all model specifications that we tested, we did observe a sig-

reported by the participants) did not significantly impact the results either (M4).

We created regression models including further demographic and explanatory variables. However, none of them had a significant effect on the security of submitted solutions.

### Appendix C: Pattern Annotation Tool

Our security annotations generally comply with rules and annotation heuristics given by [12, 13, 17]. However, manual analysis of patterns was not restricted to simple application of these heuristics, but was based on detecting insecure patterns in general. Whenever an unknown pattern has been detected, both annotators discussed them until agreement on a label. For example, [13] only reports empty trust manager implementations, while many insecure *TM* patterns on Stack Overflow are not empty, but provide insufficient certificate verification (e.g., only validating that the certificate is not expired).

To further speed up the labeling process and manage the large amount of samples, we created a code annotation tool. It automatically iterates through code snippets and displays them to the user, using a source code editor. Seed statements were already highlighted in order to allow the annotator to detect relevant patterns quickly. The annotator was able to assign labels (e.g., secure/insecure) to different keyboard buttons. While iterating through the seed statements, the annotator would investigate the related pattern and label it accordingly. Moreover, the annotator had the option to add seed statements, that she wanted to have highlighted and labeled. Whenever the annotator identified new patterns or wanted to share and discuss a pattern, the related code snippet was marked and other annotators were notified to comment on it. After agreement, the pattern was labeled by the initial annotator. Further, annotation heuristics obtained during the discussion were shared among all annotators.

# Wireless Attacks on Aircraft Instrument Landing Systems

Harshad Sathaye, Domien Schepers, Aanjhan Ranganathan, and Guevara Noubir  
*Khoury College of Computer Sciences*  
*Northeastern University, Boston, MA, USA*

## Abstract

Modern aircraft heavily rely on several wireless technologies for communications, control, and navigation. Researchers demonstrated vulnerabilities in many aviation systems. However, the resilience of the aircraft landing systems to adversarial wireless attacks have not yet been studied in the open literature, despite their criticality and the increasing availability of low-cost software-defined radio (SDR) platforms. In this paper, we investigate the vulnerability of aircraft instrument landing systems (ILS) to wireless attacks. We show the feasibility of spoofing ILS radio signals using commercially-available SDR, causing last-minute *go around* decisions, and even missing the landing zone in low-visibility scenarios. We demonstrate on aviation-grade ILS receivers that it is possible to fully and in fine-grain control the course deviation indicator as displayed by the ILS receiver, in *real-time*. We analyze the potential of both an overshadowing attack and a lower-power single-tone attack. In order to evaluate the complete attack, we develop a tightly-controlled closed-loop ILS spoofer that adjusts the adversary's transmitted signals as a function of the aircraft GPS location, maintaining power and deviation consistent with the adversary's target position, causing an undetected off-runway landing. We systematically evaluate the performance of the attack against an FAA certified flight-simulator (X-Plane)'s AI-based autoland feature and demonstrate systematic success rate with offset touch-downs of 18 meters to over 50 meters.

## 1 Introduction

Today, the aviation industry is experiencing significant growth in air traffic with more than 5000 flights [14] in the sky at any given time. It has become typical for air traffic control towers to handle more than a thousand takeoffs and landings every day. For example, Atlanta's Hartsfield-Jackson International airport handles around 2500 takeoffs and landings every day. Boston's Logan airport which is not one of the busiest airports in the world managed an average of 1100 flights every day in August 2018. The modern aviation ecosystem heavily relies on a plethora of wireless technologies for their safe

and efficient operation. For instance, air traffic controllers verbally communicate with the pilots over the VHF (30 to 300 MHz) radio frequency channels. The airplanes continuously broadcast their position, velocity, callsigns, altitude, etc. using the automatic dependent surveillance-broadcast (ADS-B) wireless communication protocol. Primary and secondary surveillance radars enable aircraft localization and provide relevant target information to the air traffic controllers. Traffic Alert and Collision Avoidance System (TCAS), an airborne wireless system independent of the air traffic controller enables the aircraft to detect potential collisions and alert the pilots. Air traffic information, flight information and other operational control messages between the aircraft and ground stations are transferred using the Aircraft Communications Addressing and Reporting System (ACARS) which uses the VHF and HF radio frequency channels for communication. Similarly, many radio navigation aids such as GPS, VHF Omnidirectional Radio Range (VOR), Non-directional radio beacons (NDB), Distance Measuring Equipment (DME), and Instrument Landing System (ILS) play crucial roles during different phases of an airplane's flight.

Many studies have already demonstrated that a number of the above-mentioned aviation systems are vulnerable to attacks. For example, researchers [22] injected non-existing aircraft in the sky by merely spoofing ADS-B messages. Some other attacks [37] modified the route of an airplane by jamming and replacing the ADS-B signals of specific victim aircraft. ACARS, the data link communications system between aircraft and ground stations was found to leak a significant amount of private data [50], e.g., passenger information, medical data and sometimes even credit card details were transferred. GPS, one of the essential navigation aids is also vulnerable to signal spoofing attacks [32]. Furthermore, an attacker can spoof TCAS messages [42] creating false resolution advisories and forcing the pilot to initiate avoidance maneuvers. Given the dependence on wireless technologies, the threats described above are real and shows the importance of building secure aviation control, communication and navigation systems.

One of the most critical phases of an airplane’s flight plan is the final approach or landing phase as the plane descends towards the ground actively maneuvered by the pilot. For example, 59% of the fatal accidents documented by Boeing [16] occurred during descent, approach and landing. Several technologies and systems such as GPS, VOR, DME assist the pilot in landing the aircraft safely. The Instrument Landing System (ILS) [17] is today the de-facto approach system used by planes at a majority of the airports as it is the most precise system capable of providing accurate horizontal and vertical guidance. At Boston’s Logan International Airport, 405,822 [1] flight plans were filed in 2017. Out of these 405,822 flight plans, 95% were instrument flight rule (IFR) plans. Instrument flight rules are a set of instructions established by the FAA to govern flight under conditions in which flying by visual reference is either unsafe or just not allowed. Also, several European airports [9] prohibit aircraft from landing using visual flight rules during the night. ILS incorporates radio technology to provide all-weather guidance to pilots which ensures safe travel and any interference can be catastrophic.

As recently as September 2018, the pilots of Air India flight AI-101 reported an instrument landing system (ILS) malfunction and were forced to do an emergency landing. Even worse, TCAS, ACARS, and a majority of other systems that aid a smooth landing were unusable. Furthermore, NASA’s Aviation Safety Reporting System [25] indicate over 300 ILS related incidents where pilots reported the erratic behavior of the localizer and glideslope—two critical components of ILS. ILS also plays a significant role in autoland systems that are capable of landing aircraft even in the most adverse conditions without manual interference. Autoland systems have significantly advanced over the years since its first deployment in De Havilland’s DH121 Trident, the first airliner to be fitted with an autoland system [15]. However, several near-catastrophic events [4, 8, 12] have been reported due to the failure or erratic behavior of these autoland systems with ILS interference as one of the principal causes. With increasing reliance on auto-pilot systems and widespread availability of low-cost software-defined radio hardware platforms, adversarial wireless interference to critical infrastructure systems such as the ILS cannot be ruled out.

In this work, we investigate the security of aircraft instrument landing system against wireless attacks. To the best of our knowledge, there has been no prior study on the security guarantees of the instrument landing system. Specifically, our contributions are as follows.

- We analyze the ILS localizer and glideslope waveforms, the transmitters and receivers, and show that ILS is vulnerable to signal spoofing attacks. We devise two types of wireless attacks i) overshadow, and ii) single-tone attacks.
- For both the attacks, we generate specially crafted radio signals similar to the legitimate ILS signals using

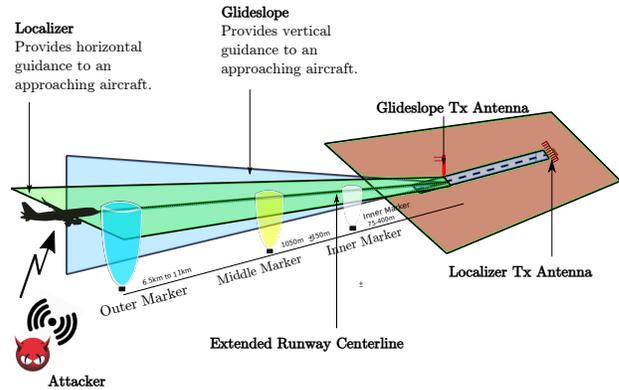

Figure 1: Overview of ILS sub-systems. The ILS consists of three subsystems: i) Localizer, ii) glideslope, and (iii) marker beacons.

low-cost software-defined radio hardware platform and successfully induce aviation-grade ILS receivers, in *real-time*, to lock and display arbitrary alignment to both horizontal and vertical approach path. This demonstrates the potential for an adversary to the least be able to trigger multiple aborted landings causing air traffic disruption, and in the worst case, cause the aircraft to overshoot the landing zone or miss the runway entirely.

- In order to evaluate the complete attack, we develop a tightly-controlled closed-loop ILS spoofer. It adjusts the the adversary’s transmitted signals as a function of the aircraft GPS location, maintaining power and deviation consistent with the adversary’s target position, causing an undetected off-runway landing. We demonstrate the integrated attack on an FAA certified flight-simulator (X-Plane), incorporating a spoofing region detection mechanism, that triggers the controlled spoofing on entering the landing zone to reduce detectability.
- We systematically evaluate the performance of the attack against X-Plane’s AI-based autoland feature, and demonstrate the systematic success rate with offset touchdowns of 18 meters to over 50 meters.
- We discuss potential countermeasures including failsafe systems such as GPS and show that these systems also do not provide sufficient security guarantees. We highlight that implementing cryptographic authentication on ILS signals is not enough as the the system would still be vulnerable to record and replay attacks. Therefore, through this research, we highlight an open research challenge of building secure, scalable and efficient aircraft landing systems.

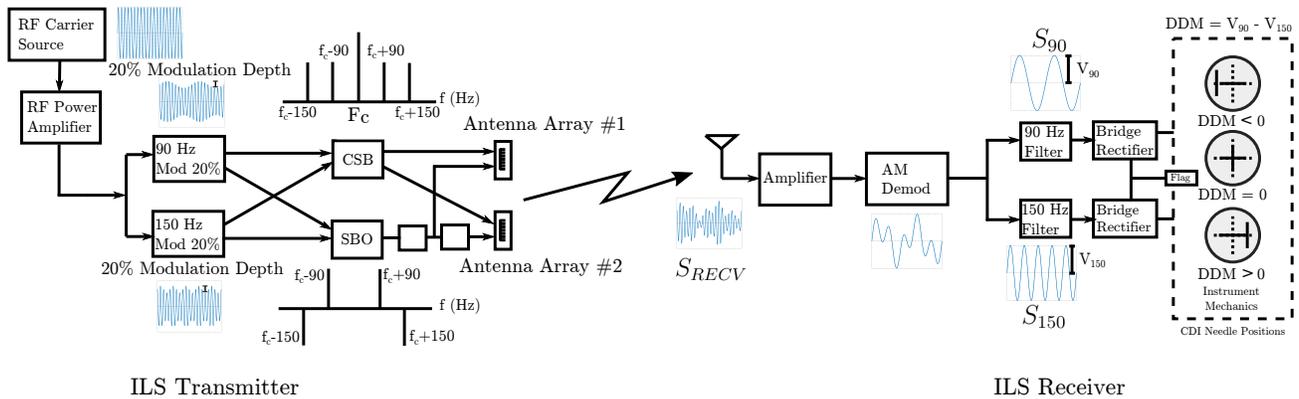

Figure 2: Block diagram of ILS transmitter and receiver describing the process of generation and reception of ILS signal along with waveforms at each stage.

## 2 Background

Approach systems enable pilots to land airplanes even in extreme weather conditions and are classified into non-precision and precision approach systems based on the accuracy and type of approach guidance provided to an aircraft. Non-precision approach systems provide only horizontal or lateral guidance (heading/bearing). Examples of non-precision approach systems are VHF Omnidirectional Range (VOR) [58], Non-Directional Beacon (NDB) [57], and satellite systems such as GPS. With the development of precision approach systems, the use of non-precision approach systems such as VOR and NDB has significantly decreased today. Precision approach systems provide both horizontal (heading/bearing) as well as vertical (glide path) guidance to an approaching aircraft. The Instrument Landing System (ILS) is the most commonly deployed precision approach system in use today. Other examples of precision approach systems include Microwave Landing System (MLS), Transponder Landing System (TLS), Ground Based Augmentation Landing System (GLS), and Joint Precision Approach and Landing System (JPALS). It is important to note that these alternate landing systems fundamentally still use existing ILS concepts and equipment mostly in scenarios where ILS is unavailable. For example, TLS enables precision landing guidance in places where the terrain is uneven, and the ILS signal reflections off the ground cause undesirable needle deflections by *emulating* the ILS signals using only one base tower (in contrast to two for ILS) whose placement allows more flexibility. However, TLS still leverages the same fundamental concepts of ILS. In short, ILS plays a key, de-facto role in providing precision landing guidance at the majority of airports today and it is, therefore, essential to evaluate its resilience to modern-day cyber-physical attacks.

## 2.1 Instrument Landing System (ILS)

The first fully operational ILS was deployed in 1932 at the Berlin Tempelhof Central Airport, Germany. ILS enables the pilot to align the aircraft with the centerline of the runway and maintain a safe descent rate. ITU defines ILS [28] as “a radio navigation system which provides aircraft with horizontal and vertical guidance just before and during landing and at certain fixed points, indicates the distance to the reference point of landing”. Autopilot systems on some modern aircraft [49] use ILS signals to execute a fully autonomous approach and landing, especially in low visibility settings. ILS (Figure 1) comprises of three independent subsystems: i) localizer, ii) glideslope and iii) marker beacons. The localizer and the glideslope guide the aircraft in the horizontal and vertical plane respectively. The marker beacons act as checkpoints that enable the pilot to determine the aircraft’s distance to the runway. ILS has three operational categories: i) CAT I, ii) CAT II and, iii) CAT III. CAT III further has three sub-standards IIIa, IIIb and, IIIc. These operational categories are decided based on ILS installations at the airport <sup>1</sup> and is independent of the receiver on the aircraft. With the advent of GPS and other localization technologies, the marker beacons are less important today and increasingly obsolete. However, the localizer and the glideslope play a major role in an aircraft’s safe landing today and is expected to remain so for many years.

### 2.1.1 ILS Signal Generation

ILS signals are generated and transmitted such that the waves form a specific radio frequency signal pattern in space to create guidance information related to the horizontal and vertical

<sup>1</sup>Procedures for the Evaluation and Approval of Facilities for Special Authorization Category I Operations and All Category II and III Operations [http://fsims.faa.gov/wdocs/Orders/8400\\_13.htm](http://fsims.faa.gov/wdocs/Orders/8400_13.htm)

positioning. ILS signal generators leverage *space modulation* i.e., use multiple antennas to transmit an amplitude modulated radio frequency signals with various powers and phases. The transmitted signals combine in the airspace to form signals with different depths of modulation (DDM) at various points within the 3D airspace. Each DDM value directly indicates a specific deviation of the aircraft from the correct touchdown position. For example, the signals combine in space to produce a signal with zero difference in the depth of modulation (DDM) along the center-line of the runway. It is important to note that unlike traditional modulation techniques where the modulation occurs within the modulating hardware, in space modulation, the signals mix within the airspace.

The process of generating the localizer and glideslope signals ( Figure 2 ) are similar with differences mainly in the carrier frequency used and how they are combined in space to provide the relevant guidance information. The carrier signal is amplitude modulated with 90 Hz and 150 Hz tones to a certain depth of modulation. The depth of modulation or modulation index is the measure of the extent of amplitude variation about an un-modulated carrier. The depth of modulation is set at 20% and 40% respectively for localizer and glideslope signals. The output of both the 90 Hz and 150 Hz modulator is then combined to yield two radio frequency signals: a carrier-plus-sidebands (CSB) and a sidebands-only (SBO) signal. The names of the signal directly reflect their spectral energy configuration with the CSB containing both the sideband energy and the assigned carrier frequency while in the SBO signal the carrier frequency component is suppressed. The CSB and SBO signals are subjected to specific phase shifts before being transmitted. The phase shifts are carefully chosen such that when the CSB and SBO signals combine in space, the resulting signal enables the aircraft to determine its horizontal and vertical alignment with the approach path.

**Localizer.** The localizer subsystem consists of an array of multiple antennas that emit the CSB and SBO signals such that the 150 Hz modulation predominates to the right of the runway centerline and the 90 Hz signal prevails to the left. In other words, if the flight is aligned to the right of the runway during the approach, the 150 Hz dominant signal will indicate the pilot to steer left and vice versa. The antenna array of the localizer is located at the opposite end (from the approach side) of the runway. Each runway operates its localizer at a specific carrier frequency (between 108.1 MHz to 111.95 MHz) and the ILS receiver automatically tunes to this frequency as soon as pilot inputs the runway identifier in the cockpit receiver module. Additionally, the runway identifier is transmitted using a 1020 Hz morse code signal over the localizer's carrier frequency.

**Glideslope.** The glideslope subsystem uses two antennas to create a signal pattern similar to that of the localizer except on a vertical plane. The two antennas are mounted on a tower

at specific heights defined by the glide-path angle suitable for that particular airport's runway. In contrast to the localizer, the glideslope produces the signal pattern in the airspace based on the sum of the signals received from each antenna via the direct line-of-sight path and the reflected path. The mixing of the CSB and SBO signals results in a pattern in which the 90 Hz component of the signal predominates in the region above the glide-path while the 150 Hz prevails below the glide-path. The glideslope uses carrier frequencies between 329.15 MHz and 335.0 MHz, and the antenna tower is located near the touchdown zone of the runway. Typically, the center of the glide-slope defines a glide path angle of approximately 3°. For every localizer frequency, the corresponding glideslope frequency is hardcoded i.e., the localizer-glideslope frequencies occur in pairs and the instrument automatically tunes to the right glideslope frequency when the pilot tunes to a specific runway's localizer frequency.

### 2.1.2 ILS Receiver

The combined signals received at the aircraft are amplified, demodulated, and filtered to recover the 90 Hz and 150 Hz components. A bridge rectifier is used to convert the amplitude of the recovered tones to DC voltage levels. The DC voltage output is directly proportional to the depth of the modulation of the 90 Hz and 150 Hz tones—a direct measure of the dominating frequency signal. The DC voltage causes the course deviation indicator needle to deflect based on the difference in the depth of the modulation of the two tones thereby precisely indicating the aircraft's lateral and vertical deviation from approach path.

For example, an aircraft that is on-course will receive both 90 and 150 Hz signals with the same amplitude, i.e., equal depth of modulation and will result in zero *difference in the depth of modulation* and therefore cause no needle deflections. However, an aircraft that is off-course and not aligned with the approach path will receive signals with a non-zero difference in the depth of modulation resulting in a corresponding deflection of the needle. The instruments are calibrated to show full scale deflection if  $DDM > 0.155$  or  $DDM < -0.155$  for localizer and if  $DDM > 0.175$  or  $DDM < -0.175$  for glideslope [20]. These values correspond to 2.5° offset on the left side of the runway, 2.5° offset on the right side of the runway, 0.7° offset above the glide path angle and 0.7° below the glide path angle respectively.

## 2.2 Typical Approach Sequence

Pilots use aeronautical charts containing vital information about the terrain, available facilities and their usage guidelines throughout a flight. Approach plates are a type of navigation chart used for flying based on instrument readings. Every pilot is required to abide by the routes and rules defined in an approach plate unless ordered otherwise by the air traffic controller. The approach plate contains information like active localizer frequency of the runway, the runway identifier

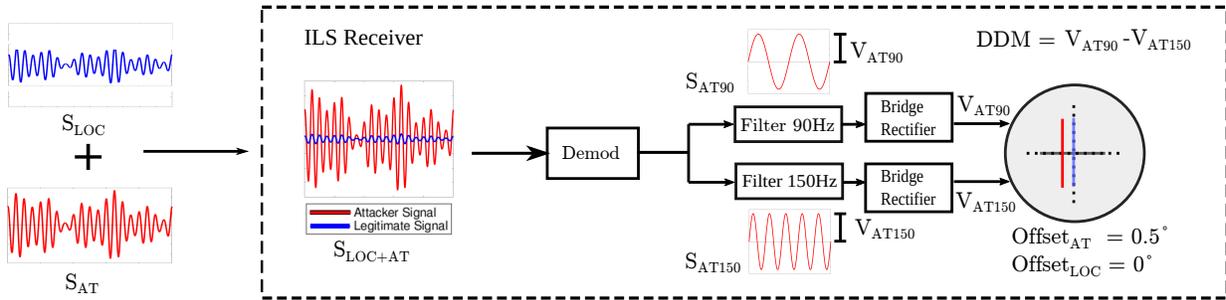

Figure 3: Schematic of the overshadow attack. The attacker’s signal has a preset DDM corresponding to  $0.5^\circ$  to the right of the runway. Attacker’s signal overshadows the legitimate signal. The blue line represents the needle position without attack.

in Morse code, glideslope interception altitude, ATC tower frequencies, and other information crucial for a safe landing.

Once the pilot receives the clearance to land at an assigned runway, the pilot enters the localizer frequency associated with the designated runway and enters the course of the runway into the auto-pilot. Note that the localizer and glideslope frequencies occur in pairs and therefore the pilot does not have to manually enter the corresponding glideslope frequency. When the pilot intercepts the localizer, the course deviation indicator needle is displayed on the cockpit. The pilot then verifies whether the receiver is tuned to the right localizer by confirming the runway identifier which is transmitted as morse code on the localizer frequency. For example, for landing on runway 4R (Runway Ident - IBOS) at Logan International Airport, Boston, the pilot will tune to 110.3 MHz and will verify this by confirming the Morse code: .. / -... / --- / ... Based on the deviation of the aircraft from the runway and the approach angle, the indicator will guide the pilot to appropriately maneuver the aircraft. Modern autopilot systems are capable of receiving inputs from ILS receivers and autonomously land the aircraft without human intervention.

In fact, pilots are trained and instructed to trust the instruments more than their intuition. If the instruments ask them to fly right, the pilots will fly right. This is true specifically when flying in weather conditions that force the pilots to follow the instruments. Detecting and recovering from any instrument failures during crucial landing procedures is one of the toughest challenges in modern aviation. Given the heavy reliance on ILS and instruments in general, malfunctions and adversarial interference can be catastrophic especially in autonomous approaches and flights. In this paper, we demonstrate vulnerabilities of ILS and further raise awareness towards the challenges of building secure aircraft landing systems.

### 3 Wireless Attacks on ILS

We demonstrate two types of wireless attacks: i) Overshadow attack and ii) Single-tone attack. In the overshadow attack, the attacker transmits pre-crafted ILS signals of higher signal strength; thus overpowering the legitimate ILS signals. The

single-tone attack is a special attack where it is sufficient for the attacker to transmit a single frequency tone signal at a specific signal strength (lower than the legitimate ILS signal strength) to interfere and control the deflections of the course deviation indicator needle.

**Attacker model.** We make the following assumptions regarding the attacker. Given that the technical details of ILS are in the public domain, we assume that the attacker has complete knowledge of the physical characteristics of ILS signals e.g., frequencies, modulation index etc. We also assume that the attacker is capable of transmitting these radio frequency signals over the air. The widespread availability of low-cost (less than a few hundred dollars) software-defined radio platforms has put radio transmitters and receivers in the hands of the masses. Although not a necessary condition, in the case of single-tone, the knowledge of the flight’s approach path, the airplane’s manufacturer and model will allow the attacker to significantly optimize their attack signal. We do not restrict the location of the attacker and discuss pros and cons of both an on-board attacker as well as a attacker on the ground.

#### 3.1 Overshadow attack

The overshadow attack is an attack where the attacker transmits specially crafted ILS signals at a power level such that the legitimate signals get overpowered by the attacker’s signal at the receiver. The main reason why such an attack works is that the receivers “lock” and process only the strongest received signal. Figure 3 shows how the attacker’s fake ILS signal completely overshadows the legitimate ILS signal resulting in the deflection of the CDI needle. We note that the attacker signal can be specially crafted to force the CDI needle to indicate a specific offset as demonstrated in Section 4.2.

**Attack Signal Generation.** Recall that the ILS receiver on-board receives a mix of the transmitted CSB and SBO signals that contain the 90 and 150 Hz tones (Figure 2). The amplitude of received 90 and 150 Hz tones depends on the position of the aircraft relative to the runway and its approach path

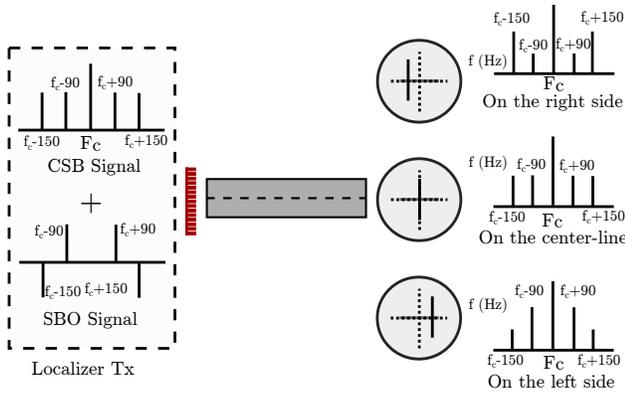

Figure 4: Frequency domain representation of the received signal showing the amplitudes of the sidebands as observed at various lateral offsets

angle. For example, as shown in Figure 4, the 90 Hz tone will dominate if the aircraft is offset to the left of the runway and the 150 Hz dominates to the right. Similarly, for glideslope, the 90 Hz tone dominates glide angles steeper than the recommended angle, and the 150 Hz tone dominates otherwise. Both 90 and 150 Hz will have equal amplitudes for a perfectly aligned approach. Therefore, to execute an overshadow attack, it is sufficient to generate signals similar to the received legitimate ILS signals and transmit at a much higher power as compared to legitimate ILS signals. In other words, the attacker need not generate CSB and SBO signals separately; instead can directly transmit the combined signal with appropriate amplitude differences between the 90 and 150 Hz tones. The amplitude differences are calculated based on the offset the attacker intends to introduce at the aircraft. The attacker's signal (Figure 5) is generated as follows. There are two tone generators for generating the 90 and the 150 Hz signals. It is important to enable configuration of each individual tone's amplitude to construct signals with a preset difference in the depth of modulation corresponding to the required deviation to spoof. The tones are then added and amplitude modulated using the runway's specific localizer or glideslope frequency. Recall that the amplitude differences i.e., difference in depth of modulation (DDM) between the two tones directly corresponds to the required offset to spoof. In the absence of the adversarial signals the estimated  $DDM = V_{LOC90} - V_{LOC150}$ . In the presence of the attacker's spoofing signals, the estimated  $DDM = [V_{LOC90} + V_{AT90}] - [V_{LOC150} + V_{AT150}]$ . Since  $V_{AT90} \gg V_{LOC90}$  and  $V_{AT150} \gg V_{LOC150}$ , the resulting  $DDM = V_{AT90} - V_{AT150}$ . Thus by manipulating the amplitude differences between the transmitted 90 Hz and 150 Hz tones, the attacker can acquire precise control of the aircraft's course deviation indicator and the aircraft's approach path itself.

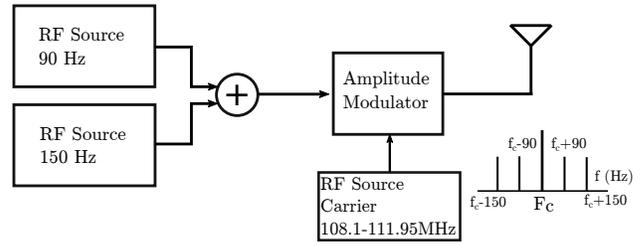

Figure 5: Signal generator used for generating the required attack signal with specific amplitudes of the 90 Hz and 150 Hz components

### 3.2 Single-tone attack

Single-tone attack is an attack where the attacker transmits only one of the sideband tones (either the 90 Hz or the 150 Hz) to cause deflections in the course deviation indicator needle. In contrast to the overshadow attack, single-tone attack does not require high powered spoofing signals. Recall that the aircraft's horizontal and vertical offset is estimated based on the difference in the depth of the modulation of the 90 Hz and the 150 Hz tones. As indicated in Figure 4, depending on the offset either of the frequency tones dominates. In the case of an overshadow attack, the spoofing signal was constructed with all the necessary frequency components. However, in the single-tone attack, the attacker aims to interfere with only one of the two sideband frequencies directly affecting the estimated offset.

**Attack Signal Generation.** The working of the single-tone attack is shown in Figure 6. The legitimate localizer signal's spectrum contains the carrier and both the sideband tones of 90 Hz and 150 Hz. As described previously, the amplitudes of the sideband tones depend on the true offset of the aircraft. In a single-tone attack, the attacker generates only one of the two sideband tones i.e.,  $f_c \pm 90$  or  $f_c \pm 150$  with appropriate amplitude levels depending on the spoofing offset (e.g., left or right off the runway) introduced at the aircraft. For example, consider the scenario where the attacker intends to force the aircraft to land on the left of the runway with an offset of  $0.5^\circ$ . The legitimate difference in depth of modulation will be zero as the aircraft is centered over the runway. To cause the aircraft to go left, the attacker must transmit signals that will spoof the current offset to be at the right side of the runway. As shown in Figure 4, the 150 Hz component dominates in the right side of the runway approach and therefore the attacker needs to transmit the  $f_c \pm 150$  signal with an appropriate amplitude to force the aircraft to turn left. For the specific example of  $0.5^\circ$  offset, the amplitude of the  $f_c \pm 150$  component should be such that the difference in the depth of modulation equals 0.03 [20].

Notice that the single-tone attack signal is similar to a double-sideband suppressed-carrier signal which is well-

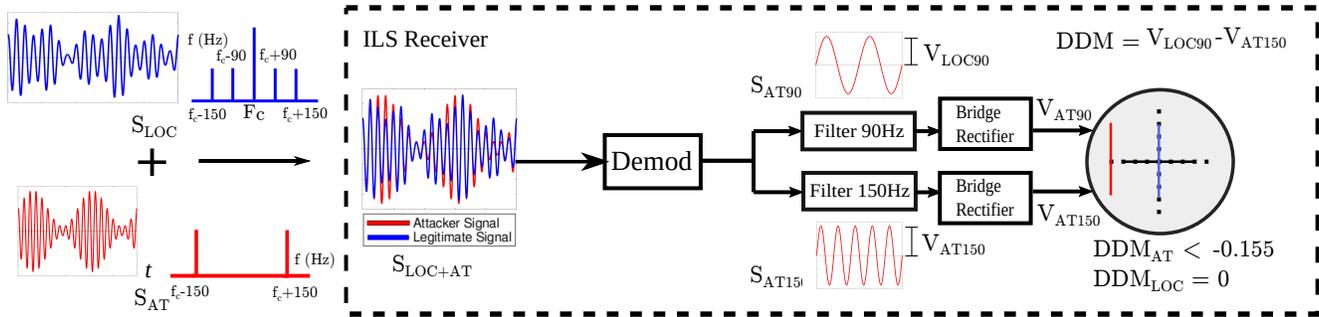

Figure 6: Schematic of the single-tone attack. Attacker constructs a DSB-SC signal without the 90 Hz component and the carrier. The blue line represents the needle position without the attack

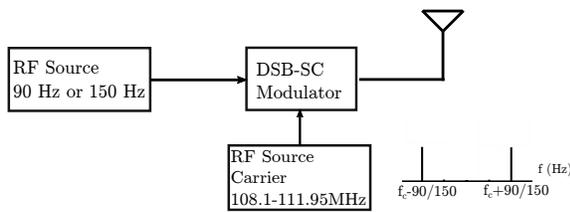

Figure 7: Single-tone attack signal generator with a DSB-SC modulator

known to be spectrally efficient than the normal amplitude modulation signal. Specifically, it is possible for the attacker to reduce the required power to almost 50% of the overshadow attack as there is no need to transmit the carrier signal and one of the sideband signals. One of the important limitations of the single-tone is the effect of the attacker’s synchronization with the legitimate signal. To precisely control the spoofing offset, the attacker needs to coarsely control the spoofing signal such that the phase difference between the attacker and the legitimate signals remain constant throughout the attack. We evaluate and show in Section 4.3.1 the effect of phase synchronization on this attack. Additionally, the spectral efficiency of the single-tone attack can be exploited to execute a low-power last-minute denial of service on the ILS system. This is specifically dangerous while an aircraft is executing an auto-pilot assisted approach. The block diagram of the single-tone attack signal generator is shown in Figure 7.

## 4 Implementation and Evaluation of Attacks

In this section, we demonstrate the feasibility and evaluate the effectiveness of the attack with the help of both simulations and actual experiments conducted using commercial aviation-grade receivers and an advanced flight simulator qualified for FAA certification.

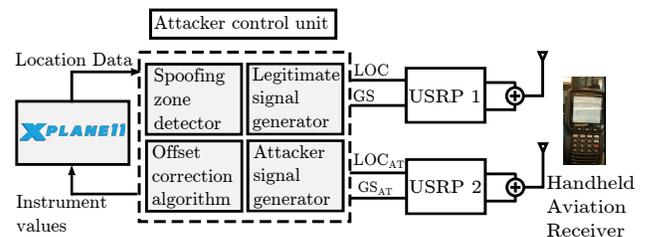

Figure 8: Schematic of the experiment setup used for evaluating the attacks on ILS. The attacker control unit interfaces with the simulator and USRP B210s. A flight yoke and throttle system is connected to the machine running X-Plane flight simulator software. Attacker control unit interfaces with the flight simulator over a UDP/IP network.

### 4.1 Experimental Setup

Our experimental setup is shown in Figure 8 and Figure 9. The setup consists of four main components: i) X-Plane 11 flight simulator, ii) attacker control unit, iii) software-defined radio hardware platforms (USRP B210s) and iv) commercial aviation grade handheld navigation receiver. We use X-Plane 11 flight simulator to test the effects of spoofing attack on the ILS. X-Plane is a professional flight simulator capable of simulating several commercial, military, and other aircraft. X-Plane can also simulate various visibility conditions and implements advanced aerodynamic models to predict an aircraft’s performance in abnormal conditions. It is important to note that X-Plane qualifies for FAA-certified flight training hours when used with computer systems that meet the FAA’s minimum frame rate requirements. The certified versions of the software are used in numerous pilot training schools. X-Plane allows interaction with the simulator and instruments through a variety of mobile apps and UDP/IP networks. This feature allowed us to manipulate the instrument readings for evaluating our ILS attacks. Additionally, X-Plane has autopilot

Figure 9: Photo of the experiment setup.

lot and AI-based autoland features which we leverage in our experiments. In other words, X-Plane contains all the features and flexibility to evaluate our proposed attacks in a close to the real-world setting. The second component of our setup is the attacker control unit module which takes the location of the aircraft as input from X-Plane and generates signals for the attack. The module is also responsible for manipulating X-Plane’s instrument panel based on the effect of the spoofing signal on the receiver. The attacker control unit module is a laptop running Ubuntu and contains four submodules: spoofing zone detector, offset correction algorithm, legitimate signal generator, and attacker signal generator. The spoofing zone detector identifies whether an aircraft is entering its first waypoint of the final approach and triggers the start of spoofing. The spoofing zone detector plays an important role in timely starting of the spoofing attack so as to prevent any abrupt changes in the instrument panel and therefore avoid suspicion. The offset correction algorithm uses the current location of the aircraft to continuously correct its spoofing signals taking into consideration aircraft’s corrective actions. Note that the location data received from X-Plane can be analogous to receiving the location data through ADS-B signals [29] in the real world. The output of the offset correction algorithm is used to generate fake ILS signals. We also generate legitimate signals to evaluate the effect of overshadow and single-tone attacks. We use two USRP B210s [2], one each for transmitting legitimate ILS signals and attacker signals. We conducted the experiments in both wired and wireless settings. For the experiments conducted in wireless settings, the receiver was placed at a distance of 2 meters from the transmitter. Northeastern University has access to a Department of Homeland Security laboratory which provides RF shielding thus preventing signal leakage. This is necessary as it is illegal to transmit ILS signals over the air. We use two different ILS receivers, a Yaesu FTA-750L [10] and a Sporty’s SP-400 Handheld NAV/COM Aviation [3] to evaluate the attacks.

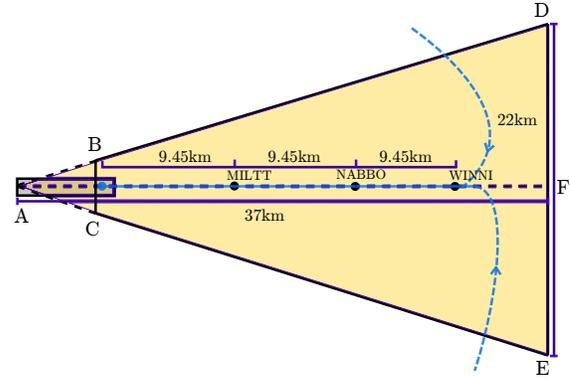

Figure 10: The spoofing zone is defined by points B, C, D, and E. WINNI, NABBO, and MILTT are the waypoints for the final approach as published for a mid-sized airport. The spoofing zone has a wide aperture as the air-traffic controller can vector in the aircraft onto the final approach in multiple ways.

#### 4.1.1 Spoofing Zone Detection

The spoofing zone detection algorithm enables automated and timely triggering of the spoofing signal. One of the key requirements of the zone detector is to trigger the spoofing signals without causing any abrupt changes to the instrument readings; thereby avoiding detection by the pilots. The spoofing region is shaped like a triangle following the coverage of the localizer and glideslope signals. For example, the localizer covers  $17.5^\circ$  on either side of the extended runway centerline and extends for about 35 km beyond the touchdown zone. Figure 10 shows the zone measurements. The attacker signals are triggered when the aircraft approaches the shaded region. The shaded region is decided based on the final approach patterns for a specific runway. We used even-odd algorithm [27] for detecting the presence of the aircraft within this spoofing zone. Absolute locations cannot be used as aircraft enter the final approach path in many different ways based on their arrival direction and air traffic controller instructions. The even-odd algorithm is extensively used in graphics software for region detection and has low computational overhead. The attacker automatically starts transmitting the signals as soon as the aircraft enters the spoofing region from the sides and the needle is yet to be centered. This prevents any sudden noticeable jumps thus allowing a seamless takeover.

#### 4.1.2 Offset correction algorithm

The attacker’s signals are pre-crafted to cause the aircraft to land with a specific offset without being detected. The pilot or the autopilot system will perform course correction maneuvers to align with the runway centerline based on the instrument readings. At this point, the instruments will continuously indicate the spoofed offset irrespective of the aircraft’s location and maneuvers raising suspicion of an instrument failure. To prevent this, we developed a real-time offset correc-

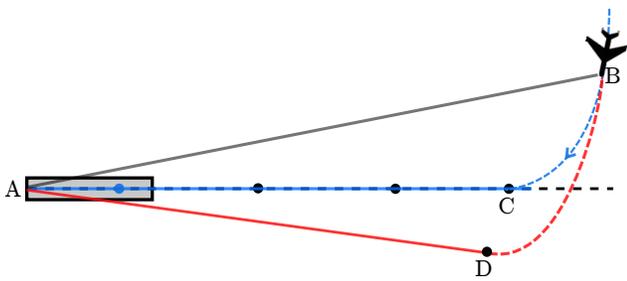

Figure 11: Offset correction algorithm takes into account aircraft’s current position to calculate the difference in the spoofed offset and the current offset.

tion and signal generation algorithm that crafts the spoofing signals based on the aircraft’s current location in real-time. The attacker can use the GPS coordinates if present inside the aircraft or leverage the ADS-B packets containing location information on the ground. We explain the offset correction algorithm using Figure 11. Consider an aircraft at point B, cleared to land and entering the spoofing zone. The air-traffic controller instructs the aircraft to intercept point C on the extended runway centerline. Assuming that the attacker’s spoofing signal contains a pre-crafted offset to the left of the runway forcing the aircraft to follow path DA instead of CA. The offset correction module computes the current offset of the aircraft with respect to the centerline and subtracts the current offset from the spoofed offset to estimate the desired change in the course. Thus, the correction  $\Delta$  required to be introduced is the difference between required offset angle  $\angle DAC$  and the current offset angle  $\angle BAC$ . Note that offsets to the left of centerline are considered negative offsets and offsets to the right are considered positive offsets. The current offset  $\theta$  can be estimated using  $\theta = \tan^{-1}[(m_{CA} - m_{BA}) / (1 + m_{BA} * m_{CA})]$ , where  $m$  is the slope.  $m_{CA}$  is typically hardcoded and is specific for each runway.  $m_{BA}$  can be estimated using the longitude and latitudes of the touchdown point and the current location of the aircraft. Now, the correction  $\Delta$  is converted to the respective difference in depth of modulation value using the formula  $DDM = (DDM_{fullscale} * \Delta) / 2.5$ , where 2.5 is the angle that results in full-scale deviation and  $DDM_{fullscale}$  is the difference in depth of modulation that causes full-scale deviation. The amplitude of the individual 90 and 150 Hz components is estimated using the formula  $0.2 + (DDM / 2)$  and sent to the signal generator module which then transmits the required signal. Note that the value 0.2 comes from the legitimate signal’s depth of modulation. The algorithm was implemented on a laptop running Ubuntu and took less than 5 ms on average to compute the offsets. The complete algorithm is shown in Algorithm 1.

### 4.1.3 Setup Validation

We verified the working of our experimental setup as follows. First, we ensure consistency between the CDI needle displayed on the flight simulator and the handheld receiver. To this extent, we disabled the attacker signal and output only the legitimate signal to the handheld receiver based on the aircraft’s location obtained from X-Plane. We manually validated that the alignment shown on the handheld receiver is the same as that of the flight simulator throughout the final approach. The uploaded attack demonstration video <sup>2</sup> also contains this validation for reference. We conducted the same experiment over the air in a controlled environment and verified consistency between the handheld receiver and the flight simulator cockpit. Second, we test our offset correction algorithm by maneuvering (swaying) the aircraft during its final approach. During this experiment, the offset correction algorithm should account for the maneuvers and generate corresponding ILS signals to the handheld receiver. We ensure the correctness of the algorithm by validating the consistency between the handheld receiver’s CDI needle and the flight simulator cockpit. Note that we do not update the flight simulator’s instrument readings for this experiment and the readings displayed in the simulator cockpit are only because of the simulator software engine. Finally, we validate the spoofing zone detector algorithm by entering the final approach from various directions and checking the trigger for beginning the spoofing attack. We are now ready to perform our attack evaluations.

### 4.2 Evaluation of Overshadow Attack

We evaluate the effectiveness of overshadow attack as follows. We leverage the autopilot and autoland feature of X-Plane to analyze the attack’s effects avoiding any inconsistency that might arise due to human error. We configured X-Plane to land on the runway of a mid-sized airport in the US. This configuration is analogous to the pilot following approach instructions from the air-traffic controller. As soon as the aircraft entered the spoofing zone, the spoofing signals were transmitted along with the legitimate signals. The spoofing

<sup>2</sup>Video demonstration of the attack <https://youtu.be/Wp4CpyxYJq4>

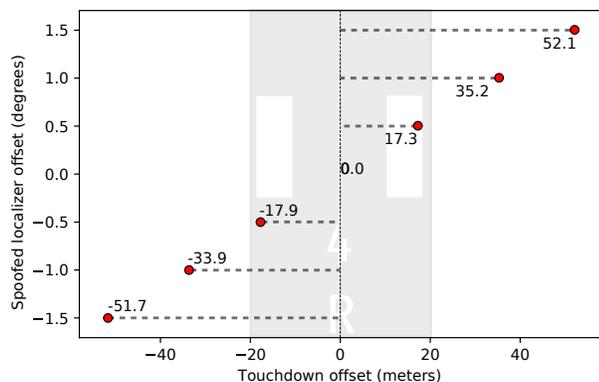

Figure 12: Results of localizer spoofing. 5 automated landings per spoofed localizer offset were executed and the touchdown offset in meters from the runway centerline was recorded.

signals were generated to fake various vertical and horizontal offsets. Note that the spoofing signals were generated in real-time based on the current position of the aircraft. For the localizer (horizontal offset), spoofing signals corresponding to 0.5, 1.0, and 1.5° offset on both sides of the runway were generated. The spoofing glideslope angles were between 2.8° and 3.3°. For each spoofing angle and offset, we performed five automated landings and the results are shown in Figure 12 and Figure 13. Throughout the attack, we continuously monitored the path of the aircraft using Foreflight<sup>3</sup>, a popular app used both by aviation enthusiasts and commercial pilots as well as X-Plane’s own interfaces. We did not observe any abrupt changes in the readings and observed a smooth takeover. The aircraft landed with an 18 m offset from the runway centerline for a spoofing offset of just 0.5°. Note that this is already close to the edge of the runway and potentially go undetected by both the air-traffic controllers as well as pilots onboard, especially in low visibility conditions. In the case of glideslope, a shift in the glide path angle by 0.1° i.e., 2.9° glide path angle instead of the recommended 3°, caused the aircraft to land almost 800 m beyond the safe touchdown zone of the runway. We have uploaded a video demonstration of the attack for reference (<https://youtu.be/Wp4CpyxYJq4>).

### 4.3 Evaluation of Single-tone Attack

We evaluate the effectiveness and feasibility of the proposed single-tone attack using the experimental setup described in Section 4.1. Recall that in the single-tone attack, the attacker transmits only one of the sideband tones (either the  $f_c \pm 90$  or the  $f_c \pm 150$  Hz) to cause deflections in the course deviation indicator needle. We implemented the attack by configuring one of the USRPs (attacker) to transmit the sideband signals and observed its effect on the handheld navigation re-

<sup>3</sup>Advanced Flight Planner <https://www.foreflight.com>

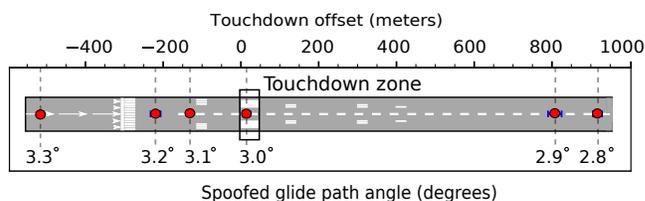

Figure 13: Results of glideslope spoofing. 5 automated landings per spoofed glideslope angle offset were executed and the touchdown offset in meters beyond the touchdown zone was recorded.

ceiver. We observed that the spoofing signal caused the needle to deflect to the configured offset. However, the needle was not as stable as in the overshadow attack and displayed minor oscillations. This is because the specific attack is sensitive to carrier phase oscillations and therefore must be accounted for to avoid detection. A significant advantage of this attack is the power required to cause needle deflections as the attacker only transmits one of the sideband components without the carrier. This gives an almost 50% increase in power efficiency and therefore can act as a low-power last-minute denial of service attack in case the attacker is unable to establish full synchronization with the legitimate signal. In the following sections, we evaluate the effect of phase synchronization on the single-tone attack and develop a real-time amplitude scaling algorithm that can counter the phase oscillations.

#### 4.3.1 Effect of Phase Synchronization

Recall that the single-tone attack signal is similar to a conventional double-sideband suppressed-carrier (DSB-SC) signal. It is well known that one of the drawbacks of a DSB-SC communication system is the complexity of recovering the carrier signal during demodulation. If the carrier signal used at the receiver is not synchronized with the carrier wave used in the generation of the DSB-SC signal, the demodulated signal will be distorted. In the scenario of the single-tone attack, this distortion can potentially result in changes in the difference in the depth of modulation estimates causing the needle to oscillate. We simulated the effect of phase synchronization on the single-tone attack effectiveness and present our results in Figure 14 and Figure 15. We generated the single-tone attack signal to cause full-scale deviation i.e.,  $\geq 2.5^\circ$  for localizer and  $\geq 2.5^\circ$  for the glideslope while perfectly in sync with the legitimate carrier signal. We observe that the phase difference causes the resultant offset to change. We also noted an uncertainty region around the 90° and 270° phase difference region. This is due to the dependency in a DSB-SC system [26] between the carrier phase difference  $\phi$  and the resulting distortion at the output which is directly proportional to the  $\cos\phi$ . Therefore, at angles around 90° and 270°, there is an uncertainty region for the resulting offset. However, in our experiments on the handheld receiver, we noticed that

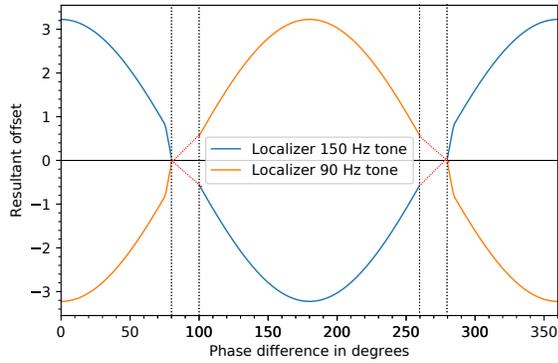

Figure 14: Comparison of calculated offset and the phase difference for localizer

although the needle oscillated, it was not as pronounced as the simulation results indicate. One of the reasons is the rate at which the sensor measurements are being calculated and displayed on the screen. Additionally, the aircraft is in motion, therefore, causing the phase differences to cycle more rapidly than the display’s refresh rate. A knowledgeable attacker can potentially leverage these properties to generate controlled spoofing signals and succeed with an optimized transmission power.

#### 4.3.2 Real-time Amplitude Scaling

In the following, we propose and evaluate a strategy to counter the effect of phase synchronization on the single-tone attack. It is clear that the phase differences cause the output to be distorted. Besides the uncertainty region around the 90° and 270°, it is possible to predict the phase given sufficient knowledge such as aircraft speed, current location, and antenna positions. We assume such a motivated attacker for the single-tone attack evaluation in this section. It is also well known that tightly controlling the phase of a signal is not trivial and therefore our algorithm proposes to manipulate the amplitude of the attacker signal instead of the phase. Changing the amplitude of the attacker signal will compensate for the effect of phase on the signal at the receiver and we call this “real-time amplitude scaling” algorithm. The algorithm itself is inspired from prior works on amplitude scaling for DSB-SC systems [26]. We use the distance between the transmitter and the receiver to estimate the received phase of the signal by measuring complete and incomplete wave-cycles. In the simulation, we then create an ILS signal with the necessary phase shift. We also create the attacker’s signal and add it to the legitimate signal to estimate the DDM. This allows us to assess the impact of phase on the transmitted signal and use this information to calculate the amplitude that will be required to counter the effects of phase. For example, if the predicted phase offset is zero, then to spoof a certain offset, the attacker needs to reduce the amplitude of its signal. We present the results of our amplitude scaling experiment

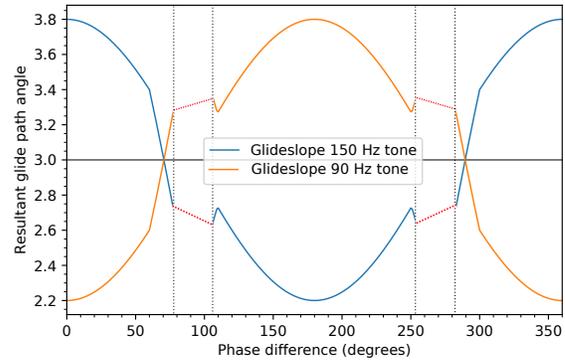

Figure 15: Comparison of calculated offset and the phase difference for glideslope

in Figure 16 and Figure 17.

## 4.4 Comparison of Power Requirements

One of the major advantages of the single-tone attack is the improvement over the power required to execute the attack, given sufficient knowledge and environmental conditions. In this section, we evaluate and compare the power requirements of the overshadow and the single-tone attacks. We note that the absolute power profiles are specific for the handheld receivers used in the experiments. The goal of the power comparison is to verify whether there is indeed an improvement in terms of attacker’s required transmission power. We present our results in Figure 18 and Figure 19. Our evaluations show the required signal strength to successfully cause 0.5° and 0.1° deviation in localizer and glideslope respectively. The received signal strength profile is shown in blue acts as a reference for the attacker based on which the attacker can compute its required power to transmit the spoofing signals. We performed the experiment by transmitting the signals to the handheld receiver and observing the success of the attack (needle indicating the intended offset). The values are a result of over 400 trials with 95% confidence interval and we find that on an average the difference in power required reaches close to 20.53 dB and 27.47 dB for the localizer and the glideslope respectively. Thus, given sufficient knowledge of the scenario, a motivated attacker can execute the single-tone attack successfully and with less power than the overshadow attack. We acknowledge that the single-tone attack has its drawbacks as described previously, however, we note that given the low power requirements, an attacker can exploit the single-tone attack to cause a low-power denial of service attack. Such an attack, especially in an aircraft’s final moments before landing can be disastrous.

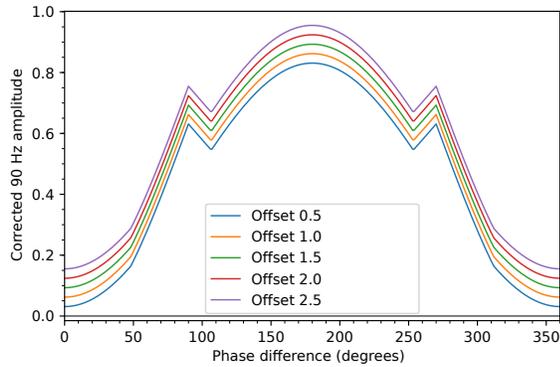

Figure 16: Amplitude scaling algorithm evaluation localizer. Amplitude required to compensate for the effect of phase

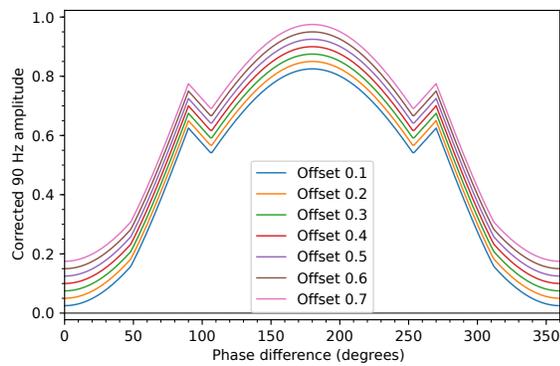

Figure 17: Amplitude scaling algorithm evaluation glideslope. Amplitude required to compensate for the effect of phase

## 5 Discussion

**Receiving antenna characteristics and location of the attacker.** The receiver hardware and its characteristics<sup>4</sup> vary depending on the type of aircraft it is mounted on. For example, Cessna aircraft have their ILS antennas on the tail-fin or the vertical stabilizer. We note that the same antenna is typically used for a number of systems such as VOR, ILS, and DME; each signal arriving from a different direction. For commercial aircraft, the antennas are typically located on the nose of the plane with a forward-looking single broad lobe receiving beam pattern. Certain large aircraft, specifically those capable of landing with high nose attitude, the antennas are located either on the underside or on the landing gear of the aircraft itself<sup>5</sup>. The antenna equipment onboard plays an important role in determining the optimum location of the attacker to execute the attack. The ideal location of an on-ground attacker is at a point along the centerline of the runway

<sup>4</sup><https://www.easa.europa.eu/certification-specifications/cs-23-normal-utility-aerobatic-and-commuter-aeroplanes>

<sup>5</sup>[https://www.casa.gov.au/sites/g/files/net351/f/\\_assets/main/pilots/download/ils.pdf](https://www.casa.gov.au/sites/g/files/net351/f/_assets/main/pilots/download/ils.pdf)

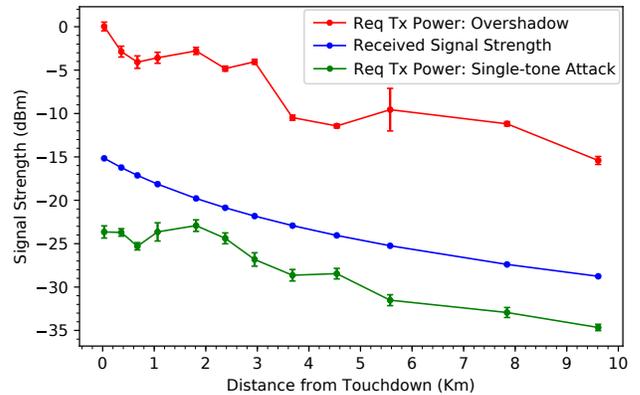

Figure 18: Comparison of required received signal strength for attack methodologies for the localizer

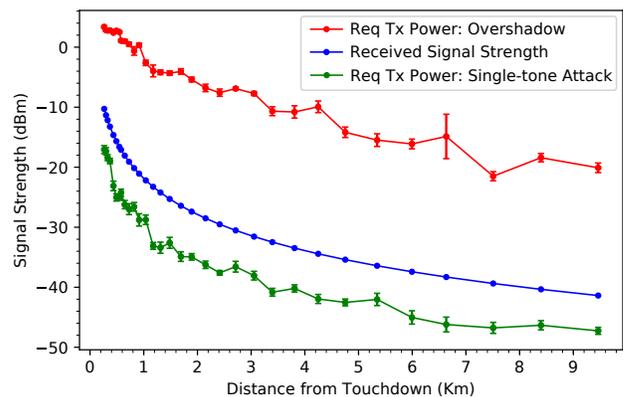

Figure 19: Comparison of required received signal strength for attack methodologies for glideslope

that falls within the receiving lobe of the onboard antennas. Attackers inside the plane will have to deal with signal attenuation caused by the body of the aircraft itself and position the spoofing signal transmitter accordingly. A thorough investigation is required to fully understand the implications and feasibility of an on-board attacker and we intend to pursue the experiments as future work. The location of the attacker plays a more significant role in the scenario of the single-tone attacker since the attacker has to carefully predict the phase and accordingly manipulate the amplitude of the spoofing signal. The problem of identifying optimum locations for the attack is an open problem very similar to the group spoofing problem [56] proposed as a countermeasure for GPS spoofing attacks. In our context, the attacker has to identify locations on the ground such that the phase difference between the legitimate signal and the spoofing signal remains a constant along the line of approach. Recall that in the single-tone attack, the

offset indicated by the cockpit is sensitive to phase changes and therefore locations that allow constant phase differences can result in a fixed spoofing offset and therefore minimal oscillations in the readings.

**ILS Categories.** The main advantage of ILS is that the pilot need not have visuals of the runway during the final approach as the ILS system is intended to guide the aircraft to a safe landing. The ILS categories are classified based on the maximum decision height at which a missed approach must be initiated if the pilot does not have a visual reference to continue the approach. In CAT I the decision height is at 60 m above the ground i.e., if the pilot does not have a visual reference at this height, a missed approach or go around must be initiated. The decision height for CAT III is as low as 15 m above the ground. The demonstrated attacks can cause severe consequences in CAT III systems due to the low decision height. It might potentially be too late to execute a missed approach in case of an attack. The consequences of the attack on CAT I and CAT II systems are less catastrophic. However, they can still cause major air traffic disruptions. Note that CAT I approach is mostly used by smaller flights. Commercial flights typically fly a CAT II or CAT III approach.

**Alternative technologies and potential countermeasures.** Many navigation technologies such as HF Omnidirectional Range, Non-directional Beacons, Distance Measurement Equipment and GPS provide guidance to the pilot during the different phases of an aircraft's flight. All the mentioned navigation aids use unauthenticated wireless signals and therefore vulnerable to some form of a spoofing attack. Furthermore, it is worth mentioning that only ILS and GPS are capable of providing precision guidance during the final approach. Also, ILS is the only technology today that provides both lateral and vertical approach guidance and is suitable for CAT III ILS approaches.

Most security issues faced by aviation technologies like ADS-B, ACARS and TCAS can be fixed by implementing cryptographic solutions [50] [52]. However, cryptographic solutions are not sufficient to prevent localization attacks. For example, cryptographically securing GPS signals [24, 33] similar to military navigation can only prevent spoofing attacks to an extent. It would still be possible for an attacker to relay the GPS signals with appropriate timing delays and succeed in a GPS location or time spoofing attack. One can derive inspiration from existing literature on mitigating GPS spoofing attacks [30, 31, 34, 35, 46, 56] and build similar systems that are deployed at the receiver end. An alternative is to implement a wide-area secure localization system based on distance bounding [19] and secure proximity verification techniques [45]. However, this would require bidirectional communication and warrant further investigation with respect to scalability, deployability etc.

**Experiment Limitations.** Our experimental setup described in Section 4 was carefully constructed in consultation

with aviation experts. Since we use an FAA accredited flight simulator, we sent our configuration files and scripts to a licensed pilot for them to perform final approaches using the instruments and give us feedback. We were mainly concerned whether there was any other indicator on the cockpit that raises suspicion about the attack. We conducted our attack evaluations in both wired and controlled wireless settings. Note that it is illegal to transmit ILS signals over the air in a public space. Effects due to aircraft's motion such as Doppler shift do not affect the attacker signal as these are receiver end problems and the receiver hardware already accounts for such effects for the legitimate signal. Note that the attacker closely imitates the legitimate signals in frequency and amplitude. In short, we made the best effort to replicate a real-world approach. However our setup has its limitations. We did not perform the experiments on a real aircraft which would give us more insights on the effects of aircraft's construction, antenna placements, cockpit display sensitivity, etc. One of the factors that will get affected is the power required by the attacker. Note that commercial ILS transmitters use a 25 watts transmitter for localizer signals and a 5 W power for the glideslope signals. To put things in perspective, a standard 12 V 10 Ah battery can power a 24 Watts amplifier for about 5 hours. Furthermore, we are in touch with a leading aircraft manufacturer for access to such an experiment. We also note that we are in the process of acquiring IRB approval to recruit commercial pilots and studying their response to the attack proposed in this paper.

## 6 Related Work

Over the years, the aviation industry has largely invested and succeeded in making flying safer. Security was never considered by design as historically the ability to transmit and receive wireless signals required considerable resources and knowledge. However, the widespread availability of powerful and low-cost software-defined radio platforms has altered the threat landscape. In fact, today the majority of wireless systems employed in modern aviation have been shown to be vulnerable to some form of cyber-physical attacks. In this section, we will briefly describe the various attacks demonstrated in prior work. Strohmeier et al. [53] provide a comprehensive analysis of the vulnerabilities and attacks against the various wireless technologies that modern aviation depends on. Voice communication over VHF is primarily used to transfer information between the air traffic controller and the aircraft. There have already been incidents [51] related to spoofed VHF communications and several efforts [23] to design a secure radio communication system. Primary surveillance radars have been shown to be vulnerable to signal jamming attacks [40]. Secondary surveillance radars [6] leverage the ability of the aircraft to respond to ground-based interrogations for aircraft localization. Due to the unauthenticated nature of these messages, it is possible for an attacker to use publicly available implementations for software-defined radio platforms to mod-

ify, inject and jam messages creating a false picture of the airspace. Such attacks were even demonstrated to be low-power, targeted, and stealthy against sophisticated wireless systems such as Wi-Fi [59], and WPA-Enterprise [21]. The ADS-B protocol used by aircraft to transmit key information such as position, velocity and any emergency codes also face the same challenges of active and passive attacks due to the unauthenticated nature of the signals. Several works have repeatedly demonstrated the vulnerabilities of ADS-B signals [7, 18, 22, 38, 47, 48, 52, 54, 60]. ACARS [5], the data link communications system between aircraft and ground stations was found to leak a significant amount of private data [36, 50, 55] e.g., passenger information, medical data and sometimes even credit card details were transferred. Furthermore, an attacker can spoof TCAS messages [42, 48] creating false resolution advisories and forcing the pilot to initiate avoidance maneuvers. For navigation, the aviation industry relies on a number of systems such as ILS, GPS, VOR, and DME. Although the use of VOR and DME are rapidly decreasing, ILS and GPS will be in use for a very long time and are the only technologies available today for enabling autonomous landing. It is also well established that GPS is vulnerable to signal spoofing attacks [11, 13, 32, 39, 41, 56, 61]. Researchers have also demonstrated [43, 44] the feasibility of signal manipulation in the context of data communication systems. However, there has been no prior work on the security guarantees of ILS and this paper is a work in that direction. It is important to note that although many of the security issues in the aviation industry can be fixed by implementing some sort of cryptographic authentication, they are ineffective against the ILS attacks demonstrated in this paper.

## 7 Conclusion

In this work, we presented a first security evaluation of aircraft instrument landing system against wireless attacks. Through both simulations and experiments using aviation grade commercial ILS receivers and FAA recommended flight simulator, we showed that an attacker can precisely control the approach path of an aircraft without alerting the pilots, especially during low-visibility conditions. We discussed potential countermeasures including failsafe systems such as GPS and showed that these systems do not provide sufficient security guarantees and there are unique challenges to realizing a scalable and secure aircraft landing system.

# Please Pay Inside: Evaluating Bluetooth-based Detection of Gas Pump Skimmers

Nishant Bhaskar, Maxwell Bland, Kirill Levchenko<sup>†</sup>, and Aaron Schulman  
*University of California, San Diego*     <sup>†</sup>*University of Illinois Urbana-Champaign*

## Abstract

Gas pump skimming is one of the most pervasive forms of payment card attacks in the U.S. today. Gas pump skimmers are easy to install and difficult to detect: criminals can open gas pump enclosures and hide a skimmer in internal payment wiring. As a result, officials have resorted to detecting skimmers by performing laborious manual inspections of the wiring inside gas pumps. In addition, criminals can also avoid being caught using skimmers: many gas pump skimmers have Bluetooth connectivity, allowing criminals to collect payment data safely from inside their car.

In this work, we evaluate if the use of Bluetooth in skimmers also creates an opportunity for officials to detect them without opening gas pumps. We performed a large-scale study where we collected Bluetooth scans at 1,185 gas stations in six states. We detected a total of 64 Bluetooth-based skimmers across four U.S. states—all of which were recovered by law enforcement. We discovered that these skimmers were clearly distinguishable from legitimate devices in Bluetooth scans at gas stations. We also observed the nature of gas station skimming: skimmers can be installed for months without detection, and MAC addresses of skimmers may reveal the criminal entity installing or manufacturing them.

## 1 Introduction

Payment card skimming attacks at gas pumps have reached alarming levels. In 2018, law enforcement officials recovered 972 skimmers from gas pumps in Florida [11] and 148 skimmers from Arizona [10] alone. Based on industry estimates, a single skimmer can capture 30–100 credit cards per day [5] and each card, based on estimates from law enforcement officials, nets the criminal an estimated \$500 [53], resulting in a daily loss of \$15,000–50,000 per day of operation for each skimmer.<sup>1</sup> Less is known about how long a skimmer remains in operation, but allowing for even one day

<sup>1</sup>In Section 2.2, we compare these quoted estimates to other sources, and find them to be in agreement.

of operation per skimmer, 2018 losses exceed \$16 million across these two states.

Gas pumps are an ideal skimming target. Gas pumps have relatively weak security: their payment circuitry can be accessed with universal keys or crowbars, and reading payment data is as easy as tapping into a ribbon cable (Section 2.1). Gas pump skimmers can be hidden inside of a gas pump enclosure, making them difficult to detect. As a result, inspectors have resorted to manually opening the pumps to inspect their wiring for skimmers. Gas pump skimming has become so pervasive that the Arizona Department of Agriculture, Weights and Measures Division (AZWMSD) now checks for skimmers while doing routine inspections.<sup>2</sup> From 2016 to 2018, the AZWMSD looked for skimmers in 7,325 gas station inspections. Inspectors found skimmers in only 1.5% of these inspections.

Unfortunately, Law Enforcement (LE) rarely catch criminals while they are collecting payment data from gas pump skimmers. The reason is, many gas pump skimmers are equipped with Bluetooth connectivity [26, 27, 28, 29]. This allows criminals to remain in their car while wirelessly retrieving card payment data. While Bluetooth is a vital tool for criminals to exfiltrate data from gas pumps, it also could be an opportunity to make it easier to detect skimmers.

In this paper, we evaluate the effectiveness of detecting skimmers with Bluetooth scanning from a smartphone. Indeed, if a skimmer can be detected with a smartphone, then authorities can discover and remove skimmers passively and quickly while they visit a gas station for other reasons. We built a smartphone application to perform this study, called Bluetana. Bluetana collects all Bluetooth scan data that is available via the Android Bluetooth APIs. We equipped 44 volunteers in six U.S. states with smartphones running Bluetana. Our volunteers have collected scans at 1,185 gas stations, where they observed a total of 2,562 Bluetooth devices. In these scans, Bluetana detected a total of 64 skimmers installed at gas stations in Arizona, California, Nevada,

<sup>2</sup>For example, the “Vapor Recovery Inspection Pre-Test Checklist” has a checkbox for “Checked for Skimmers”.

and Maryland, and it was the sole source of information that led law enforcement to find 33 skimmers.

The primary result of this study is the first comprehensive look at how skimmers can appear in Bluetooth scans. Namely, we observe that it is feasible to differentiate skimmers from other common Bluetooth devices that appear in Bluetooth scans at gas stations (e.g., vehicle telemetry collectors). The main differentiating factor for the skimmers we observed, is that the Bluetooth Class-of-Device—a parameter not collected by any consumer Bluetooth scanning applications that we are aware of—is “Uncategorized”. We also find that signal strength is a reliable way to determine if a Bluetooth device is located near a gas pump, and thus could be a skimmer.

Our study reveals several problems with consumer Bluetooth-based skimmer detection applications [46, 2, 51]: (1) there are many legitimate products that appear at gas stations that use the same Bluetooth modules as known skimmers; therefore, MAC address-prefix based detection may lead to false positives, (2) there are many Bluetooth modules used in skimmers that do not comply with IEEE MAC assignment requirements. We also debunk advice on how to find skimmers with Bluetooth scans from authorities [4] and viral information from social media [33]. For instance, none of the skimmers we found using Bluetooth scans have a name that is a long string of letters and numbers.

Performing this in-depth study brought to light several important operational lessons learned about the importance of detecting skimmers with Bluetooth. Using Bluetooth scans, officials detected skimmers while driving by gas stations that they otherwise would not have inspected. We also witnessed several instances where an inspector tried to find a skimmer, but could not find it on their first pass looking inside a gas pump. However they persisted and found it based on the knowledge that a suspected skimmer had appeared in Bluetooth scans. Surprisingly, we observed that there are skimmers installed in the same gas station, or city, that have very similar MAC addresses—indicating their source is a single criminal entity. We even found skimmers installed hundreds of miles away that had surprisingly close MAC addresses.

The rest of the paper is organized as follows: Section 2 provides background on internal gas pump skimming: their construction, monetary incentive, and prevalence in the wild. Section 3 is an overview of our large-scale Bluetooth scan collection methodology. In Section 4, we present the results of our study: what the skimmers we detected look like, how they compare to skimmers recovered independently by Law Enforcement, and whether they are well hidden in the Bluetooth environment. In Section 5, we present possible counter measures to the Bluetooth detection. In Section 6 we present the operational lessons we learned about skimming and criminal investigation procedure, while performing our large scale measurement study. Section 7 is related work, and we conclude in Section 8.

Figure 1: An internal Bluetooth-based skimmer wrapped in grey tubing to blend in with the cabling inside the fuel pump. This skimmer was detected by Bluetana in Tempe, AZ.

## 2 Background

*Skimmers* are illicit devices that capture credit card magnetic stripe data when a card is used at a point-of-sale (PoS) terminal or automatic teller machine (ATM). External skimmers use a magnetic head concealed in a false faceplate to read the magnetic stripe of a card as it is inserted into the real card reader. However, this paper is concerned with a newer class of skimmers, called *internal skimmers*, that are installed entirely inside a PoS terminal or ATM, leaving no visual evidence of its presence [47]. Internal skimmers are attached inline to the cable that connects the card reader to the main circuit board of the PoS terminal, tapping into the data and drawing power. To make data collection easier, many internal skimmers include a Bluetooth-to-serial module that allows the perpetrator to covertly collect the “skimmed” card data from a safe distance. These skimmers are built using commodity hardware with a total unit cost of \$20 or less.

Fuel pumps with a built-in PoS terminal have become a very popular target for such internal skimmers: they are unattended, easy to access, and have poor physical security, which make it easy to install a skimmer without being noticed. In a typical installation scenario, an attacker positions a van at a fuel station to block the station attendant’s view of the target pump (Excerpt in A.2), opens the fuel pump using a common master key or crowbar, and clips a discreet gumstick-sized skimmer to the ribbon cable between reader and main circuit board using a vampire clip (Figure 1). The entire process to install skimmer can take less than 10 seconds [1]. The perpetrator can then return to the station with a smartphone, and without leaving their vehicle, connect to the skimmer using Bluetooth and download the card data.

### 2.1 Internal Bluetooth Skimmers

The subject of our study are *internal, Bluetooth-based skimmers* that are installed in fuel pump PoS terminals. Figure 2 shows a typical Bluetooth skimmer, recovered from a fuel station in Southern California. This skimmer consists of a “Teensy” development board with an ARM Cortex-M4F micro-controller and a Roving Networks RN-42 Bluetooth-to-serial module. It also includes connectors for tapping into the wiring inside the pump (not shown).

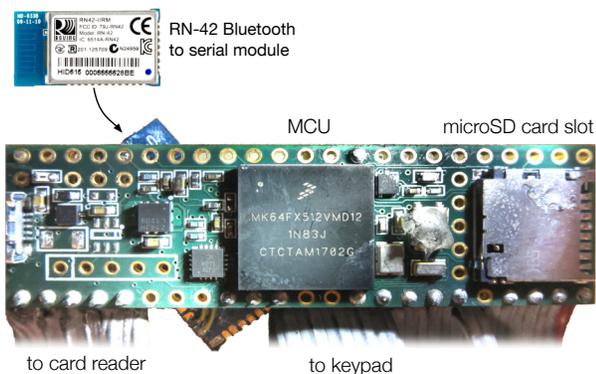

Figure 2: Parts of a typical internal Bluetooth-based fuel pump skimmer. This skimmer was detected by Bluetana.

**Connections.** In the figure, the ribbon cable on the left intercepts or replaces the ribbon cable that connects the magnetic stripe reader to the PoS terminal main board. The skimmer also uses this connection for power: the power and ground pins of the Teensy (on far left of board, not visible in Figure 2) are connected to power and ground on the card reader cable. The ribbon cable on the right intercepts or replaces the ribbon cable from the PoS keypad. This allows the perpetrator to capture additional card verification data, namely the debit card PIN or credit card billing ZIP Code. Availability of a PIN code with a stolen debit card in particular, can increase its value five-fold on the black market (Table 1). However, not all skimmers capture keypad data.

Most gas station skimmers read the unencrypted data pulled from magnetic stripe readers. Card issuers feel that removing sensitive data from the magnetic stripe on cards will help to solve the problem [42]. Newer literature has demonstrated attacks on chip payment systems [13, 15], and law enforcement in Latin America have begun to find EMV skimmers that are Bluetooth enabled [30, 3].

**Controller board.** The skimmer pictured in Figure 2 used a Teensy micro-controller development board equipped with a 120 MHz ARM Cortex-M4F micro-controller made by Freescale Semiconductor. By using a development board, a skimmer requires only rudimentary electronic assembly: soldering wires to the development board.

However, skimmers have also been found using what appeared to be fully custom-designed boards. These are compact, making them better for hiding in the dispenser. Examples of micro-controllers used in recovered skimmers include Microchip PIC18F4550 [2] and Atmel XMEGA128A4U [3].

**Storage.** The Teensy board also has a microSD card slot for additional data storage. Skimmers built on custom PCBs have also used flash and EEPROM ICs for storage. The storage capacities vary across designs, with examples using the PCT25VF032B (32-Mbit) [3] and M25P16VP (16-Mbit) [2].

**Bluetooth module.** The skimmer shown in Figure 2 uses a Roving Networks RN-42 module, an inexpensive Bluetooth-to-serial module found in many skimmers. In Section 3.1 we describe characteristics of popular Bluetooth-to-serial modules used in recovered skimmers for wireless data exfiltration. On the Bluetooth side, a Bluetooth-to-serial module provides a Serial Port Peripheral interface, which most operating systems recognize as a Bluetooth modem and instantiate a serial device for it. Operating systems will create a corresponding serial device, allowing user-space applications, namely a criminal’s card dumping application, to communicate with the module. On the hardware side, a Bluetooth-to-serial module provides a TTL-level receive and transmit pin, allowing it to interface to any micro-controller UART. The module this allows even the simplest micro-controller to communicate via Bluetooth with a host device. The 2.4GHz Bluetooth antenna is included on the module’s circuit board (exposed area to the left of the metal shield for the module shown in Figure 2), so the antenna is also hidden.

Bluetooth-to-serial modules generally require no configuration, however, most can be reconfigured using Hayes-style modem AT commands. In Section 4.1 we describe the configuration capabilities of popular modules. Notably, all of the Bluetooth-to-serial modules we found in skimmers support changing the device MAC address, Bluetooth device name, changing the pairing password, and the ability to become non-discoverable once paired.

## 2.2 Economics of Carding

Stealing and monetizing stolen credit and debit card data, called *carding* by its practitioners, is a well-studied form of financial fraud, however, reliable estimates of losses resulting from a single skimmer are difficult to find. To the criminal operating a skimmer, the expected revenue per skimmer breaks down as:

$$W = (\text{card value}) \times (\text{cards per day}) \times (\text{days deployed}).$$

Of these, we found published estimates for only the first two quantities, and very little about skimmer lifetimes. Here, we summarize the available data with the goal of estimating the losses incurred by a single skimmer.

**Card value.** To monetize stolen credit card data, skimmer installers have two options: sell the data on the black market, or cash out the cards on themselves. Based on our survey of sites selling stolen card data, black market prices for stolen cards fall in the \$10–220 range, depending on whether the card is a debit or credit card, and whether it comes with a PIN (for debit) or billing ZIP code (for credit). Table 1 provides a summary of these prices with references.

Criminals can also cash out the cards themselves. Debit cards with a PIN are often cashed out by withdrawing money from an ATM, while credit cards are often cashed out by

<i>Scheme</i>	<i>Value</i>	<i>Reference</i>
<b>Black market price</b>		
Debit, no PIN	\$20–30	[35, 49, 21, 44]
Debit with PIN	\$110–220	[31, 49, 44]
Credit, no ZIP	\$10–25	[35, 49, 21, 44]
Credit with ZIP	\$25–60	[35, 49, 21, 44]
<b>Cash-out value</b>		
Credit or Debit (standard)	\$400–800	[19, 40, 18, 56]
Credit (premium)	\$1,000	[40, 45, 20]
<b>Bank and merchant loss</b>		
Credit	\$1,003	[1]
Debit	\$650	[12]
<b>Consumer liability</b>		
Debit (> 60 days)	unlimited	15 USC 1693g
Debit (< 60 days)	max \$500	15 USC 1693g
Debit (< 2 days)	max \$50	15 USC 1693g
Credit	max \$50	15 USC 1643
<b>Prosecuted loss</b>		
Credit or debit	\$500	[6]
<b>Court documents</b>		
Credit	\$362–400	[36, 16, 8, 7]
Debit	\$665–1132	[9, 50]

Table 1: Value of stolen credit and debit cards.

purchasing high-value merchandise (e.g. iPhones) and reselling them. Reported cash-out values for debit and credit cards range between \$400 and \$1,000, depending on credit limit associated with the card. We also conducted a survey of cash-out values reported in court documents involving skimmers.<sup>3</sup> Several cases reported specific cash-out values, rather than ranges. The debit card cash-out values were \$1132 [36], \$444 [16] \$665 [8], \$1354 [7]. The credit card cash-out values were \$362 [50] and \$400 [9].

Losses due to credit and debit card fraud are borne largely by banks and merchants. This is likely because consumer liability for fraud in the U.S. is limited to \$50 for credit cards, and \$50 or more for debit cards (depending on how quickly the consumer reports the fraud). Industry estimates for losses per-card incurred by banks are \$650 for debit cards and, \$1,003 for credit cards [1, 12]. The U.S. Sentencing Commission estimates per-card losses at \$500 or more.

**Cards per day.** The number of cards a skimmer captures each day depends on the number of transactions at that pump, which will vary by station. Ripplshot, a payment fraud prevention service, states: “a single compromised pump can capture data from roughly 30–100 cards per day” [5]. The lower end Ripplshot’s estimate agrees with the estimate of 20–50 cards per day we received from U.S. law enforcement agents. In addition, we found two court documents that report criminals captured 25 [9] and 30 [8] cards per day. We

<sup>3</sup>We surveyed only documents available without fee from Court Listener.

Table 2: Prevalence of skimming in three regions of the U.S.

also studied 10 skimmers recovered from the field, which we were told were used and wiped daily. We found an average of 20 cards per skimmer, divided evenly between debit and credit cards.<sup>4</sup>

**Days deployed.** Internal skimmers are not limited by battery life and can remain in operational indefinitely, because they draw power from the PoS circuitry, Skimmer lifetime, then, is limited only by how long they can remain undetected. Unfortunately, there is little reliable data on this. Our only direct experience is our discovery of a pair of skimmers that remained undetected for six months (Section 3.1). However, LE informed us that criminals may leave skimmers in gas pumps after only a few days of retrieving card data and moving on to another location. Given the very limited data available on skimmer lifetimes, we instead consider skimmer value *per day of operation*.

**Cashout success rate.** Our analysis of court documents revealed that criminals are often unsuccessful when trying to cashout a skimmed card. This may be due to a variety of reasons, such as the following: incorrectly reading card data, hitting daily withdrawal limits, and activating fraud alerts. Several cases mentioned that criminals were not successful in cashing all skimmed cards. One case mentions a specific cashout success rate of 47% [7].

**Total skimmer value.** Finally, we estimate the range of per-day revenue from a skimmer based on the prior figures. Our low end estimate is \$4,253 (25 cards per day, cashout of \$362 per card, and 47% cashout success rate), and our high end estimate is \$63,638 (100 cards per day per day, \$1,354 cashout per card, and cashout success rate of 47%).

<sup>4</sup>These skimmers were provided to us because they were removed by the station owner, rather than LE, making them unsuitable for use as evidence.

## 2.3 Skimmers Recovered in the Wild

To understand the prevalence of skimmers in the wild, we obtained data on recovered skimmers from three regions in the United States: San Diego and Imperial counties of California, with a combined population of 3.5 million; the state of Arizona, with a population of 7 million inhabitants; and the state of Florida, with a population of 21 million inhabitants. Table 2 summarizes the statistics. We note that these numbers do not represent *all* recovered skimmers. For San Diego and Imperial counties, our statistics represent the number of skimmers found by or reported to a U.S. federal law enforcement agency. For Arizona and Florida, our statistics represent skimmers found by or reported to the AZWMSD and the Florida Department of Agriculture and Consumer Services.

The number of recovered skimmers has increased from 2016 to 2018 in both Florida and Arizona. The total number of skimmers recovered in 2018 across the three geographic regions is significant: if each skimmer operated for just one day, we estimate their total monetary impact would be \$17.43 million. Yet, as the skimmers-per-million people number shows, the possibility of an average consumer encountering a skimmer at a gas station is quite small.

## 3 Data Collection Methodology

Driven by the observation that skimmers are hard to find—few pumps in San Diego, Arizona, and Florida have been found to have skimmers installed in them (Table 2)—we created a tool, called Bluetana, to evaluate the effectiveness of Bluetooth-based skimmer detection. We begin by presenting an overview of the tool and the data it collects. Then we describe how Bluetana identifies suspicious devices and directs users to collect additional data. Finally, we discuss how we retroactively inspect data to find skimmers.

### 3.1 Crowdsourcing Bluetooth Scanning

We developed Bluetana, an Android-based measurement tool that officials and volunteers use to scan for skimmers at gas stations. Bluetana scans for nearby Bluetooth—both Classic and Bluetooth Low Energy (BLE)—devices every 5 seconds using Android’s Bluetooth API. It collects the Bluetooth scans and geo-location data, and uploads this data to a secure database over a cellular link. Bluetana collects all of the Bluetooth scan data that Android makes available, including Device name, MAC Address, Class-of-Device<sup>5</sup>, and signal strength (RSSI).

**How we visited 1200 gas stations.** We outfitted 44 volunteers and inspectors in six U.S. states (CA, AZ, MD, NC, NV, IL) with low-end smartphones running Bluetana in kiosk

<sup>5</sup>Class-of-Device is twenty four bits indicating the device’s intended use, such as *smartphone* or *speaker*.

mode (they could not close the application). We selected officials who frequent gas stations as part of their daily job duties. Primarily, they were Weights and Measures inspectors.

### Indicating suspicious devices to inspire data collection

The Bluetana display shows a list of Bluetooth devices detected during scanning. When Bluetana detects a potential skimmer, it indicates this to the user by highlighting the device record (Figure 4). The Bluetooth scan profile of the modules that have been found in skimmers inform which devices we highlight in Bluetana.

Skimmers recovered by LE are often found to use CSR (Qualcomm) chip-set-based Bluetooth modules. Our highlighting procedure primarily looks for the default Bluetooth profile of these modules—with the exception of the Device Name which can be missing due to poor signal strength, and modified by criminals in an attempt to hide the device (Section 4). The factory default Bluetooth scan profile (i.e., MAC prefix, Device Name, and Class-of-Device) of these modules are as follows:

Mod.	MAC Prefix	Dev. Name	Class of Dev.
RN	00:06:66	“RBNT-*”	Uncategorized
HC	<i>Various</i>	“HC-05/06”	Uncategorized

Bluetana chooses a highlight color via a three-step decision process, depicted in Figure 3. First, the app checks the device’s class. All skimmers studied within this work, whether discovered by Bluetana or not, had a device class of *Uncategorized*. If the device class is not uncategorized, the data is saved for later analysis. The device’s MAC prefix is then compared against a “hitlist” of prefixes used in skimming devices recovered by law enforcement. If the device has a MAC that is not on this hitlist, it is unlikely to be a skimmer, and the app highlights the record yellow. Next, if the device name matches a common product using the same MAC prefix, the record highlights in orange. If all three fields (MAC prefix, Class-of-Device, and Device Name) indicate the device is likely to be a skimmer, Bluetana highlights the record in red. The highlighting procedure is the result of a year of refinements based on our experience finding skimmers in the field, and Bluetana includes a remote update procedure to account for these incremental changes.

This simple highlighting proved to be vital to our data collection. Red serves as a cue to perform signal strength localization: it directed our users to collect more samples of signal strength to determine if a device is located in the gas pump area—and is therefore likely to be a skimmer. In several cases, Bluetana highlighting a device in red was the only reason officials performed a manual skimmer inspections: out of the 64 skimmers we found, 33 were recovered because an official started an inspection only after noticing a device was highlighted in red in Bluetana.

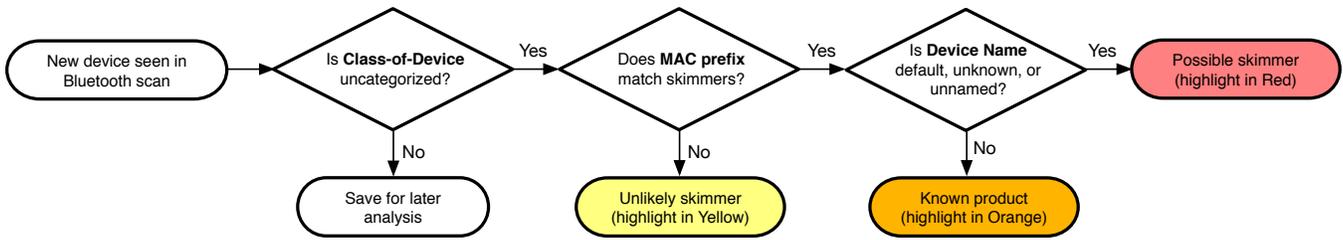

Figure 3: The procedure Bluetana uses for highlighting suspicious devices.

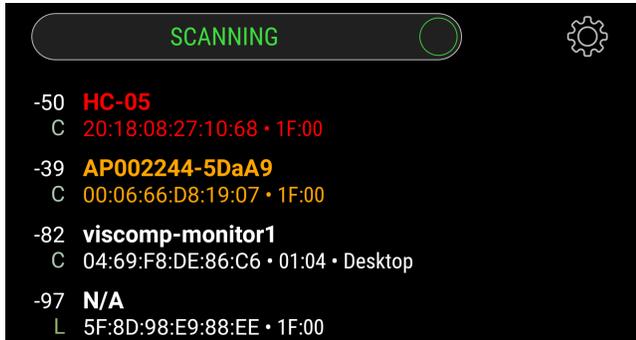

Figure 4: The Bluetana user interface. Bluetana highlights suspicious devices, inspiring users to collect more signal strength samples, and even perform inspections.

In one instance, an Arizona Weights and Measures inspector was driving by a gas station when two red highlighted devices appeared in Bluetana. He made an unscheduled stop at the gas station, performed a skimmer inspection, and discovered two skimmers. Figure 5 shows a portion of the official Arizona inspection report documenting this incident.

Bluetana’s highlighting procedure is more comprehensive than other skimmer detection apps on the Play Store. Scaife et al. [46] investigated the behavior of these apps and found that they flag skimmers based on either MAC prefix or Device Name. These apps would miss skimmers with non-standard MAC prefixes or customized (missing) device names which Bluetana was able to find (Section 4.1). Bluetana also found legitimate devices that would be considered skimmers by these apps (Section 4.2).

### Identifying skimmers after data collection

During the study, we manually examined every Classic Bluetooth device observed at a gas station visit in real time (as Bluetana users upload their scan data). At the beginning of our study, we relied primarily on the signal strength of the device to determine if it was a suspected skimmer. By the nature of being installed inside a gas pump, the Bluetooth signal of a skimmer is strongest in the pump area. Other devices that we suspected to be skimmers all had a low signal strength in the pump area, because aside from the cars

parked at the pumps, the only places where a Bluetooth device would be located in the pump area would be inside the pump. Combining the signal strength and geo-location with satellite imagery of the gas station, we were able to easily detect when the signal was emanating from inside of a gas pump (example shown in Figure 6). While at a gas station, Bluetana users also noticed this by moving toward the pump area to see if the device’s signal strength increases.

If we saw any suspicious devices in the dataset, we alerted officials that they should inspect the pumps at the station in question. Initially, we did not know which of these devices were skimmers: many initial inspections we requested turned up empty handed. However, as the study progressed, we improved our understanding of the profile of skimmers.

### A natural experiment observing deployment duration

Having a database of all prior scans made it possible for us to look for skimmers that we may have missed in the past. In particular, looking back in at the database led to us to discover two skimmers that we had initially missed. A retroactive analysis of two stations discovered skimmers that were still operating even though we first detected them *six months* earlier. This natural experiment is likely the first concrete data on how long skimmers can be installed without being found in a routine or complaint-induced pump inspection.

## 3.2 Limitations

### Selection bias

We designed our data collection to look for a specific type of gas pump skimmer: one that uses a Classic Bluetooth module, and is discoverable in Bluetooth scans. Our contacts in LE confirmed that this type of skimmer has been found in gas stations across the entire U.S. They also reported that these skimmers are particularly common in Arizona and California; therefore, these states were the focus of our study.

The results of our study may not be representative of the nature of gas pump skimming across the country. Criminals in other regions may evade Bluetooth-based detection by using alternate exfiltration methods (e.g., Bluetooth Low Energy and SMS), or configurations (e.g., non-discoverable mode). We outline these countermeasures in Section 5.

Figure 5: Bluetooth scanning helps inspectors find more skimmers because they detect skimmers when driving by a gas station.

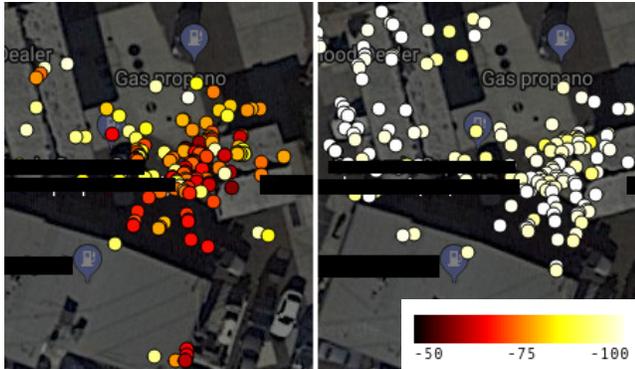

Figure 6: Combining RSSI data with satellite imagery reveals if a device is located in the pump area of a gas station.

### Bluetana does not connect to devices

We could collect more data about Bluetooth devices by trying to connect to them. This could be useful for conclusively detecting a skimmer or collecting information about the type of Bluetooth device. By sending commands that skimmers are known to respond to, Bluetana would be able to see if the device responds equivalently to known skimmers. This is precisely what one of the current Bluetooth skimmer scanning applications on the Play Store does.

This practice may seem innocuous, but our discussions with law enforcement indicate that this could overwrite information critical to future investigations. The problem is, internal registers in many skimmer Bluetooth modules records the last-paired MAC address. This information can be used to link a suspect possessing a smartphone or laptop with their skimmers. The typical forensic evidence collection performed by law enforcement on skimmers includes collecting the last-paired MAC address [48].

## 4 Results

In this section, we present the results of our 19 month study of Bluetooth devices observed with Bluetana at 1,185 gas stations across six U.S. states (CA, AZ, NV, MD, IL, NC). During the course of this study, Bluetana detected 64 skimmers operating in 34 gas stations; all of the skimmers were

removed from the pumps by local and federal law enforcement agents. Bluetooth scanning is a surprisingly effective way of detecting skimmers: in Arizona, Bluetana has detected skimmers at 1.58% of the 491 stations it scanned, and routine inspections by state inspectors had a similar detection rate of 1.5% from 2016 to 2018.

The primary result of this study is as follows: there are distinct characteristics of the 64 internal skimmers detected by Bluetana that differentiate them from the 2,562 other Bluetooth devices that Bluetana found at gas stations (e.g., car stereos). Namely, these skimmers were predominately using the default Bluetooth module configuration. Additionally, we discovered that some criminals use a custom Device Name in an apparent attempt to hide their skimmers from Bluetooth scans. These custom Device Names stand out, making them easier to differentiate from other devices.

### 4.1 What Do Skimmers Look Like in Scans?

We begin by presenting how skimmers we observed appear in Bluetooth scans. We describe the properties of two sets of skimmers: 64 skimmers that we detected in the field during the course of this study, as well as 23 skimmers that were independently recovered by two LE agencies. The 23 skimmers recovered independently by LE have similar characteristics to the 64 that Bluetana detected in the field. The Bluetooth characteristics of these skimmers are detailed in Table 3. We now analyze the following properties: Class-of-Device, MAC prefix, and Device Name.

#### All of the skimmers are “Uncategorized” Class-of-Device

Class-of-Device is primarily used to select the icon that indicates the category of a device in a Bluetooth scan (e.g., Headphones). Bluetooth modules used in skimmers analyzed in this study (i.e., HC and RN), have an “Uncategorized” Class-of-Device assigned by default. Changing Class-of-Device on these modules is trivial: the modules provide a serial command to set it. Despite this, criminals do not appear to be modifying the Class-of-Device on any of the skimmers we observed: all of the 87 skimmers detected by Bluetana and recovered independently by LE used the default “Uncategorized” device class.

<b>Total</b>	<b>64</b>	<b>23</b>

Table 3: Bluetooth scan properties of skimmers observed during our study. The exact Device Names are not shown, instead we describe the names we found.

### MAC prefixes are often manufacturer defaults

Bluetooth module manufacturers burn a MAC address into the module’s EEPROM. Although it is possible to change the MAC with a SPI-based reprogramming of the CSR chip’s EEPROM, we have not observed any skimmers that have a modified MAC. The first three bytes (prefix) of the MAC address typically correspond to the manufacturer of the device.

Although MAC address prefixes are often assigned by IEEE (e.g., all of the RN Bluetooth modules have the same manufacturer MAC prefix) the HC modules have a wide variety of MAC prefixes. Of the HC modules we observed, only one has a MAC prefix assigned by the IEEE. This could make it significantly more difficult to detect an HC-equipped skimmer. However, looking at of the MAC prefixes of the skimmers that we observed, a clear pattern emerges: manufacturers appear to be burning module manufacture date into the first four bytes of the MAC address in the following format: YY:YY:MM:(DD).

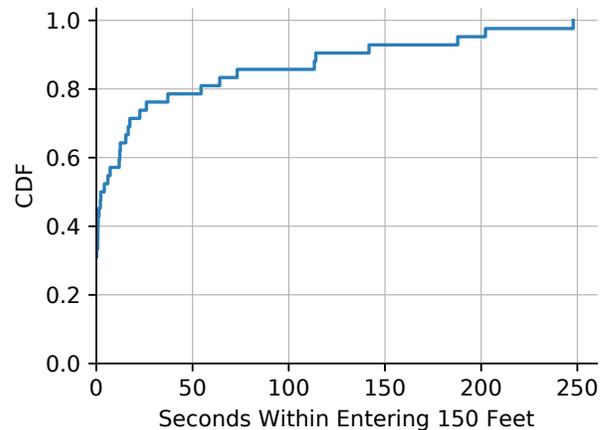

Figure 7: Skimmers are detected within a minute of passing near a gas station.

### Device names are often default, occasionally customized

Device Names allow users to identify their devices in Bluetooth scans. They are assigned a factory default value by the manufacturers, and are modifiable by users. Most of the skimmers we observed had a default Device Name: namely, all of the skimmers provided by LE, and more than half the skimmers we detected in with Bluetana. A skimmer with a default Device Name looks innocuous, because some legitimate products using the same modules are also shipped with the default module name (Section 4.3). Occasionally, we found that criminals set a custom device name on their skimmers. This appears to be an attempt to make the skimmer look less suspicious. Bluetana detected custom-named skimmers with a variety of names. The custom names of skimmers discovered by Bluetana had variety: some were random strings of numbers, and others masqueraded as LE.

Bluetana did not detect a Device Name for several skimmers. This is expected because the device sends its MAC and Class-of-Device in the first scan response packet; it sends the device name in a subsequent packet (that may be missed).

### Skimmers are detected within one minute

Bluetooth scanning has the benefit of detecting some skimmers without manually inspecting each of the pumps. However, attenuation from a gas pump’s metal enclosure, may limit the range that Bluetooth scans are effective. We analyzed the scans from Bluetana to see how long an official had to spend at a gas station before they detected the skimmers installed there (Figure 7). The median time to detection was 3 seconds, and 80% of the skimmers were detected within one minute. This is a 99% decrease in search time compared to the average of 30 minutes that inspectors take

State	Stations	Devices Observed			Days	Skimmers
		#	Avg.	Std.		
CA	571	1148	2.01	1.94	152	22
AZ	491	1140	2.32	2.03	130	36
NV	38	93	2.45	3.44	21	4
MD	23	42	1.83	1.86	14	2
IL	18	37	2.06	2.01	13	0
NC	10	20	2	1.67	10	0

Table 4: On average there are two Classic Bluetooth devices seen at each gas station; infrequently, there are skimmers.

to check a gas station for skimmers.<sup>6</sup>, This result indicates that inspectors can quickly stop at gas stations to check for Bluetooth-detectable internal skimmers.

## 4.2 Are Skimmers Distinguishable in Scans?

Next, we evaluate if the skimmers detected by Bluetana were clearly distinguishable from the other devices observed at gas stations. The primary result of this study is that these skimmers were not hidden well. Many of these skimmers use the default configuration of their Bluetooth modules. Legitimate devices using the same Bluetooth modules may have some default parameters, and a few have all of parameters set to the default. We conclude that by combining multiple characteristics: MAC prefix, Class-of-Device, and Device Name, there are only a small number of devices that could be confused with skimmers.

This study also reveals that when criminals creatively modify their skimmer’s Device Name, it makes detection easier. We also found that criminals could improve how they hide skimmers in Bluetooth scans. For example, they could change the Class-of-Device to hide as a more popular device (e.g., a smartphone).

### Dataset Overview

Over the course of the 19 month study, Bluetana users visited 1,185 gas stations across six states (Table 4). During these visits, Bluetana detected a total of 64 skimmers—all of which were recovered by officials. These skimmers were in the presence of 2,562 other devices. On average, Bluetana saw 2.2 devices per station ( $\sigma = 2.05$ ). Given that there are only a small number of Bluetooth devices seen per station, it may seem likely that these devices are all skimmers. However, only a small fraction (4.25%) of these devices matched the characteristics of the skimmers we observed during the course of our study.

We performed this study on Classic Bluetooth devices only. We did not include BLE because we are not aware of

<sup>6</sup>Source: discussions with inspectors.

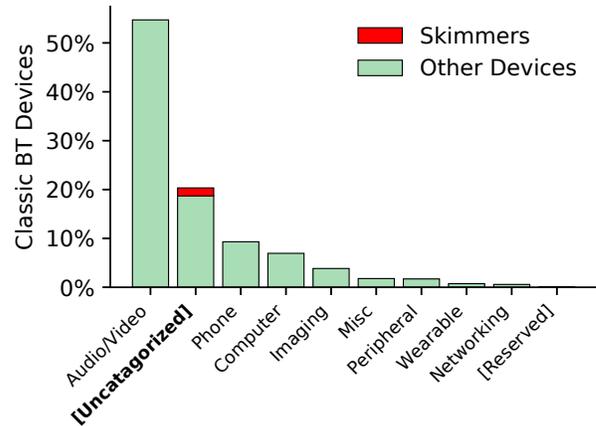

Figure 8: Skimmers appear in the second most common class of Bluetooth devices.

any internal gas station skimmers using BLE modules. However, we observed a large number of BLE devices at gas stations; therefore, switching skimmers to BLE modules may make them more difficult to detect with scanning tools like Bluetana (Section 5.1).

For this analysis, we only include the scan data that is collected the first time a Bluetana user visits a station. Restricting the dataset in this way ensures fairness in our results. Analyzing all inspections may bias our observation of what Bluetooth devices tend to be found at gas stations to those that were visited multiple times. Specifically, we only analyze scans performed the first time Bluetana is near a gas station (within 150 feet) for at least 30 seconds and up to 5 minutes. 22 out of 64 of the skimmers were detected on subsequent visits to gas stations, so they are not included in this analysis.

### Skimmers are Uncategorized, but so are other devices

The only Bluetooth property that is common among all skimmers we observed is that they have an Uncategorized Class-of-Device. Figure 8 shows that Uncategorized devices are commonly seen at gas stations: they are 20.3% of devices found by Bluetana. Out of the 1,185 gas stations that Bluetana users visited, Uncategorized devices were only observed at 315 gas stations (26.6%).

### Other devices use the same modules as skimmers

Within the set of Uncategorized devices, we next look at the distribution of their MAC prefixes (Figure 9). We find that the Bluetooth modules used in skimmers are also used in many other legitimate devices. Specifically, more than half of the RN modules seen at gas stations were in skimmers, but there were many other devices that had RN modules. This is

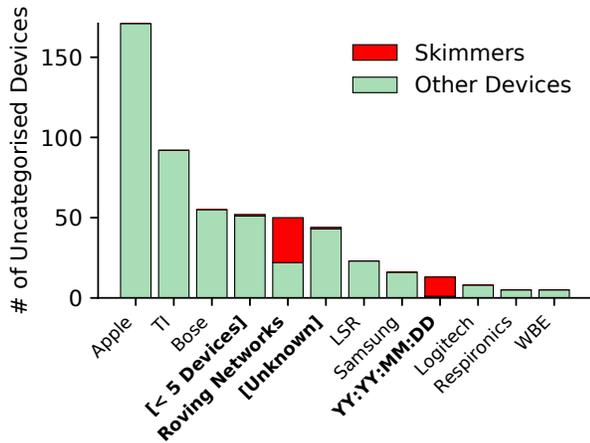

Figure 9: Many other devices appear to be using the same Bluetooth modules as skimmers.

an important observation because a popular detection application, SkimPlus [51], only flags skimmers based on a hitlist of MAC prefixes [46]; it may incorrectly flag legitimate devices as skimmers.

The devices observed with MAC prefixes that were in the YY:YY:MM:DD format (likely HC modules) were mostly skimmers. There were many devices that had IEEE assigned MAC prefixes that were infrequently seen at gas stations (< 5 Devices). Only one of these devices was a skimmer. Also, there were many devices with MAC prefixes unknown to the IEEE, but not in the date format, only one of these devices was a skimmer. Overall, 159 devices out of 353 Uncategorized devices matched the MAC prefixes of Bluetana-observed skimmers. This reduces the number of stations where Bluetana detected skimmers to 119 out of the 315 stations where it found Uncategorized devices.

#### Default- and custom-named modules are often skimmers

Finally, we investigate if skimmers can be differentiated from other devices by their Device Name. The remaining 159 devices are Uncategorized and their MAC prefixes are either: Roving Networks, YY:YY:MM:DD, Unknown, or seen on less than five devices. Only 42 of these devices were confirmed to be skimmers.<sup>7</sup> In Figure 10, we divide the remaining devices by their category of Device Name, including: *unnamed*, manufacturer *default*, known legitimate *product*, and *customized*. Devices observed by Bluetana with default names were often skimmers. Custom named devices were not common at gas stations but had a higher probability of being skimmers. Three skimmers were disguised as products, however all three were distinguishable because their

<sup>7</sup>We do not include 22 of the Bluetana-detected skimmers in this analysis because they were not detected on the first visit to a gas station.

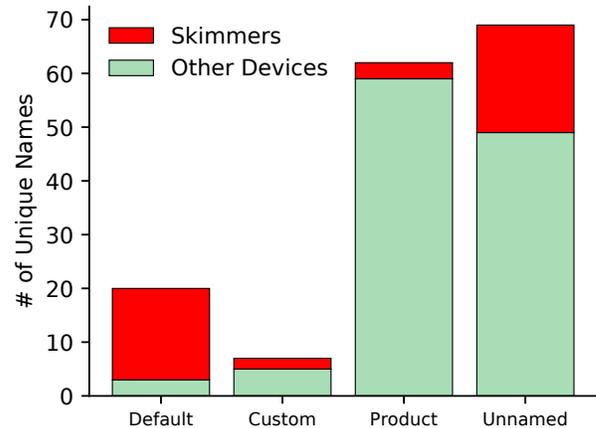

Figure 10: Default and custom names distinguish skimmers from legitimate devices.

names were popular smartphones, which should not have the MAC prefix of Bluetooth-to-Serial modules. Bluetana missed capturing the Device Name for many of the skimmers, as well as other devices that it detected.

### 4.3 Accuracy of Bluetooth-based Detection

To evaluate the accuracy of Bluetooth-based detection, we analyze Bluetana scan data collected during inspections in Arizona. Specifically, there was a 7-month time period in which Bluetana was used by many of the Arizona inspectors (October 7, 2018 – May 7, 2019), and we compare the reports filed during these inspections with the scan data that Bluetana collected.

#### Missed skimmers

During this time period, there were 27 inspections where skimmers were found while an inspector was running Bluetana. A total of 42 skimmers were recovered during these inspections, of which Bluetana was able to detect 36. Therefore, Bluetana missed detecting 14.3% of the total skimmers recovered during these inspections.

We do not know exactly why Bluetooth-based scanning missed these skimmers. Half of the missed skimmers were from inspections where Bluetana detected other skimmers at the gas station. It is likely that these missed skimmers were not powered on due to improper installation. The remaining missing skimmers may have been built with alternate exfiltration methods, such as SMS [46], or even require physical recovery [47].

## Incorrectly detected skimmers

Bluetana highlighted a device in red during 45 Arizona inspections where no skimmer was found. There were 757 total inspections where inspectors used Bluetana<sup>8</sup>, Bluetana may have incorrectly detect skimmers in 5.9% of inspections.

Incorrectly identifying skimmers is likely due to the fact that RN and HC modules are used in a variety of legitimate products, some of which are seen in and around gas stations. We found RN and HC modules in radar-based speed limit signs, weather sensors [38] automotive diagnostic scanners, scales [37] and fleet tracking systems [52]. Some of these devices have Device Names that clearly indicate what product they are, but would be confused with skimmers if the Device Name is missing. Unfortunately, several of these products also use the default Device Names on their Bluetooth modules (*RNBT-xxxx* or *HC-05*). These legitimate devices will look exactly like skimmers. In such cases, inspectors will need to rely on RSSI localization to determine if these devices are located inside a gas pump.

## 5 Countermeasures and Responses

This work is a single snapshot in an evolving landscape of attacks on payment systems. While Bluetana has proven effective at finding Bluetooth skimmers, it by no means represents the last move in the cat-and-mouse game. In the remainder of this section, we discuss what the next few steps in this arms race might look like. That is, given that inspectors and volunteers are using Bluetana, what can be the skimmer installers' next move, its cost, and what our response might be. It is possible for a determined and resourceful criminal to implement the countermeasures that we will be describing (particularly non-discoverable mode).

### 5.1 Switching to Bluetooth Low Energy

We have observed that by switching to BLE, criminals have *many* more places to hide. Figure 11 shows the cumulative distribution of the number of BLE and Bluetooth devices we saw at each fuel station. Under the filtering of Section 4, over 8,000 unique BLE devices were seen, making the ratio of Classic to BLE approximately 1:4.

**Cost to attacker.** There is almost no cost to criminals in switching their Bluetooth modules to BLE. In fact, newer EMV skimmers discovered in other countries are BLE enabled [30]. However, none of our contacts in law enforcement have encountered BLE-based gas station skimmers. It is possible that there is simply no incentive to switch: the same reason criminals have not yet adapted to masking their Bluetooth device class.

<sup>8</sup>This includes both routine and complaint/prior knowledge triggered inspections

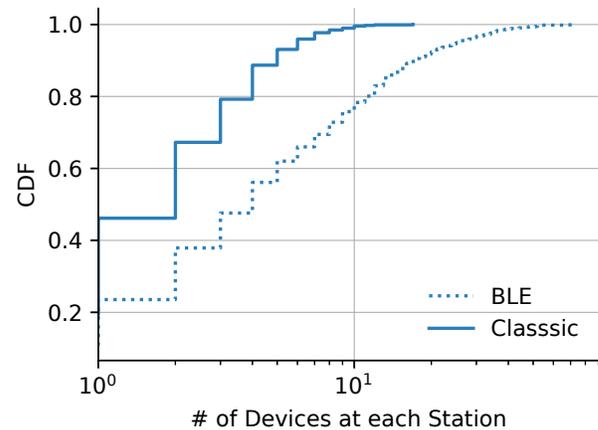

Figure 11: BLE devices are more common than Classic.

**Response.** BLE devices may be harder to differentiate due to the higher number of devices at each gas station and a lack of distinguishing features. 89% of BLE devices we saw had an uncategorized device class. With more sophisticated filtering techniques, it may still be possible to isolate BLE skimmers within this larger set of devices. One possibility is automated RSSI localization to the fuel dispenser location, a possible subject of future research.

### 5.2 Non-Discoverable Skimmers

The most natural way to evade discovery via Bluetooth would be to put the module in non-discoverable mode. When a Bluetooth device is non-discoverable, it does not respond to normal Bluetooth scans. Instead, it only responds to paging packets specifically addressed to its MAC address.

**Cost to attacker.** Non-discoverability would make exfiltration more difficult for criminals. One possibility is creating a pre-paired data collection device. However, we have been informed by law enforcement that the individual who installs the skimmer is often independent from the individual responsible for data recovery (called a “mule”). The criminal would not be able to send a mule to recover card data without first delivering them the device. Alternately the criminal could record the MAC address of the skimmer Bluetooth module. This would require careful bookkeeping and the use of tools that support the creation of a non-discoverable connection.

**Response.** It is still possible to discover a non-discoverable device. For a small set of target address ranges, e.g.,  $00:06:66$  used by Roving Networks modules, we believe it would be practical to attempt to guess all 16.8 million possible addresses. Prior work has shown that it is possible to discover any non-discoverable device via brute force in 18.64 hours; knowledge of OUI would ideally allow us to reduce this search time [17]. Unfortunately, this requires specialized hardware, rather than an inexpensive Android phone.

### 5.3 Impersonating Common Benign Devices

Another natural response to Bluetana would be to change the MAC address and name of the device to that of a common benign device, such as a mobile phone or a Bluetooth-enabled car entertainment system. This would make the skimmer appear innocuous to Bluetana.

**Cost to attacker.** Reprogramming the MAC address on the CSR-based Bluetooth modules, which include the Roving Networks and HC-05 and HC-06 modules, cannot be done using the AT commands used to change device name and pairing. Instead, the skimmer installer would need to re-flash the CSR firmware using a special programming cable. While, in principle, not difficult, it would require an additional degree of sophistication than programming a simple micro-controller development board. The skimmer installer could also change the device name but not the MAC address, say, to one of the known benign devices using the same module, something that is possible to do by issuing AT commands from the micro-controller to the module. While this may cause Bluetana to detect these as a skimmer, signal strength can still be used to identify location of the module.

**Response.** Because Bluetana collects all Bluetooth data, we can identify skimmers retroactively when we learn of a new MAC address and name used by known skimmers. Thus, if attacks switch to impersonating benign devices, we can update the Bluetana highlighting mechanism to identify those devices as suspicious. This would result in additional inspections, but would still provide significant gain over the state of the art.

### 5.4 Using Non-Bluetooth Communications

During discussions with law enforcement agencies tasked with identifying skimmers, we were told about skimmers that use GSM modems or WiFi as an alternative to Bluetooth. In the case of WiFi, we believe that the Bluetana methodology will still be effective. GSM poses a more serious challenge for detection.

**Cost to attacker.** While using GSM would avoid detection using Bluetana, it creates an additional trail of evidence linking the perpetrator to the skimmer. Law enforcement officers could obtain information about the SMS recipient through subpoenas, so receiving the SMS messages on another phone on a US carrier, for example, would be easy to trace. The perpetrator would need to use an SMS service that would not expose his/her identity.

**Response.** In addition to legal tools available to law enforcement to trace SMS messages, a GSM modem could be detected using a Software-Defined Radio.

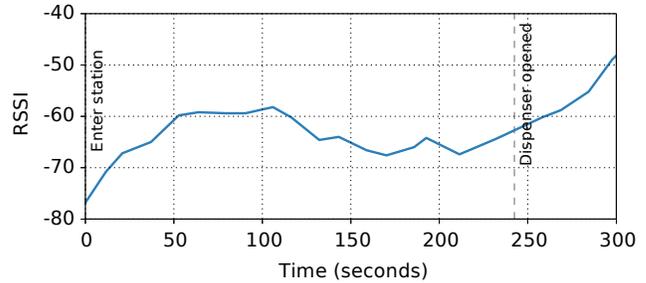

Figure 12: Opening of the gas pump enclosure results in a significant jump in observed Bluetooth signal strength from a skimmer.

### 5.5 Attacker Bottlenecks

The attacker (skimmer installer) has several practical ways to evade detection using Bluetana. Each of these, however, has an additional cost to the attacker in terms of effort, risk exposure, or expertise. We do not yet have a strong understanding to which of these costs attackers are most sensitive. Indeed, the very low price of stolen credit card numbers, compared to their potential cash out value (Table 1) suggests that the bottleneck in the carding value chain is *not* getting card information but cashing out cards. Thus, while Bluetana may raise the cost for attackers, we do not believe that it will raise it so much as to make fuel dispenser skimming unprofitable.

## 6 Operational Lessons Learned

While performing the Bluetana study, we learned several lessons about the operational use of Bluetooth scanning for skimmer detection. In this section, we provide an overview of two most important lessons we learned.

### 6.1 Bluetooth Helps During Inspections

Criminals hide skimmers in the crevices of gas pumps to avoid detection during inspections. We witnessed several instances where investigators were unable to locate skimmers via physical inspection alone. In one incident, Bluetana flagged four devices at a station; however, no skimmers were located. This result led officials more experienced in skimmer recovery to perform a second thorough inspection of the station. These officials located all four skimmers. The evidence provided by Bluetana forced them to continue the inspection, instead of abandoning it and leaving the devices in the field.

Figure 12 demonstrates an instance of how the signal strength measurements helped inspectors determine which pump had a skimmer. When the gas pump's metal door was opened, the signal strength increased significantly, prompting inspectors to look carefully for the skimmer in that pump.

	Group				
	1	2	3	4	5
Skimmers	3	5	6	4	3
Gas stations	2	2	5	4	2
Min. difference in MACs	1	4	9	10	4
Closest MAC distance (in miles)	0	17	59	203	448

Table 5: Several geographically separated skimmers had similar MAC addresses.

## 6.2 MAC Addresses May Indicate the Source

Network equipment vendors (e.g., Bluetooth module manufacturers) tend to allocate MAC addresses sequentially by production time [34]. Therefore, if two devices have similar MAC addresses, they are likely part of the same batch of devices sold. This information can be used to associate skimmer Bluetooth modules to the same board designer or crew.

We group the skimmers found by Bluetana with the same first 5 bytes of MAC address. Table 5 shows five such groups. We list the difference in MAC address and the geographic distance between the closest MACs in each group. Skimmers in group 1 and 2 were recovered at gas stations in the same county, separated by at most 17 miles. From LE sources, we know that criminals often plant skimmers across multiple stations in a given city/county, and the MAC address data collected indicates this. Groups 3-5 are the most interesting, as the closest MACs in the same group are in stations across different counties. The closest MACs in group 5 are at stations separated by 448 miles. This may seem surprising, but LE informs us that skimmer crews avoid detection by migrating from city to city.

## 7 Related Work

**Skimmer Detection and Prevention.** In recent work, Scaife et al. surveyed gas pump skimmer detection and prevention mechanisms [46]. They found that several popular Bluetooth-based skimmer detection applications use a only MAC prefix or device name matching. The results of our study show how the Bluetooth profile of skimmers in these applications can be improved to detect more skimmers, and to flag fewer legitimate devices as skimmers. We also find that Bluetooth-based scanning is an effective way to augment manual gas pump inspections. Scaife et al. also introduced SkimReaper [47], an effective tool for detecting external skimmers. SkimReaper is a credit-card shaped device that an official can swipe in a card reader to detect if the reader has an additional read head: indicating that the reader has an external skimmer attached to it. However, SkimReaper can not detect internal skimmers because they do not add an additional read head. Additionally, the PCI

Security Standards Council have released guidelines for preventing external skimming [41]. Criminals may start using Bluetooth to retrieve card data from external skimmer. If they do, we demonstrate that Bluetooth scanning can augment these existing external skimmer detection and prevention methods.

**Bluetooth.** Prior work has evaluated the effectiveness of Bluetooth scanning for detecting and localizing Bluetooth devices. They found that Bluetooth signal strength (measured by an Android smartphone) is effective for localizing Bluetooth devices [32, 57]. This work inspired us to use signal strength to detect if a Bluetooth device appears to be installed inside of a gas pump. Previous studies also examined how long it takes to detect a Bluetooth device from stationary observers and moving vehicles. They found that Bluetooth devices are often detected in less time than the Bluetooth standard suggests [39, 43, 24]. This work supports our findings that skimmers are often discovered within the first few seconds of passing by a gas station.

**Inventory Attacks.** Prior work has demonstrated that user privacy can be violated by inspecting the characteristics of a user’s device [58]. These so called *inventory attacks* have been demonstrated for Bluetooth Low-Energy, RFID, and even web browsers [54, 55, 23]. Our work demonstrates a Bluetooth-based inventory attack against malicious devices, can be used to protect the privacy of consumers.

## 8 Future Work and Conclusion

As new skimmer detection tools gain popularity, criminals will adapt skimming designs to evade detection. We expect future skimmers will use techniques such those described in Section 5. Similar to Bluetana, future work in this area should emphasize designing easy-to-deploy systems for detecting skimmers, and evaluating their effectiveness with large-scale studies.

Push-back from banks and card issuers has led to wide-scale adoption of EMV in retail PoS systems. However, EMV adoption in gas stations across the U.S. has been slow due to high costs. Therefore, Visa and Mastercard have pushed the EMV adoption deadline for gas stations from 2017 to October 2020 [22]. As gas stations begin migrating to EMV, skimmers targeting EMV will become more common. Future research should focus on the detection of EMV “shimmers” that are gaining in popularity.

Finally, we believe gas pump skimming is the harbinger of an era of attacks using wireless implants. For example, there is an internal Bluetooth-based implant for unlocking door access control systems [14]. Future work should also identify other systems that are vulnerable to using such implants.

In this paper, we presented results of a 19-month long measurement study of Bluetooth scanning as a mechanism to detect internal gas pump skimmers. Our evaluation showed

that Bluetooth characteristics of some internal skimmers can be distinguished from other Bluetooth devices commonly seen at gas stations. We detected, and LE recovered, 64 skimmers at 34 gas stations across four states in the U.S. For 33 of the detected skimmers, Bluetooth was the only source of information that prompted investigators to conduct an inspection. In conclusion, crowdsourced Bluetooth scanning is an effective way to detect Bluetooth-based internal gas pump skimmers.

## 9 Acknowledgements

We would like to express our appreciation for the local and federal law enforcement agents who introduced us to gas pump skimming and guided us throughout this project. We also thank the Kevin Allen, and the field investigators at the Arizona Department of Agriculture, Weights and Measures Services Division, for their invaluable help in understanding and analyzing the skimming problem in Arizona. We also thank the Sacramento County Sheriff's Detectives Sean Smith and Matt Deaux, both are assigned to the Sacramento Valley Hi-Tech Crimes Task Force, for their help in understanding gas pump skimming in depth. We are also very grateful to the various individuals who drove to gas stations in several states and collected Bluetooth scan data. We also thank our shepherd Joseph Calandrino, and the anonymous reviewers for their insightful feedback and suggestions.

## A Court Cases

The appendix contains excerpts from various public court documents related to cases of credit card skimming. These excerpts provide anecdotal data about the monetary impact of the skimmer problem.

### A.1 Cashout Value

#### USA v. Hristov et al [36]

"... Bank of America suffered a loss of \$33,000 with 36 compromised customer accounts. Citizens Bank suffered a loss of \$91,580 with 74 compromised customer accounts ..."

#### USA v. Cristea et al [16]

"... Altogether, on February 21, 2016, FBI surveillance observed Cristea, Co-conspirator #1, and Co-conspirator #2 go to approximately 12 different locations, where, according to CardTronic's records, they withdrew at least \$7,000 from at least 18 First National Bank accounts ..."

#### USA v. Khasanov et al [7]

"... USPS agents thereafter conducted record checks on the purchased USPS money orders and discovered that 10 of the 57 money orders had been purchased with 5 payment numbers issued by Citibank ..."

Date	Location of USPS	Amount
Aug 4 2017	Waldorf, MD	\$2,904.80
Aug 7 2017	Washington, DC	\$1,492.80
Aug 7 2017	McLean, VA	\$1,400.00
Aug 7 2017	Washington, DC	\$1,803.20
Aug 7 2017	Hyattsville, MD	\$792.05

#### USA v. Aqel [50]

"... the Probation Officer also notes that the actual loss to victims was \$8,327.58. Id. Similarly, the Probation Officer notes that while Mr. Aqel possessed 120 stolen credit card numbers, only 23 of those numbers were used to make purchases ..."

#### USA v. Rodriguez et al [25]

"... Between on or about July 7, 2016, and on or about July 20, 2016, Defendant ... attempted to conduct approximately 133 retail transactions totaling in excess of \$27,000 ... using approximately 90 counterfeit access devices re-encoded with credit/debit account information that were obtained by a skimming device placed on the point of sale terminal of a gas pump ..."

#### Application for Search Warrant, 2:18mj1277[9]

"... On April 14, 2016, a man (later identified as Estrada) used a fraudulent Visa credit card and a fraudulent MasterCard to purchase two \$300.00 gift cards from the Kohl's store ..."

#### USA v. Konstantinov et al [8]

"... In total, the defendants compromised approximately 524 debit card accounts and made approximately 779 fraudulent withdrawals, totaling \$348,376.80 ..."

### A.2 Credit/Debit cards per skimmer per day

#### Application for Search Warrant, 2:18mj1277 [9]

"... On September 9, 2016, an employee at Jilly's Mobil ... reported to Detective Craig Meyer that he had found what appeared to be a skimmer on pump #8 ... Detective Meyer downloaded and exported the data stored on the skimmer taken from Jilly's Mobil pump #8. The results showed data for 221 victim credit card accounts ...  
... Detective Meyer reviewed the video surveillance footage for Jilly's Mobil from September 1, 2016. At 1:38 PM on September 1st, a red Ford Explorer drove to pump 8. The Ford Explorer was positioned in a manner whereby the opened passenger door blocked the view of the gas pump by the store employee inside the Jilly's Mobil ..."

# CANvas: Fast and Inexpensive Automotive Network Mapping

## Abstract

Modern vehicles contain tens of Electronic Control Units (ECUs), several of which communicate over the Controller Area Network (CAN) protocol. As such, in-vehicle networks have become a prime target for automotive network attacks. To understand the security of these networks, we argue that we need tools analogous to network mappers for traditional networks that provide an in-depth understanding of a network's structure. To this end, our goal is to develop an automotive network mapping tool that assists in identifying a vehicle's ECUs and their communication with each other. A significant challenge in designing this tool is the broadcast nature of the CAN protocol, as network messages contain no information about their sender or recipients. To address this challenge, we design and implement *CANvas*, an automotive network mapper that identifies transmitting ECUs with a pairwise clock offset tracking algorithm and identifies receiving ECUs with a forced ECU isolation technique. *CANvas* generates network maps in under an hour that identify a previously unknown ECU in a 2009 Toyota Prius and identify lenient message filters in a 2017 Ford Focus.

## 1 Introduction

Recent efforts have demonstrated numerous vulnerabilities in automotive networks, particularly those that employ the CAN communication protocol. Although CAN is the prevailing standard for intra-vehicular communication due to its low cost and robustness, its broadcast nature has enabled many exploits initially exposed by the early work of Koscher et al. [20]. These exploits target the intra-vehicular CAN bus via either direct physical access [9, 20] or the remote exploitation of an ECU with existing direct access [26]. For the purpose of planning their well-known exploit [26], Miller et al. [25] analyzed the intra-vehicular networks of several vehicles, which revealed that the 2014 Jeep Cherokee was the “most hackable” based on its layout of ECUs. Once the authors gained access to the CAN via an exploited ECU, they simply had to discover which ECUs and real physical functions react to injected messages.

From these anecdotes, we can see that the set of ECUs and their inter-ECU communication channels determine the vulnerability of a vehicle's ECU network. Consequently, we argue that the automotive security world needs tools similar to Nmap [21], which are used to map the structure of modern IP networks. Such mapping tools prove useful in both attack and defense scenarios, such as identifying potentially malicious servers, attesting server configurations, and auditing firewalls by identifying available network connections. Analogously, with such a tool for scanning a car's network, we could (1) discover potentially malicious ECUs inserted through an attacker, (2) attest to the network configuration of ECUs over time, and (3) identify potential ECUs that are vulnerable to a recent type of attack (§2).

To aid in these scenarios, an ideal network mapper would require three main outputs: (1) the transmitting ECU for each unique CAN message, (2) the set of receiving ECUs for each unique CAN message and (3) a list of all active ECUs in the vehicle. To ensure that our network mapper is practical for our envisioned use cases, we ideally want our tool to be (a) *fast* to permit analysis of multiple vehicles at a time and limit the time a vehicle must be running and (b) *inexpensive* to avoid requiring costly equipment such as an oscilloscope or logic analyzer.

Unfortunately, extracting the necessary information to map these communication channels requires an unreasonable amount of effort. In the work by Koscher et al. [20], the authors analyzed the security of a vehicle's components by manually extracting ECUs to isolate and interact with them. This type of analysis requires significant time and effort or access to limited or proprietary information [25]. Second, obtaining vehicles for extended time and with permission to disassemble is costly and expensive. Considering new model years and over-the-air update capabilities, the frequency of analyzing an intra-vehicular network will quickly increase in time and cost requirements.

A key challenge we face in realizing this vision in practice is the lack of source information in CAN messages. CAN messages are “contents-addressed,” i.e. messages are labeled
