Blockchains offer attractive advantages over traditional payments such as the ability to operate without a trusted authority and increased user privacy. However, the verification of blockchain payments requires the user to download and process the entire chain which can be infeasible for resource-constrained devices like mobile phones. To address this problem, most major blockchain systems support so called lightweight clients that outsource most of the computational and storage burden to full blockchain nodes. However, such verification leaks critical information about clients' transactions, thus defeating user privacy that is often considered one of the main goals of decentralized cryptocurrencies.

In this paper, we propose a new approach to protect the privacy of light clients in Bitcoin. Our main idea is to leverage the trusted execution capabilities of commonly available SGX enclaves. We design and implement a system called BITE where enclaves on full nodes serve privacy-preserving requests from light clients. However, as we will show, naive processing of client requests from within SGX enclaves still leaks client's addresses and transactions. BITE therefore integrates several private information retrieval and side-channel protection techniques at critical parts of the system. We show that BITE provides significantly improved privacy protection for light clients without compromising the performance of the assisting full nodes.

## 1 Introduction

Since its inception in 2008, Bitcoin has fueled considerable interest in decentralized currencies and other blockchain applications. The main goals of blockchains include a distributed trust model and increased user privacy. Several other blockchain platforms, such as Ethereum [4], leverage the same open or permissionless model as Bitcoin, while platforms like Hyperledger [15], Ripple [10] and R3 [9], enable closed or permissioned blockchains. Most blockchains implement a decentralized time-stamping mechanism that

ensures eventual consistency of *transactions* by collecting them from the underlying peer-to-peer (P2P) network, verifying their correctness, and including them in connected blocks. This process imposes heavy requirements on bandwidth, computing, and storage resources of blockchain nodes that need to fetch all transactions and blocks issued in the blockchain, locally index them, and verify their correctness against all prior transactions. For instance, a typical Bitcoin installation requires more than 200 GB of storage today, and the sizes of popular blockchains are growing fast [12, 5]. Therefore, users operating resource-constrained clients like mobile devices cannot afford to run their own full node.

**Lightweight clients and privacy.** To address such heavy resource requirements, most open blockchain platforms support *lightweight clients*, targeted for devices like smartphones, that only download and verify a small part of the chain. As a matter of fact, according to [24], in 73 – 85% of 5.8 – 11.5 million active Bitcoin wallets users control keys. Since there are ~ 10,000 full nodes [11], estimated 4.2-9.8 million wallets are lightweight clients. For example, Bitcoin provides the BitcoinJ [2], PicoCoin [8] and Electrum [3] clients implementing the Simple Payment Verification (SPV) mode [44], where the clients connect to a full node that has access to the complete chain and assists the client in transaction confirmation. Transactions contain inputs and outputs that are bound to *addresses* owned by users. As the full node has to learn all transactions issued and received by the requesting client to confirm them, such payment verification obviously violates user privacy.

To improve user privacy, several clients support *filters* (e.g., Bitcoin's BIP37 [31] and Ethereum's LES [6]). The goal of filters is to allow the client to define an anonymity set in an attempt to hide its real addresses from the full node. For instance, BIP37 supports Bloom filters [18] that allow the client to define a set of transactions, with false positives, that are requested from the full node. Essentially, this approach presents a trade-off between communication efficiency and privacy: a filter that returns many false positives provides a

larger anonymity set but requires more communication. Although such filters can be configured to be efficient, recent studies have shown that in practice they offer almost no privacy [25]. Ergo, none of the current light clients provides adequate privacy with practical performance overhead.

**Our solution.** Our goal is to improve the privacy of Bitcoin lightweight clients without compromising the performance of the assisting full nodes. The starting point of our solution is to leverage the commonly available trusted computing capabilities of SGX enclaves [23] on full nodes. We propose BITE (for *BI*tcoin *lightweight client privacy using Trusted Execution*), a solution in which a potentially untrusted entity runs a full node with an SGX enclave that serves transaction confirmation requests from clients. Since SGX provides code integrity and data confidentiality for enclaves, such a solution can preserve privacy (confidentiality) and completeness (integrity) of client requests.

Unfortunately, simple usage of trusted computing is not sufficient to solve our problem. While SGX prevents an adversary that controls malicious software from directly accessing enclave’s memory, secret-dependent access patterns to external storage, such as transaction databases, can reveal the client’s address. SGX is also susceptible to side-channel attacks, where malicious software on the same platform infers secret-dependent enclave data access patterns or control flow by monitoring shared resources like caches [20, 43, 27, 50]. Thus, the simple usage of SGX would still leak the client’s addresses to malicious full node.

Given such limitations of SGX, *the primary research problem and contribution of this paper is how to design and implement a solution that enables private processing of light client request in the presence of enclave leakage without compromising the system’s overall performance.* To address this non-trivial challenge, we carefully select and apply known private information retrieval (PIR) and side-channel protection techniques and combine them into a novel solution that meets our performance requirements. We emphasize that in our application the assisting full node needs to process a large blockchain database to serve client requests, and thus straightforward usage of generic SGX side-channel protection systems, such as Raccoon [47], Cloak [28] or ZeroTrace [49], would result in either excessive performance overhead or imperfect side-channel protection. Instead of using such systems directly, we pick low-level primitives and apply them at critical points in our system to achieve more complete protection and better performance.

We design two variants of our solution. Our first variant, *Scanning Window*, is similar to the current SPV clients that verify transactions using block headers and Merkle paths received from the full node. To prevent leakage from file accesses and message sizes, we design a customized chain access mechanism that hides the client’s transactions and the relationship between the size of the response and the number

of read blocks. Our second variant, *Oblivious Database*, allows the client to verify the amount of coins associated with its addresses by querying a specially-crafted version of the unspent transaction output (UTXO) database. To prevent leakage from database accesses, we leverage a well-known Oblivious RAM (ORAM) algorithm [52]. (Prior to us, usage of ORAM from enclaves has been proposed in systems like ZeroTrace [49].) This variant allows even *lighter* clients that no longer need to download and verify Merkle paths.

To prevent software-based side-channels, we adopt further protections from recent SGX research. The basic building block for our control-flow hiding is the `cmov` instruction [7] that enables building oblivious execution of branches. (We adopt this technique from the Raccoon system [47].) To prevent leakage from data access patterns we apply additional defenses, such as iterating over the entire data structure when an element is accessed based on the protected client address.

**Results.** We show that our solution provides strong privacy protection. In both of our variants, the external data access patterns are independent of the protected client address. The side-channel protections in the Oblivious Database variant also make the enclave’s memory accesses (both code and data) independent of the address, thus preventing leakage caused by known SGX side-channels [20, 43, 27, 50, 58, 36]. While similar protections can also be used for the Scanning Window variant, they impose a high overhead, which is why we recommend using Oblivious Database if side-channels are a concern. Our solutions also fail gracefully: even if the used SGX processor would be completely broken (e.g., through a physical attack), the adversary cannot double spend or steal users’ coins or wallets.

In terms of performance, our solution is comparable to the SPV scheme. The Oblivious Database variant increases the full node’s *storage* moderately (e.g., additional 4 GB). The required *communication* is significantly lower (e.g., 12 KB instead of 17 MB per client request). The *processing* cost for incoming client requests is reduced (e.g., 0.5s instead of 1.1s), but the processing cost for new blocks is higher (79s instead of 2s). Even compared to SPV without privacy protection, our solution adds no processing time or communication overhead (in fact, BITE’s processing is faster by 0.1s and the response size is 2kB smaller). The full node can be easily made responsive for incoming client request during block updates by using two enclave instances in parallel. The Scanning Window variant requires no additional storage and its communication cost is lower than in SPV. The processing cost is also comparable when full side-channel protection is not used.

We argue that BITE emerges as the *first* practical solution that provides strong privacy protection for lightweight Bitcoin clients. Our solution can be integrated into existing full nodes and lightweight clients with minor modifications to the existing software. While BITE is designed for Bitcoin,

we stress that it finds direct applicability in various other blockchain platforms as well.

**Contributions.** In summary, in this paper we make the following contributions:

- *Novel approach.* We propose leveraging commonly available trusted execution capabilities of SGX enclaves for improved lightweight Bitcoin client privacy.
- *New system.* We design and implement a system called BITE that carefully combines a number of PIR and side-channel protection techniques to prevent leakage.
- *Evaluation.* We show that BITE significantly improves client privacy without compromising full node performance. We argue that BITE is the first practical way to provide strong privacy for lightweight Bitcoin clients.

The remainder of this paper is organized as follows. Section 2 describes our problem and Section 3 outlines our approach. Section 4 explains the details of our system BITE. Section 5 covers security analysis and Section 6 provides performance results. We provide discussion in Section 7, review related work in Section 8, and conclude in Section 9.

For readers unfamiliar with SGX and ORAM, we provide brief introductions in Appendices A and B.

## 2 Problem Statement

In this section, we provide background on Bitcoin lightweight clients, explain the limitations of known approaches and define requirements for our solution.

### 2.1 Bitcoin Lightweight Clients

Bitcoin [44] is the first and still most popular cryptocurrency based on blockchain technology. It enables users to perform payments by issuing *transactions* that transfer Bitcoins (BTC) from one or more transaction inputs to one or more outputs. Each of the outputs is bound to an *address* that is derived from a user's public key. A user that knows the corresponding private key is able to spend the Bitcoin contained in the transaction output.

When a user wants to perform a payment, she creates a transaction that contains inputs, outputs, and the signatures that allow her to spend the inputs. Subsequently, the transaction is propagated to all nodes using a peer-to-peer network created by the system's participants. Miners, a special type of nodes, collect valid transactions into blocks and solve Proof-of-Work (PoW) puzzle to make the contained transactions hard to revert. A miner that successfully finds a valid PoW, broadcasts the block to all other nodes, who then verify its correctness and include it in their copy of the chain.

To verify transactions, Bitcoin users, or clients, need to store the full history of all Bitcoin transactions. This approach puts a heavy load on client implementations in terms

of network and storage, and as a consequence, makes transaction confirmation on mobile clients infeasible. To address this concern, the original Bitcoin paper proposed a solution called *Simplified Payment Verification (SPV)* [44]. In this technique, light clients store only block headers, check their PoW puzzles and then request their own transactions and the Merkle paths that are needed to verify their presence in the blocks from a full node that stores the entire chain.

Improvement proposal BIP 37 [31] introduced Bloom filters [18] that allow a light client to request a subset of all transactions to preserve some privacy without needing to download all transactions for each block. A Bloom filter [18] is a probabilistic data structure that consists of a set of hash functions and a bit array where each bit is set to one if one of the hash functions hashes one of its inputs to the index of the bit in the array. This allows checking if a value is contained in the filter by hashing the value with each of the hash functions and checking whether the corresponding bit is set. If this is not true, the value was not an input. If it is true, however, the value *might* have been an input or a false positive. The false positive rate can be set by the creator of the filter.

In Bitcoin light clients, Bloom filters are used to encode transactions or addresses, and allow a full node to determine which transactions to send to a lightweight client without letting the full node know the exact addresses. A lightweight client prepares a Bloom filter to which she adds all of her addresses and sends it to the full node. The full node then checks for incoming (or past, if requested) transactions whether they match the Bloom filter. If they match, she sends them to the client together with the Merkle path needed for verification. The client can adjust the false positive rate to increase her privacy. If the false positive rate is higher, the client will receive more irrelevant transactions, in an attempt to hide her true addresses with a larger anonymity set.

### 2.2 Limitations of Known Solutions

The use of Bloom filters to receive Bitcoin transactions from an assisting full node inherently creates a trade off between performance and privacy. If a client increases the false positive rate she receives more transactions which provides increased privacy, as any of the matching addresses could be her real addresses, but it also means that she needs the network capacity to download all of these transactions. In the extreme cases, the filter matches everything, i.e., the client downloads the full blocks, or the filter only matches the client's addresses, i.e., she has no privacy at all.

Gervais et al. [25] have shown that using Bloom filters in Bitcoin light clients leaks more information than was previously thought. In particular, if the Bloom filter only contains a moderate number of addresses, the attacker is able to guess addresses correctly with high probability. For example, with 10 addresses the probability for a correct guess is 0.99. They also show that, even with a larger number of

addresses, the attacker is able to correctly identify a client's addresses with high probability if she is in possession of two distinct Bloom filters from the same client (e.g., due to a client restart). Hearn [30] later expanded on why solving these issues is hard (e.g., need for resizing). Furthermore, it is likely that an attacker using additional de-anonymization heuristics, such as the ones described in [16, 41], could further increase the probability to guess correctly.

Finally, a lightweight client cannot be sure that she receives *all* transactions that fit her filter from a full node. While the full node cannot include faulty transactions in the response, as this would be detected by the client when re-computing the Merkle root, the client cannot detect whether she has received all requested transactions. This problem can be solved by requesting transactions from multiple nodes, which again imposes more network load on the client.

Another solution would be to run the SPV protocol with Bloom filters over a network anonymity mechanism such as Tor. While this would prevent the full node from learning the IP address of the client, the full node could still correlate queries from the same client based on the addresses that leak from Bloom filters. We argue that query unlinkability is a useful privacy property in systems like Bitcoin and can be considered similar to the transaction unlinkability in systems like Zcash (that provide more advanced privacy protection).

### 2.3 Requirements

The high-level goal of this paper is to develop a solution that provides better privacy for lightweight clients without compromising the system performance. More precisely, our solution should meet the following requirements:

**(R1) Privacy.** Lightweight clients should be able to verify that their transactions are confirmed on the blockchain or check the amount of coins associated with their addresses without revealing their addresses to the potentially untrusted entity that controls the assisting full node. The full nodes should not be able to link queries from the same light client that could allow them to incur additional information regarding the client's transactional pattern or behavior.

**(R2) Completeness.** The verification process should guarantee that no valid transactions have been omitted.

**(R3) Performance.** The performance of the system should be comparable to or better than current light client schemes.

## 3 Our Approach

The main idea behind our approach is to leverage commonly available Trusted Execution Environments (TEEs) such as Intel's SGX enclaves [33, 23] running within full nodes to provide a privacy-preserving verification service to light clients. Besides increased privacy, TEEs can enable better

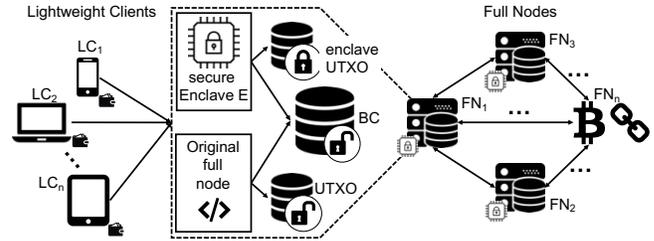

Figure 1: **System model.** Lightweight clients request transaction verification from enclaves hosted on full nodes.

performance in terms of reduced processing and bandwidth, and guarantee completeness of received responses.

In short, SGX provides a set of security enhancements in the processor that allow creation of small applications, called *enclaves*, whose data confidentiality and code integrity is protected from any malicious software running on the same platform, including the privileged OS.

A simple way to leverage SGX would be a solution where the light client sends its wallet private key to an enclave on the assisting full node. Using that key, the enclave can perform any operation on behalf of the user, including transaction verification. However, such simple solution has a critical drawback. If the used enclave is compromised, the adversary can steal all user's coins. Such approach might give the owners of full nodes an undesirable economic incentive to break their own SGX processors, e.g., using physical attacks.

To avoid such incentives, we choose a different approach. In our solution, when a client needs to verify a transaction or check the amount of coins associated with the user's addresses, the client connects to one of the full nodes that supports our service. The client performs remote attestation and establishes a secure channel to the enclave. Then, the lightweight client sends the addresses that the user is interested in to the enclave. The enclave obtains all the required verification information from the locally stored blockchain or custom unspent transactions database (UTXO) and sends back a response to the client that can verify it. Importantly, the client's private key is never shared with the enclave which enables safe adoption of our solution.

We envision two types of deployment for our system. In the first example deployment, a well-recognized company could provide such a verification service. In the second example, any volunteer currently running a Bitcoin full node could adopt our extension and start providing the service to lightweight clients. In both cases, to incentivize deployment by the full nodes, the service could be run in exchange for some small remuneration (i.e., verification fees).

### 3.1 System Model

Figure 1 shows our system model that consists of full nodes  $FN_1 \dots FN_m$  and lightweight clients  $LC_1 \dots LC_n$ . When a lightweight client  $LC_i$  wants to acquire information about its

transactions or addresses, it can connect to any full node  $FN_j$  that supports our service and hosts an enclave  $E_j$ . Full nodes download and store the entire blockchain (BC) locally and based on that maintain a database that contains all unspent transaction outputs (UTXO). Our system additionally maintains a specially-crafted version of the UTXO, called *enclave UTXO*, in an encrypted (sealed) form.

In SGX, enclave memory is limited to 128MB. Although swapping memory pages is supported (swapping requires expensive encryption and integrity verification [17]), the complete blockchain (BC) and the database of unspent transaction outputs (UTXO) are significantly larger (as of Jan 2019, 200GB [12] and 2.8GB [13] or more, respectively) than the enclave's memory limits. Therefore, these databases are stored on the local persistent storage.

### 3.2 Adversary Model

We consider an adversary who controls the OS and any other privileged software on the full node. For example, the adversary could be a malicious administrator or an external attacker who has remotely compromised the OS on the full node. Since the adversary controls the OS, she can schedule and restart enclaves, start multiple instances, and block, delay, read, or modify all messages sent by enclaves, either to the OS itself or to other entities over the network. We assume that the adversary cannot break the hardware security enforcements of Intel SGX. That is, the adversary cannot access processor-specific keys (e.g., attestation or sealing key) and she cannot access enclave runtime memory that is encrypted and integrity-protected by the CPU. (Although we consider SGX trusted, in Section 5 we discuss enclave compromise and show that our solution can handle it without any financial loss.) Finally, we assume that common cryptographic primitives like encryption or signatures are secure.

### 3.3 Challenges

Secure and practical realization of our approach under the defined attacker model involves several technical challenges.

**Leakage through external accesses.** Since the adversary controls the OS, she can observe access patterns to any *external* resources, such as files or databases stored on the disk. Although externally stored data can be sealed (encrypted by the CPU such that only the same enclave can decrypt), the OS can infer information about the accessed element by observing access patterns to individual records, such as files or database entries. In a simple implementation of our approach, the adversary could infer the client's addresses by observing which entries the enclave reads from a (sealed) UTXO database when processing a client request.

Similarly, enclaves rely on the OS to perform communication operations which allows it to infer information about

the enclave's communication patterns. Even if messages are encrypted by the enclave, the message sizes, frequency and destination can leak information. In our case, the adversary could determine how many transactions are included to the response by observing response sizes.

**Leakage through side channels.** The SGX architecture is also susceptible to *internal* leakage. Numerous, recently demonstrated side-channel attacks against SGX show that internal leakage is a relevant concern. For example, by monitoring CPU caches the OS can infer secret-dependent data and code accesses inside the enclave's memory [20, 43, 27, 50]. The OS can also infer enclave's secrets by monitoring the memory pages that the enclave requests [58]. Researchers have also demonstrated side-channel attacks using the CPU's branch prediction functionality [36]. In a simple implementation of our approach, the adversary can monitor address-dependent branching in the enclave's control flow and data accesses and thus determine the client's addresses.

## 4 BITE System

In this section we present a system called BITE that realizes the above approach securely and addresses the aforementioned challenges. In particular, we present two variants of the same approach that serve slightly different purposes.

Our first variant, *Scanning Window*, can be seen as an extension to the current SPV verification mode, but without reliance on bloom filters. Based on the client request, an enclave on the full node *scans* the blockchain and replies with a set of Merkle paths that the client can use to verify its transactions using downloaded block headers. This variant allows the client to check that each of its transactions are confirmed on the blockchain. As Bitcoin provides only eventual consensus, the client may want to additionally verify that the blocks where its transactions are placed have been extended with a sufficient number of valid blocks (e.g., six).

Our second variant, *Oblivious Database* is a completely new verification mode for lightweight clients. In this variant, the enclave on the full node maintains a specially-crafted version of the unspent transaction outputs (UTXO) database and when a client sends a verification request, it checks for the presence of client's outputs in this database using oblivious database access (ORAM [52]) and responds accordingly. Such verification allows the client to check how many coins are currently associated to its addresses, with significant performance improvements over SPV.

In both variants, the client performs remote attestation and establishes a TLS connection to the enclave. We note that current light clients communicate with the full nodes without encryption. Existing full node functionality, such as participation in the P2P network and mining, remain unaffected. Therefore, our system can be seen as a simple add-on to ex-

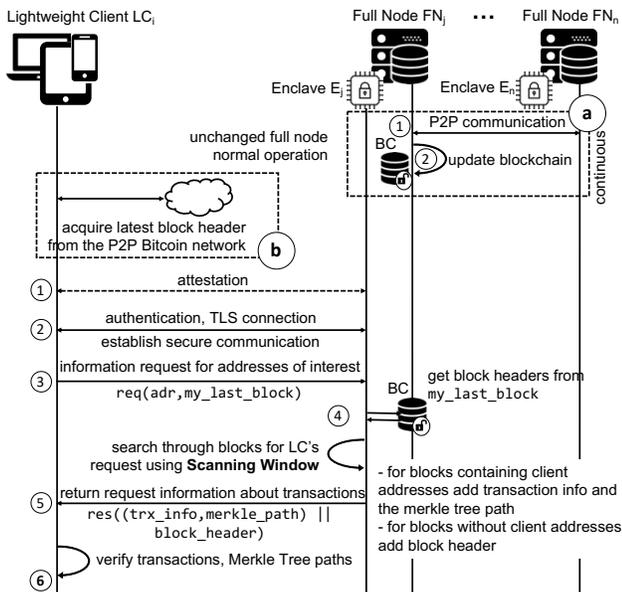

Figure 2: **Scanning Window operation.** Light client creates a secure connection to an enclave on full node and sends a request with its address and last known block. The enclave scans the locally stored chain and prepares a response with the size proportional to the number of scanned blocks.

isting full nodes. For clients, payment execution remains unchanged. Payment verification requires minor additions (attestation and TLS) when Scanning Window is used or slightly bigger changes with Oblivious Database variant.

### 4.1 Scanning Window Variant

In our first variant, we want to improve the privacy of the current SPV verification mode. When a client needs to verify transactions, it constructs a request that specifies the addresses of interest and the last block that it has in its internal state and sends that to the secure enclave residing on the full node. The enclave reads the locally stored blockchain database using a custom scanning technique that normalizes the relationship between response sizes and actually accessed data to hide the data/block access patterns and ensure client privacy. Figure 2 shows the operation of this variant, and we describe the details as follows:

#### Initialization and continuous operation.

(a) On initialization the Full Node  $FN_j$  connects to the Bitcoin network (a-1) and downloads the full blockchain (a-2). Similarly, the locally stored blockchain database is updated for each new block that is appended to the chain (i.e., as new blocks are received over the P2P network).

(b) The lightweight client installation package includes a checkpoint block header from a recent date. When the client

is started for the first time, it downloads all newer block headers from the peer-to-peer network and verifies that (i) they all have correct Proof of Work and (ii) the hash chain of the downloaded headers leads to the checkpoint. Once the client’s internal state it synchronized with the peer-to-peer network, it stores a small number of the newest headers (e.g., six blocks from the head of the chain to handle shallow forks). The client can update its internal state by downloading newest block headers periodically or before each transaction verification request. The network and storage requirements of this process are minor and easily met even by clients with severe resource constraints.<sup>1</sup>

#### Client request handling.

(1) The Lightweight Client  $LC_i$  performs attestation with the secure Enclave  $E_j$  residing on the full node  $FN_j$ .

(2) If the attestation was successful, the Lightweight Client  $LC_i$  establishes a secure communication channel to the Enclave  $E_j$  using TLS.

(3) The Lightweight Client  $LC_i$  sends a request containing the addresses of interest and a block number that specifies how deep in the chain transactions should be searched for verification. Typically, this number would be saved from the previous interaction with a full node or in the case of the first transaction verification the number could roughly match the date when the client started using Bitcoin.

(4) The Enclave  $E_j$  starts *scanning* its locally stored copy of the blockchain (BC) for the requested address and range of blocks using a scanning technique described in detail below.

(5) In preparation of the response, the Enclave  $E_j$  does the following: for blocks containing client addresses it adds the full transaction information and the corresponding Merkle tree path to the response, while for blocks without client addresses it only adds the block header.

(6) The Lightweight Client  $LC_i$  verifies that (i) the received block headers match its internal state and (ii) the received transactions and Merkle Tree paths match to the block headers. The client considers such received transactions as confirmed (assuming that they are sufficiently deep in the chain). The client updates its internal state regarding the latest verified block number and closes the connection to the enclave.

**Block scanning details.** As explained in Section 3.3, enclave execution can leak information in various ways. For example, if our solution would simply return each matching transaction (and the corresponding Merkle Tree) in the specified range of blocks, based on the size of the response the adversary could deduce how much information of interest

<sup>1</sup> For example, obtaining block headers for a checkpoint that is one month old, would require 300 kB of downloaded data (one-time operation) and updating the block headers once per day would require 10 kB of communication per day. Storing the latest six headers takes less than 1 kB of storage.

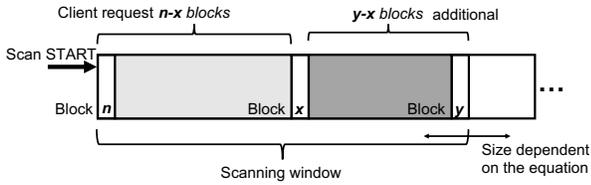

Figure 3: **Block reading in Scanning Window.** Depending on the number of requested blocks (up to  $x$ ) and the number of matching transaction in them, we read potentially extraneous blocks (up to  $y$ ) to keep the ratio between the read blocks and the response message size constant.

for the client was contained within the scanned blocks. Over a period of time, by tracking requests and response sizes, the adversary could gain significant information about the client’s addresses and transactions.

We address such leakage by using a custom-made block scanning scheme. The main goal of the scheme is to fully hide the ratio between the response size (that indicates the number of transactions returned to the client) and the number of scanned blocks. When this ratio is constant, the adversary cannot deduce any meaningful information.

Figure 3 depicts the details of our scanning scheme. The newest block in the blockchain observed by the Bitcoin network is  $n$ . A client’s request contains an addresses of interest and the number block  $x$  indicating how deep the chain should be scanned. The enclave starts scanning from  $n$  and moves towards  $x$ . It stores intermediate responses and when it reaches block  $x$  it performs a check. The total size of the response,  $r$ , is divided by the threshold size,  $t$ . The threshold indicates the maximum response size per block such that if we are to scan  $n - x$  blocks, the maximum response size for the client can be  $r = (n - x) * t$ . If the given response size  $r$  is greater, then the enclave has to scan up to block  $y$  (or  $y - x$  more blocks), such that  $r = (n - y) * t$ . If the response size is smaller, i.e., if after scanning  $n - x$  blocks  $r \leq (n - x) * t$ , we pad the response size such that  $r = (n - x) * t$ . The exact size of the threshold is empirically determined in Section 6.

**Side-channel protection.** The scanning technique described above prevents external leakage through response sizes and disk accesses. However, if the adversary is able to mount high-granularity digital side-channel attacks (e.g., one that allows her to observe execution paths with instruction-level granularity), she will be able to determine the transactions that were accessed, and thus infer the client’s addresses.

To make our system more robust against such attacks, we optionally add side-channel protections at the expense of performance (cf. Section 6). To protect against timing leakage we compute the Merkle path for all transactions in each of the scanned block in contrast to only computing the path for

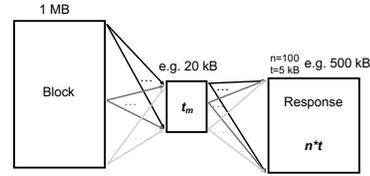

Figure 4: **Oblivious copying in Scanning Window.** The data is copied in an oblivious fashion from the block to a temporary array, i.e., every transaction is conditionally moved using `cmov` to every possible destination. The data contained in the temporary array is then copied to the response in an oblivious fashion, again using `cmov` to conditionally copy everything to all possible locations in the response.

the transactions of client’s interest. For protection against control-flow side channels we make use of the `cmov` assembly instruction to hide execution paths. `cmov` is a conditional move such that “*If the condition specified in the opcode (cc) is met, then the source operand is written to the destination operand. If the source operand is a memory operand, then regardless of the condition, the memory operand is read*” [7]. We use the `cmov` instruction in form of a wrapper (originally presented in [47]) that allows us to remove branches from our code resulting in the same control flow with no leakage.

The same technique is also used in previous side-channel protection solutions like Raccoon [47]. However, since using such a general purpose side-channel defense system directly would incur an extremely high performance overhead in our particular setting (due to large amounts of accessed data), we customize these techniques to our setting. Specifically, we apply the following modifications, as per Figure 4:

- (i) Instead of continuing to scan the chain if the size of the response exceeds the threshold, we stop scanning after the specified number of blocks. If not all transactions fit in the response, the client does not receive all transactions and is informed of this through a flag in the response. This allows the allocation of a response array that does not change size during processing. The client can request the remaining transactions in a new query (potentially from a different node).
- (ii) For each block, we allocate a temporary array of size  $t_m$  (see Figure 4), where  $t_m$  is a threshold that specifies the maximum data per block, as opposed to the threshold  $t$  that specifies the average data per block. While the block is parsed, each transaction is moved to the temporary array in an oblivious fashion, i.e., we use the `cmov` instruction to conditionally move each word of each transaction to every entry in the array. This means that for every transaction we access every entry in the array and since the same instruction is used for each possible copy – independent of whether the data is actually copied – even an attacker with an instruction level view of the control flow cannot determine which data is actually copied. After processing the block, the temporary array is traversed and all entries are copied to the response array (see

Figure 4). This is again done in an oblivious fashion, i.e., each entry is copied conditionally using the `cmov` method to every possible position in the response array.

This method of copying transactions from the block to the response is required to efficiently keep the data accesses oblivious. Specifically, for a block of size  $m$ , a temporary array of size  $t_m$  and  $n$  requested blocks, this method requires  $\mathcal{O}(m \cdot t_m + t_m \cdot n \cdot t)$  instead of  $\mathcal{O}(m \cdot n \cdot t)$  operations when naively copying the data obliviously from the block to the response. Since  $t_m$  is usually much smaller than  $m$  and  $n \cdot t$ , this method is in practice orders of magnitude faster.

## 4.2 Oblivious Database Variant

In our second variant, we focus on reducing the load of lightweight clients in terms of computation and network while offering even better privacy preservation (namely, the block number that specifies how deep the chain should be searched does not leak). The main idea behind this variant is to allow lightweight clients to send requests containing addresses of their interest and directly receive information regarding unspent outputs, without the need to verify block headers and Merkle tree paths.

In order to achieve such verification, a new indexed database of unspent transactions (denoted as *enclave UTXO*) is created and searched for every client request using an Oblivious RAM algorithm. Figure 5 shows the operation of this variant, and we describe the details as follows:

### Initialization and continuous operation.

(a) Similar to a standard full node, on initialization the full node  $FN_j$  connects to the peer-to-peer network and downloads and verifies the entire blockchain. After initialization, when new blocks are available in the peer-to-peer network,  $FN_j$  downloads and verifies them.

(b) During initialization Enclave  $E_j$  reads the locally stored blockchain and verifies each block. The enclave builds its own *enclave UTXO* database that is a special version of the original structure present in standard full nodes. In particular, this UTXO set is encrypted on the disk as sealed storage, indexed for easy and fast access depending on the client request, and accessed using ORAM to prevent information leakage through disk accesses. After initialization, the enclave updates this UTXO using ORAM when new blocks are available in the locally stored blockchain.

(c) As in the Scanning Window variant, the client obtains the latest block headers from the peer-to-peer network.

### Client request handling.

(1) The Lightweight Client  $LC_i$  performs an attestation with the secure Enclave  $E_j$  residing on the full node  $FN_j$ .

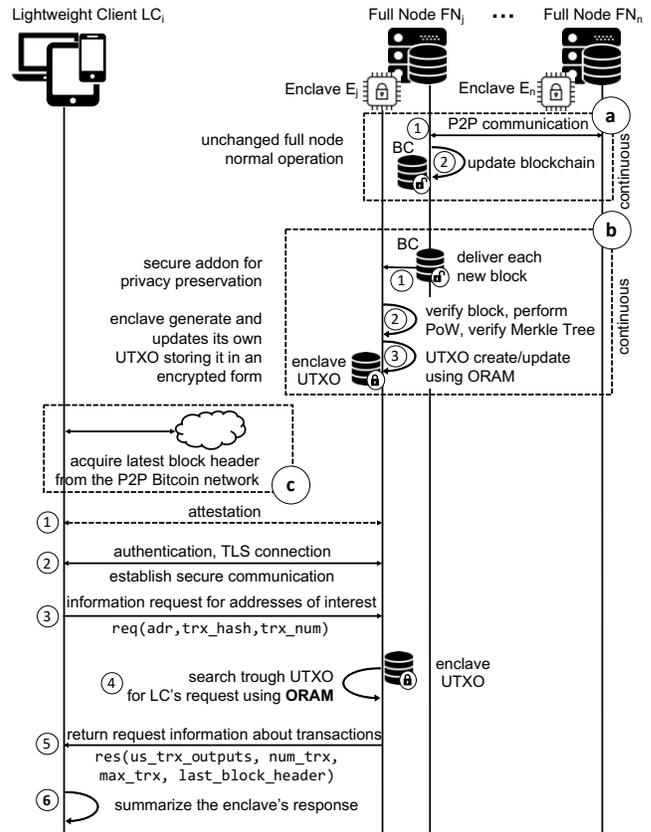

Figure 5: **Oblivious Database operation.** Lightweight client sends a request containing its address and the last transaction to an enclave on full node. Enclave queries a specially-constructed UTXO database using ORAM and provides a response back to the client.

(2)  $LC_i$  establishes a secure communication channel to the Enclave  $E_j$  using TLS.

(3)  $LC_i$  sends a request containing the addresses of interest, along with the hash and number of the latest transaction known to the client. The last two parameters are needed in case the number of unspent outputs contained by an address is larger than the maximum size of the message. For example,  $LC_i$  receives the first response containing  $x$  transaction outputs with an indication that there is more, and in a consequent request specifies the same address as in the first request along with the  $x$ -th transaction hash and transaction number. This gives an indication to the enclave to respond with the second batch of outputs starting from that transaction. The process repeats (possibly with a different node) until the client is satisfied. To prevent information leakage through the message sizes, requests are always of constant size, i.e., the client pads shorter requests and splits up larger queries. The size is defined to accommodate the majority of requests. Since a lightweight client can choose any available node to connect to, she can choose to send requests to

different nodes to hide the number of sent requests.

(4) The Enclave  $E_j$  reads the enclave UTXO database to get the unspent transaction output information in respect to the client's request.  $E_j$  uses ORAM and the previously created index to access the enclave UTXO in an oblivious fashion.

(5) In preparation of the response,  $E_j$  includes the relevant information as explained in step (3), which encompasses the currently included and maximum number of unspent transactions found for a specific address. When these numbers match, the  $LC_i$  knows that she has received all the unspent outputs of a specific address. The enclave additionally includes the block hash of the last known block from the local blockchain (longest chain). With this information the client can deduce whether the enclave has been served with the latest block and that the enclave's database is fully updated. Responses are always of constant size, i.e., shorter responses are padded and if a response is too large, the client is informed of missing outputs, such that she can later retrieve the rest of the outputs (e.g., from a different node). The size of the response is chosen such that it accommodates the majority of responses.

(6) The Lightweight Client  $LC_i$  can summarize the unspent transaction outputs received from the Enclave  $E_j$ . The enclave guarantees completeness in terms of transaction confirmation and the current state of the chain, so the client does not have to perform any additional checks by herself. Successful update of the client's internal state results in the connection termination between the enclave and the client.

**Oblivious Database details.** In this variant, we use an ORAM algorithm called Path ORAM [52] to protect data access patterns of our enclaves. For readers unfamiliar with this algorithm, a brief description is in Appendix B.

*Database Initialization.* The ORAM database is initialized by creating dummy buckets on disk and filling the *position map* with randomized entries. The *stash* is also filled with dummy chunks. After that the ORAM database is fully initialized and can be used to add new unspent outputs from the blockchain. To ensure that the enclave always uses the latest version of the sealed UTXO database, SGX counters or rollback-protection systems such as ROTE [39] can be used.

*Database Update.* When a new Bitcoin block is added, the enclave first verifies the proof of work. It then extracts all transaction inputs and outputs and bundles them by address. For each address found in the block, the UTXO database entry is requested and then updated with the new information. If too many entries are added, resulting in the chunk getting too big, the chunk is split into two and the index is updated to reflect the changes made to the UTXO database. All accesses are performed using the ORAM algorithm and, therefore, do not leak any information about the access patterns.

*Database Access.* Accesses to the ORAM database follow the normal procedure described in [52] and in Appendix B.

**Side-channel protection.** While the usage of ORAM protects against all external leakage, side-channel attacks, and thus, internal leakage remains a challenge. If we consider the most powerful attacker that can perform all digital side-channel attacks (see Section 3.3), this variant would be forfeit due to the leakage of the code access patterns, specifically, execution paths in the *if* statements when the stash, indexes and the position map is being accessed. This would leak the exact address which is used to search for the unspent transactions in the internal database.

To remedy internal leakage, we deploy several mechanisms that protect our code and execution. First, when accessing the security critical data structures, specifically, the position map, stash, and the indexes containing information about which chunks contain unspent transactions of a certain Bitcoin address we pass over them entirely in the memory to hide the memory access pattern. Second, to hide the execution paths we remove all branching in the code that accesses these data structures and deploy the *cmov* assembly instruction (see Section 4.1). Observation of the control flow and memory access does not leak whether the operation performed by the enclave was a read or a write, and since there is a single control flow without creating multiple branches depending on the condition, we effectively hide the execution and thus protect this variant from internal leakage in full.

## 5 Security Analysis

In this section, we provide an informal security analysis. First, we analyze our solution with respect to our adversary model where SGX security enforcements cannot be broken. In particular, we show that our solution ensures confidentiality of the requested client addresses, as the attacker cannot infer the requested address from disk access patterns, response sizes, side-channels, or a combination thereof. Second, we discuss implication of potential SGX compromise and show that our solution can handle such cases gracefully.

### 5.1 External Leakage Protection

**Scanning window.** This variant scans complete blocks from the blockchain database, instead of accessing individual transactions within them, and thus prevents direct information leakage from disk access patterns. The constant ratio of response size to scanned blocks prevents information leakage from the response size. The adversary may only infer the number of blocks that are accessed and not which addresses are sent by the client or how many transactions are returned.

**Oblivious Database.** To protect against information leakage attacks on the disk access, our second variant utilizes the well-studied Path ORAM [52] algorithm. Our setting is slightly different than the typical client-server model considered in ORAM. In our case, the enclave corresponds to

the client. Because the adversary can run the enclave freely, she can use it as an oracle, i.e., she can influence the data that is written (by delivering blocks to the enclave) and can query for values herself. Regardless of that, due to the unlinkability property of ORAM, the attacker learns nothing about what is accessed and the probability to guess correctly which ORAM block was accessed is equal to that of a random guess, as shown in [52]. Also, the adversary learns nothing from responses as they are of constant size.

## 5.2 Side-channel Protection

Most known side-channel attacks on SGX provide imperfect data-access or control-flow traces and require many repetitions to filter out noise [20, 43, 27, 50]. In BITE, queries from legitimate clients cannot be replayed due to the authenticated TLS channel and since the enclave is either stateless across power cycles or protected against rollback. The adversary can create his own client and send requests to the enclave, but this will not result in any advantage against legitimate clients. For these reasons, mounting side-channel attacks against BITE is more challenging than performing side-channel attacks against enclaves in general. To analyze our solution against future adversaries that may be able to mount more precise attacks, below we consider the worst case scenario, i.e., side-channel attacks that obtain perfect data access and control flow traces from enclave's execution.

**Scanning Window.** To harden our Scanning Window variant against side-channels, we provide optional protections that incur significant performance penalty. When the enclave scans through both the temporary array and the final response array in their entirety, it performs `cmov` operations for all possible transactions. This allows replacing branches in our code with a few instructions resulting in the same control flow with no leakage to the attacker since all data is accessed and the same operation is executed every time.

**Oblivious Database.** For our Oblivious Database variant we always include side-channel protections to our solution, since the performance overhead is negligible. When accessing the security critical data structures such as stash, indexes and the position map, we pass over them entirely to hide the memory access pattern. Second, to hide the execution paths, we remove all branching in the code that accesses these data structures and replace them with `cmov` assembly instructions (see Section 4.2). Observation of the control flow and memory access does not leak whether the operation performed by the enclave was a read or a write, and since there is a single control flow without creating multiple branches depending on the condition, we effectively hide the execution path and thus protect this variant from internal leakage in full.

The usage of `cmov` for protecting against digital side-channel and internal leakage was previously studied in Rac-

coon [47] and with respect to protecting ORAM-based systems it was studied in other SGX-related works [49, 14]. These works show the effectiveness of `cmov` in protecting against internal leakage. Our solution uses the same techniques, and thus directly inherits the security guarantees that successfully protect against the same type of attacks, i.e., those based on digital side-channel leakage.

## 5.3 Completeness

In the Scanning Window variant, the client herself performs the verification of the block headers, Merkle paths and transactions. Since the client can retrieve block headers from the P2P network and the enclave returns all transactions from its view of the chain, the client can ensure completeness of the response by checking that she received data from the longest chain. In the Oblivious Database variant, the enclave performs all verifications for the client. To ensure completeness, the client can compare the latest block hash from received response to information from other sources.

An adversary that controls the OS of the full node server can deliver incomplete blocks to BITE enclave or decide to not deliver specific new blocks to the enclave. However, this would be noticed by the light clients. Remember that light clients are required to obtain the latest block hash from an alternative source in order to verify the completeness of BITE responses. (Another approach to solve this would be to use systems such as TownCrier [59] or TLS-N [48], that enable the enclave to get an authenticated feed that could confirm the correctness of the blocks received from the full node.)

## 5.4 Implications of a Full SGX break

Our adversary model assumes that side-channel leakage from enclave's execution may happen, but the adversary cannot fully break SGX, i.e., the adversary cannot read all enclave's secrets and modify its control flow arbitrarily. However, SGX was never intended to provide tamper resistance against physical attacks and recent research has demonstrated that platform vulnerabilities like Spectre [35] and Meltdown [38] can be adapted to extract attestation keys from SGX processors [21, 54]. Therefore, it becomes relevant to ask how BITE handles a full SGX compromise.

In the Scanning Window variant, the client only loses the privacy protections provided by our system and all of his funds remain secure. Since the client still performs SPV, the security is otherwise not affected and our system provides the same guarantees as current light clients, i.e., a node may omit transactions, but cannot steal funds or make a client falsely accept a payment.

In the Oblivious Database variant, a compromised enclave could make the client accept false payments by sending invalid UTXOs. However, we argue that this will not be a realistic threat since it would require the client to sell some

System	Our implementation		Libraries	Total
	Bitcoin <sup>1</sup>	Network <sup>2</sup>	<i>mbed-tls</i>	
Scanning Window	1'876	1'613	53'831	57'320
Oblivious Database	4'117	1'613	53'831	59'561

<sup>1</sup> Processing the Bitcoin blockchain.

<sup>2</sup> Parsing responses from the client over TLS.

Table 1: Trusted Computing Base in LOC.

goods or service to the provider of the node, i.e. this is not a realistic issue for most users. Merchants that see a full break of SGX as a realistic threat can instead use the Scanning Window variant. Additionally, such an attack would be easily detectable after the fact and result in loss of reputation of the provider of our service and would thus likely only be profitable for high value transactions for which most merchants would probably run a full node.

We conclude that BITE can provide as much security and privacy as traditional lightweight clients even given a full break of SGX. This is in contrast to the naive solution of storing the clients' private keys in the enclave and using it as a remote wallet. Lastly, we emphasize that our approach and BITE as a solution are not limited to SGX. Our main ideas could most likely be applied to other TEEs as well, such as the open-source Keystone TEE [1], thus reducing the reliance on SGX (and thereby Intel) even further.

## 6 Performance Evaluation

In this section, we describe our implementation and provide performance evaluation results.

### 6.1 Implementation Details

The centerpiece of our system is an original blockchain parser. For TLS connections we use the *mbed-tls* library from ARM [37]. Table 1 shows the trusted computing base.

**Scanning Window.** The implementation of Scanning Window is very small since it only involves scanning the blockchain and does not have to keep state. The network code including the *mbed-tls* library contributes the most to the TCB with over 96%. The same work for matching and non-matching transactions is performed in order to keep the scanning time per block constant for all requests.

The response size per block allows for around 5 transactions. We believe this is a reasonable choice that satisfies common usage patterns for light clients. For  $n$  included and  $N$  total transactions in the block, an upper bound for the Merkle path size is  $n * \log(N)$  and each entry is 32 bytes long. This results in an approximate upper bound of 2.2kB for  $N = 4000$ , the current limit in Bitcoin. As of today (November 2018) the average transaction size is around 500 bytes, therefore, a response size per block of 5kB is enough to fit

around 5 transactions ( $5 * 500B + 2200B < 5kB$ ). If more or larger transactions are found, following from Section 4, the enclave scans more blocks of the blockchain until the response can fit all requested transactions.

**Oblivious Database.** The implementation of Oblivious Database is more complex than Scanning Window and the enclave has to keep state and store a large UTXO set on disk. At the time of writing, the UTXO size (indexed by Bitcoin address) is around 3GB while our ORAM overhead accounts for 2 times the original size, totaling around 6GB.

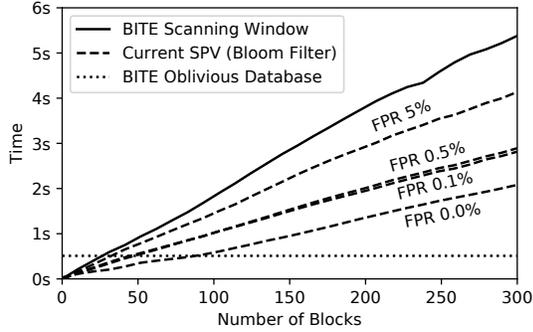

We use Path ORAM to store the UTXO set and have evaluated various chunk sizes for the implementation. The chosen chunk size accounts for 32kB, meaning a single chunk can fill up to 32kB with outputs from one address. If an address has more unspent outputs, the outputs are stored in multiple chunks. Assuming an average output size of 100B, one ORAM read can return up to 320 outputs for one address. The outputs are grouped by the receiving address and then ordered alphabetically. This is necessary in order to keep the size of the index small enough to fit in the enclave's memory. In the worst case the maximum index size involves the lower and upper limits for addresses (20B) and transaction hashes (32B) for every ORAM block resulting in a maximum of  $(8GB/32kB) \cdot (32B * 2 + 20B * 2) \approx 19.5MB$ .

To set the response size, we analyzed the typical unspent outputs per active address in the Bitcoin network. Our results show that 95% of all addresses have 5 or fewer unspent outputs and 98% have fewer than 12 outputs. Based on this data, we settled on 12 average outputs per request, resulting in around 1.2kB.

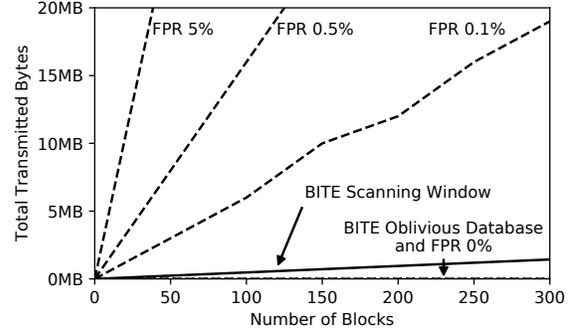

### 6.2 Performance Results and Comparison

In this section, we evaluate both variants of BITE and compare them to the current SPV performance using *python-bitcoinlib* [53]. The focus is put on three different metrics: processing time, communication overhead, and storage requirements. Processing time encompasses both the request handling from the client to the enclave as well as the time needed for the enclave to update the UTXO for new blocks. Communication overhead is evaluated through the response size, thus directly affecting the client's necessary bandwidth. Lastly, we report the necessary storage requirements on the full nodes that these system need for operation. A summary of all reported results can be found later on in Table 3.

Note that in all our data points, the TLS handshake times are omitted. Matetic et al. [40] report around 100ms for a new handshake and <10ms for TLS session resumption using *mbed-tls* in SGX. We do not evaluate the performance of a client since the client-side storage and network overhead are insignificant. We tested our implementation on an Intel i7-8700k with a Samsung 960 SSD for local storage.

(a) **Processing cost (client request)** for Scanning Window, Oblivious Database and current SPV protocols using Bloom filters.

(b) **Communication cost** for Scanning Window, Oblivious Database and current SPV protocols using bloom filters.

Figure 6: Performance evaluation of Scanning Window and Oblivious Database.

	$t_m$		
	5kB	10kB	20kB
Blocks			
100	0.7s ( $\pm 0.2s$ )	1.3s ( $\pm 0.5s$ )	2.7s ( $\pm 0.9s$ )
200	0.7s ( $\pm 0.2s$ )	1.4s ( $\pm 0.5s$ )	2.8s ( $\pm 0.9s$ )
300	0.7s ( $\pm 0.2s$ )	1.5s ( $\pm 0.5s$ )	3.0s ( $\pm 0.9s$ )

Table 2: Processing time per block with oblivious execution for Scanning Window depending on the number of requested blocks and the temporary size, averaged over 100 blocks.

**Processing.** Figure 6a shows the processing cost to filter blocks for BITE and current SPV protocols. Note that the measurements in Figure 6a do not account for the network speed. For client update requests over the last 100 blocks, the current SPV mode takes 0.62s, 1.06s, 1.06s, 1.5s, with the false positive rates of Bloom filters set to 0.0% 0.1%, 0.5% and 5%, respectively. Note that the numbers regarding standard SPV with the Bloom filter false positive rate of 0.0% actually indicates a solution with no privacy, e.g. the light client sends only his addresses in the request without any masquerading.

For the Scanning Window variant without side-channel protections we report 1.9s, corresponding to an 81% overhead compared to the SPV with FPR 0.1% and 0.5%. If the side-channel protection is added to Scanning Window, the oblivious execution and memory access adds a significant overhead. Table 2 shows the time per block for various requests and  $t_m$  size. Higher  $t_m$  allows to cope with high variance of relevant activity within the requested blocks. Note that the blocks vary in size, and thus the time per block fluctuates a lot leading to a high standard deviation. Synchronizing 100 blocks with  $t_m = 5kB$  takes around 73 seconds corresponding to an overhead of approximately 40x. Note that the oblivious Scanning Window variant is not shown in Figure 6a due to its size.

In our Oblivious Database variant, the unspent outputs are directly fetched from the enclave UTXO and the individual blocks are not scanned. Thus, the performance does not de-

pend on the client’s last known block, but only on the ORAM database access times. A request that fetches the information regarding 10 client addresses accounts only for 0.5s and is completely independent on the number of requested blocks, thus making it even faster than the standard SPV mode used without any privacy protections.

Contrary to the Scanning Window, in the Oblivious Database variant, the enclave needs to update its UTXO set after each new block arrives in the ORAM database which takes 78.5s. To reach permanent availability we propose to use 2 systems in parallel which update with an offset between each other. If a user requests the result from a node that is not fully up to date, the remaining blocks can be scanned by utilizing oblivious Scanning Window. The number of clients that can be served by a single SGX enclave can be estimated by using around 120s (pessimistic estimate) for updating the state and then the remaining 8 out of 10 minutes (Bitcoin block interval) to continuously answer client requests, leading to an approximate 10000 clients per enclave.

**Communication.** Figure 6b shows the bandwidth comparison between all discussed protocols. Our variants use significantly smaller response sizes compared to SPV since they do not need to hide relevant information with false positives. A device with a decent 4G connection that operates at 100Mbit/s additionally requires around 1.4s to retrieve 100 blocks (17MB) with the current SPV protocol and a 0.5% false positive rate while Scanning Window only takes 0.04s (500kB). The Oblivious Database variant reduces the communication overhead even more and accounts only for 0.0001s (only 12kB), which is insignificantly small since only unspent outputs are included and not the entire transaction information along with the Merkle paths. The SPV with no privacy protections performs slight less effective than the Oblivious Database of BITE as it was the case when the processing performance was compared.

	Processing		Communication	Storage		Leakage Protection
	Request	UTXO Update	Response	Blockchain	UTXO	
Scanning Window <sup>1</sup>	1.9s	-	500kB	200GB	0	✓/✗ <sup>4</sup>
Oblivious SW <sup>1</sup>	73s	-	500kB	200GB	0	✓
Oblivious Database <sup>3</sup>	0.5s	78.5s	12kB	50MB <sup>5</sup>	6GB	✓
Stan. SPV FPR 0.5% <sup>1</sup>	1.1s	≈2s	17MB	200GB	2.8GB	✗
Stan. SPV FPR 0.0% <sup>1,2</sup>	0.6s	≈2s	14kB	200GB	2.8GB	✗

<sup>1</sup> For 100 blocks. <sup>2</sup> SPV with no privacy protection. <sup>3</sup> For 10 addresses.  
<sup>4</sup> Protects against external leakage but not side-channels.  
<sup>5</sup> Only the block headers need to be stored.

Table 3: Performance comparison and requirements on the full node for supporting light clients.

**Storage.** The SPV mode has to store both the whole blockchain (200GB) and the UTXO set (2.8GB), while our Scanning Window variant only needs to store the blockchain. Moreover, our Oblivious Database variant does not need the whole blockchain (except during initialization) but only the block headers (50MB in total) and the special enclave UTXO stored in the ORAM database. This database accounts to 6GB, a 100% overhead compared to the regular UTXO set, due to the ORAM algorithm requirements. It is clear that both our variants require less storage, and our Oblivious Database variant’s requirements are insignificant compared to all mentioned solutions.

**Comparison of BITE variants.** Table 3 shows a performance comparison between all our variants and the standard SPV mode from the full node’s perspective. The performance of Scanning Window is heavily dependent if side-channels are a concern. The original Scanning Window offers a slightly worse performance than the standard SPV but offers increased privacy, protecting against external leakage, and requires significantly less bandwidth. Adding protection from side-channels greatly increases the processing time, while the communication load stays the same. Oblivious Database, on the other hand, offers the same full privacy guarantees as the oblivious Scanning Window, and has the smallest footprint in both the processing time and the network overhead. The enclave UTXO does require regular updating affecting the uptime. However, the previously mentioned solution of having two parallel enclaves with operation offset effectively removes this limitation. In conclusion, we have shown that our variants offer comparable or better performance with increased end client’s privacy.

**Comparison to side-channel protection systems.** Finally, we compare the performance and security of BITE to previous SGX side-channel protection systems. For our comparison we use Raccoon [47] that addresses internal leakage due to secret-dependent memory accesses and

	Leakage			Performance Overhead
	External	Internal	Response Size	
Raccoon[47]	✗	✓	✗	~ 100x <sup>1</sup>
Obliviate[14]	✓	✗	✗	> 4x <sup>1</sup>
Raccoon[47] + Obliviate[14]	✓	✓	✗	100x – 400x <sup>2</sup>
BITE Scanning Window <sup>3</sup>	✓	✓	✓	40x
BITE Oblivious Database	✓	✓	✓	1x

<sup>1</sup> Based on the performance evaluation of [47] and [14].  
<sup>2</sup> Combination of the two primitives can yield an overhead in this range.  
<sup>3</sup> Fully oblivious Scanning Window variant.

Table 4: Performance overhead and security comparison between existing primitives and BITE.

Obliviate [14] that addresses external leakage due to file accesses. We note that ZeroTrace [49] also provides similar external leakage protection as Obliviate, but since the ZeroTrace paper does not report performance overhead numbers suitable for comparison, we exclude it from our discussion.

Table 4 summarizes our comparison. By applying Raccoon to the target enclave code, the performance overhead of the enclave’s execution can range up to 1000x depending on the complexity of the original code that is made oblivious. In our case, the complexity of the original code matches the examples that report the overhead of around 100x. Applying techniques from Obliviate can cause a performance overhead of >4x. Neither Raccoon nor Obliviate alone provide full leakage protection, as Raccoon prevents only from internal leakage and Obliviate protects only against external leakage. Neither of these two systems protects against leakage from response sizes. The combination of Raccoon and Obliviate would protect both internal and external leakage, but still not leakage from response sizes. We estimate that the combined overhead of these two protection tools would amount to 100x-400x.

Our fully oblivious Scanning Window variant has a performance overhead of 40x while the Oblivious Database variant has practically no overhead. More importantly, both of the BITE variants protect against external leakage, internal leakage, and leakage from the response sizes, and therefore achieve more complete protection than any of the previous solutions.

## 7 Discussion

**Usage and long-term privacy.** Lightweight clients can use BITE in different ways and the chosen usage model can have implications on the clients’ long-term privacy. For example, in what we consider *non-recommended usage*, the client (i) performs payment verification requests only when the payment appears in the ledger, (ii) always uses the same full node for verification, and (iii) only uses a single or few Bitcoin address. If all of the above conditions are met, although the adversary controlling the full node does not learn the client’s address from a single verification request, he might be able to *correlate* the timing of the verification re-

quest events and the Bitcoin addresses visible in the ledger at roughly the same time, and thus construct a set of candidate addresses that may belong to the served client. We acknowledge that our solution cannot eliminate this type of correlation completely. However, we stress that such correlation would require long-term tracking of verification requests from the adversary and that the same limitation applies to any light client payment verification scheme.

In *recommended* usage of BITE, the client (i) uses different full nodes for payment verification, (ii) regularly uses fresh Bitcoin addresses (e.g., using an HD wallet [57]), and (iii) introduces unpredictability to the timing pattern of payment verification requests like a small number of extra requests at random time points. Following such a usage model, the above mentioned correlation becomes very difficult.<sup>2</sup>

**Large responses.** Some client requests might result in a larger response than our defined threshold for message size. As our performance analysis shows, the number of these requests is almost negligible. However, our mechanism still allows these types of request with the distinctive factor that the client would have to request them in batches. For example, if a client in the Scanning Window variant requests transactions for 10 of his addresses from the last 300 blocks using the full-side-channel protection, there might be more transaction data than the  $300 * t$  kB message size. In this case, the enclave sets a flag indicating there is more information to be delivered. After receiving the response, the client can repeat the request with the defined flag and receive the rest of the information. The protocol operates in the same way, thus no distinction between these two requests can be observed by the attacker. However, the attacker can see the repeated request and infer that the specific client has more transactions of interest in the designated blocks. To mitigate this problem one could wait a period of time before requesting the rest of the response, obfuscate the IP address or change to a completely different service provider (another enclave) for finishing the request.

**Denial of service.** A malicious user might attempt DoS by asking for a very long scan window, incurring large processing times for full nodes and making the service momentarily unavailable for other clients. DoS (and spam) are common in systems where there is no significant cost involved (e.g., sending 1M emails is practically free). In our setting, one could easily remedy such denial of service attacks by applying fees based on the nature of the request. Large balance updates for lightweight clients would incur higher costs than just frequent updates, thus limiting the attacker from

<sup>2</sup>To quantify how accurately the adversary can correlate the client's addresses with these best practices, would be an interesting direction for future work. As building an accurate model would require collecting significant amount data about the behavioral patterns of light clients, we consider this task a research project on its own and outside our scope.

performing “free” DoS attacks. On the other hand, a malicious node can easily block all enclave messages or interrupt enclave execution, thereby preventing the enclave to access the blockchain, update its UTXO or serve client requests. This however falls in a domain which is impossible to fully prevent. If this would occur, the light client can just send its request to another enclave hosted by another entity.

**Unbounded enclave memory.** The performance of our system is mostly bounded by the slower disk operations. However, if future versions of Intel SGX would allow more enclave memory (i.e., currently the limit is 128MB without the expensive page swapping) ranging up to the RAM limit on the residing platform, one could keep the UTXO database and all other security critical data in the memory and not on the disk, similar to recently proposed SGX-based in-memory database systems like EnclaveDB [46].

## 8 Related Work

**Lightweight client privacy.** The idea of light clients for Bitcoin was already included in the Bitcoin paper by Satoshi Nakamoto [44] in the form of *Simple Payment Verification* (SPV). Hearn and Corallo later introduced Bloom filters [18] in BIP 37 [31] that allow a client to probabilistically request a subset of all transactions in a block to mask which addresses are owned by the client. Gervais et al. later showed that the information leaked by the use of Bloom filters in Bitcoin can in many cases enable the identification of client addresses [25]. Hearn later expanded on these issues and discussed the difficulties of solving them [30].

Osuntokun et al. recently proposed modifications to Bitcoin nodes and lightweight clients that move the application of the filter to the client [45]. Full nodes create a filter (with a low false positive rate) for the set of all transactions in a block. A lightweight client then fetches the filter from one or more full nodes and can then check whether the block contains transactions that she is interested in. If that is the case, the client will request the full block from any node.

This approach suffers from a number of shortcomings. First, the gained privacy largely depends on the client behavior and how well the client is connected to distinct entities. If the client does not request the filter headers from multiple entities and then requests the blocks from a different one, she can be easily tricked into revealing her addresses by using forged filters: A node prepares a filter matching half of all addresses and sends it to the client. If the client requests the block, at least one of her addresses lies within that set, otherwise all of her addresses lie in the other half. The node can then further reduce the possible set using binary search by sending modified filters for the following blocks, allowing bitwise recovery of client addresses. Second, depending on how often a transaction is of interest to the client, she might

end up downloading the full blockchain after all. Since the client always either requests the full block or nothing at all, she will download almost every block if a large fraction of blocks contain at least one transaction that is of interest.

Other research on Bitcoin privacy shows that using different heuristics, large parts of the Bitcoin transaction graph can be deanonymized [16, 41]. These techniques are orthogonal to the problem of light client privacy and out of our scope.

Lastly, there exist alternative solutions that tackle limited computation abilities of light clients, such as VerSum [55]. The main idea is that the complex computation is outsourced to a set of remote servers. Even though these solutions do not focus on privacy preservation directly, they do offer alternative ways to construct support systems for light clients that do not require the creation of UTXO type databases for proving correctness.

**SGX Leakage Protection.** During the last few years, the research community has studied information leakage from SGX enclaves extensively and proposed a number of defenses. In this section we explain why none of the existing systems solves our problem directly and which prior systems use similar protective primitives as our solution.

Raccoon [47] addresses both internal and external information leakage for both code and data accesses. For control-flow obfuscation, Raccoon uses taint analysis to determine execution paths that should be hidden and transforms enclave code such that it executes extraneous decoy paths to hide the enclave’s actual control flow. The basic building block for such control-flow obfuscation is the `cmov` instruction that we use as well. Raccoon also uses Path ORAM to hide external secret-dependent data accesses and “streaming” over data structures (i.e., accessing every element) in the internal enclave memory. The main difference between Raccoon and our solution is that by tailoring our implementation, we avoid the need for taint analysis and extra decoy paths enabling a more efficient solution.

Other related systems include Cloak [28] that prevents cache leakage using hardware-based transactional memory features in processors; ZeroTrace [49] and Obliviate [14] that provide a library for data structures protected using ORAM; DR.SGX [19] that randomizes and periodically re-randomizes all data locations in enclave’s memory with cache-line granularity; and, T-SGX [51] and Deja Vu [22] that detect and prevent side-channel attacks based on repeated interrupts. The main limitation of Cloak is that it requires hardware features that are not available on all SGX CPUs and it only prevents cache-based leakage. ZeroTrace and Obliviate are limited to data access protection and does not prevent leakage from secret-dependent control flow. DR.SGX is also limited to data accesses and imposes a high performance overhead when configured to prevent all leakage. T-SGX and Deja Vu are limited to attacks that perform repeated interrupts (subset of known attacks).

Oblix [42] presents a new ORAM algorithm tailored to SGX. We use Path ORAM, but our solution is agnostic to the used ORAM algorithm and we could easily replace it.

## 9 Conclusion

Improved user privacy is one of the main goals of decentralized currencies like Bitcoin. However, payment verification requires downloading and processing the entire chain which is impossible for most mobile clients. Therefore, all popular blockchains support simplified verification modes where lightweight clients can verify transactions with the help of full nodes. Unfortunately, such payment verification does not preserve user privacy and thus defeats one of the main benefits of using systems like Bitcoin. In this paper, we have proposed a new approach to improve the privacy of lightweight clients using trusted execution. We have shown that our solution provides strong privacy protection and additionally improves performance of current lightweight clients. We argue that BITE is the first practical solution to ensure privacy for light clients, such as mobile devices, in Bitcoin.

## Acknowledgments

The research work leading to these results has been supported by Zurich Information Security and Privacy Center (ZISC). We would also like to thank our shepherd Rob Jansen for his insightful comments.

## A Intel SGX

Intel’s SGX [23, 32] entails a security enhancement for new Intel CPUs in form of a TEE for security-critical applications in commodity PC platforms. The SGX architecture enables protected applications, called *enclaves* that are *isolated* from software running outside of the enclave. This isolation protects the integrity and confidentiality of the enclave’s execution from any malicious software running on the same system, including BIOS, OS and hypervisor, or even malicious peripherals such as compromised network cards [56, 34, 29]. Enclave memory is handled in plaintext only inside the processor and is encrypted by the processor whenever it leaves the CPU (e.g., to DRAM) to ensure that neither the OS nor malicious hardware can access it.

Even though the OS is untrusted, it is responsible for starting and managing enclaves. To protect the integrity of the execution, the CPU securely records all initialization actions to create a *measurement* that records the code and initial state of the enclave. This can be later used by a third party to verify that the correct code is running on the system supported by SGX. This process is called *remote attestation*. A system service called Quoting Enclave signs the attestation statement – which contains the mentioned measurements – for remote verification. Using an online attestation service run by Intel, the verifier can check that signature. An enclave can attach data to the attestation statement, such as a public key, that it sends to the verifier. This can be used to establish a secure communication channel to an enclave.

In addition, SGX enables enclaves to store data for persistent storage in an encrypted form through a process called *sealing*. The processor provides a sealing key that can only be accessed by the same enclave running on the same platform, i.e. only the enclave that sealed data can later unseal it. This provides confidentiality and integrity for the stored data, but it does not protect from so called rollback attacks [39] when the enclave is restarted. Finally, enclaves cannot execute system calls and do not have access to secure peripherals. For this reason, software using SGX has to be split into two parts, a protected enclave and an unprotected component that runs in normal user space and handles communication with the OS, i.e. operations concerning networking and file accesses. For further details, we refer the reader to [23, 32].

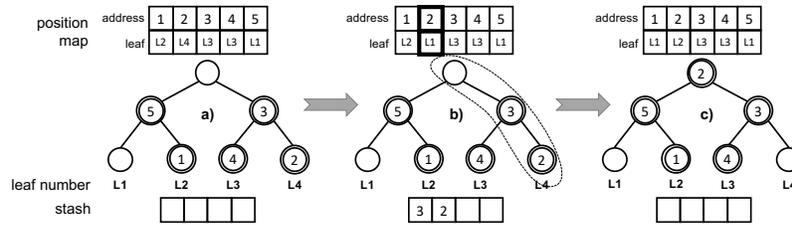

Figure 7: a) The client wants to access the chunk 2 that is stored in Path ORAM. b) The position map specifies that the chunk 2 is on the path to leaf 4. Therefore, the server reads all entries on the path into the stash and re-randomizes the position map entry of the requested chunk. c) The server writes back as many chunks as possible on the previously read path.

## B Oblivious RAM

Oblivious RAM (ORAM) [26], is a well-known technique that hides access patterns to an encrypted storage medium. A typical ORAM model is one where a trusted client wants to store sensitive information on an untrusted server. Encrypting each data record before storing it on the server provides confidentiality, but access patterns to stored encrypted records can leak information, such as correlation of multiple accesses to the same record. The intuition behind the security definition of ORAM is to prevent the adversary from learning anything about the access pattern. In ORAM, the adversary does not learn any information about which data is being accessed and when, whether the same data is being repeatedly accessed (i.e., unlinkability), the pattern of the access itself, and lastly the purpose, type of the access (i.e., write or read). However, one should note that ORAM techniques cannot hide access timing.

In this work, we use a popular and simple algorithm called Path ORAM [52] that provides a good trade-off between client side storage and bandwidth. The storage is organized as a binary tree with buckets containing  $Z$  chunks each. The

position of each chunk is stored in a *position map* that maps a database entry to a leaf in the tree, and for every access the leaf of the accessed entry is re-randomized. A small amount of entries is stored in a local (i.e., memory) structure – *stash*.

Every access involves reading all buckets of a path from the root to a leaf into the *stash* and then writing back new or old re-randomized data from the *stash* to the same path resulting in an overhead of  $O(\log N)$  read/write operations. If the requested chunk is already in the stash, an entire path still gets read and written. The summary of ORAM operations is:

- (1) get leaf from *position map* and generate new random leaf for the database entry. Insert it into the *position map*, read all buckets along the path to the leaf and put them into the *stash*
- (2) if access is a write, replace the specified chunk in the stash with the new chunk
- (3) write back some chunks from the *stash* to the path. Chunks can only be put into the path if their leaf from the *position map* allows it. Chunks are pushed down as far as possible into the tree to minimize *stash* capacity.
- (4) return requested chunk

# FASTKITTEN: Practical Smart Contracts on Bitcoin

## Abstract

Smart contracts are envisioned to be one of the killer applications of decentralized cryptocurrencies. They enable self-enforcing payments between users depending on complex program logic. Unfortunately, Bitcoin – the largest and by far most widely used cryptocurrency – does not offer support for complex smart contracts. Moreover, simple contracts that can be executed on Bitcoin are often cumbersome to design and very costly to execute. In this work we present FASTKITTEN, a practical framework for executing arbitrarily complex smart contracts at low costs over decentralized cryptocurrencies which are designed to only support simple transactions. To this end, FASTKITTEN leverages the power of trusted computing environments (TEEs), in which contracts are run off-chain to enable efficient contract execution at low cost. We formally prove that FASTKITTEN satisfies strong security properties when all but one party are malicious. Finally, we report on a prototype implementation which supports arbitrary contracts through a scripting engine, and evaluate performance through benchmarking a provably fair online poker game. Our implementation illustrates that FASTKITTEN is practical for complex multi-round applications with a very small latency. Combining these features, FASTKITTEN is the *first* truly practical framework for complex smart contract execution over Bitcoin.

## 1 Introduction

Starting with their invention in 2008, decentralized cryptocurrencies such as Bitcoin [51] currently receive broad attention both from academia and industry. Since the rise of Bitcoin, countless new cryptocurrencies have been launched to address some of the shortcomings of Nakamoto’s original proposal. Examples include Zerocash [47] which improves on Bitcoin’s limited anonymity, and Ethereum [16] which offers complex smart contract support. Despite these developments, Bitcoin still remains by far the most popular and intensively studied cryptocurrency, with its current market capitalization of \$109 billion which accounts for more than 50% of the total cryptocurrency market size [2].

A particular important shortcoming of Bitcoin is its limited support for so-called smart contracts. Smart contracts are (partially) self-enforcing protocols that allow emitting transactions based on complex program logic. Smart contracts enable countless novel applications in, e.g., the financial industry or for the Internet of Things, and are often quoted as a glimpse into our future [9]. The most prominent cryptocurrency that currently allows to run complex smart contracts is Ethereum [16], which has been designed to support Turing complete smart contracts. While Ethereum is continuously gaining popularity, integrating contracts directly into a cryptocurrency has several downsides as frequently mentioned by the advocates of Bitcoin. First, designing large-scale secure distributed systems is highly complex, and increasing complexity even further by adding support for complex smart contracts also increases the potential for introducing bugs. Second, in Ethereum, smart contracts are directly integrated into the consensus mechanics of the cryptocurrency, which requires in particular that all nodes of the decentralized system execute all contracts. This makes execution of contracts very costly and limits the number and complexity of applications that can eventually be run over such a system. Finally, many applications for smart contracts require confidentiality, which is currently not supported by Ethereum.

There has been significant research effort in addressing these challenges individually. Some works aim to extend the functionality of Bitcoin by showing how to build contracts over Bitcoin by using multiparty computation (MPC) [37, 38, 40], others focus on achieving privacy-preserving contracts (e.g., Hawk [35], Ekiden [19]) by combining existing cryptocurrencies with trusted execution environments (TEEs). However, as we elaborate in Section 2, all of these solutions suffer from various deficiencies: they cannot be integrated into existing cryptocurrencies such as Bitcoin, are highly inefficient (e.g., they use heavy cryptographic techniques such as non-interactive zero-knowledge proofs or general MPC), do not support money mechanics, or have significant financial costs due to complex transactions and high collateral (money blocked by the parties in MPC-based solutions).

In this work, we propose FASTKITTEN, a novel system that leverages trusted execution environments (TEEs) utilizing well-established cryptocurrencies, such as Bitcoin, to offer full support for arbitrary complex smart contracts. We emphasize that FASTKITTEN does not only address the challenges discussed above, but is also highly efficient. It can be easily integrated into existing cryptocurrencies and hence is ready to use today. FASTKITTEN achieves these goals by using a TEE to isolate the contract execution inside an enclave, shielding it from potentially malicious users. The main challenges of this solution, such as for instance how to load and validate blockchain data inside the enclave or how to prevent denial of service attacks, are discussed in Section 3.1. Moving the contract execution into the secure enclave guarantees correct and private evaluation of the smart contract even if it is not running on the blockchain and verified by the decentralized network. This approach circumvents the efficiency shortcoming of cryptocurrencies like Ethereum, where contracts have to be executed in parallel by thousands of users. Most related to our work is the recently introduced Ekiden system [19], which uses a TEE to support execution of multiparty computations but does support contracts that handle coins. While Ekiden is efficient for single round contracts, it is not designed for complex reactive multi-round contracts, and their off-chain execution. The latter is one of the main goals of FASTKITTEN.

We summarize our main goals and contributions below.

- **Smart Contracts for Bitcoin:** We support arbitrary multi-round smart contracts executed amongst any finite number of participants, where our system can be run on top of any cryptocurrency with only limited scripting functionality. We emphasize that Bitcoin is only one example over which our system can be deployed today; even cryptocurrencies that are simpler than Bitcoin can be used for FASTKITTEN.
- **Efficient Off-Chain Execution:** Our protocol is designed to keep the vast majority of program execution off-chain in the standard case if all parties follow the protocol. Since our system incentivizes honest behavior for most practical use cases, FASTKITTEN can thus run in real-time at low costs.
- **Formal Security Analysis:** We formally analyze the security of FASTKITTEN in a strong adversarial model. We prove that either the contract is executed correctly, or all honest parties get their money back that they have initially invested into the contract, while a malicious party loses its coins. Additionally, the service provider who runs the TEE is provably guaranteed to not lose money if he behaves honestly.
- **Implementation and benchmarking:** We provide an in-depth analysis of FASTKITTEN’s performance and costs and evaluate our framework implementation with respect to several system parameters by offering benchmarks on real-world use cases. Concretely, we show that

online poker can run with an overall match latency of 45ms and costs per player are in order of magnitude of one USD, which demonstrates FASTKITTEN’s practicality.

We emphasize that FASTKITTEN requires only a single TEE which can be owned either by one of the participants or by an external service provider which we call the *operator*. In addition, smart contracts running in the FASTKITTEN execution framework support private state and secure inputs, and thus, offer even more powerful contracts than Ethereum. Finally, we stress that FASTKITTEN can support contracts that may span over multiple different cryptocurrencies where each participant may use her favorite currency for the money handled by the contract.

## 2 Related Work

Support for execution of arbitrary complex smart contracts over decentralized cryptocurrencies was first proposed and implemented by the Ethereum cryptocurrency. As pointed out in Section 1, running smart contracts over decentralized cryptocurrencies results in significant overheads due to the replicated execution of the contract. While there are currently huge research efforts aiming at reducing these overheads (for instance, via second layer solutions such as state channels [24, 49], Arbitrum [34] or Plasma [55], outsourcing of computation [58], or permissioned blockchains [46]), these solutions work only over cryptocurrencies with support complex smart contracts, e.g. over Ethereum. Another line of work, which includes Hawk [36] and the “Ring of Gyges” [33], is addressing the shortcoming that Ethereum smart contracts cannot keep private state. However, also these solutions are based on complex smart contracts and hence cannot be integrated into popular legacy cryptocurrencies such as Bitcoin, which is the main goal of FASTKITTEN.

In this section we will focus on related work, which considers smart contract execution on Bitcoin. We separately discuss multiparty computation based smart contracts and solutions using a TEE. We provide a more detailed discussion on how the above-mentioned Ethereum based solutions compare to FASTKITTEN in Appendix A. Additionally, in Section 8 we discuss some exemplary contract use cases and compare their execution inside FASTKITTEN with the execution over Ethereum.

**Multiparty computation for smart contracts** An interesting direction to realize complex contracts over Bitcoin is to use so-called multiparty computation with penalties [38–40]. Similar to FASTKITTEN these works allow secure  $m$ -round contract execution but they rely on the claim-or-refund functionality [39]. Such a functionality can be instantiated over Bitcoin and hence these works illustrate feasibility of generic contracts over Bitcoin. Unfortunately, solutions supporting generic contracts require complex (and expensive) Bitcoin transactions and high collateral locked by the parties which makes them impractical for most use-cases. Concretely, in

Approach	Minimal # TX	Collateral	Generic Contracts	Privacy
Ethereum contracts	$\mathcal{O}(m)$	$\mathcal{O}(n)$	✓	✗
MPC [38–40]	$\mathcal{O}(1)$	$\mathcal{O}(n^2m)$	✓	✓
Ekiden [19]	$\mathcal{O}(m)$	no support for money	✓	✓
<b>FASTKITTEN</b>	$\mathcal{O}(1)$	$\mathcal{O}(n)$	✓	✓

Table 1: Selected solutions for contract execution over Bitcoin and their comparison to Ethereum smart contracts. Above,  $n$  denotes the number of parties and  $m$  is the number of reactive execution rounds.

all generic  $n$ -party contract solutions we are aware of, each party needs to lock  $\mathcal{O}(nm)$  coins, which overall results in  $\mathcal{O}(n^2m)$  of locked collateral. In contrast, the total collateral in FASTKITTEN is  $\mathcal{O}(n)$ , see column “Collateral” in Table 1. It has been shown that for specific applications, concretely, a multi-party lottery, significant improvements in the required collateral are possible when using MPC-based solutions [48]. This however comes at the cost of an inefficient setup phase, communication complexity of order  $\mathcal{O}(2^n)$ , and  $\mathcal{O}(\log n)$  on-chain transactions for the execution phase. Let us stress that the approach used in [48] cannot be applied to generic contracts.

Overall, while MPC-based contracts are an interesting direction for further research, we emphasize that these systems are currently far from providing a truly practical general-purpose platform for contract execution over Bitcoin—which is the main goal of FASTKITTEN.

**TEEs for blockchains** There has recently been a large body of work on using TEEs to improve certain features of blockchains [10, 43, 59, 63, 64]. A prominent example is Teechain [43], which enables off-chain payment channel systems over Bitcoin. Most of these prior works do not use the TEE for smart contract execution. Some notable exceptions include Hawk [36] and the “Ring of Gyges” [33], who propose privacy preserving off-chain contracts execution, but, as already mentioned, do not work over Bitcoin.

Probably most related to our work is Ekiden [19], which proposes a system for private off-chain smart contract execution using TEEs. While Ekiden focuses on solutions over Ethereum, it does not require a powerful scripting language of the underlying blockchain technology – just like FASTKITTEN. Despite the conceptual similarities of Ekiden and FASTKITTEN, the goals of these systems are orthogonal. Ekiden aims at moving heavy smart contract execution off the chain in order to reduce the cost of executing complex contract functions. In contrast, FASTKITTEN focuses on efficient off-chain execution of multi-round contracts between a set of parties. Importantly, we require our system to natively handle coins of the underlying blockchain. A joint goal of both systems is to provide state privacy of the contracts.

Ekiden considers clients (contract parties) and computing

nodes which have a similar task as FASTKITTEN’s TEE operator since they also execute contracts inside a TEE. In contrast to FASTKITTEN, Ekiden sends the encryption of the resulting contract state to the blockchain after every function call. If a client requests another function call, a selected computing node takes the state from the blockchain, decrypts it inside its enclave and performs the contract execution. This implies that reactive multi-round contracts are very costly even in the standard case when all participating parties are honest (c.f. column “Minimal # TX” in Table 1).

Ekiden relies on multiple TEEs and guarantees service availability as long as at least one TEE is controlled by an honest computing node. We note in Section 9.2 that fault tolerance can be integrated into FASTKITTEN in a straightforward way. Additionally, Ekiden aims to achieve forward secrecy even if a small fraction of TEEs gets corrupted via, e.g., a side-channel attack. Their strategy is to secret-share a long-term secret key between the TEEs and use it to generate a short-term secret key every “epoch”. Hence, an attacker learning the short-term key can only decrypt state from the current epoch. While side-channel attacks are out of scope of this work, note that FASTKITTEN can achieve forward secrecy of states in case of side-channel attacks using the same mechanism as Ekiden. An important part of the FASTKITTEN construction is the fair distribution of coins through the enclave. Ekiden does neither model nor discuss the handling of coins. It is not straightforward to add this feature to their model since the contract state is encrypted and hence the money cannot be unlocked automatically on-chain.

### 3 Design

FASTKITTEN allows a set of  $n$  users  $P_1, \dots, P_n$  to execute an arbitrary complex smart contract over a decentralized cryptocurrency that only supports very simple scripts. Concretely, FASTKITTEN considers cryptocurrencies that, in addition to supporting simple transactions between users, offer so-called *time-locked transactions*. A transaction is time-locked if it is only processed and integrated into the blockchain after a certain amount of time has passed. Moreover, FASTKITTEN requires that transactions contain space for storing arbitrary raw data. We emphasize that these are very mild requirements on the underlying cryptocurrency that, for instance, are satisfied by the most prominent cryptocurrency Bitcoin.<sup>1</sup> FASTKITTEN leverages these properties together with the power of trusted execution environments to provide an efficient general-purpose smart contract execution platform.

As discussed in the introduction, a contract is a program that handles coins according to some—possibly complex—program logic. In this work, we consider  $n$ -party contracts, which are run among a group of parties  $P_1, \dots, P_n$  and have the following structure. During the initialization phase, the contract receives coins from the parties and some initial in-

<sup>1</sup>Bitcoin transactions can store up to 97 KB of data [44]; multiple transactions can be used for bigger payloads.

puts. Next, it runs for  $m$  reactive rounds, where in each round the contract can receive additional inputs from the parties  $P_i$ , and produces an output. Finally, after the  $m$ -th round is completed the contract pays out the coins to the parties according to its final state and terminates.

A key feature of FASTKITTEN is very low execution cost and high performance compared to contract execution over cryptocurrencies such as Ethereum. This is achieved by not executing contracts *by all parties maintaining the cryptocurrency* but instead running the contract within a TEE which could, e.g., be owned and operated by a single service provider which we call the *operator*  $Q$ . In the standard case when all parties are honest, FASTKITTEN runs the entire contract off-chain within the enclave and only needs to touch the blockchain during contract initialization and finalization. More concretely, during initialization, the parties transfer their coins to the enclave by time-locking coins with *deposit transactions*, while at the end of finalization the enclave produces transactions that transfer coins back to the users according to the results of the contract execution. These transactions are called *output transactions* and can be published by the users of the system to receive their coins.

### 3.1 Design Challenges of FASTKITTEN

Leveraging TEEs for building a general-purpose contract execution platform requires us to resolve the following main challenges.

**Protection against malicious operator.** The operator runs the TEE and hence controls its interaction with the environment (e.g., with other parties or the blockchain). Thus, the operator can abort the execution of the TEE, delay and change inputs, or drop any ingoing or outgoing message. To protect honest users from such an operator, the enclave program running inside the TEE must identify such malicious behavior and punish the operator. In particular, we require that even if the TEE execution is aborted, all parties must be able to get their coins refunded eventually. To achieve this, we let the operator create a so-called *penalty transaction*: the penalty transaction time-locks coins of the operator, which in case of misbehavior can be used to refund the users and punish the operator.

Note that designing such a scheme for punishment is highly non-trivial. Consider a situation where party  $P_i$  was supposed to send a message  $x$  to the contract. From the point of view of the enclave that runs the contract, it is not clear whether the operator was behaving maliciously and did not forward a message to the enclave, or, e.g., party  $P_i$  did not send the required message to the operator. To resolve this conflict, we leverage a challenge-response mechanism carried out via the blockchain. We emphasize that this challenge-response mechanism is only required when parties are malicious, and typically will not be executed often due to the high financial costs for an adversary.

**Verification of blockchain evidence.** To ensure that a malicious operator cannot make up false blockchain evidence, we need to design a secure blockchain validation algorithm which can efficiently be executed inside a TEE. We achieve this by simplifying the verification process typically carried out by full blockchain nodes by using a *checkpoint block* to serve as the initial starting point for verification. This drastically reduces blockchain verification time in comparison to verification starting from the genesis block. To further speed up the transaction verification, we only validate correctness of block headers. Finally, when the TEE needs to verify whether a certain transaction was integrated into a block, we set a minimum number of blocks that must confirm a transaction as part of the security parameter within our protocol. This guarantees that faking a valid-looking chain is computationally infeasible for a malicious operator. Finally, it is computationally infeasible for a malicious operator to load a fake (but valid-looking) chain into the enclave before the penalty transaction is published on the blockchain.

**Minimizing blockchain interaction.** Since blockchain interactions are expensive, FASTKITTEN only requires interaction with the blockchain in the initialization and finalization phases if all parties follow the protocol. As already discussed above, however, in case of malicious behavior FASTKITTEN may require additional interaction with the blockchain for conflict resolution. This is required to allow the TEE to attribute malicious behavior either to the operator or to some other participant  $P_i$  that provides input to the contract. We achieve this through a novel challenge-response protocol, where the TEE will ask the operator to challenge  $P_i$  via the blockchain. The operator can then either deliver a proof that he challenged  $P_i$  via the blockchain but did not receive a response, in which case  $P_i$  will get punished; or the operator receives  $P_i$ 's input and can continue with the protocol.

Of course, this challenge-response protocol adds to the worst-case execution time of our system, and additionally will result in fees for blockchain interaction. To address the latter, our protocol ensures that both parties involved in the challenge-response mechanism have to split the fees resulting from blockchain interaction equally.<sup>2</sup> This incentivizes honest behavior if parties aim to maximize their personal profits.

**Preventing denial of service attacks.** Complex smart contracts may take a very long time to complete, and in the worst case not terminate. Hence, a malicious party may carry out a denial-of-service attack against the contract execution platform, where the platform is asked to execute a contract that never halts. It is well known that determining whether a program terminates is undecidable. Hence, general-purpose contract platforms, such as Ethereum, mitigate this risk by letting users pay via fees for every step of the contract execution. This effectively limits the amount of computation that

---

<sup>2</sup>In the cryptocurrency community, this is often referred to as grieving factor 1 : 1, meaning that for every coin spent by the honest users on fees the adversary is required to also spend one coin.

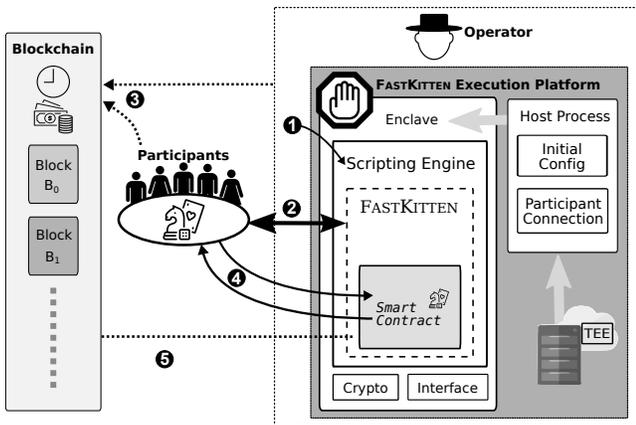

Figure 1: Architecture of the FASTKITTEN Smart Contract Execution Platform. Dashed arrows indicate interaction with the blockchain and non-dashed arrows depict communication between parties.

can be carried out by the contract. Since FASTKITTEN allows multiple parties to provide input to the contract in the same round, it might be impossible to decide which party (parties) caused the denial of service and should pay the fee. To this end, FASTKITTEN protects against such denial-of-service attacks using a time-out mechanism. As all users of the system (including the operator) have to agree on the contract to be executed, we assume that this agreement includes a limit on the maximum amount of execution steps that can be performed inside the enclave per one execution round. See Section 6.5 for more details.

### 3.2 Architecture and Protocol

To enable secure off-chain contract execution, our architecture builds on existing TEEs, which are widely available through commercial off-the-shelf hardware. In particular, our architecture can be implemented using Intel’s Software Guard Extensions (SGX) [4, 29, 45] which is a prominent TEE instantiation built into most recent Intel processors. SGX incorporates a set of new instructions to create, control and communicate with enclaves. While enclaves are part of a legacy host process, SGX enforces strict isolation of computation and memory between enclave and host process on the hardware level. Another prominent instantiation of the TEE concept is ARM TrustZone [6], which provides similar functionality for mobile devices. We note that only the operator  $Q$  is required to own TEE-enabled hardware.

As depicted in Figure 1, our FASTKITTEN Execution Facility is run by the operator  $Q$  and consists of a host process and an enclave. The untrusted host process takes care of setting up the enclave with an *initial config*, handles the *participant connections*, and blockchain communication over the network. While this means that  $Q$  has complete control over these parts, the influence of a malicious operator on a running enclave is limited: he can interrupt enclave execution, but not tam-

per with it. Further, the enclave will sign and hash all code and data as part of its *attestation* towards parties, so they can verify correctness of the setup before placing deposits. To support arbitrary contract functionality, FASTKITTEN includes a *scripting engine* inside the enclave and several helper libraries, such as the *Crypto library* to generate and verify transactions, and an *Interface library* to pass data between host process and enclave. The individual contracts are loaded into the FASTKITTEN enclave during the initialization of our protocol by the underlying host process and participants can verify that contracts are loaded correctly. Our protocol then proceeds in three phases, which we call *setup phase*, *round computation*, and *finalization phase*. Figure 1 depicts the architecture of the FASTKITTEN framework.

During the setup phase (Steps 1–3) the contract is loaded into the enclave. Using the TEE’s attestation functionality, all parties  $P_1, \dots, P_n$  can verify that this step was completed correctly. Then the operator and all parties block their coins for the contract execution. If any party aborts in this phase, the money is refunded to all parties that deposited money and the protocol stops. Otherwise, all parties receive a time-locked penalty transaction, needed in case  $Q$  aborts the protocol.

Afterwards, the round computation phase (Step 4) starts, in which  $Q$  sends the previous round’s output to all parties. If a party  $P_i$  receives such an output, which is correctly signed by the enclave, it signs and sends the input for the following round to  $Q$ . If all parties behave honestly,  $Q$  will forward the received round inputs to the enclave, which computes the outputs for the next round. In case that the enclave does not receive an input from party  $P_i$  the enclave needs to determine whether  $P_i$  failed to send its input or if  $Q$  behaved maliciously (e.g., by dropping the message). Therefore, the enclave will punish  $Q$  unless it can prove, that it sent the last round output to  $P_i$  but did not receive a response. This proof is generated via the blockchain:  $Q$  publicly challenges  $P_i$  to respond with the input for the next round by posting the output of the previous round to the blockchain. As soon as this challenge transaction is confirmed,  $P_i$  needs to respond publicly by spending the coins of the challenge transaction and include its input for the next round. If  $P_i$  responds,  $Q$  can extract  $P_i$ ’s input and continue with the protocol execution. If  $P_i$  did not respond,  $Q$  forwards the respective blocks as a transcript to the enclave, to prove that  $P_i$  misbehaved.<sup>3</sup> So, while a malicious party (or the operator) can force this on-chain challenge-response procedure without direct punishment, posting these transactions will also act against its own financial interests by extending the time lock of its own coins and leading to transaction fees. Nevertheless, such malicious behavior cannot prevent the fair termination of our protocol.

The last phase of the protocol is the payout phase (Step 5). In

<sup>3</sup>Alternatively, we could allow the operator to spend the challenge transaction after a timeout has passed. While this would result in easier verification for the TEE, the operator would need to publish an additional transaction, increasing both fees and the overall time for the challenge-response phase.

this phase the enclave returns the output transaction generated by the *Crypto library*. This transaction distributes the coins according to the terminated contract. In case of a protocol abort, the coins initially put by the users will be refunded to all honest parties. If any party was caught cheating, this party will not receive back its coins. This means the money will stay in control of the enclave and will never be spent.

## 4 Adversary Model

The FASTKITTEN protocol is executed  $n$  parties  $P_1, \dots, P_n$  and an operator  $Q$  (who owns the TEE) with the goal of executing a smart contract  $C$ . FASTKITTEN's design depends on a TEE to ensure its confidentiality and integrity. Our design is TEE-agnostic, even if our implementation is based on Intel SGX. Recent research showed that the security and privacy guarantees of SGX can be affected by memory-corruption vulnerabilities [11], architectural [13] and micro-architectural side-channel attacks [60]. For the operator, we assume that  $Q$  has full control over the machine and consequently can execute arbitrary code with supervisor privileges. While memory corruption vulnerabilities can exist in the enclave code, a malicious operator must exploit such vulnerabilities through the standard interface between the host process and the enclave. For the enclave code, we assume a common code-reuse defense such as control-flow integrity (CFI) [3, 15], or fine-grained code randomization [23, 42] to be in place and active. Architectural side-channel attacks, e.g., based on caches, can expose access patterns [13] from SGX enclaves (and therefore our FASTKITTEN prototype). However, this prompted the community to develop a number of software mitigations [12, 18, 27, 56, 57] and new hardware-based solutions [22, 28, 52]. Microarchitectural side-channel attacks like Foreshadow [60] can extract plaintext data and effectively undermine the attestation process FASTKITTEN relies on, leaking secrets and enabling the enclave to run a different application than agreed on by the parties; however, the vulnerability enabling Foreshadow was already patched by Intel [32]. Since existing defenses already target SGX vulnerabilities and since FASTKITTEN's design is TEE agnostic (i.e., it can also be implemented using ARM TrustZone or next-generation TEEs), we consider mitigating side-channel leakage as an orthogonal problem and out of scope for this paper.

For our protocol we consider a *byzantine adversary* [41], which means that corrupted parties can behave arbitrarily. In particular, this includes aborting the execution, dropping messages, and changing their inputs and outputs even if it means that they will lose money. FASTKITTEN is secure even if  $n$  parties are corrupt (including the two cases where only the operator is honest, and only one party is honest but the operator is corrupt). We show that no honest party will lose coins, a corrupt party will be penalized and that no adversary can tamper with the result of the contract execution. While we prove security in this very strong adversarial model, we

additionally observe that incentive-driven parties (i.e., parties that aim at maximizing their financial profits) will behave honestly, which significantly boosts efficiency of our scheme. We stress that security of FASTKITTEN relies on the security of the underlying blockchain. We require that the underlying blockchain systems satisfies three security properties: *liveness*, *consistency* and *immutability* [26]. *Liveness* means that valid transactions are guaranteed to be included within the next  $\delta$  blocks. *Consistency* guarantees that eventually all users have the same view on the current state of the blockchain (i.e., the transactions processed and their order). In addition, blockchains also are *immutable*, which means that once transactions end up in the blockchain they cannot be reverted. Most blockchain based cryptocurrencies guarantee consistency and immutability only after some time has passed, where time is measured by so-called *confirmations*. A block  $b_i$  is confirmed  $k$ -times if there exists a valid chain extending  $b_i$  with  $k$  further blocks. Once block  $b_i$  has been sufficiently often confirmed, we can assume that the transactions in  $b_i$  cannot be reverted and all honest parties agree on an order of the chain  $(b_0, b_1, b_2, \dots, b_i)$ . For most practical purposes  $k$  can be a small constant, i.e., in Bitcoin it is generally believed that for  $k = 6$  a block can be assumed final.<sup>4</sup>

## 5 The FASTKITTEN Protocol

In this section we give a more detailed description of our protocol, which includes the specification of the protocol run by  $Q$  and honest parties  $P_1, \dots, P_n$ , all transactions and a description of the enclave program FASTKITTEN. The interaction between  $Q, P_i$  and the blockchain is depicted in Figure 2. We first describe the interactions with the blockchain and TEE.

### 5.1 Modeling the Blockchain

We will introduce some basic concepts of cryptocurrencies that are relevant for our work before we describe our high-level design. Cryptocurrencies are built using blockchains—a distributed data structure that is maintained by special parties called *miners*. The blockchain is comprised as a chain of blocks  $(b_0, b_1, b_2, \dots)$  that store the transactions of the system. The miners create new blocks by verifying new transactions and comprising them into new blocks that extend the tail of the chain. New blocks are created within some period of time  $t$ , where, for instance, in Bitcoin a new valid block is created every 10 minutes on average.

In cryptocurrencies users are identified by addresses, where an address is represented by a public key. To send coins from one address to another, most cryptocurrencies rely on transactions. If a user  $A$  with address  $pk_A$  wants to send  $x$  coins to user  $B$  with address  $pk_B$ , she creates a transaction tx which states that  $x$  coins from address  $pk_A$  are transferred to  $pk_B$ . Such a

<sup>4</sup>We notice that in blockchain-based cryptocurrencies there is no guaranteed finality, and even for very large values of  $k$  blocks can be reverted in principle. We emphasize however that even for small values of  $k$  reverting blocks becomes impossible in practice very quickly.

transaction  $\text{tx}$  is represented by the following tuple:

$$\text{tx} := (\text{tx.Input}, \text{tx.Output}, \text{tx.Time}, \text{tx.Data}),$$

where  $\text{tx.Input}$  refers to a previously unspent transaction,  $\text{tx.Output}$  denotes the address to which  $\text{tx.Value}$  are going to be transferred to. Note that a transaction  $\text{tx}$  is unspent if it is not referred to by any other transaction in its Input field. Further,  $\text{tx.Time} \in \mathbb{N}$ , which denotes the block counter after which this transaction will be included by miners, i.e.,  $\text{tx}$  can be integrated into blocks  $b_i, b_{i+1}, \dots$ , where  $i = \text{tx.Time}$ . Finally,  $\text{tx.Data} \in \{0, 1\}^*$  is a data field that can store arbitrary raw data. Similar to [5], we will often represent transactions by tables as shown exemplarily in the table below, where the first row of the table gives the name of the transaction.

Transaction $\text{tx}$	
$\text{tx.Input}$ :	Coins from unspent input transaction
$\text{tx.Output}$ :	Coins to receiver address
$\text{tx.Time}$ :	Some timelock (optional)
$\text{tx.Data}$ :	Some data (optional)

Notice that a transaction  $\text{tx}$  only becomes valid if it is signed with the corresponding secret key of the output address from  $\text{tx.Input}$ . We emphasize that the properties described above are very mild and are for instance achieved by the most prominent cryptocurrency Bitcoin.

In order to model interaction with the cryptocurrency, we use a simplified blockchain functionality  $\text{BC}$ , which maintains a continuously growing chain of blocks. Internally it stores a block counter  $c$  which starts initially with 0 and is increased on average every  $t$  minutes. Every time the counter is increased, a new block will be created and all parties are notified. To address the uncertainty of the block creation duration we give the adversary control over the exact time when the counter is increased but it must not deviate more than  $\Delta \in [t - 1]$  seconds from  $t$ . Whenever any party publishes a valid transaction, it is guaranteed to be included in any of the next  $\delta$  blocks.

Parties can interact with the blockchain functionality  $\text{BC}$  using the following commands.

- $\text{BC.post}(\text{tx})$ : If the transaction  $\text{tx}$  is valid (i.e., all inputs refer to unspent transactions assigned to creator of  $\text{tx}$  and the sum of all output coins is not larger than the sum of all input coins) then  $\text{tx}$  is stored in any of the blocks  $\{b_{c+1}, \dots, b_{c+\delta}\}$ .
- $\text{BC.getAll}(i)$ : If  $i < c$ , this function returns the latest block count  $c - 1$  and a list of blocks that extend  $b_i$ :  $\mathbf{b} = (b_{i+1}, \dots, b_c)$
- $\text{BC.getLast}()$ : The function  $\text{getLast}$  can be called by any party of the protocol and returns the last (finished) block and its counter:  $(c, b_c)$ .

For every cryptocurrency there must exist a validation algorithm for validating consistency of the blocks and transactions

therein, which we model using the function  $\text{Extends}$ . It takes as input, a chain of blocks  $\mathbf{b}$  and a checkpoint block  $b_{\text{cp}}$  and outputs 1 if  $\mathbf{b} = (b_{\text{cp}+1}, \dots, b_{\text{cp}+i})$  is a valid chain of blocks extending  $b_{\text{cp}}$  and otherwise it outputs 0. In Section 6 we give more details on the validation algorithm, and how this function is implemented for the Bitcoin system. Recall, that we assume an adversary which cannot compute a chain of blocks of length  $k$  by itself (c.f. Section 4). This guarantees that he cannot produce a false chain such that this function outputs 1. To make the position of some transaction  $\text{tx}$  inside a chain of blocks explicit, we write  $\ell := \text{Pos}(\mathbf{b}, \text{tx})$  when the transaction is part of the  $\ell$ -th block of  $\mathbf{b}$ . If the transaction is in none of the blocks, the function returns  $\infty$ . For more details on the transaction and block verification we refer the reader to [7, 26, 51].

## 5.2 Modeling the TEE

In order to model the functionality of a TEE, we follow the work of Pass et. al. [54]. We explain here only briefly the simplified version of the TEE functionality whose formal definition can be found in [54, Fig. 1]. On initialization, the TEE generates a pair of signing keys  $(\text{mpk}, \text{msk})$  which we call master public key and master secret key of the TEE. The TEE functionality has two enclave operations:  $\text{install}$  and  $\text{resume}$ . The operation  $\text{TEE.install}$  takes as input a program  $p$  which is then stored under an enclave identifier  $\text{eid}$ . The program stored inside an enclave can be executed via the second enclave operation  $\text{TEE.resume}$  which takes as input an enclave identifier  $\text{eid}$ , a function  $f$  and the function input  $\text{in}$ . The output of  $\text{TEE.resume}$  is the output  $\text{out}$  of the program execution and a quote  $\varrho$  over the tuple  $(\text{eid}, p, \text{out})$ . In the protocol description we abstract from the details how the users verify the quote that is generated through the enclave attestation. Since we only consider one instance  $E$  of the specific program  $p$ , we will simplify the resume command  $[\text{out}, \varrho] := \text{TEE.resume}(\text{eid}, f, \text{in})$  and write<sup>5</sup>:

$$[\text{out}, \varrho] := E.f(\text{in})$$

For every attestable TEE there must exist a function  $\text{vrfyQuote}(\text{mpk}, p, \text{out}, \varrho)$  which on input of a correct quote  $\varrho$  outputs 1, if and only if  $\text{out}$  was outputted by an enclave with master public key  $\text{mpk}$  and which indeed loaded  $p$ . Again, we assume that the adversary cannot forge a quote such that the function  $\text{vrfyQuote}()$  outputs 1. For more information on how this verification of the attestation is done in practice we refer the reader to [54].

## 5.3 Detailed Protocol Description

As explained in Section 3, our protocol  $\pi_{\text{FASTKITTEN}}$  proceeds in three phases. During the *setup phase* the contract is installed in the enclave, attested, and all parties deposit their

<sup>5</sup>Since we only need the quote of the first activation of  $E$ , we will omit this parameter from there on.

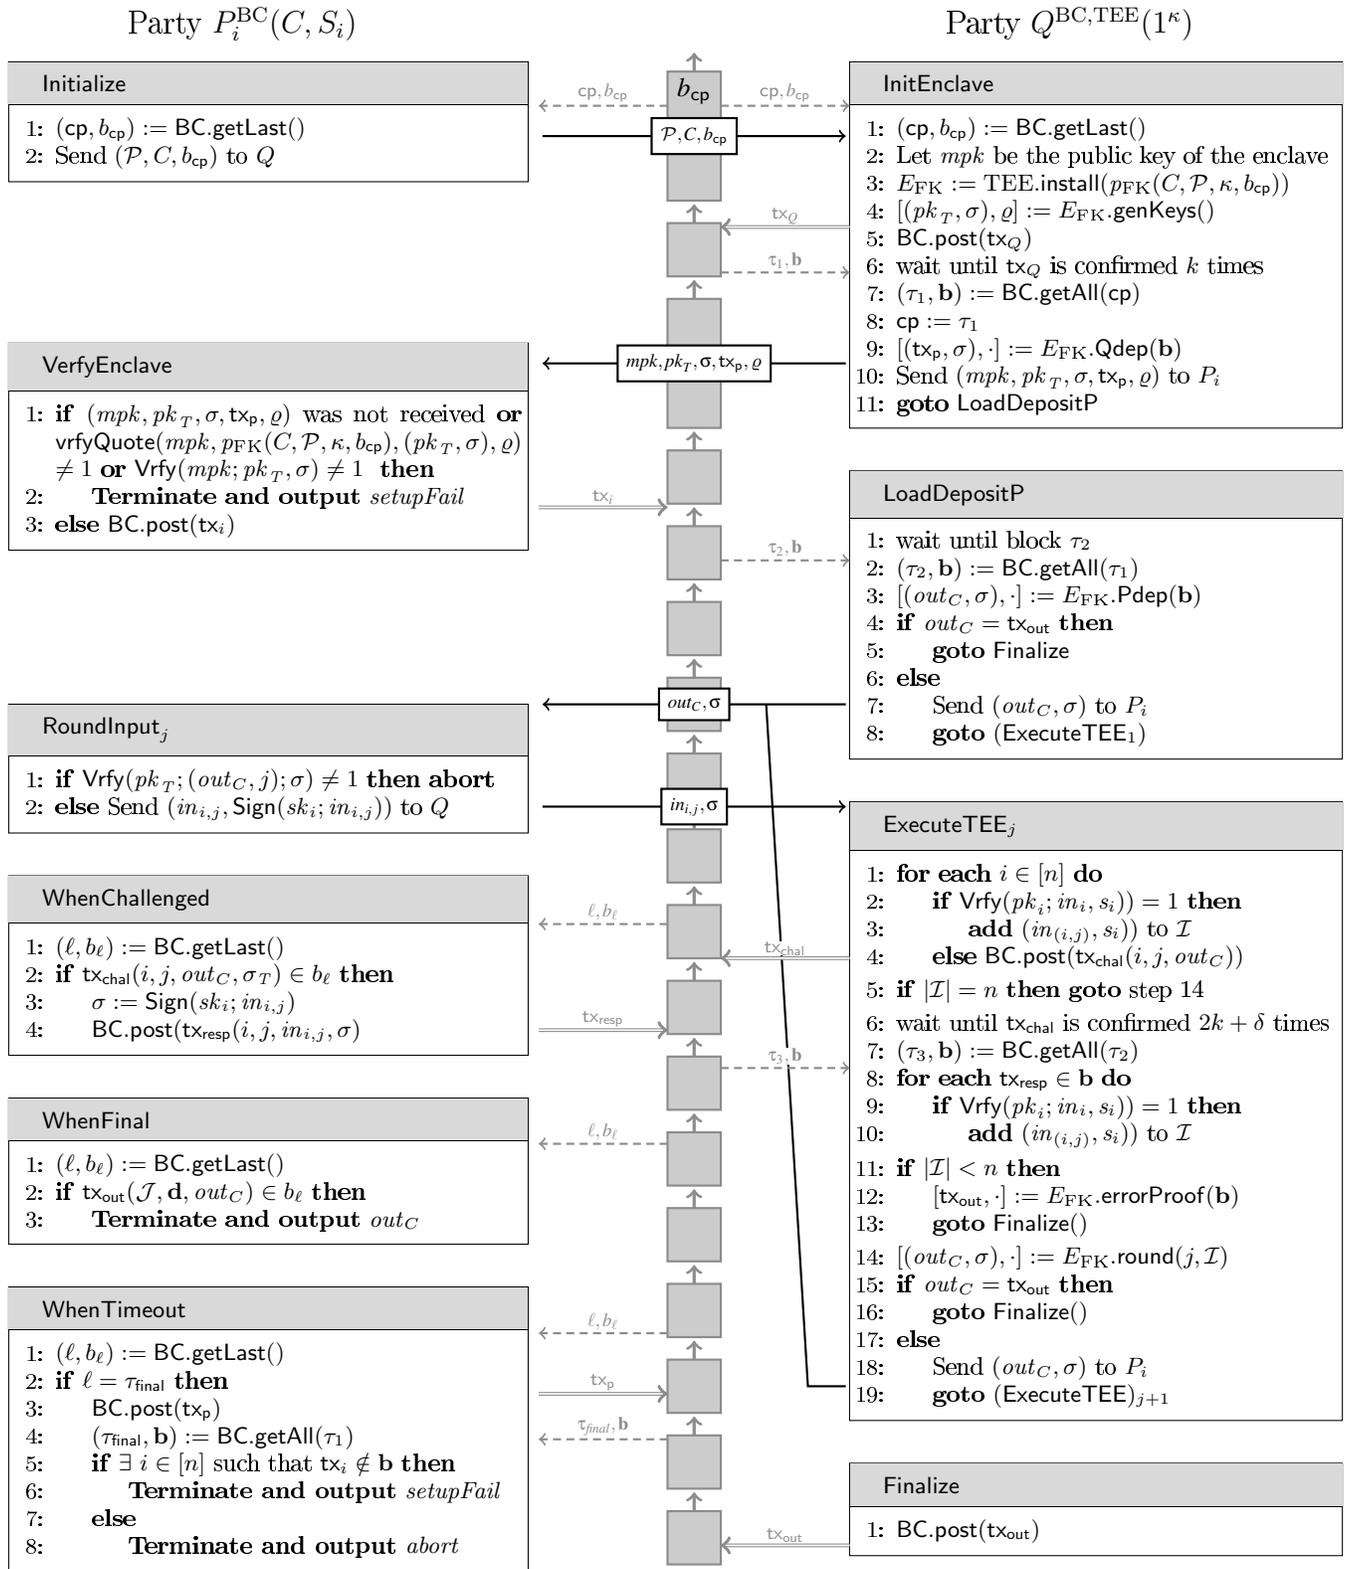

Figure 2: Protocol  $\pi_{\text{FASTKITTEN}}$ . Direct black arrows indicate communication between the parties and  $Q$ , gray dashed arrows indicate reading from the blockchain and gray double arrows posting on the blockchain.

coins. Then the *round execution* follows for all  $m$  rounds of the interactive contract. When the contract execution aborts or finishes, the protocol enters the *finalize phase*. We now explain all phases and the detailed protocol steps for all involved parties and the operator  $Q$  in depth. The detailed interactions as well as the subprocedure of the parties and the operator are displayed in Figure 2, Figure 3 describes the FASTKIT-TEN enclave program  $p_{\text{FK}}$ . Overall the protocol requires six different type of transactions.

**Setup phase.** In the setup phase, each party  $P_i$  first runs Initialize to generate its key pairs and gets the latest block  $b_{\text{cp}}$  which serves as a genesis block or checkpoint of the protocol. Then  $P_i$  sends the set of parties  $\mathcal{P}$ , the  $b_{\text{cp}}$  and the contract  $C$  to the operator  $Q$ . Upon receiving the initial values from all  $n$  parties,  $Q$  runs the subprocedure InitEnclave to initialize the trusted execution of the enclave program  $p_{\text{FK}}(\mathcal{P}, C, \kappa, b_{\text{cp}})$  where  $\kappa$  is the security parameter of the scheme. This security parameter  $\kappa$  also determines the values for the timeout period  $t$  and the confirmation constant  $k$ . This ensures that all parties and the TEE agree on these fixed values. Once  $p_{\text{FK}}$  is installed in the enclave, it generates key pairs for the protocol execution and in particular the blockchain public key  $pk_T$ <sup>6</sup>. Now,  $Q$  can make its deposit transaction  $\text{tx}_Q$  which assigns  $q$  coins to the enclave public key.

Q's Deposit Transaction $\text{tx}_Q$	
tx.Input:	Some unspent tx from $Q$
tx.Output:	Assign $q$ coins to $pk_T$

Let block counter  $\tau_1$  denote the time when this transaction has been included and confirmed in the blockchain.  $Q$  loads all blocks from  $\text{cp}$  to  $\tau_1$  as evidence to the enclave. If this evidence is correct, the execution of  $p_{\text{FK}}$  function  $Q\text{dep}$  outputs a penalty transaction  $\text{tx}_p$ , stating that after timeout  $\tau_{\text{final}}$  (after which the protocol must be terminated) the  $q$  coins of  $Q$ 's deposit transaction  $\text{tx}_Q$  are payed out to the parties  $P_1, \dots, P_n$ .

Penalty Transaction $\text{tx}_p$	
tx.Input:	$Q$ 's Deposit Transaction $\text{tx}_Q$
	For all $i \in [n]$ :
tx.Output <sub><math>i</math></sub> :	Assign $c_i$ coins to $P_i$
tx.Time:	Spendable after $\tau_{\text{final}}$

$Q$  sends the penalty transaction to all parties  $P_1, \dots, P_n$ , who run subprocedure VerifyEnclave. This transaction is used whenever the protocol does not finish before the final timeout  $\tau_{\text{final}}$ , which equals  $(3 + 2m) \times (\delta + k)$  blocks after the protocol start (recall, that we use  $\delta$  to bound the time until some transaction is guaranteed to be included and it will be

<sup>6</sup>For simplicity we omit here, that the enclave might need multiple key pairs for signing transactions and messages.

confirmed after  $k$  blocks).<sup>7</sup> Only if participant  $P_i$  received this penalty transaction from  $Q$  during the setup and verified that the program  $p_{\text{FK}}(\mathcal{P}, C, \kappa, b_0)$  is installed in the enclave, it creates and publishes its deposit transaction.

P <sub>i</sub> 's Deposit Transaction $\text{tx}_i$	
tx.Input:	Some unspent tx from $P_i$
tx.Output:	Assign $c_i$ coins to TEE

After time  $\tau_2 < \tau_1$ ,  $Q$  executes LoadDepositP and again provides the block evidence to the enclave execution of  $p_{\text{FK}}$ . If all parties published the deposit transactions, the first-round execution starts. Otherwise the enclave proceeds to the finalize phase and outputs a refund transaction  $\text{tx}_{\text{out}}(T, \vec{c})$  that returns the deposit back to honest users and  $Q$ , where  $T \subset \mathcal{P}$  is the set of all parties that submitted the deposit transaction until time  $\tau_2$ . Note, that the internal state of the contract execution is maintained by the  $p_{\text{FK}}$  program inside the enclave. This guarantees that the contract is not executed on outdated state.

**Round computation phase.** When the protocol arrives to the round computation phase,  $Q$  sends the authenticated output of the enclave to every party  $P_i$  and requests input for the next round. Each party  $P_i$  runs the round algorithm. Internally it verifies whether the input request came from the enclave by verifying the attached signature. Then it generates and signs its round input and sends it to  $Q$ . While  $P_i$  waits for the next round,  $Q$  verifies all received inputs and their signatures in the ExecuteTEE subprocedure. If all the parties  $P_i$  responded with correctly signed round inputs,  $Q$  triggers the execution of the contract in the enclave. Let us emphasize that in this simplified description of our protocol we do not focus on the privacy aspect and hence we omit that all round inputs to the contract could be encrypted with the public key of the enclave. In this case the trusted enclave execution needs to decrypt them before it evaluates the contract on them. See Section 9.3 for more details.

Note that the operator  $Q$  may be malicious and refrain from requesting a party  $P_i$  for the input to a round computation. Instead  $Q$  may pretend that it actually did not receive any input from the party  $P_i$ . On the other hand, one can imagine a scenario where  $Q$  is behaving honestly but the party  $P_i$  is dishonest and does not send the correctly signed round input to  $Q$ . Note, that the program  $p_{\text{FK}}$  cannot distinguish between these two cases without additional information. We will next show how an honest  $Q$  can generate a proof to attribute the malicious behavior to  $P_i$ . First,  $Q$  has to publish a challenge transaction  $\text{tx}_{\text{chal}}$  which includes the signed output of the previous step.  $\text{tx}_{\text{chal}}$  spends a very small amount  $\mu$  of coins from  $Q$  and assign them to party  $P_i$ <sup>8</sup>.

<sup>7</sup>The definition of  $\tau_{\text{final}}$  guarantees that even if the execution is delayed in every round, an honest operator will not be penalized.

<sup>8</sup>Cryptocurrencies like Bitcoin allow transactions with very small denominations (e.g. fractions of cents).

Challenge Transaction $\text{tx}_{\text{chal}}(i, j, \text{out}_C, \sigma_T)$	
tx.Data:	Store $i, j, \text{out}_C, \sigma_T$
tx.Input:	Some unspent tx from $Q$
tx.Output:	Assign $\mu$ coins to $P_i$

Once  $\text{tx}_{\text{chal}}$  is included in the blockchain, party  $P_i$  can read the correct output information from the transaction. The party should respond with  $\text{tx}_{\text{resp}}$ , which includes its signed round input.  $\text{tx}_{\text{resp}}$  spends the  $\text{tx}_{\text{chal}}$  and assigns the  $\mu$  coins back to  $Q$ . The action of  $P_i$  is depicted via the WhenChallenged subprocedure.

Response Transaction $\text{tx}_{\text{resp}}(\mathbf{i}, \mathbf{j}, \text{in}, \sigma_i)$	
tx.Data:	Store $i, j, \text{in}, \sigma_i$
tx.Input:	Challenge Transaction $\text{tx}_{\text{chal}}(i, j, \text{state})$
tx.Output:	Assign $\mu$ coins to $Q$

If some party does not send the response after it was challenged,  $Q$  can prove this misbehavior to the FASTKITTEN program, by providing the blockchain evidence of the challenge-response transcript. If the enclave program identifies a cheating party, it proceeds to the finalize phase. Otherwise, if all the parties' inputs were received with authentication (possibly after challenge-response phase),  $Q$  instructs the enclave to execute the contract on the accumulated input.

The result of the contract execution is the output  $\text{out}_C$ , the updated state  $\text{state}$ , and a coin distribution denoted by  $\mathbf{d}$ . If  $\text{state}$  equals  $\perp$ , the contract execution is finished, and the protocol proceeds to the finalize phase. Otherwise, FASTKITTEN internally stores the state and outputs  $\text{out}_C$  to  $Q$  who sends this output to all parties and waits for next round inputs.

**Finalize phase.** In the finalize phase, the enclave publishes a final output transaction  $\text{tx}_{\text{out}}$  which distributes the coins back to all honest parties. It is parameterized by a set of parties to receive coins  $\mathcal{J}$ , a final coin distribution  $\vec{e}$  and a final state  $\text{out}_C$ . The transaction  $\text{tx}_{\text{out}}(\mathcal{J}, \vec{e}, \text{out}_C)$ , spends all deposit transactions  $\text{tx}_i$  for all  $i \in \mathcal{J}$  and  $Q$ 's deposit transaction  $\text{tx}_Q$ . It includes the  $\text{out}_C$  in the data field and assigns  $q$  coins back to  $Q$  and  $e_i$  coins to party  $P_i$ , for every  $i \in \mathcal{J}$ . Let us note that  $\mathcal{J} = [n]$  implies correct protocol termination. If  $\mathcal{J} \neq [n]$ , then some party misbehaved and the protocol failed. Either a party did not make a deposit in the setup phase (signaled by  $\text{out}_C = \text{setupFail}$ ) or some party aborted in the round computation phase (signaled by  $\text{out}_C = \text{abort}$ ). In both cases all other parties get their initial deposits back. Note, that if a party  $P_j$  is caught cheating by the TEE, it will lose its deposit.

$Q$  now has to publish this transaction to get his coins before time  $\tau_{\text{final}}$  and by that also distributes coins and reveals  $\text{out}_C$  to honest parties. The participants need to constantly monitor the blockchain for transactions which challenge them or indicate final output. When they see a challenge transaction they respond as described above. If they see an output transaction

Output Transaction $\text{tx}_{\text{out}}(\mathcal{J}, \vec{e}, \text{out}_C)$	
tx.Data:	Store $\text{out}_C$
tx.Input:	Deposit Transactions $\text{tx}_Q, \{\text{tx}_i\}_{i \in \mathcal{J}}$
tx.Output <sub>1</sub> :	$q$ coins to $Q$ For all $i \in \mathcal{J}$ :
tx.Output <sub><math>i+1</math></sub> :	$e_i$ coins to $P_i$

they know the protocol execution ended and output the final contract output according to subroutine WhenFinal.

## 6 Execution Facility

As shown in Figure 1, we leverage a TEE for smart contract execution. For our prototype, we implemented FASTKITTEN for the Bitcoin blockchain using Intel SGX as a TEE. We chose Python as our scripting engine because it's memory safe, very well known, and widely available. To interact with the Bitcoin blockchain data in the enclave, we implemented our *Crypto library* using the open-source *breadwallet-core* [14], a simplified payment verification (SPV) library for Bitcoin used by the *Breadwallet* mobile wallet app. To abstract from SGX's peculiarities, and thus simplify smart contract development, we use the Graphene Library OS [17] (referred to as "Graphene" in the rest of the paper) as a basis. Graphene enables running arbitrary native Linux binaries in SGX enclaves while providing compatible library interfaces for networking and other OS services. Note that the design of the FASTKITTEN protocol does not require a trusted time source in the TEE.

### 6.1 The Enclave Program FASTKITTEN

An execution facility in the sense of FASTKITTEN must provide a set of abstract functionalities like key generation, transaction generation, smart contract execution, and error handling, all executed inside the enclave. This set of procedures is described in detail in Figure 3. We implemented each of the procedures using equivalent Python scripts. It is parameterized by the set of parties  $\mathcal{P}$ , the contract  $C$  which internally specifies the expected deposits  $\mathbf{c}$ , a security parameter  $\kappa$  and a genesis block  $b_{\text{cp}}$ . This does not need to be the actual genesis block of the underlying blockchain but it can be a later block which is used as a checkpoint. All parties must verify that this block is indeed a block of the blockchain. The security parameter  $\kappa$  also determines the waiting time  $k$  which is needed for the verification of the blocks.

### 6.2 Blockchain Verification

Blockchain communication is important for the setup and the finalization phase in the protocol. Thanks to the integrity properties of blockchains, a secure connection between the enclave and the blockchain is not needed if verification of received data can be done in the enclave. As it is not practical to download a complete copy of the blockchain to the enclave, we only concentrate on transactions caused by FASTKITTEN

The execution of  $p_{FK}$  is initialized with the secret key  $msk$ , the set of parties (where every  $P_i \in \mathcal{P}$  is identified by its key  $pk_i$ ), a contract  $C$ , a security parameter  $\kappa$  (which also defines the waiting period  $t$  and confirm period  $k$ ) and a checkpoint  $b_{cp}$ . Internally it stores the state of the contract  $state$  and the status flag  $s$  initially set to  $state = \emptyset$  and  $s = \text{genKeys}$ .

---

**procedure**  $\text{genKeys}()$

---

```

1: if  $s \neq \text{genKeys}$  then abort
2:  $(sk_T, pk_T) := \text{Gen}(1^\kappa)$ 
3:  $s := \text{Qdep}$ 
4: return  $pk_T, \text{Sign}(msk; pk_T)$ 

```

---

**procedure**  $\text{Qdep}(\mathbf{b})$

---

```

1: if  $s \neq \text{Qdep}$  or  $\text{Extends}(b_{cp}, \mathbf{b}) \neq 1$  or  $\text{Pos}(\mathbf{b}, tx_Q) > |\mathbf{b}| - k$  then abort
2:  $s := \text{Pdep}$ 
3:  $b_{cp} := \text{last block of } \mathbf{b}$ 
4: return  $tx_p$  ▷ Else, output penalty transaction

```

---

**procedure**  $\text{Pdep}(\mathbf{b})$

---

```

1: if  $s \neq \text{Pdep}$  or  $\text{Extends}(b_{cp}, \mathbf{b}) \neq 1$  then abort
2: set  $\mathcal{J} := \emptyset$ 
3: for  $i \in \mathcal{P}$  do
4:    $\ell_i := \text{Pos}(\mathbf{b}, tx_i)$ 
5:   if  $\ell_i < \delta$  and  $\ell_i < |\mathbf{b}| - k$  then add  $i$  to  $\mathcal{J}$ 
6: if  $\mathcal{J} = [n]$  then
7:    $s := \text{round}_1$ 
8:    $b_{cp} := \mathbf{b}.\text{last}$ 
9:   return  $\emptyset, \text{Sign}(sk_T; \emptyset, b_{cp})$ 
10: else
11:    $s := \text{terminated}$ 
12:   return  $tx_{out}(\mathcal{J}, \mathbf{c}, \text{setupFail})$ 

```

---

**procedure**  $\text{round}(j, (in_1, \sigma_1) \dots, (in_n, \sigma_n))$

---

```

1: if  $s \neq \text{round}_j$  or for any  $i \in [n] : \text{Vrfy}(pk_i; in_i, s_i) \neq 1$  then abort
2:  $(out_C, state', \mathbf{d}) := C(state, \vec{in})$ 
3: if  $state' \neq \perp$  then
4:    $s := \text{round}_{j+1}$ 
5:    $state := state'$ 
6:   return  $out_C, \text{Sign}(sk_T; (out_C, j))$ 
7: else
8:    $s := \text{terminated}$ 
9:   return  $tx_{out}([n], \mathbf{d}, out_C)$ 

```

---

**procedure**  $\text{errorProof}, (j, \mathbf{b})$

---

```

1: if  $s \neq \text{round}_j$  or  $\text{Extends}(b_{cp}, \mathbf{b}) \neq 1$  then abort
2: Let  $\sigma := \text{Sign}(sk_T; (out_C, j))$ 
3:  $\mathcal{J} := [n]$ 
4: for  $i \in \mathcal{P}$  do
5:   if  $\text{Pos}(\mathbf{b}, tx_{chal}(i, j, out_C, \sigma)) < |\mathbf{b}| - \delta - k$  then
6:     if  $\text{Pos}(\mathbf{b}, tx_{resp}(i, j, in, \sigma)) > |\mathbf{b}| - k$  then
7:       delete  $i$  from  $\mathcal{J}$ 
8:     else if  $\text{Vrfy}(pk_i; in, \sigma) \neq 1$  then
9:       delete  $i$  from  $\mathcal{J}$ 
10:  $s = \text{terminated}$ 
11: if  $\mathcal{J} \neq [n]$  then
12:   return  $tx_{out}(\mathcal{J}, \mathbf{c}, \text{abort})$ 

```

---

Figure 3: FASTKITTEN enclave program  $p_{FK}(\mathcal{P}, C, \kappa, b_{cp})$

protocol invocation. Thus, it is sufficient to verify that these transactions are part of a valid block—without downloading entire blocks, which can be done efficiently using simplified payment verification (SPV). However, SPV libraries can only prove that a transaction *is* part of a block on the blockchain, but they cannot prove that a transaction *is not* part of any block. As required by the challenge-response case, we added an alternative verification mode that fully downloads every block that could potentially contain the transaction and checks whether its present in any of those blocks.

### 6.3 Participant Communication

To place the deposits and receive them later, as well for sending input, communication between participants (including the Operator  $Q$ ) is needed in the off-chain phase. We secure this communication using TLS sockets provided by Python. This transparently encrypts participants' communication, and thus ensures input integrity and confidentiality of parties' messages towards the operator.

### 6.4 Enclave Setup

In the FASTKITTEN prototype, we leverage Intel SGX as a TEE. SGX is a TEE included in recent Intel CPUs which introduces the concept of isolated hardware *enclaves* that can be created and managed using new CPU instructions. SGX enclaves are even shielded from the operating system; only the CPU is trusted. To support smart contract execution in these enclaves we provide a run-time environment based on Graphene, which replaces the Intel SDK in both the enclave and the host process. This allows Graphene to transparently provide services from the untrusted OS (and check the integrity of the results). To protect the enclave application from the host process, a *manifest* has to be provided at enclave initialization. The manifest includes interfaces, services, and respective integrity checksums, e.g., hashes of files the enclave requires. Accesses to these files will be checked against hashes in the manifest to guarantee integrity.

As depicted by Figure 3, the Execution Facility incorporates a set of functionalities. For key derivation (*genKeys*) we leverage the `rand` instruction to get high-entropy randomness inside of the enclave. After checking that  $tx_Q$  (*Qdep*) is in the blockchain, the derived private key  $sk_T$  is used to generate the penalty transaction  $tx_p$  using our Crypto library.  $tx_p$  is distributed to the other participants over a TLS connection. Other participants can generate their deposit transactions  $tx_i$  (*Pdep*) using a regular wallet. This concludes the setup phase, and the smart contract gets executed (*round*).

The Graphene run-time environment enables FASTKITTEN to support arbitrary Linux binaries, thus, can be used to implement smart contracts. However, instead of allowing binaries, we use a scripting engine based on a Python interpreter in our proof-of-concept implementation. First, this makes development easier for contract developers, as they are not always familiar with lower-level programming languages, and second,

this makes smart contracts less prone to memory corruption vulnerabilities. Two use cases we implemented are presented and evaluated in Section 8.

## 6.5 Denial of Service Protection

The protocol as described in Section 5 assumes instantaneous contract execution meaning that the execution of a contract inside a TEE takes no time. For most practical contracts, this simplifying assumption is reasonable since executing a simple contract function inside a TEE is much faster than the network/blockchain delay. However, this is not true when considering arbitrary contracts which might potentially contain endless loops. Moreover, the halting problem states that it is impossible to predict if a certain algorithm will halt within a certain number of steps. A simple protection against endless loops and denial-of-service attacks, is letting the enclave monitor the execution of the smart contract and terminate execution if the number of execution steps exceeds a predefined limit. If the contract execution is aborted due to an execution timeout, the enclave signs an outputs transaction  $tx_{out}$  which returns deposited coins back to parties and to the operator.

## 7 Security

In this section we present the underlying security considerations of FASTKITTEN.

### 7.1 Protocol Security

Due to limited space, we present our novel model in the extended version of this paper, where we also formally state the security properties, the formal statement of the theorem as well as the proof. Here we will only briefly explain the security properties.

In order to guarantee security for the protocol, we require three security properties: *correctness*, *fairness* and *operator balance security*.

Intuitively, correctness states that in case all parties behave honestly (including the operator), every party  $P_i \in \mathcal{P}$  outputs the correct result and earns the amount of coins she is supposed to get according to the correct contract execution. The fairness property guarantees that if at least one party  $P_i \in \mathcal{P}$  is honest, then (i) either the protocol correctly completes an execution of the contract or (ii) all honest parties output *setupFail* and stay financially neutral or (iii) all honest parties output *abort*, stay financially neutral, and at least one corrupt party must have been financially punished. Finally, the operator balance security property says that in case the operator behaves honestly, he cannot lose money.

**Theorem 1** (Informal statement). *The protocol  $\pi_{\text{FASTKITTEN}}$  as defined in Section 5 satisfies correctness, fairness and operator balance security property.*

The most challenging part of the proof is the fairness property. We need to show how honest parties reach consensus on the result of the execution and prove that coins are always

distributed between parties according to this result (even if malicious parties collude with the operator). In order to prove the operator balance security, we show that an honest operator has always enough time to publish a valid output transaction which pays him back his deposit, before the time-locked penalty transaction can be posted on the blockchain.

**Incentive-driven adversary** If we consider only incentive-driven adversaries, then statement (iii) of the fairness property is never true. Hence, if the setup phase completes successfully, then the result of the protocol is a correct contract execution. This follows directly from the fact, that when the protocol aborts the misbehaving parties lose coins. By definition of incentive-driven parties, losing coins is against their interest. This is why the only possible outcome of the protocol is correct execution of the contract. Moreover, when we consider fees for positing transaction on the blockchain, parties are additionally incentivized to prevent the challenge-response transactions. These additional incentives enforce fast and protocol compliant behavior of the parties.

### 7.2 Architecture Security

The main goal of FASTKITTEN is to enable efficient execution of general multi-round smart contracts. Hence, we analyze the security of FASTKITTEN with regards to its system architecture and implementation. Possible adversaries can be malicious participants, a malicious operator, or a combination of both.

We note that participating clients are only required to send and receive transactions from the blockchain (e.g., to enter an execution) and the ability to exchange protocol messages (e.g., to play rounds). Hence, client implementations can be based on a diverse set of entirely different code bases in practice, possibly using memory-safe languages such as Python, Go, or Rust. Malicious participants are further limited to interacting with other parties and the operator through the exchange of messages as specified within our protocol, and hence, we focus on the TEE-based execution facility in the following.

A malicious operator could deny execution, however, he is incentivized to adhere to the protocol or lose money. Thus, we assume that the goal of a malicious operator is to try and exploit the execution facility at runtime. Since the operator already controls the host process, the main target would be the enclave that executes the contract. Enclaves have a well-defined interface with the rest of the system, and any attack has to be launched using this interface. By providing fake data through this interface, the attacker could try to exploit a memory-corruption vulnerability in the low-level enclave code to launch (a) a code-reuse attack, e.g., by manipulating enclave stack memory, or (b) a data-only attack, e.g., to leak information about the game state or manipulate Bitcoin addresses in contracts. As mentioned in Section 4, for (a) we assume a standard code-reuse defense such as control-flow integrity [3, 15, 50, 62, 65] or fine-grained code randomization [21, 23, 30, 42, 53, 61]. The core functionality of

FASTKITTEN additionally tackles both attack vectors by implementing the main enclave code in Python, which provides memory-safety features such as implicit bounds checking. The only parts that are implemented in unsafe languages are the initialization code of Graphene [17] and the Simple Payment Verification (SPV) library [14]. FASTKITTEN actually has no strong dependency on Graphene in principle, it was mainly used to simplify and speed up prototype implementation. Finally, SPV represents a standard library used by most blockchain clients and an adversary that is able to construct a data-only attack against it would be able to exploit any of those clients connected to the Bitcoin network using the same data-only attack.

## 8 FASTKITTEN Contracts

In this section we take a look at applications and performance through a number of benchmarks.

### 8.1 Complexity

The FASTKITTEN protocol consists of *setup*, *round computation* and *finalize* phases. During the *setup* phase, each party  $P_i$  deposits a constant amount of coins  $c_i$ . The operator needs to deposit an amount  $\sum_{i \in [n]} c_i$  which equals the sum of all other deposits from  $\mathcal{P}$  together. To post the deposit transactions  $\text{tx}_S$  and  $\text{tx}_Q$ , a total of  $n + 1$  transactions is necessary.

During the *round computation phase*, in the optimistic case FASTKITTEN can operate completely off-chain without any blockchain interaction. Any user can force that challenge response transactions are posted to attribute misbehavior of a party, in any given round. If this (pessimistic) case occurs, it can add 2 to another  $2n$  transactions. In the worst case, a challenge response transaction pair needs to be posted on the blockchain for every party  $P_i$  at every round  $j \in [m]$  leading to  $\mathcal{O}(nm)$  blockchain interactions. In *finalize* phase, FASTKITTEN requires one additional payout transaction  $\text{tx}_{\text{out}}$  to settle money distribution among parties. Scenarios of missing deposit at the *Setup* phase or an abort by a party at the *round computation* phase are dealt with by posting the refund transaction  $\text{tx}_{\text{out}}$  and the penalty transaction  $\text{tx}_p$  respectively.

**Setup time** In the optimistic case (which we have shown is the standard case when considering incentive-driven parties) the overall execution of the protocol only requires  $n + 2$  transactions on the blockchain. This also indicates at what speed the protocol can be executed in this case. If all parties agree, the setup phase can be finished in 2 blockchain rounds and from that point on the protocol can be played off-chain. In the next subsection we give some indication how fast this second part can be achieved. Running the protocol as fast as possible is in the interest of every party since it shortens the locking time of the deposits.

### 8.2 Performance Evaluation

We performed a number of performance measurements to demonstrate the practicality of FASTKITTEN using our lab

setup, which consists of three machines: First, an SGX-enabled machine running Ubuntu 16.04.5 LTS with an Intel i7-7700 CPU clocked at 3.60GHz and 8GB RAM, where we installed FASTKITTEN's contract execution facility to play the role of the operator's server. Second, a machine running Ubuntu 14.04.4 LTS on an Intel i7-6700 CPU clocked at 3.40GHz with 32GB RAM, which provides unmodified blockchain nodes in a local test network using Bitcoin Core version 0.16.1. Third, a laptop machine with macOS 10.13.6 on with Intel i7-4850HQ CPU clocked at 2.30GHz and 16GB of RAM, which takes the role of the participants in the protocol. All three machines are connected through a Gigabit Ethernet LAN. For tests involving the real Bitcoin network the individual machines are connected through the Internet using our Internet connection.

**Block validation** In our experiments, the enclave takes approximately 5 s to validate one block from the Bitcoin main network, thus proving that it is capable of validating real blocks in real time.

**Enclave Startup** The time to setup an enclave until it is ready is 2 s, proving that instantiating enclaves on the fly is feasible.

**End-to-end Time** Assuming all parties are incentive-driven and, thus, comply with the protocol, the total time required by FASTKITTEN is the time of 2 blockchain interactions (see Section 8.1), plus the computation time (a few milliseconds in our use cases), plus the time required by the parties to choose the next inputs.

### 8.3 Applications

FASTKITTEN allows to run complex smart contracts on top of cryptocurrencies that would not natively support such contracts, like Bitcoin. But in contrast to Turing-complete contract execution platforms like Ethereum, a secure off-chain execution such as FASTKITTEN puts some restrictions on the contracts it can run:

- The number of parties interacting with the contract must be known at the start of the protocol.
- It must be possible to estimate an upper bound on the number of rounds and the maximum run time of any round.

All of these restrictions make FASTKITTEN contracts different from smart contracts running on Ethereum itself. The restrictions above come from the fact that the contract can be completely (and repeatedly) executed without blockchain interactions. Other off-chain solutions (like state channels [20,24,49]) come with similar caveats. By allowing additional blockchain interaction we could get around those restrictions but we would lose efficiency in the optimistic case (which is also similar to state channel constructions).

FASTKITTEN has important features which are supported by neither Bitcoin nor Ethereum — FASTKITTEN allows private inputs and batched execution of user inputs. Overall, this leads to cheaper, faster and private contract execution than what

is possible with on-chain contracts in Ethereum. Below, we highlight these efficiency gains by presenting four concrete use-cases in which FASTKITTEN outperforms contracts run over Ethereum or in Ethereum state channels.

**Lottery** A lottery contract takes coins from every involved party as input, and randomly selects one winner, who gets all the coins. The key challenge for such a contract is to fairly generate randomness to select the winner. In Ethereum or Bitcoin the randomness is computed from user inputs through an expensive commit-reveal scheme [48]. In FASTKITTEN, all parties can immediately send their random inputs to the enclave which will securely determine a winner. Hence, we reduce the round complexity from  $\mathcal{O}(\log n)$  [48] to  $\mathcal{O}(1)$ .

**Auctions** Another interesting use-case for smart contracts are auctions, where parties place bids on how much they are willing to pay and the contract determines the final price. In a straightforward auction, the bids can be public, but more fair versions, like second bid auctions, require the users not to learn the other bids before they place their own. The privacy features of FASTKITTEN can be used to reduce the round complexity for such auctions which would otherwise require complex cryptographic protocols [25].

**Rock-paper-scissors** We implemented the popular two-party game rock-paper-scissors to show the feasibility of FASTKITTEN contracts. Again, the privacy features allow one match to be executed in a single round, which would have required at least 3 rounds in Ethereum. The pure execution time in the optimistic case, excluding delays due to human reaction times, is 12ms for one round (averaged over 100 matches). This demonstrates that off-chain protocols, like FASTKITTEN, are highly efficient when the same set of parties wants to run complex contracts (like multiple matches of a game).

**Poker** We also implemented a Texas Hold'em Poker game, to prove that multi-party contracts which inherently require multiple rounds can also be efficiently executed in FASTKITTEN. In our implementation, each player starts with an equal chip stack and participates in an initial betting round and in additional rounds after the flop, river, and turn have been dealt by the enclave. If more than two players remain in the game after the final bets, the enclave reveals the winner and distributes the chips in the current pot to the winner. The game continues until only one player remains. We measured 50 matches between 10 players resulting in an average time of 45ms per match (multiple betting rounds are included in each match). The run time was measured starting from the moment all deposits are committed to the blockchain.

**Real-world Fees** We generated examples of the transaction types used in our protocol for a 10-player poker match. In Table 2 we estimate the fees required to commit to the blockchain our transactions, in addition to a typical deposit transaction. Assuming all parties comply with the protocol, each party (including  $Q$ ) must pay between 0.05 USD and

Transaction	Size (Bytes)	Fees (BTC)	Fees (USD)
Deposit (typical)	250	0.000007-0.000073	0.05-0.46
Penalty ( $tx_p$ )	504	0.000015-0.000148	0.09-0.93
Challenge ( $tx_{chal}$ )	293	0.000009-0.000086	0.05-0.54
Response ( $tx_{resp}$ )	266	0.000008-0.000078	0.05-0.49
Output ( $tx_{out}$ )	1986	0.000058-0.000582	0.36-3.65

Table 2: Estimated fees for a typical deposit transaction and the FASTKITTEN transactions, using data from CoinMarket-Cap [2] and BlockCypher [1] retrieved on Nov. 14, 2018.

0.46 USD for the deposit. Additionally, the output transaction  $tx_{out}$  requires between 0.36 USD and 3.65 USD in fees.

**Other Well-known Contracts** Certain well-known contracts like ERC20 token and CryptoKitties inherently need to be publicly available on the blockchain, since they are accessed frequently by participants which are not previously known. In contrast, contracts resembling our examples above, which rely on private data and where a fixed set of participants sends a large number of transactions, are highly efficient when moved off-chain using a system like FASTKITTEN. The nature of off-chain solutions like FASTKITTEN or state channels requires advance knowledge of the participants. Open contracts like ERC20 and CryptoKitties that require continuous synchronization with the blockchain and are meant to be publicly accessible would eliminate the advantages of off-chain solutions.

## 9 Discussion and Extensions

In order to explain and analyze the FASTKITTEN protocol, we presented a simplified protocol version which only includes the building blocks required to guarantee security. Depending on the use case one might be interested in further properties. Possible extensions discussed in this section include the option to pay the operator for his service, protect the operator against TEE faults, hide the contract output from through a layer of output encryption and allow cross-currency smart contracts. In the following, we explain how to achieve these features and at what cost they can be added to the simplified protocol.

### 9.1 Fees for the Operator

The owner of the TEE provides a service to the users who want to run a smart contract and, naturally, he wants to be paid for it. In addition to the costs of buying, maintaining and running the trusted hardware, he also needs to block the security deposit  $q$  for the duration of the protocol. While the security of FASTKITTEN ensures that he will never lose this money, he still cannot use it for other purposes. The goal of the operator-fees is to make both investments attractive for  $Q$ . We assume that the operator will be paid  $\xi$  coins for each protocol round for each party. Since the maximum number of rounds  $m$  is fixed at the protocol start,  $Q$  will receive  $\xi \times$

$n \times m$  coins if the protocol succeeds (even if the contract terminated in less than  $m$  rounds). If the operator proves to the TEE in round  $x$  that another party did not respond to the round challenge, he will only receive a fee for the passed  $x$  number of rounds (namely  $\xi \times x \times n$ ). This pay-per-round model ensures that the operator does not have any incentive to end the protocol too early. If the protocol setup does not succeed or the operator cheats, he will not receive any coins. The extended protocol with operator fees requires each party to lock  $c_i + m \times \xi$  coins and the operator needs to level this investment with  $qc_i + m \times \xi$  coins.

## 9.2 Fault Tolerance

In order to ensure that the execution of the smart contract can proceed even in the presence of software or hardware faults, the enclave can save a snapshot of the current state in an encrypted format, e.g., after every round of inputs. This encrypted state would be sent to the operator and stored on redundant storage. If the enclave fails, the operator can instantiate a new enclave which will restart the computation starting from the encrypted snapshot. If the TEE uses SGX, snapshots would leverage SGX's sealing functionality [31] to protect the data from the operator while making it available to future enclave instances.

## 9.3 Privacy

As mentioned in the introduction, traditional smart contracts cannot preserve privacy of user inputs and thus always leak internal data to the public. In contrast to common smart contract technologies, the FASTKITTEN protocol supports privacy preserving smart contracts as proposed in Hawk [36]. This requires *private contract state* to hide the internal execution of the contract and *input privacy*, which means that no party (including the operator) sees any other parties' round input before sending its own.

It is straightforward to see that FASTKITTEN has a secret state, since it is stored and maintained inside the enclave. Input privacy can easily be achieved by encrypting all inputs with the public key of the enclave. This guarantees that only the FASTKITTEN execution facility and the party itself knows the inputs. If required, FASTKITTEN could also be extended to support privacy of outputs from the contract to the parties, by letting the enclave encrypt the individual outputs with the parties' public keys. But this additional layer should only be used when the contract requires it, since in the worst case this increases the output complexity of the challenge and output transaction.

## 9.4 Multi-currency Contracts

FASTKITTEN requires from the underlying blockchain technology that transactions can contain additional data and can be timelocked. Any blockchain like Bitcoin, Ethereum, Litecoin and many others which allow these transaction types can be used for the FASTKITTEN protocol. With some minor

modifications FASTKITTEN can even support contracts which can be funded via multiple different currencies. This allows parties that own coins in different currencies to still execute a contract (play a game) together. The main modification to the FASTKITTEN protocol is that the operator and the enclave need to simultaneously handle multiple blockchains in parallel. In particular, for each of the considered currencies,  $Q$  needs to deposit the sum of all coins that were deposited by parties in that currency. This is in order to guarantee that if the operator cheats, players get back their invested coins in the correct currency. In addition, the operator is obliged to challenge each party via its blockchain. If the execution completes (or the operator proves to the enclave that one of the players cheated), the enclave signs one output transaction for each of the currencies. While this extension adds complexity to the enclave program and leads to more transactions and thus transaction-fees, the overall deposit amount stays identical to the single blockchain use case.<sup>9</sup> A complete design and proof of correctness of a cross-ledger FASTKITTEN is left to future work.

## 10 Conclusion

In this paper we have shown that efficient smart contracts are possible using only standard transactions by combining blockchain technology with trusted hardware. We present FASTKITTEN, our Bitcoin-based smart contract execution framework that can be executed off-chain. Since FASTKITTEN is the first work that supports efficient multi-round contracts handling coins, for the first time, this enables real-time application scenarios, like interactive online gaming, with millisecond round latencies between participants. We formally prove and thoroughly analyze the security of our general framework, also extensively evaluating its performance in a number of use cases and benchmarks.

Additionally, we discuss multiple extensions to our protocol, such as adding output privacy or operator fees, which enrich the set of features provided by our system.

## Acknowledgments

We are grateful to our anonymous reviewers and our shepherd Mihai Christodorescu for their constructive feedback.

This work has been supported by the German Research Foundation (DFG) as part of projects HWSec, P3 and S7 within the CRC 1119 CROSSING and the Emmy Noether Program FA 1320/1-1, by the German Federal Ministry of Education and Research (BMBF) and the Hessen State Ministry for Higher Education, Research and the Arts (HMWK) within CRISP, by BMBF within the iBlockchain project, by the Intel Collaborative Research Institute for Collaborative Autonomous & Resilient Systems (ICRI-CARS).

<sup>9</sup>This solution assumes that any party can receive coins in any of the considered currencies.

## Availability

An extended version of this paper, which includes the byte-code of our sample Bitcoin transactions, will be publicly available at the Cryptology ePrint Archive at <https://eprint.iacr.org>.

## A Further Related Work

There is a large body of work trying to improve the scalability of blockchains by moving a major part of smart contract executions off the blockchain (for example, via second layer solutions [24, 34, 49, 55] or outsourcing of computation [58]). As discussed in the main body of this paper, all of these solutions run on top of blockchains with sufficiently complex scripting language, e.g., on Ethereum. However, they cannot be integrated into popular legacy cryptocurrencies such as Bitcoin, which is their main difference compared to our work. Recall that one of the main goals of FASTKITTEN is make minimal assumption on the underlying blockchain technology and in particular, to run over the Bitcoin blockchain.

Another motivation for off-chain contract execution might be the goal of protecting privacy. Hawk [36] and the “Ring of Gyges” [33] are examples of works that do keep the state, all inputs and outputs private. It is also true for the scaling solutions mentioned above; These techniques work only over cryptocurrencies with support for complex smart contracts, e.g. over Ethereum.

Below we discuss the differences between these solutions and FASTKITTEN when run on top of Ethereum.

### A.1 Second-layer Scaling Solutions

**State Channels** State channels [20, 24, 49] are a prominent second layer scaling solution. They allow a set of parties

to execute complex smart contracts off-chain. As long as all parties are honest and agree on the state transitions, the blockchain is contacted only during the channel creation, when parties lock funds in the channel, and during channel closure, when the locked funds are distributed back to the parties according to the result of contract execution. However, once parties run into disagreement off-chain, they have to resolve their dispute on-chain and perform the state transition via the blockchain.

While in the optimistic case when all parties are honest, state channels are very efficient, a potentially heavy computation might need to be done on-chain in case of disagreement. This is in contrast to the FASTKITTEN protocol which does not require any computation to be performed on the blockchain even in case of disputes.

**Plasma** Another promising second-layer scaling solution is Plasma, first introduced by Poon and Buterin [55]. The main idea of Plasma is to build new chains (Plasma chains) on top of the Ethereum blockchain. Each Plasma chain has its own operator that is responsible for validating transactions and regularly posting a short commitment about the current state of the Plasma chain to a smart contract on the Ethereum blockchain. The regular commitments guarantee to the participants of the Plasma chain that in case the operator cheats, his misbehavior can be proven to the Ethereum smart contract and parties can exit the Plasma chain with all their funds.

While the original goal of Plasma [55] was to support arbitrary complex smart contracts, to the best of our knowledge, there is no concrete protocol that would achieve this goal (the existing Plasma designs support only payment transactions). Moreover, the plasma research community currently conjectures that Plasma with general smart contracts might be impossible to construct [8].

## A.2 Incentive-driven Verification

**Arbitrum** The disadvantage of state channels, i.e., the potentially heavy on-chain execution in case of dispute, is being addressed by the work Arbitrum [34]. Every smart contract, which Arbitrum models as a virtual machine (VM), to be executed off-chain has a set of “manager” parties responsible for correct VM execution. As long as managers reach consensus on the VM state transitions, execution progresses off-chain similarly as in state channels. In case of dispute, managers do not perform the VM state transition on-chain as in state channel. Instead, one manager can propose the next VM state which other managers can challenge. If the newly posted state is challenged, the proposer and the challenger run an interactive protocol via the blockchain, so-called “bisection” protocol, in which one disputable computation step is eventually identified and whose correct execution is verified on-chain. Hence, instead of executing the entire state transition on-chain (which might potentially require a lot of time/space), only one computation step of the state transition

has to be performed on-chain in addition to the bisection protocol (which might require  $\mathcal{O}(\log(s))$  blockchain transactions, where  $s$  is the number of computations steps in the state transition). The Arbitrum protocol works under the assumption that at least one manager of the VM is honest and challenges false states if they are posted by other managers. Since the blockchain interaction during the bisection protocol is rather expensive, Arbitrum uses monetary incentives to motivate managers to behave honestly and follow the protocol.

**TrueBit** Another solution that supports off-chain execution of smart contracts using incentive verification is TrueBit [58]. For each off-chain execution, the TrueBit system selects (using a lottery) one party, called the “Solver”, that is responsible for performing the state transition and inform all other parties about the new contract state. The TrueBit system incentivizes parties to become so called “verifiers” and check the correctness of the computation performed by the Solver. In case they detect misbehavior, they are supposed to challenge the Solver on the blockchain and run the “verification game” which works similarly as the “bisection protocol” of Arbitrum. Similar to Arbitrum, TrueBit relies on the assumption that there is at least one honest verifier which correctly performs all the validations and challenges malicious Solvers. In contrast to Arbitrum, all inputs and the contract state are inherently public even in the optimistic case when everyone is honest.

Apart from the different trust model and lower requirement on the underlying blockchain technology, FASTKITTEN differs from Arbitrum and TrueBit by providing stronger privacy guarantees, meaning that in both the optimistic and the pessimistic case, inputs of honest parties as well as the state of the smart contract remains private.

## A.3 TEEs for privacy

None of the solutions discussed above achieves privacy preserving off-chain contract execution. This is tackled by the work Hawk [36] which keeps the state, all inputs and all outputs private. Hawk contracts [35] achieve these properties using Ethereum smart contracts that judge computations done by a third party (a manager), who executes the contract on private inputs and is trusted not to reveal any secrets. First all parties submit their encrypted inputs to the contract, then the manager computes the result and proves its correctness with a zero knowledge proof. If the proof is correct, the contract pays out money accordingly. While the authors of Hawk discuss the possibility to use SGX for instantiating the manager and reducing the trust assumptions in this party, it still leverages the blockchain for every user input, and it only supports single round protocols which is their main difference to FASTKITTEN. A possible extension to multi-round protocols would be difficult to achieve without letting the smart contract verify the correctness of every round individually, and thus create a large blockchain communication overhead.

# StrongChain: Transparent and Collaborative Proof-of-Work Consensus

## Abstract

Bitcoin is the most successful cryptocurrency so far. This is mainly due to its novel consensus algorithm, which is based on proof-of-work combined with a cryptographically-protected data structure and a rewarding scheme that incentivizes nodes to participate. However, despite its unprecedented success Bitcoin suffers from many inefficiencies. For instance, Bitcoin's consensus mechanism has been proved to be incentive-incompatible, its high reward variance causes centralization, and its hardcoded deflation raises questions about its long-term sustainability.

In this work, we revise the Bitcoin consensus mechanism by proposing StrongChain, a scheme that introduces transparency and incentivizes participants to collaborate rather than to compete. The core design of our protocol is to reflect and utilize the computing power aggregated on the blockchain which is invisible and “wasted” in Bitcoin today. Introducing relatively easy, although important changes to Bitcoin's design enables us to improve many crucial aspects of Bitcoin-like cryptocurrencies making it more secure, efficient, and profitable for participants. We thoroughly analyze our approach and we present an implementation of StrongChain. The obtained results confirm its efficiency, security, and deployability.

## 1 Introduction

One of the main novelties of Bitcoin [28] is Nakamoto consensus. This mechanism enabled the development of a permissionless, anonymous, and Internet-scale consensus protocol, and combined with incentive mechanisms allowed Bitcoin to emerge as the first decentralized cryptocurrency. Bitcoin is successful beyond all expectations, has inspired many other projects, and has started new research directions. Nakamoto consensus is based on proof-of-work (PoW) [8] in order to mitigate Sybil attacks [6]. To prevent modifications,

a cryptographically-protected append-only list [2] is introduced. This list consists of transactions grouped into blocks and is usually referred to as a *blockchain*. Every active protocol participant (called a *miner*) collects transactions sent by users and tries to solve a computationally-hard puzzle in order to be able to write to the blockchain (the process of solving the puzzle is called *mining*). When a valid solution is found, it is disseminated along with the transactions that the miner wishes to append. Other miners verify this data and, if valid, append it to their replicated blockchains. The miner that has found a solution is awarded by a) the system, via a rewarding scheme programmed into the protocol, and b) fees paid by transaction senders. All monetary transfers in Bitcoin are expressed in its native currency (called bitcoin, abbreviated as BTC) whose supply is limited by the protocol.

Bitcoin has started an advent of decentralized cryptocurrency systems and as the first proposed and deployed system in this class is surprisingly robust. However, there are multiple drawbacks of Bitcoin that undermine its security promises and raise questions about its future. Bitcoin has been proved to be incentive-incompatible [9, 11, 39, 47]. Namely, in some circumstances, the miners' best strategy is to not announce their found solutions immediately, but instead withhold them for some time period. Another issue is that the increasing popularity of the system tends towards its centralization. Strong competition between miners resulted in a high reward variance, thus to stabilize their revenue miners started grouping their computing power by forming *mining pools*. Over time, mining pools have come to dominate the computing power of the system, and although they are beneficial for miners, large mining pools are risky for the system as they have multiple ways of abusing the protocol [9, 11, 18, 39]. Recently, researchers rigorously analyzed one of the impacts of Bitcoin's deflation [4, 27, 47]. Their results indicate that Bitcoin may be unsustainable in the long term, mainly due to decreasing miners' rewards that will eventually stop completely. Besides that, unusually for a transaction system, Bitcoin is designed to favor availability over consistency. This choice was motivated by its open and

\*This work was done while the author was at SUTD.

permissionless spirit, but in the case of inconsistencies (i.e., *forks* in the blockchain) the system can be slow to converge.

Motivated by these drawbacks, we propose StrongChain, a simple yet powerful revision of the Bitcoin consensus mechanism. Our main intuition is to design a system such that the mining process is more transparent and collaborative, i.e., miners get better knowledge about the mining power of the system and they are incentivized to solve puzzles together rather than compete. In order to achieve it, in the heart of the StrongChain’s design we employ *weak solutions*, i.e., puzzle solutions with a PoW that is significant yet insufficient for a standard solution. We design our system, such that a) weak solutions are part of the consensus protocol, b) their finders are rewarded independently, and c) miners have incentives to announce own solutions and append solutions of others immediately. We thoroughly analyze our approach and show that with these changes, the mining process is becoming more transparent, collaborative, secure, efficient, and decentralized. Surprisingly, we also show how our approach can improve the freshness properties offered by Bitcoin. We present an implementation and evaluation of our scheme.

## 2 Background and Problem Definition

### 2.1 Nakamoto Consensus and Bitcoin

The Nakamoto consensus protocol allows decentralized and distributed network comprised of mutually distrusting participants to reach an agreement on the state of the global distributed ledger [28]. The distributed ledger can be regarded as a linked list of blocks, referred to as the *blockchain*, which serializes and confirms “transactions”. To resolve any *forks* of the blockchain the protocol specifies to always accept the longest chain as the current one. Bitcoin is a peer-to-peer cryptocurrency that deploys Nakamoto consensus as its core mechanism to avoid double-spending. Transactions spending bitcoins are announced to the Bitcoin network, where miners validate, serialize all non-included transactions, and try to create (mine) a block of transactions with a PoW embedded into the block header. A valid block must fulfill the condition that for a cryptographic hash function  $H$ , the hash value of the block header is less than the target  $T$ .

Brute-forcing the nonce (together with some other changeable data fields) is virtually the only way to produce the PoW, which costs computational resources of the miners. To incentivize miners, the Bitcoin protocol allows the miner who finds a block to insert a special transaction (see below) minting a specified amount of new bitcoins and collecting transaction fees offered by the included transactions, which are transferred to an account chosen by the miner. Currently, every block mints 12.5 new bitcoins. This amount is halved every four years, upper-bounding the number of bitcoins that will be created to a fixed total of 21 million coins. It implies that after around the year 2140, no new coins will be created,

and the transaction fees will be the only source of reward for miners. Because of its design, Bitcoin is a deflationary currency.

The overall hash rate of the Bitcoin network and the difficulty of the PoW determine how long it takes to generate a new block for the whole network (the block interval). To stabilize the block interval at about 10 minutes for the constantly changing total mining power, the Bitcoin network adjusts the target  $T$  every 2016 blocks (about two weeks, i.e., a *difficulty window*) according to the following formula

$$T_{new} = T_{old} \cdot \frac{\text{Time of the last 2016 blocks}}{2016 \cdot 10 \text{ minutes}}. \quad (1)$$

In simple terms, the difficulty increases if the network is finding blocks faster than every 10 minutes, and decrease otherwise. With dynamic difficulty, Nakamoto’s longest chain rule was considered as a bug,<sup>1</sup> as it is trivial to produce long chains that have low difficulty. The rule was replaced by the strongest-PoW chain rule where competing chains are measured in terms of PoW they aggregated. As long as there is one chain with the highest PoW, this chain is chosen as the current one.

Bitcoin introduced and uses the *unspent transaction output* model. The validity of a Bitcoin transaction is verified by executing a script proving that the transaction sender is authorized to redeem unspent coins. The only exception is the first transaction in the transaction list of a block, which implements how the newly minted bitcoins and transaction fees are distributed. It is called a *coinbase transaction* and it contains the amount of bitcoins (the sum of newly minted coins and the fees derived from all the transactions) and the beneficiary (typically the creator of the block). Also, the Bitcoin scripting language offers a mechanism (OP\_RETURN) for recording data on the blockchain, which facilitates third-party applications built-on Bitcoin.

Bitcoin proposes the simplified payment verification (SPV) protocol, that allows resource-limited clients to verify that a transaction is indeed included in a block provided only with the block header and a short transaction’s inclusion proof. The key advantage of the protocol is that SPV clients can verify the existence of a transaction without downloading or storing the whole block. SPV clients are provided only with block headers and on-demand request from the network inclusion proofs of the transactions they are interested in.

In the original white paper, Nakamoto heuristically argues that the consensus protocol remains secure as long as a majority (> 50%) of the participants’ computing power honestly follow the rule specified by the protocol, which is compatible with their own economic incentives.

<sup>1</sup><https://goo.gl/thhusi>

## 2.2 Bitcoin Mining Issues

Despite its popularity, Nakamoto consensus and Bitcoin suffer from multiple issues. Bitcoin mining is not always incentive-compatible. By deviating from the protocol and strategically withholding found blocks, a miner in possession of a proportion  $\alpha$  of the total computational power may occupy more than  $\alpha$  portion of the blocks on the blockchain, and therefore gain disproportionately higher payoffs with respect to her share [1, 11, 39]. More specifically, an attacker tries to create a private chain by keeping found blocks secret as long as the chain is in an advantageous position with one or more blocks more than the public branch. She releases her private chain only when the public chain has almost caught up, hence invalidating the public branch and all the efforts made by the honest miners. This kind of attack, called *selfish mining*, can be more efficient when a well-connected selfish miner's computational power exceeds a certain threshold (around more than 30%). Thus, selfish mining does not pay off if the mining power is sufficiently decentralized.

Unfortunately, the miners have an impulse to centralize their computing resources due to Bitcoin's rewarding scheme. In Bitcoin, rewarding is a zero-sum game and only the lucky miner who manages to get her block accepted receives the reward, while others who indeed contributed computational resources to produce the PoW are completely invisible and ignored. Increasing mining competition leads to an extremely high variance of the payoffs of a miner with a limited computational power. A solo miner may need to wait months or years to receive any reward at all. As a consequence, miners are motivated to group their resources and form mining pools, that divide work among pool participants and share the rewards according to their contributions. As of November 2018, only five largest pools account for more than 65% of the mining power of the whole Bitcoin network.<sup>2</sup> Such mining pools not only undermine the decentralization property of the system but also raise various in-pool or cross-pool security issues [5, 9, 22, 37].

Another seemingly harmless characteristic of Bitcoin is its finite monetary supply. However, researchers in their recent work [4, 27, 47] investigate the system dynamics when incentives coming from transaction fees are non-negligible compared with block rewards (in one extreme case the incentives come only from fees). They provide analysis and evidence, indicating an undesired system degradation due to the rational and self-interested participants. Firstly, such a system incentivizes large miner coalitions, increasing the system centralization even more. Secondly, it leads to a mining gap where miners would avoid mining when the available fees are insufficient. Even worse, rational miners tend to mine on chains that do not include available transactions (and their fees), rather than following the block selection rule specified by the protocol, resulting in a backlog of transac-

tions. Finally, in the sole transaction fee regime, selfish mining attacks are efficient for miners with arbitrarily low mining power, regardless of their network connection qualities. These results suggest that making the block reward permanent and accepting the monetary inflation may be a wise design choice to ensure the stability of the cryptocurrency in the long run.

Moreover, the chain selection rule (i.e., the strongest chain is accepted), together with the network delay, occasionally lead to forks, where two or more blocks pointing to the same block are created around the same time, causing the participants to have different views of the current system state. Such conflicting views will eventually be resolved since with a high probability one branch will finally beat the others (then the blocks from the "losing" chain become *stale blocks*). The process of fork resolution is quite slow, as blocks have the same PoW weight and they arrive in 10-minute intervals (on average).

Finally, the freshness properties provided by Bitcoin are questionable. By design, the Bitcoin blockchain preserves the order of blocks and transactions, however, the accurate estimation of time of these events is challenging [43], despite the fact that each block has an associated timestamp. A block's timestamp is accepted if a) it is greater than the median timestamp of the previous eleven blocks, and b) it is less than the network time plus two hours.<sup>3</sup> This gives significant room for manipulation — in theory, a timestamp can differ in hours from the actual time since it is largely determined by a single block creator. In fact, as time cannot be accurately determined from the timestamps, the capabilities of the Bitcoin protocol as a timestamping service are limited, which may lead to severe attacks by itself [3, 17].

## 2.3 Requirements

For the purpose of revising a consensus protocol of PoW blockchains in a secure, well-incentivized, and seamless way, we define the following respective requirements:

- **Security** – the scheme should improve the security of Nakamoto consensus by mitigating known attack vectors and preventing new ones. In essence, the scheme should be incentive-compatible, such that miners benefit from following the consensus rules and have no gain from violating them.
- **Reward Variance** – another objective is to minimize the variance in rewards. This requirement is crucial for decentralization since a high reward variance is the main motivation of individual miners to join centralized mining pools. Centralization is undesirable as large-enough mining pools can attack the Bitcoin protocol.
- **Chain Quality** – the scheme should provide a high chain quality, which usually is described using the two following properties.

<sup>2</sup>[https://btc.com/stats/pool?pool\\_mode=month](https://btc.com/stats/pool?pool_mode=month)

<sup>3</sup>[https://en.bitcoin.it/wiki/Block\\_timestamp](https://en.bitcoin.it/wiki/Block_timestamp)

- **Mining Power Utilization** – the ratio between the mining power on the main chain and the mining power of the entire blockchain network. This property describes the performance of mining and its ideal value is 1, which denotes that all mining power of the system contributes to the “official” or “canonical” chain. A high mining power utilization implies a low stale block rate.
- **Fairness** – the protocol should be fair, i.e., a miner should earn rewards proportionally to the resources invested by her in mining. We denote a miner with  $\alpha$  of the global mining power as an  $\alpha$ -strong miner.
- **Efficiency and Practicality** – the scheme should not introduce any significant computational, storage, or bandwidth overheads. This is especially important since Bitcoin works as a replicated state machine, therefore all full nodes replicate data and the validation process. In particular, the block validation time, its size, and overheads of SPV clients should be at least similar as today. Moreover, the protocol should not introduce any assumptions that would be misaligned with Bitcoin’s spirit and perceived as unacceptable by the community. In particular, the scheme should not introduce any trusted parties and should not assume strong synchronization of nodes (like global and reliable timestamps).

### 3 High-level Overview

#### 3.1 Design Rationale

Our first observation is that Bitcoin mining is not transparent. It is difficult to quickly estimate the computing power of the different participants, because the only indicator is the found blocks. After all, blocks arrive with a low frequency, and each block is equal in terms of its implied computational power. Consequently, the only way of resolving forks is to wait for a stronger chain to emerge, which can be a time-consuming process. A related issue is block-withholding-like attacks (e.g., selfish mining) which are based on the observation that sometimes it is profitable for an attacker to deviate from the protocol by postponing the announcement of new solutions. We see transparency as a helpful property also in this context. Ideally, non-visible (hidden) solutions should be penalized, however, in practice it is challenging to detect and prove that a solution was hidden. We observe that an alternative way of mitigating these attacks would be to promote visible solutions, such that with more computing power aggregated around them they get stronger. This would incentivize miners to publish their solutions immediately, since keeping it secret may be too risky as other miners could strengthen a competing potential (future) solution over time. Finally, supported by recent research results [4, 11, 27, 39, 47], we envision that redesigning the Bit-

coin reward scheme is unavoidable to keep the system sustainable and more secure. Beside the deflation issues (see Section 2.2), the reward scheme in Bitcoin is a zero-sum game rewarding only lucky miners and ignoring all effort of other participants. That causes fierce competition between miners and a high reward variance, which stimulates miners to collaborate, but within mining pools, introducing more risk to the system. We aim to design a system where miners can benefit from collaboration but without introducing centralization risks.

#### 3.2 Overview

Motivated by these observations, we see weak puzzle solutions, currently invisible and “wasted” in Bitcoin, as a promising direction. Miners exchanging them could make the protocol more transparent as announcing them could reflect the current distribution of computational efforts on the network. Furthermore, if included in consensus rules, they could give blocks a better granularity in terms of PoW, and incentivize miners to collaborate. In our scheme, miners solve a puzzle as today but in addition to publishing solutions, they exchange weak solutions too (i.e., almost-solved puzzles). The lucky miner publishes her solution that embeds gathered weak solutions (pointing to the same previous block) of other miners. Such a published block better reflects the aggregated PoW of a block, which in the case of a fork can indicate that more mining power is focused on a given branch (i.e., actually it proves that more computing power “believes” that the given branch is correct). Another crucial change is to redesign the Bitcoin reward system, such that the finders of weak solutions are also rewarded. Following lessons learned from mining pool attacks, instead of sharing rewards among miners, our scheme rewards weak solutions proportionally to their PoW contributed to a given block and all rewards are independent of other solutions of the block. (Note, that this change requires a Bitcoin *hard fork*.)

There are a few intuitions behind these design choices. First, a selfish miner finding a new block takes a high risk by keeping this block secret. This is because blocks have a better granularity due to honest miners exchanging partial solutions and strengthening their prospective block, which in the case of a fork would be stronger than the older block kept secret (i.e., the block of the selfish miner). Secondly, miners are actually incentivized to collaborate by a) exchanging their weak solutions, and b) by appending weak solutions submitted by other miners. For the former case, miners are rewarded whenever their solutions are appended, hence keeping them secret can be unprofitable for them. For the latter case, a miner appending weak solutions of others only increases the strength of her potential block, and moreover, appending these solutions does not negatively influence the miner’s potential reward. Finally, our approach comes with another benefit. Proportional rewarding of weak solutions

decreases the reward variance, thus miners do not have to join large mining pools in order to stabilize their revenue. This could lead to a higher decentralization of mining power on the network.

In the following sections, we describe details of our system, show its analysis, and report on its implementation.

## 4 StrongChain Details

### 4.1 Mining

As in Bitcoin, in StrongChain miners authenticate transactions by collecting them into blocks whose headers are protected by a certain amount of PoW. A simplified description of a block mining procedure in StrongChain is presented as the *mineBlock()* function in Algorithm 1. Namely, every miner tries to solve a PoW puzzle by computing the hash function over a newly created header. The header is constantly being changed by modifying its nonce field,<sup>4</sup> until a valid hash value is found. Whenever a miner finds a header *hdr* whose hash value  $h = H(hdr)$  is smaller than the *strong target*  $T_s$ , i.e., a  $h$  that satisfies the following:

$$h < T_s,$$

then the corresponding block is announced to the network and becomes, with all its transactions and metadata, part of the blockchain. We refer to headers of included blocks as *strong headers*.

One of the main differences with Bitcoin is that our mining protocol handles also headers whose hash values do not meet the strong target  $T_s$ , but still are low enough to prove a significant PoW. We call such a header a *weak header* and its hash value  $h$  has to satisfy the following:

$$T_s \leq h < T_w, \quad (2)$$

where  $T_w > T_s$  and  $T_w$  is called the *weak target*.

Whenever a miner finds such a block header, she adds it to her local list of weak headers (i.e., *weakHdrsTmp*) and she propagates the header among all miners. Then every miner that receives this information first validates it (see *onRecvWeakHdr()*) by checking whether

- the header points to the last strong header,
- its other fields are correct (see Section 4.2),
- and Equation 2 is satisfied.

Afterward, miners append the header to their lists of weak headers. We do not limit the number of weak headers appended, although this number is correlated with the  $T_w/T_s$  ratio (see Section 5).

Finally, miners continue the mining process in order to find a strong header. In this process, a miner keeps creating candidate headers by computing hash values and checking whether the strong target is met. Every candidate header

---

---

```

function mineBlock()
  weakHdrsTmp ← ∅;
  for nonce ∈ {0, 1, 2, ...} do
    hdr ← createHeader(nonce);
    /* check if the header meets the strong target */
    htmp ← H(hdr);
    if htmp < Ts then
      B ← createBlock(hdr, weakHdrsTmp, TxS);
      broadcast(B);
      return; /* signal to mine with the new block */
    /* check if the header meets the weak target */
    if htmp < Tw then
      weakHdrsTmp.add(hdr);
      broadcast(hdr);

function onRecvWeakHdr(hdr)
  hw ← H(hdr);
  assert(Ts ≤ hw < Tw and validHeader(hdr));
  assert(hdr.PrevHash == H(lastBlock(hdr)));
  weakHdrsTmp.add(hdr);

function rewardBlock(B)
  /* reward block finder with R */
  reward(B.hdr.Coinbase, R + B.TxFees);
  w ← γ * Ts / Tw; /* reward weak headers proportionally */
  for hdr ∈ B.weakHdrSet do
    reward(hdr.Coinbase, w * c * R);

function validateBlock(B)
  assert(H(B.hdr) < Ts and validHeader(B.hdr));
  assert(B.hdr.PrevHash == H(lastBlock(hdr)));
  assert(validTransactions(B));
  for hdr ∈ B.weakHdrSet do
    assert(Ts ≤ H(hdr) < Tw and validHeader(hdr));
    assert(hdr.PrevHash == H(lastBlock(hdr)));

function chainPoW(chain)
  sum ← 0;
  for B ∈ chain do
    /* for each block compute its aggregated PoW */
    Ts ← B.hdr.Target;
    sum ← sum + Tmax / Ts;
    for hdr ∈ B.weakHdrSet do
      sum ← sum + Tmax / Tw;
  return sum;

function getTimestamp(B)
  sumT ← B.hdr.Timestamp;
  sumW ← 1.0;
  /* average timestamp by the aggregated PoW */
  w ← Ts / Tw;
  for hdr ∈ B.weakHdrSet do
    sumT ← sumT + w * hdr.Timestamp;
    sumW ← sumW + w;
  return sumT / sumW;

```

---

<sup>4</sup>In fact, other fields can be modified too if needed.

“protects” all collected weak headers (note that all of these weak headers point to the same previous strong header).

In order to keep the number of found weak headers close to a constant value, StrongChain adjusts the difficulty  $T_w$  of weak headers every 2016 blocks immediately following the adjustment of the difficulty  $T_s$  of the strong headers according to Equation 1, such that the ratio  $T_w/T_s$  is kept at a constant (we discuss its value in Section 5).

## 4.2 Block Layout and Validation

A block in our scheme consists of transactions, a list of weak headers, and a strong header that authenticates these transactions and weak headers. Strong and weak headers in our system inherit the fields from Bitcoin headers and additionally enrich it by a new field. A block header consists of the following fields:

- PrevHash*: is a hash of the previous block header,
- Target*: is the value encoding the current target defining the difficulty of finding new blocks,
- Nonce*: is a nonce, used to generate PoW,
- Timestamp*: is a Unix timestamp,
- TxRoot*: is the root of the Merkle tree [24] aggregating all transactions of the block, and
- Coinbase*: represents an address of the miner that will receive a reward.

As our protocol rewards finders of weak headers (see details in Section 4.4), every weak header has to be accompanied with the information necessary to identify its finder. Otherwise, a finder of a strong block could maliciously claim that some (or all) weak headers were found by her and get rewards for them. For this purpose and for efficiency, we introduced a new 20B-long header field named *Coinbase*. With the introduction of this field, StrongChain headers are 100B long. But on the other hand, there is no longer any need for Bitcoin coinbase transactions (see Section 2.1), as all rewards are determined from headers.

In our scheme, weak headers are exchanged among nodes as part of a block, hence it is necessary to protect the integrity of all weak headers associated with the block. To realize it, we introduce a special transaction, called a *binding transaction*, which contains a hash value computed over the weak headers. This transaction is the first transaction of each block and it protects the collected weak headers. Whenever a strong header is found, it is announced together with all its transactions and collected weak headers, therefore, this field protects all associated weak headers. To encode this field we utilize the OP\_RETURN operation as follows:

$$\text{OP\_RETURN } H(\text{hdr}_0||\text{hdr}_1||\dots||\text{hdr}_n), \quad (3)$$

where  $\text{hdr}_i$  is a weak header pointing to the previous strong header. Since weak headers have redundant fields (the *PrevHash*, *Target*, and *Version* fields have the same values as

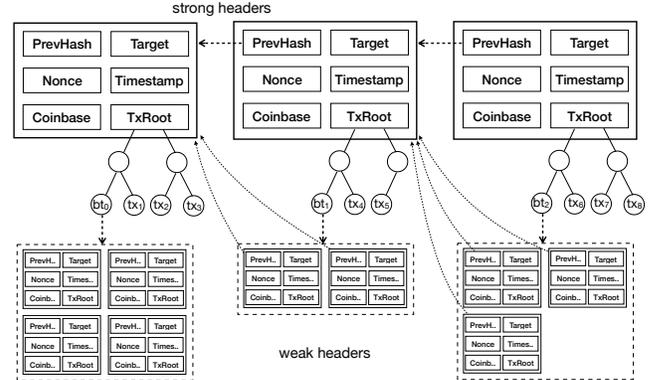

Figure 1: An example of a blockchain fragment with strong headers, weak headers, and binding and regular transactions.

the strong header), we propose to save bandwidth and storage by not including these fields into the data of a block. This modification reduces the size of a weak header from 100B to 60B only, which is especially important for SPV clients who keep downloading new block headers.

With our approach, a newly mined and announced block can encompass multiple weak headers. Weak headers, in contrast to strong headers, are not used to authenticate transactions, and they are even stored and exchanged *without* their corresponding transactions. Instead, the main purpose of including weak headers is to contribute and reflect the aggregated mining power concentrated on a given branch of the blockchain. We present a fragment of a blockchain of StrongChain in Figure 1. As depicted in the figure, each block contains a single strong header, transactions, and a set of weak headers aggregated via a binding transaction.

On receiving a new block, miners validate the block by checking the following (see *validateBlock()* in Algorithm 1):

1. The strong header is protected by the PoW and points to the previous strong header.
2. Header fields have correct values (i.e., the version, target, and timestamp are set correctly).
3. All included transactions are correct and protected by the strong header. This check also includes checking that all weak headers collected are protected by a binding transaction included in the block.
4. All included weak headers are correct: a) they meet the targets as specified in Equation 2, b) their *PrevHash* fields point to the previous strong header, and c) their version, targets, and timestamps have correct values.

If the validation is successful, the block is accepted as part of the blockchain.

## 4.3 Forks

One of the main advantages of our approach is that blocks reflect their aggregated mining power more precisely. Each block beside its strong header contains multiple weak head-

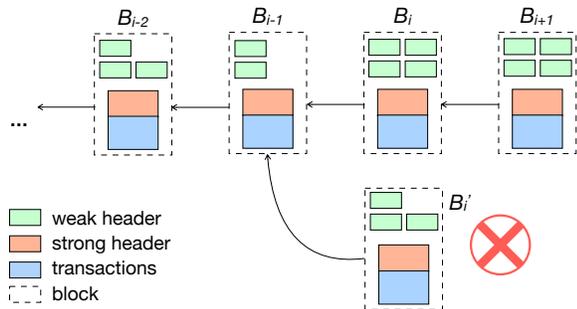

Figure 2: An example of a forked blockchain in StrongChain.

ers that contribute to the block’s PoW. In the case of a fork, our scheme relies on the strongest chain rule, however, the PoW is computed differently than in Bitcoin. For every chain its PoW is calculated as presented by the *chainPoW()* procedure in Algorithm 1. Every chain is parsed and for each of its blocks the PoW is calculated by adding:

1. the PoW of the strong header, computed as  $T_{max}/T_s$ , where  $T_{max}$  is the maximum target value, and
2. the accumulated PoW of all associated weak headers, counting each weak header equally as  $T_{max}/T_w$ .

Then the chain’s PoW is expressed as just the sum of all its blocks’ PoW. Such an aggregated chain’s PoW is compared with the competing chain(s). The chain with the largest aggregated PoW is determined as the current one. As difficulty in our protocol changes over time, the strong target  $T_s$  and PoW of weak headers are relative to the maximum target value  $T_{max}$ . We assume that nodes of the network check whether every difficulty window is computed correctly (we skipped this check in our algorithms for easy description).

Including and empowering weak headers in our protocol moves away from Bitcoin’s “binary” granularity and gives blocks better expression of the PoW they convey. An example is presented in Figure 2. For instance, nodes having the blocks  $B_i$  and  $B'_i$  can immediately decide to follow the block  $B_i$  as it has more weak headers associated, thus it has accumulated more PoW than the block  $B'_i$ .

An exception to this rule is when miners solve conflicts. Namely, on receiving a new block, miners run the algorithm as presented, however, they also take into consideration PoW contributions of known weak headers that point to the last blocks. For instance, for a one-block-long fork within the same difficulty window, if a block  $B$  includes  $l$  weak headers and a miner knows of  $k$  weak headers pointing to  $B$ , then that miner will select  $B$  over any competing block  $B'$  that includes  $l'$  weak and has  $k'$  known weak headers pointing to it if  $l + k > l' + k'$ . Note that this rule incentivizes miners to propagate their solutions as quickly as possible as competing blocks become “stronger” over time.

## 4.4 Rewarding Scheme

The rewards distribution is another crucial aspect of StrongChain and it is presented by the *rewardBlock()* procedure from Algorithm 1. The miner that found the strong header receives the full reward  $R$ . Moreover, in contrast to Bitcoin, where only the “lucky” miner is paid the full reward, in our scheme all miners that have contributed to the block’s PoW (i.e., whose weak headers are included) are paid by commensurate rewards to the provided PoW. A weak header finder receive a fraction of  $R$ , i.e.,  $\gamma * c * R * T_s / T_w$ , as a reward for its corresponding solution contributing to the total PoW of a particular branch, where the  $\gamma$  parameter influences the relative impact of weak header rewards and  $c$  is just a scaling constant (we discuss their potential values and implications in Section 5). Moreover, we do not limit weak header rewards and miners can get multiple rewards for their weak headers within a single block. Similar reward mechanisms are present in today’s mining pools (see Section 8), but unlike them, weak header rewards in StrongChain are independent of each other. Therefore, the reward scheme is not a zero-sum game and miners cannot increase their own rewards by dropping weak headers of others (actually, as we discuss in Section 5, they can only lose since their potential solutions would have less PoW without others’ weak headers). Furthermore, weak header rewards decrease significantly the mining variance as miners can get steady revenue, making the system more decentralized and collaborative.

As mentioned before, the number of weak headers of a block is unlimited, they are rewarded independently (i.e., do not share any reward), and all block rewards in our system are proportional to the PoW contributed. In such a setting, a mechanism incentivizing miners to terminate a block creation is needed (without such a mechanism, miners could keep creating huge blocks with weak headers only). In order to achieve this, StrongChain always attributes block transaction fees ( $B.Tx Fees$ ) to the finder of the strong header (who also receives the full reward  $R$ ).

Note that in our rewarding scheme, the amount of newly minted coins is always at least  $R$ , and consequently, unlike Bitcoin or Ethereum [48], the total supply of the currency in our protocol is not upper-bounded. This design decision is made in accordance with recent results on the long-term instability of deflationary cryptocurrencies [4, 27, 47].

## 4.5 Timestamps

In StrongChain, we follow the Bitcoin rules on constraining timestamps (see Section 2.1), however, we redefine how block timestamps are interpreted. Instead of solely relying on a timestamp put by the miner who mined the block, block timestamps in our system are derived from the strong header and all weak headers included in the corresponding block. The algorithm to derive a block’s timestamp is presented as

*getTimestamp()* in Algorithm 1. A block’s timestamp is determined as a weighted average timestamp over the strong header’s timestamp and all timestamps of the weak headers included in the block. The strong header’s timestamp has a weight of 1, while weights of weak header timestamps are determined as their PoW contributed (namely, a weak header’s timestamp has a weight of the ratio between the strong target and the weak target). Therefore, the timestamp value is adjusted proportionally to the mining power associated with a given block. That change reflects an average time of the block creation and mitigates miners that intentionally or misconfigured put incorrect timestamps into the blockchain. We show the effectiveness of this approach in Section 5.5.

## 4.6 SPV Clients

Our protocol supports light SPV clients. With every new block, an SPV client is updated with the following information:

$$hdr, hdr_0, hdr_1, \dots, hdr_n, BTproof, \quad (4)$$

where *hdr* is a strong header, *hdr<sub>i</sub>* are associated weak headers, and *BTproof* is an inclusion proof of a binding transaction that contains a hash over the weak headers (see Equation 3). Note that headers contain redundant fields, thus as described in Section 4.2, they can be provided to SPV clients efficiently.

With this data, the client verifies fields of all headers, computes the PoW of the block (analogous, as in *chainPoW()* from Algorithm 1), and validates the *BTproof* proof to check whether all weak headers are correct, and whether the transaction is part of the blockchain (the proof is validated against *TxRoot* of *hdr*). Afterward, the client saves the strong header *hdr* and its computed PoW, while other messages (the weak headers and the proof) can be dropped.

## 5 Analysis

In this section, we evaluate the requirements discussed in Section 2.3. We start with analyzing StrongChain’s efficiency and practicality. Next, we study how our design helps with reward variance, chain quality, and security.

### 5.1 Efficiency and Practicality

For the efficiency, it is important to consider the main source of additional load on the bandwidth, storage, and processing power of the nodes: the weak headers. Hence, in the following section we analyze the probability distribution of the number of weak headers. Next, we discuss the value of the impact of the parametrization on the average block rewards.

#### 5.1.1 Number of Weak Headers

In Bitcoin, we assume that hashes are drawn randomly between 0 and  $T_{max} = 2^{256} - 1$ . Hence, a single hash being smaller than  $T_w$  is a *Bernoulli trial* with parameter  $p_w = T_w/2^{256}$ . The number of hashes tried until a weak header is found is therefore *geometrically* distributed, and the time in seconds between two weak headers is approximately *exponentially* distributed with rate  $\eta p_w$ , where  $\eta$  is the total hash rate per second and  $p_w$  is chosen such that  $\eta p_w \approx 1/600$ . When a weak header is found, it is also a strong block with probability  $p_s/p_w$  (where  $p_s = T_s/2^{256}$ ), which is again a Bernoulli trial. Hence, the probability distribution of the number of weak headers found between two strong blocks is that of the number of trials before the first successful trial — as such, it also follows a geometric distribution, but with mean  $p_w/p_s - 1$ .<sup>5</sup> For example, for  $T_w/T_s = 2^{10}$  this means that the average number of weak headers per block equals 1023. With 60 bytes per weak header (see Section 4.2) and 1MB per Bitcoin block, this would mean that the load increases by little over 6% on average with a small computational overhead introduced (see details in Section 7). The probability of having more than 16667 headers (or 1MB) in a block would equal.<sup>6</sup>

$$\left(1 - \frac{p_s}{p_w}\right)^{16668} = \left(1 - 2^{-10}\right)^{16668} \approx 8.4603 \cdot 10^{-8}.$$

Since around 51,000 Bitcoin blocks are found per year, this is expected to happen roughly once every 230 years.

#### 5.1.2 Total Rewards

To ease the comparison to the Bitcoin protocol, we can enforce the same average mining reward per block (currently 12.5 BTC). Let  $R$  denote Bitcoin’s mining reward. Since we reward weak headers as well as strong blocks, we need to scale all mining rewards by a constant  $c$  to ensure that the total reward remains unchanged — this is done in the *rewardBlock* function in Algorithm 1. As argued previously, we reward all weak headers equally by  $\gamma R T_s/T_w$ . Since the average number of weak headers per strong block is  $T_w/T_s - 1$ , this means that the expected total reward per block (i.e., strong block and weak header rewards) equals  $cR + cR\gamma T_s/T_w \cdot (T_w/T_s - 1)$ . Hence, we find that

$$c = \frac{1}{1 + \gamma(T_w/T_s - 1)T_s/T_w},$$

<sup>5</sup>Another way to reach this conclusion is as follows: the number of weak headers found in a fixed time interval is Poisson distributed, and it can be shown that the number of Poisson arrivals in an interval with exponentially distributed length is geometrically distributed.

<sup>6</sup>For an actual block implementation, we advice to introduce separate spaces for weak headers and transactions. With such a design, miners do not have incentives and trade-offs between including more transactions instead of weak headers.

which for large values of  $T_w/T_s$  is close to  $1/(1+\gamma)$ . This means that if  $\gamma = 1$ , the strong block and weak header rewards contribute almost equally to a miner's total reward.

## 5.2 Reward Variance of Solo Mining

The tendency towards centralization in Bitcoin caused by powerful mining pools can largely be attributed to the high reward variance of solo mining [15, 37]. Therefore, keeping the reward variance of a solo miner at a low level is a central design goal.

Let  $\mathbf{R}^{BC}$  and  $\mathbf{R}^{SC}$  be the random variables representing the per-block rewards for an  $\alpha$ -strong solo miner in Bitcoin and in StrongChain, respectively. For any given strong block in both protocols, we define the random variable  $\mathbf{I}$  as follows:

$$\mathbf{I} = \begin{cases} 1 & \text{the block is mined by the solo miner,} \\ 0 & \text{otherwise.} \end{cases}$$

By definition,  $\mathbf{I}$  has a Bernoulli distribution, which means that  $\mathbb{E}(\mathbf{I}) = \alpha$  and  $\text{Var}(\mathbf{I}) = \alpha(1-\alpha)$ , where  $\mathbb{E}$  and  $\text{Var}$  are the mean and variance of a random variable respectively. The following technical lemma will aid our analysis of the reward variances of solo miners:

**Lemma 1.** *Let  $X_1, X_2, \dots$  be independent and identically distributed random variables. Let  $N$  be defined on  $\{0, 1, \dots\}$  and independent of  $X_1, X_2, \dots$ . Let  $N$  and all  $X_i$  have finite mean and variance. Then*

$$\text{Var}\left(\sum_{i=1}^N X_i\right) = \mathbb{E}(N)\text{Var}(X) + \text{Var}(N)(\mathbb{E}(X))^2.$$

*Proof.* See [7]. □

**Reward Variance of Solo Mining in Bitcoin.** Bitcoin rewards the miner of a block creator with the fixed block reward  $R$  and the variable (total) mining fees, which we denote by the random variable  $\mathbf{F}$ . Therefore, we have

$$\mathbf{R}^{BC} = \mathbf{I}(R + \mathbf{F}),$$

which implies that

$$\text{Var}(\mathbf{R}^{BC}) = R^2\text{Var}(\mathbf{I}) + \text{Var}(\mathbf{IF}). \quad (5)$$

Since  $\mathbf{IF} = \sum_{i=0}^{\mathbf{I}} \mathbf{F}$ , we can use Lemma 1 (substituting  $\mathbf{I}$  for  $N$  and  $\mathbf{F}$  for  $X$ ) to obtain

$$\text{Var}(\mathbf{IF}) = \mathbb{E}(\mathbf{I})\text{Var}(\mathbf{F}) + \text{Var}(\mathbf{I})\mathbb{E}^2(\mathbf{F}). \quad (6)$$

Combining (5) and (6) gives

$$\begin{aligned} \text{Var}(\mathbf{R}^{BC}) &= \mathbb{E}(\mathbf{I})\text{Var}(\mathbf{F}) + \text{Var}(\mathbf{I})\left(\mathbb{E}^2(\mathbf{F}) + R^2\right) \\ &= \alpha\text{Var}(\mathbf{F}) + \alpha(1-\alpha)\left(\mathbb{E}^2(\mathbf{F}) + R^2\right). \end{aligned} \quad (7)$$

When the fees are small compared to the mining reward, this simplifies to  $\alpha(1-\alpha)R^2$ . By comparison, in [37] the variance of the block rewards (without fees) earned by a solo miner across a time period of  $t$  seconds is studied, and found to equal  $\alpha R^2 t / 600$ .<sup>7</sup> The same quantity can be obtained by using (7), Lemma 1, and the total number of strong blocks found (by any miner) after  $t$  seconds of mining (which has a Poisson distribution with mean  $t/600$ ).

**Reward Variance of Solo Mining in StrongChain.** For  $\mathbf{R}^{SC}$ , we assume that the solo miner has  $\mathbf{N}$  weak headers included in the strong block, and that she obtains  $c\gamma RT_s/T_w$  reward per weak header. Then the variance equals

$$\mathbf{R}^{SC} = \mathbf{I}(cR + \mathbf{F}) + c\gamma RT_s/T_w \mathbf{N},$$

where  $c$  is the scaling constant derived in Section 5.1.2. Hence, by applying Lemma 1, we compute the variance of  $\mathbf{R}^{SC}$  as

$$\begin{aligned} \text{Var}(\mathbf{R}^{SC}) &= (cR)^2\text{Var}(\mathbf{I}) + \text{Var}(\mathbf{IF}) \\ &\quad + (c\gamma RT_s/T_w)^2\text{Var}(\mathbf{N}). \end{aligned} \quad (8)$$

The first term, which represents the variance of the strong block rewards, is similar to Bitcoin but multiplied by  $c^2$ . If we choose  $T_w/T_s = 1024$  and  $\gamma = 10$  (this choice is motivated later in this section),  $c^2$  roughly equals 0.0083, which is quite small. Hence, the strong block rewards have a much smaller impact on the reward variance in our setting than in Bitcoin. The second term, which represents the variance of the fees, is precisely the same as for Bitcoin. The third term represents the variance of the weak header rewards, which in turn completely depends on  $\text{Var}(\mathbf{N})$ .

To evaluate  $\text{Var}(\mathbf{N})$ , we again use Lemma 1: let, for any weak header,  $\mathbf{J}$  equal 1 if it is found by the solo miner, and 0 otherwise. Also, let  $\mathbf{L}$  be the total number of weak headers found in the block, so including those not found by the solo miner. Then  $\mathbf{N}$  is the sum of  $\mathbf{L}$  instances of  $\mathbf{J}$ , where  $\mathbf{J}$  has a Bernoulli distribution with success probability  $\alpha$  (and therefore  $\mathbb{E}(\mathbf{J}) = \alpha$  and  $\text{Var}(\mathbf{J}) = \alpha(1-\alpha)$ ), and  $\mathbf{L}$  has a geometric distribution with success probability  $T_s/T_w$  (and therefore  $\mathbb{E}(\mathbf{L}) = T_w/T_s - 1$  and  $\text{Var}(\mathbf{L}) = (T_w/T_s)^2 - T_w/T_s$ ). By substituting this into (8), we obtain:

$$\begin{aligned} \text{Var}(\mathbf{N}) &= \mathbb{E}(\mathbf{L})\text{Var}(\mathbf{J}) + \text{Var}(\mathbf{L})(\mathbb{E}(\mathbf{J}))^2 \\ &= (T_w/T_s - 1)\alpha(1-\alpha) \\ &\quad + ((T_w/T_s)^2 - T_w/T_s)\alpha^2 \end{aligned} \quad (9)$$

Substituting (9) for  $\text{Var}(\mathbf{N})$  and  $\alpha(1-\alpha)$  for  $\text{Var}(\mathbf{I})$  into (8) then yields an expression that can be evaluated for different values of  $T_w/T_s$ ,  $\gamma$ , and  $\alpha$ , as we discuss in the following.

<sup>7</sup>In particular, it is found to be  $htR^2/(2^{32}D)$ , where  $h = \alpha\eta$  and  $\eta/(2^{32}D) \approx 1/600$ .

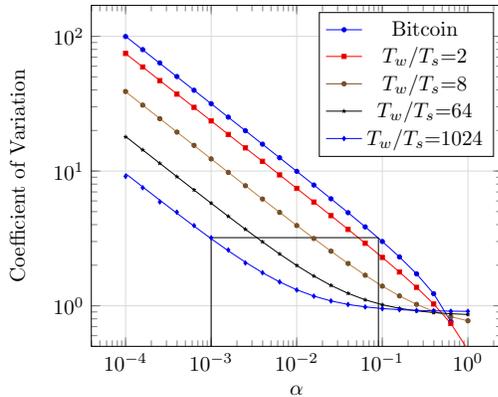

Figure 3: *Coefficients of variation* for the total rewards of  $\alpha$ -strong miners for different strong/weak header difficulty ratios ( $T_w/T_s = 1$  corresponds to Bitcoin). The lines indicate the exact results obtained using our analysis, whereas the markers indicate simulation results. We used  $\gamma = \log_2(T_w/T_s)$ . The black lines indicate that for  $T_w/T_s = 1024$ , a 0.1%-strong miner has a coefficient of variation that is comparable to a 9%-strong miner’s in Bitcoin.

**Comparison** The difference between between (7) and (8) in practice is illustrated in Figure 3. This is done by comparing for a range of different values of  $\alpha$  the block rewards’ *coefficient of variation*, which is the ratio of the square root of the variance to the mean.

To empirically validate the results, we have also implemented a simulator in Java that can evaluate Bitcoin as well as StrongChain. We use two nodes, one of which controls a share  $\alpha$  of the hash rate, and another controls a share  $1 - \alpha$ . The nodes can broadcast information about blocks, although we abstract away from most of the other network behavior. We do not consider transactions (i.e., we mine empty blocks), and we use a simplified model for the propagation delays: delays are drawn from a Weibull distribution with shape parameter 0.6 [31], although for Figure 3 the mean was chosen to be negligible (more realistic values are chosen for Table 1).

The black lines in Figure 3 demonstrate that when  $T_w/T_s = 1024$ , a miner with share 0.1% of the mining power has the same coefficient of reward variation as a miner with stake 9% in Bitcoin. Also note that for  $T_w/T_s = 1024$  and  $\alpha \geq 1\%$ , the coefficient of variation does not substantially decrease anymore, because nearly all of the reward variance is due to the number of weak headers. Hence, there would be fewer reasons for miners in our system to join large and cooperative mining pools, which has a positive effect on the decentralization of the system.

### 5.3 Chain Quality

One measure for the ‘quality’ of a blockchain is the stale rate of blocks [16], i.e., the percentage of blocks that appear during forks and do not make it onto the main chain. This is closely related to the notion of mining power utiliza-

tion [10], which is the fraction of mining power used for non-stale blocks. In StrongChain, the stale rate of strong blocks may increase due to high latency. After all, while a new block is being propagated through the network, weak headers that strengthen the previous block that are found will be included by miners in their PoW calculation. As a result, some miners may refuse to switch to the new block when it arrives. However, the probability of this happening is very low: because each weak header only contributes  $T_s/T_w$  to the difficulty of a block, it would take on average 10 minutes to find enough weak headers to outweigh a block. As we can see in Table 1, the effect on the stale rate is negligible even for very high network latencies (i.e., 53 seconds). We also emphasize that the strong block stale rate is less important in our setting, as the losing miner still would benefit from her weak headers appended to the winning block.

Regarding the fairness, defined as the ratio between the observed share of the rewards (we simulate using one 10%-strong miner and a 90%-strong one) and the share of the mining power, we see that StrongChain does slightly worse than Bitcoin for high network latencies. The most likely cause is that due to the delay in the network, the 10%-strong miner keeps mining on a chain that has already been extended for longer than necessary. This gives the miner a slight disadvantage compared to the 90%-strong miner.

### 5.4 Security

One of the main advantages of StrongChain is the added robustness to selfish mining strategies akin to those discussed in [11] and [39]. In selfish mining, attackers aim to increase their share of the earned rewards by tricking other nodes into mining on top of a block that is unlikely to make it onto the main chain, thus wasting their mining power. This may come at a short-term cost, as the chance of the attacker’s blocks going stale is increased — however, the difficulty rescale that occurs every 2016 blocks means that if the losses to the honest nodes are structural, the difficulty will go down and the gains of the attacker will increase.

In the following, we will consider the selfish mining strategy of [11],<sup>8</sup> described as follows:

- The attacker does not propagate a newly found block until she finds at least a second block on top of it, and then only if the difference in difficulty between her chain and the strongest known alternative chain is between zero and  $R$ .
- The attacker adopts the strongest known alternative chain if its difficulty is at least greater than her own by  $R$ .

<sup>8</sup>The ‘stubborn mining’ strategy of [39] offers mild improvements over [11] for powerful miners, but the comparison with StrongChain is similar. We have also modeled StrongChain using a Markov decision process, in a way that is similar to the recently proposed framework of [51]. Due to the state space explosion problem, we could only investigate the protocol with a small number of expected weak headers, but we have not found any strategies noticeably that are better than those presented.

		StrongChain							
		Bitcoin	$T_w/T_s = 2$		$T_w/T_s = 64$		$T_w/T_s = 1024$		
Latency			$\gamma = 1$	$\gamma = 1$	$\gamma = 7$	$\gamma = 63$	$\gamma = 1$	$\gamma = 10$	$\gamma = 1023$
strong stale rate	low	.0023	.0025	.0021	.0026	.0028	.0023	.0025	.0019
	medium	.0073	.0082	.0087	.0077	.0078	.0084	.0067	.0081
	high	.0243	.0297	.0242	.0263	.0247	.0274	.0249	.0263
weak stale rate	low	—	.0043	.0047	.0049	.0046	.0049	.0047	.0047
	medium	—	.0142	.0151	.0154	.0149	.0145	.0147	.0149
	high	—	.0400	.0459	.0474	.0452	.0469	.0455	.0463
fairness	low	.9966	.9814	.9749	.9747	.9838	.9645	.9809	.9812
	medium	.9276	.9384	.9570	.9360	.9364	.9329	.9400	.9385
	high	.7951	.7640	.7978	.7820	.7757	.7756	.7766	.7775

Table 1: For several different protocols, the strong block stale rate, weak header rate, and the ‘fairness’ for an  $\alpha$ -strong honest miner with  $\alpha = 0.1$ . Here, fairness is defined as the ratio between the observed share of the reward and the ‘fair’ share of the rewards (i.e., 0.1). ‘Low’, ‘medium’, and ‘high’ latencies refer to the mean of the delay distribution in the simulator; these are roughly 0.53 seconds, 5.3 seconds, and 53 seconds respectively. The simulations are based on a time period corresponding to roughly 20000 blocks.

In Figure 4a, we have depicted the profitability of this selfish mining strategy for different choices of  $T_w/T_s$ . As we can see, for  $T_w/T_s = 1024$  the probability of being ‘ahead’ after two strong blocks is so low that the strategy only begins to pay off when the attackers’ mining power share is close to 45% — this is an improvement over Bitcoin, where the threshold is closer to 33%.

StrongChain does introduce new adversarial strategies based on the mining of new weak headers. Some examples include not broadcasting any newly found weak blocks (“reclusive” mining), refusing to include the weak headers of other miners (“spiteful” mining), and postponing the publication of a new strong block and wasting the weak headers found by other miners in the meantime. In the former case, the attacker risks losing their weak blocks, whereas in both of the latter two cases, the attacker risks their strong block going stale as other blocks and weak headers are found. Hence, these are not cost-free strategies. Furthermore, because the number of weak headers does not affect the difficulty rescale, the attacker’s motive for increasing the stale rate of other miners’ weak headers is less obvious (although in the long run, an adversarial miner could push other miners out of the market entirely, thus affecting the difficulty rescale).

In Figure 4b, we have displayed the relative payout (with respect to the total rewards) of a reclusive  $\alpha$ -strong miner — this strategy does not pay for any  $\alpha < 0.5$ . In Figure 4c, we have depicted the relative payoff of a spiteful mine who does not include other miners’ weak blocks unless necessary (i.e., unless others’ weak blocks together contribute more than  $R$  to the difficulty, which would mean that any single block found by the spiteful miner would always go stale). For low latencies (the graphs were generated with an average latency of 0.53 seconds), the strategy is almost risk-free, and the attacker does manage to hurt other miners more than herself, leading to an increased relative payout. However, as displayed in Figure 4d, there are no absolute gains, even mild

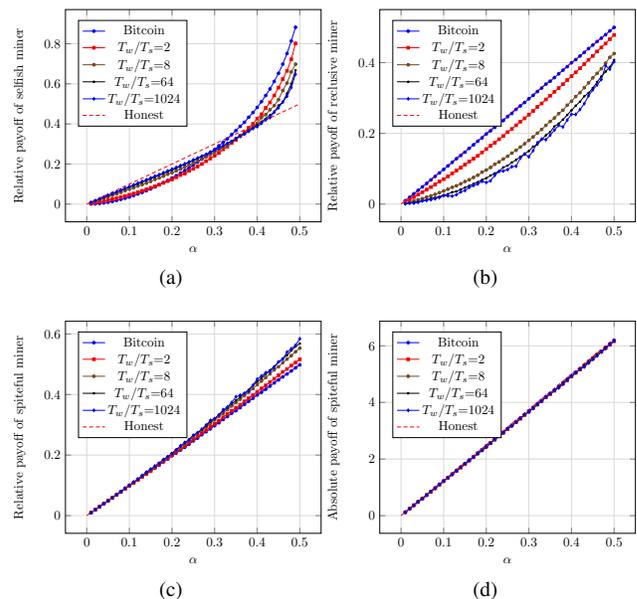

Figure 4: Payoffs of an  $\alpha$ -strong adversarial miner for different strategies. Figure (a): relative payoff of a *selfish* miner following the strategy of [11], compared to an  $(1 - \alpha)$ -strong honest miner. Figure (b): relative payoff of a *reclusive* miner who does not broadcast her weak blocks. Figure (c): *relative* payoff (with respect to the rewards of all miners combined) of a *spiteful* miner, who does not include other miners’ weak blocks unless necessary. Figure (d): *absolute* payoff of a *spiteful* miner, with 12.5 BTC on average awarded per block. We consider Bitcoin and StrongChain with different choices of  $T_w/T_s$ , with  $\gamma = \log_2(T_w/T_s)$ .

losses. As mentioned earlier, the weak headers do not affect the difficulty rescale so there is no short-term incentive to engage in this behavior — additionally there is little gain in computational overhead as the attacker still needs to process her own weak headers. In Section 6.1 we will discuss protocol updates that can mitigate these strategies regardless.

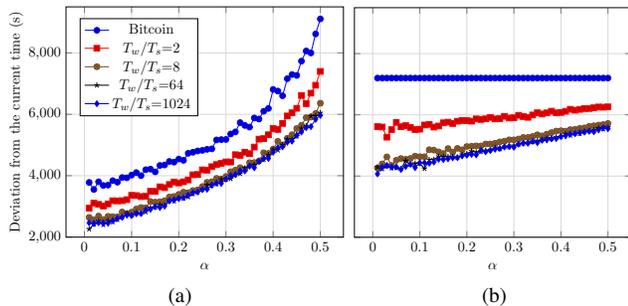

Figure 5: The deviation from the network time that an  $\alpha$ -strong adversary can introduce for its mined blocks by slowing (the left graph) and accelerating (the right graph) timestamps.

## 5.5 More Reliable Timestamps

Finally, we conducted a series of simulations to investigate how the introduced redefinition of timestamps interpretation (see `getTimeStamp()` in Algorithm 1 and Section 4.5) influences the timestamp reliability in an adversarial setting. We assume that an adversary wants to deviate blockchain timestamps by as much as possible. There are two strategies for such an attack, i.e., an adversary can either “slow down” timestamps or “accelerate” them. In the former attack, the best adversary’s strategy is to use the minimum acceptable timestamp in every header created by the adversary. Namely, the adversary sets its timestamps to the median value of the last eleven blocks (a header with a lower timestamp would not be accepted by the network – see Section 2.2). As for the latter attack, the adversary can analogously bias timestamps towards the future by putting the maximum acceptable value in all her created headers. The maximum timestamp value accepted by network nodes is two hours in the future with respect to the nodes’ internal clocks (any header with a higher timestamp would be rejected).

In our study, we assume that honest nodes maintain the network time which the adversary tries to deviate from. We consider the worst-case scenario, which is when the adversary, who also biases all her header timestamps, mines the strong block. We measure (over 10000 runs) how such a malicious timestamp can be mitigated by our redefinition of the block timestamps interpretation. We present the obtained results in Figure 5, and as shown in the slow-down case our protocol achieves much more precise timestamps than Bitcoin (the difference is around 2000 seconds). Similarly, when the adversary accelerates timestamps, our protocol can mitigate it effectively, adjusting the adversarial timestamps by 2000-3500 seconds towards the correct time. This effect is achieved due to the block’s timestamp calculation as a weighted average of all block headers. The adversary could try to remove honest participants’ weak headers in order to give a stronger weight to its malicious timestamps, but in Section 6.1 we discuss ways to mitigate it.

## 6 Discussion

### 6.1 Impact of the Parameter Choice

The results presented in Section 5 required several parameters to be fixed. First of all, we had to choose  $\gamma$ , which determines the relative contribution of the weak headers to the total mining rewards. Second, there is the contribution of the weak blocks to the chain difficulty, which in the `chainPoW()` function in Algorithm 1 was set to be only  $T_{max}/T_w$ . This means that the PoW of a weak header relative to a strong block’s PoW — we call this the *difficulty factor* — is fixed to be  $T_s/T_w$ . In the following, we first discuss the relevant trade-offs and then motivate our choice.

When both  $\gamma$  and the difficulty factor are low, the impact on the reward variance of the miners (as per Figure 3) will be mild as the strong block rewards still constitute about 50% of the mining rewards. This reliance on the block rewards also means that ‘spiteful’ mining as discussed in Section 5.4 is disincentivized as the risk of strong blocks going stale still has a considerable impact on total rewards. However, selfish mining as proposed in [11] relies on several blocks in a row being mined in secret, and even for a low difficulty factor it becomes much harder for the attacker’s chain to stay ‘ahead’ of the honest chain, as the latter accumulates strength from the weak headers at a faster rate. Hence, in this setting we only gain protection against selfish mining.

When  $\gamma$  is high but the difficulty factor is not (which is the setting of Section 5), then in addition to disincentivizing selfish mining, the reward variances become much less dependent on the irregular strong block rewards. This benefits small miners and reduces centralization, as we also discuss in Section 6.2. However, spiteful mining will have more of an impact as the possible downside (i.e., a latency-dependent increase in the strong block stale rate) will have less of an effect on the total rewards.

When both  $\gamma$  and the difficulty factor are high, the impact of spiteful mining is mitigated. The reason is that blocks quickly accumulate enough weak headers to outweigh a strong block, and in this case spiteful miners need to adopt the other weak blocks or risk their strong block becoming stale with certainty. The downside in this setting is that the system-wide block stale rate is increased. For example, if each weak header contributes  $\gamma T_s/T_w$  to the difficulty and  $\gamma = 10$ , then after (on average) one minute enough weak headers are found to outweigh a strong block, and if propagation of the block takes longer than one minute then some miners will not adopt the block, increasing the likelihood of a fork.

In this paper, we have chosen the second of the three approaches — a moderately high  $\gamma$ , yet a minor difficulty factor. The reason is that the only downside (spiteful mining) was considered less of a concern than the other downsides (namely a low impact on reward variances and a higher block

stale rate respectively) for two reasons: a) because spiteful mining does not lead to clear gains for the attacker, and b) because it only has a large impact on other miners' profits if the attacker controls a large share of the mining power, whereas the emergence of large mining pools is exactly what StrongChain discourages. The specific value of  $\gamma = 10$  for  $T_w/T_s = 1024$  (or  $\gamma = \log_2(T_w/T_s)$  in general) was chosen to sufficiently reduce mining reward variances, yet leaving some incentive to discourage spiteful mining.

The protocol can be further extended to disincentivize spiteful mining, e.g., by additionally awarding strong block finders a reward that is proportional to the number of weak headers included. This would make StrongChain more similar to Ethereum, where stale block ('uncle') rewards are paid both to the miner of a stale block and the miner of the successful block that included it (see Section 8 for additional discussion of Ethereum's protocol). However, we leave such modifications and their consequences as future work.

## 6.2 StrongChain and Centralized Mining

Decentralized mining pools aim to reduce variance while providing benefits for the system (i.e., trust minimization for pools, and a higher number of validating nodes). However, mining in Bitcoin is in fact dominated by centralized mining pools whose value proposition, over decentralized pools, is an easy setup and participation. Therefore, rational miners motivated by their own benefit, instead of joining decentralized pools prefer centralized "plug-and-play" mining. It is still debatable whether centralized mining pools are beneficial or harmful to the system. However, it has been proved multiple times, that the concentration of significant computing power caused by centralized mining is risky and should be avoided, as such a strong pool has multiple ways of misbehaving and becomes a single point of failure in the system. One example is the pool GHash.IO, which in 2014 achieved more than 51% of the mining power. This undermined trust in the Bitcoin network to the extent that the pool was forced to actively ask miners to join other pools [12].

In order to follow incentives of rational miners, StrongChain does not require any radical changes from them and is compatible with centralized mining pools; however, it is specifically designed to mitigate their main security risk (i.e., power centralization). In StrongChain such pools could be much smaller than in Bitcoin (due to minimized variance) and to support this argument we conducted a study. We listed the largest Bitcoin mining pools and their shares in the global mining power (according to <https://www.blockchain.com/en/pools> as for the time of writing). Then for each pool, we calculated what would be the pool size in StrongChain to offer the miner the same payout variance experience, and the variance reduction factor in that case. As shown in Table 2, for the Bitcoin largest mining pool with 18.1% of the global hash rate, an equivalent

Mining Pool	Pool Size		Size Reduction
	Bitcoin	StrongChain	
BTC.com	18.1%	0.245%	74×
F2Pool	14.1%	0.172%	82×
AntPool	11.7%	0.135%	87×
SlushPool	9.1%	0.099%	92×
ViaBTC	7.5%	0.079%	95×
BTC.TOP	7.1%	0.074%	96×
BitClub	3.1%	0.030%	103×
DPOOL	2.6%	0.025%	104×
Bitcoin.com	1.9%	0.018%	106×
BitFury	1.7%	0.016%	106×

Table 2: Largest Bitcoin mining pools and the corresponding pool sizes in StrongChain offering the same relative reward variance ( $T_w/T_s = 1024$  and  $\gamma = 10$ ).

pool in StrongChain (to provide miners the same reward experience) could be as small as 0.245% of the hash rate – around 74 times smaller. Even better reduction factors are achieved for smaller pools. Therefore, our study indicates that StrongChain makes the size of a pool almost an irrelevant factor for miners' benefits (i.e., there is no objective advantage of joining a large pool over a medium or a small one). Therefore we envision that with StrongChain, centralized mining pools will naturally be much more distributed.

### Limitations

As discussed, it is beneficial for the system if as many participants as possible independently run full nodes; however, miners join large centralized pools not only due to high reward variance. Other potential reasons include the minimization of operational expenses as running a full node is a large overhead, higher efficiency since large pools may use high-performance hardware and network, better ability to earn extra income from merge mining [29], better protection against various attacks, anonymity benefits, etc. This work focuses on removing the reward variance reason. Although we believe that StrongChain would produce a larger number of small pools in a natural way, it does not eliminate the other reasons, so some large centralized pools may still remain. Luckily, our system is orthogonal to multiple concurrent solutions. For instance, StrongChain could be easily combined with non-outsourcable puzzle schemes (see Section 8) to increase the number of full nodes by explicitly disincentivizing miners from outsourcing their computing power. We leave such a combination as interesting future work.

## 7 Realization in Practice

We implemented our system in order to investigate its feasibility and confirm the stated properties. We implemented a StrongChain full node with interactive client in Python, and

our implementation includes the complete logic from Algorithm 1 and all functionalities required to have a fully operational system (communication modules, message types, validation logic, etc...).<sup>9</sup> As described before, the main changes in our implementation to the Bitcoin's block layout are:

- a new (20B-long) *Coinbase* header field,
- a new binding transaction protecting all weak headers of the block,
- removed original coinbase transaction,

where a binding transaction has a single (32B-long) output as presented in Equation 3.<sup>10</sup>

Weak headers introduced by our system impact the bandwidth and storage overhead (when compared with Bitcoin). Due to compressing them (see Section 4.2), the size of a single weak header in a block is 60B. For example, with an average number of weak headers equal 1024, the storage and bandwidth overhead increases by about 61.5KB per block (e.g., with 64 weak headers, the overhead is only 3.8KB). Taking into account the average Bitcoin block size of about 1MB (the average between 15 Oct and 15 Nov 2018<sup>11</sup>), 1024 weak headers constitute around 6.1% of today's blocks, while 64 headers only 0.4%. The same overhead is introduced to SPV clients, that besides a strong header need to obtain weak headers and a proof for their corresponding binding transaction. Thus, an SPV update (every 10 minutes) would be 61.5KB or 3.8KB on average for 1024 or 64 weak headers, respectively. However, since only strong headers authenticate transactions, SPV clients do not need to store weak headers and after they are validated, they can remove them (they need to just calculate and associate their aggregated PoW with the strong header). Such an approach would not introduce any noticeable storage overhead on SPV clients.

Nodes validate all incoming weak headers; however, this overhead is a single hash computation and simple sanity checks per header. Even with our unoptimized implementation running on a commodity PC the total validation of a single weak header takes around 50 $\mu$ s on average (i.e., 51ms per 1024 headers on a single core). Given that we do not believe this overhead can lead to more serious denial-of-service attacks than ones already known and existing in Bitcoin (e.g., spamming with large invalid blocks). Additionally, StrongChain can adopt prevention techniques present in Bitcoin, like blacklisting misbehaving peers.

<sup>9</sup>Our implementation is available at <https://github.com/ivan-homoliak-sutd/strongchain-demo/>.

<sup>10</sup>An alternative choice is to store a hash of weak headers in a header itself. Although simpler, that option would incur a higher overhead if the number of weak headers is greater than several.

## 8 Related work

Employing weak solutions (and their variations) in Bitcoin is an idea [36,38] circulating on Bitcoin forums for many years. Initial proposals leverage weak solutions (i.e., *weak blocks*) for faster transaction confirmations [45,46], for signaling the current working branch of particular miners [13,14,30]. Unfortunately, most of these proposals come without necessary details or lack rigorous analysis. Below, we discuss the most related attempts that have been made to utilize weak or stale blocks in PoW-based decentralized consensus protocols. We compare these systems in Table 3 according to their reward and PoW calculation schemes.

**Subchains.** Rizun proposes Subchains [35], where a chain of weak blocks (a so-called subchain) bridging each pair of subsequent strong blocks is created. The design of Subchain puts a special focus on increasing the transaction throughput and the double-spend security for unconfirmed transactions. Rizun argues that since the (weak) block interval of subchains is much smaller than the strong block interval, it allows for faster (weak) transaction confirmations. Another claimed advantage of such an approach is that during the process of building subchains, the miners can detect forks earlier, and take actions accordingly to avoid wasting computational power. However, the design of Subchain sidesteps a concrete security analysis at the subchain level. In detail, by using a chaining data structure where one weak header referencing the previous weak header in a subchain, it introduces high stale rate on a subchain. More importantly, due to applying a Bitcoin-like subchain selection policy in case of conflicts, this approach is vulnerable to the selfish mining attack launched on a subchain.

**Flux.** Based on similar ideas as Subchain, Zamyatin et al. propose Flux [49]. In contrast to Subchain, Flux shares rewards (from newly minted coins and transaction fees) evenly among the finders of weak and strong blocks according to the computational resources they invested. This approach reduces the reward variance of miners, and therefore mitigates the need for large mining pools, which is beneficial for the system's decentralization. In addition, simulation experiments show that Flux renders selfish mining on the main chain less profitable. However, alike Subchains, Flux employs a chain structure for weak blocks, which inevitably introduces race conditions, increasing the stale rate of weak blocks and making it more susceptible to selfish mining attacks at the subchain level. The designers of Flux let both of these issues open and discuss the potential application of GHOST [41] to subchains. Another limitation of this work is that the authors do not analyze the requirements on space consumption when putting possibly a high number of overlapping transactions into Flux subchains, which could negatively influence network, storage, and processing resources.

*Remarks on Subchain and Flux.* One important difference between our approach and the above two designs is that we

	Bitcoin v0.1	Bitcoin	Fruitchains	Flux	StrongChain
Reward (strong)	$R + F$	$R + F$	0	$(R + F)/(E + 1)$	$cR + F$
Reward (weak)	0	0	$(R + F)/E$	$(R + F)/(E + 1)$	$c\gamma RT_s/T_w$
Chain weight contrib. (strong)	1	$T_{max}/T_s$	$T_{max}/T_s$	$T_{max}/T_s$	$T_{max}/T_s$
Chain weight contrib. (weak)	0	0	0	0	$T_{max}/T_w$

Table 3: The comparison of reward and PoW computation schemes of StrongChain and the related systems. ( $F$ : block transaction fees,  $E$ : expected number of weak headers per block. The entries for Flux are approximations for the PPLNS scheme in P2Pool, on which it is based.)

adopt a flat hierarchy for the weak blocks, which not only eliminates the possibility of selfish mining in a set of weak solutions, but also avoids the issue of stale rate of weak blocks. In contrast, both Subchain and Flux employ a chain structure for weak blocks, inevitably making them more susceptible to selfish mining attacks at the subchain level. Moreover, in our approach rewards are not shared, therefore miners can only benefit from appending received weak solutions. In addition, none of Subchain and Flux provide a concrete implementation demonstrating their applicability.

**FruitChains.** Another approach to address the mining variance and selfish mining issues is the FruitChains protocol proposed by Pass and Shi [32]. In FruitChains, instead of directly storing the records inside blocks, the records or transactions are put inside “fruits” with relatively low mining difficulties. Fruits then are appended to a blockchain via blocks which are mined with a higher difficulty. Mined fruits and blocks yield rewards, hence, miners can be paid more often and there is no need to form a mining pool.

However, some practical and technical details of FruitChains lead to undesired side effects. First, the scheme allows fruits with small difficulties to be announced and accepted by other miners. With too small difficulty it could render high transmission overheads or even potential denial-of-service attacks and its effects on the network are not investigated. On the other hand, too high fruit difficulty could result in a low transaction throughput and a high reward variance. Second, duplicate fruits are discarded, even though they might be found by different miners – this naturally implies some stale fruit rate (uninvestigated in the paper). Similarly, it is unclear would a block finder have an incentive to treat all fruits equally and to not prioritize her mined fruits (especially when fruits are associated with transaction fees). Moreover, fruits that are not appended to the blockchain quickly enough have to be mined and broadcast again, rendering additional overheads. Finally, the description of FruitChains lacks important details (e.g., the size of the fruits or the overheads introduced) as well as an actual implementation.

**GHOST and Ethereum.** An alternative approach for decreasing a high reward variance of miners is to shorten the block creation rate to the extent that does not hurt the overall system security – such an approach increases transaction throughput as well. The Greedy Heaviest-Observed Sub-Tree (GHOST) chain selection rule [41] makes use of

stale blocks to increase the weight of their ancestors, which achieves a 600 fold speedup for the block generation compared to Bitcoin, while preserving its security strength. Despite the inclusion of stale blocks in the blockchain, only the miners of the main chain get rewards for the inclusion of the stale blocks.

In contrast to the original GHOST, the white and yellow papers of Ethereum [44, 48] propose to reward also miners of stale blocks in order to further increase the security – not wasting with the consumed resources for mining of stale blocks. However, Ritz and Zugenmaier shows that rewarding so called “uncle blocks” lowers the threshold at which selfish mining is profitable [34] – a selfish miner can built-up the “heaviest” chain, as she can reference blocks previously not broadcast to the honest network. Likewise, the inclusive blockchain protocol [20], which increases the transaction throughput, but leaves the selfish mining issue unsolved.

**DAG-based Protocols.** SPECTRE [40] is an example of the protocols family that leverages a directed acyclic graph (DAG). This family proposed more radical design changes motivated by the observation that one essential throughput limitation of Nakamoto consensus is the data structure leveraged which can be maintained only sequentially. SPECTRE generalizes the Nakamoto’s blockchain into a DAG of blocks, while allowing miners to add blocks concurrently with a high frequency, just basing on their individual current views of the DAG. Such a design provides multiple advantages over chain-based protocols including StrongChain. Frequently published blocks increase transaction throughput and provide fast confirmation times while relaxed consistency requirements allow to tolerate propagation delays. Like StrongChain, SPECTRE also aims to decrease mining reward variance, but achieves it again via frequent blocks. However, frequent blocks have a side effect of transaction redundancy which negatively impacts the storage and transmission overheads, and this aspect was not investigated. Moreover, SPECTRE provides a weaker property than chain-based consensus protocols as simultaneously added transactions cannot be ordered. This and schemes following a similar design are payments oriented and to support order-specific applications, like smart contracts, they need to be enhanced with an additional ordering logic.

More recently, Sompolinsky and Zohar [42] proposed two DAG-based protocols improving the prior work. PHANTOM introduces and uses a greedy algorithm (called the

GHOSTDAG protocol) to determine the order of transactions. This eliminates the applicability issues of SPECTRE, but for the cost of slowing down transaction confirmation times. Combining advantages of PHANTOM and SPECTRE into a full system was left by the authors as a future work.

**Decentralization-oriented Schemes.** Mining decentralization was a goal of multiple previous proposals. One direction is to design mining such that miners do not have incentive to outsource resources or forming coalitions. Permacoin [25] is an early attempt to achieve it where miners instead of proving their work prove that their store (fragments of) a globally-agreed file. Permacoin is designed such that: a) payment private keys are bound to puzzle solutions – outsourcing private keys is risky for miners, b) sequential and random storage access is critical for the mining efficiency, thus it disincentives miners from outsourcing data. If the file is valuable, then a side-effect of Permacoin is its usefulness, as miners replicate the file.

The notion of non-outsourceable mining was further extended and other schemes were proposed [26, 50]. Miller et al. [26] introduces “strongly non-outsourceable puzzles” that aim to disincentivize pool creation by requiring all pool participants to remain honest. In short, with these puzzles any pool participant can steal the pool reward without revealing its identity. The scheme relies on zero knowledge proofs requiring a trusted setup and introducing significant computational overheads. The scheme is orthogonal to StrongChain and could be integrated with easily integrated with StrongChain, however, after a few years of their introduction no system of this class was actually deployed at scale; thus, we do not have any empirical results confirming their promised benefits.

SmartPool is a different approach that was proposed by Luu et al. [23]. In SmartPool, the functionality of mining pools was implemented as a smart contract. Such an approach runs natively only on smart-contract platforms but it allows to eliminate actual mining pools and their managers (note that SmartPool still imposes fees for running smart contracts), while preserving most benefits of pool mining.

**Rewarding Schemes for Mining Pools.** Mining pools divide the block reward (together with the transaction fees) in such a way that each miner joining the pool is paid his fair share in proportion to his contribution. Typically, the contribution of an individual miner in the pool is witnessed by showing weak solutions called *shares*.

There are various rewarding schemes that mining pools employ. The simplest and most natural method is the proportional scheme where the reward of a strong block is divided in proportion to the numbers of shares submitted by the miners. However, this scheme leads to pool hopping attacks [33]. To avoid this security issue, many other rewarding systems are developed, including the Pay-per-last-N-shares (PPLNS) scheme and its variants. We refer the reader to [37] for a systematic analysis of different pool rewarding systems.

The reward mechanisms in StrongChain can be seen conceptually as a mining pool built-in into the protocol. However, there are important differences between our design and the mining pools. The most contrasting one is that in StrongChain rewarding is not a zero-sum game and miners do not share rewards. In mining pools, all rewards are shared and this characteristic causes multiple in- and cross-pool attacks that cannot be launched against our scheme. Furthermore, the miner collaboration within Bitcoin mining pools is a “necessary evil”, while in StrongChain the collaboration is beneficial for miners and the overall system. We discuss StrongChain and mining pools further in Section 6.2.

## 9 Conclusions

In this paper, we proposed a transparent and collaborative proof-of-work protocol. Our approach is based on Nakamoto consensus and Bitcoin, however, we modified their core designs. In particular, in contrast to them, we take advantage of weak solutions, which although they do not finalize a block creation positively contribute to the blockchain properties. We also proposed a rewarding scheme such that miners can benefit from exchanging and appending weak solutions. These modifications lead to a more secure, fair, and efficient system. Surprisingly, we show that our approach helps with seemingly unrelated issues like the freshness property. Finally, our implementation indicates the efficiency and deployability of our approach.

Incentives-oriented analysis of consensus protocols is a relatively new topic and in the future we would like to extend our work by modeling our protocol with novel frameworks and tools. Another topic worth investigating in future is how to combine StrongChain with systems solving other drawbacks of Nakamoto consensus [10, 19, 21], or how to mimic the protocol in the proof-of-stake setting.

# Tracing Transactions Across Cryptocurrency Ledgers

## Abstract

One of the defining features of a cryptocurrency is that its ledger, containing all transactions that have ever taken place, is globally visible. As one consequence of this degree of transparency, a long line of recent research has demonstrated that—even in cryptocurrencies that are specifically designed to improve anonymity—it is often possible to track money as it changes hands, and in some cases to de-anonymize users entirely. With the recent proliferation of alternative cryptocurrencies, however, it becomes relevant to ask not only whether or not money can be traced as it moves within the ledger of a single cryptocurrency, but if it can in fact be traced as it moves *across* ledgers. This is especially pertinent given the rise in popularity of automated trading platforms such as ShapeShift, which make it effortless to carry out such cross-currency trades. In this paper, we use data scraped from ShapeShift over a thirteen-month period and the data from eight different blockchains to explore this question. Beyond developing new heuristics and creating new types of links across cryptocurrency ledgers, we also identify various patterns of cross-currency trades and of the general usage of these platforms, with the ultimate goal of understanding whether they serve a criminal or a profit-driven agenda.

## 1 Introduction

For the past decade, cryptocurrencies such as Bitcoin have been touted for their transformative potential, both as a new form of electronic cash and as a platform to “re-decentralize” aspects of the Internet and computing in general. In terms of their role as cash, however, it has been well established by now that the usage of pseudonyms in Bitcoin does not achieve meaningful levels of anonymity [1, 11, 17, 18, 21], which casts doubt on its role as a payment mechanism. Furthermore, the ability to track flows of coins is not limited to Bitcoin: it extends even to so-called “privacy coins” like Dash [10, 12], Monero [4, 7, 13, 24], and Zcash [6, 16] that incorporate features explicitly designed to improve on Bitcoin’s anonymity guarantees.

Traditionally, criminals attempting to cash out illicit funds would have to use exchanges; indeed, most tracking techniques rely on identifying the addresses associated with these exchanges as a way to observe when these deposits happen [11]. Nowadays, however, exchanges typically implement strict Know Your Customer/Anti-Money Laundering (KYC/AML) policies to comply with regulatory requirements, meaning criminals (and indeed all users) risk revealing their real identities when using them. Users also run risks when storing their coins in accounts at custodial exchanges, as exchanges may be hacked or their coins may otherwise become inaccessible [9, 19]. As an alternative, there have emerged in the past few years frictionless trading platforms such as ShapeShift<sup>1</sup> and Changelly,<sup>2</sup> in which users are able to trade between cryptocurrencies without having to store their coins with the platform provider. Furthermore, while ShapeShift now requires users to have verified accounts [22], this was not the case before October 2018.

Part of the reason for these trading platforms to exist is the sheer rise in the number of different cryptocurrencies: according to the popular cryptocurrency data tracker CoinMarketCap there were 36 cryptocurrencies in September 2013, only 7 of which had a stated market capitalization of over 1 million USD,<sup>3</sup> whereas in January 2019 there were 2117 cryptocurrencies, of which the top 10 had a market capitalization of over 100 million USD. Given this proliferation of new cryptocurrencies and platforms that make it easy to transact across them, it becomes important to consider not just whether or not flows of coins can be tracked within the transaction ledger of a given currency, but also if they can be tracked as coins move across their respective ledgers as well. This is especially important given that there are documented cases of criminals attempting to use these cross-currency trades to obscure the flow of their coins: the WannaCry ransomware operators, for example, were observed using ShapeShift to convert their ransomed bitcoins into Monero [3]. More generally, these

<sup>1</sup><https://shapeshift.io>

<sup>2</sup><https://changelly.com>

<sup>3</sup><https://coinmarketcap.com/historical/20130721/>

services have the potential to offer an insight into the broader cryptocurrency ecosystem and the thousands of currencies it now contains.

In this paper, we initiate an exploration of the usage of these cross-currency trading platforms, and the potential they offer in terms of the ability to track flows of coins as they move across different transaction ledgers. Here we rely on three distinct sources of data: the cryptocurrency blockchains, the data collected via our own interactions with these trading platforms, and — as we describe in Section 4 — the information offered by the platforms themselves via their public APIs.

We begin in Section 5 by identifying the specific on-chain transactions associated with an advertised ShapeShift transaction, which we are able to do with a relatively high degree of success (identifying both the deposit and withdrawal transactions 81.91% of the time, on average). We then describe in Section 6 the different transactional patterns that can be traced by identifying the relevant on-chain transactions, focusing specifically on patterns that may be indicative of trading or money laundering, and on the ability to link addresses across different currency ledgers. We then move in Section 7 to consider both old and new heuristics for clustering together addresses associated with ShapeShift, with particular attention paid to our new heuristic concerning the common social relationships revealed by the usage of ShapeShift. Finally, we bring all the analysis together by applying it to several case studies in Section 8. Again, our particular focus in this last section is on the phenomenon of trading and other profit-driven activity, and the extent to which usage of the ShapeShift platform seems to be motivated by criminal activity or a more general desire for anonymity.

## 2 Related Work

We are not aware of any other research exploring these cross-currency trading platforms, but consider as related all research that explores the level of anonymity achieved by cryptocurrencies. This work is complementary to our own, as the techniques it develops can be combined with ours to track the entire flow of cryptocurrencies as they move both within and across different ledgers.

Much of the earlier research in this vein focused on Bitcoin [1, 11, 17, 18, 21], and operates by adopting the so-called “multi-input” heuristic, which says that all input addresses in a transaction belong to the same entity (be it an individual or a service such as an exchange). While the accuracy of this heuristic has been somewhat eroded by privacy-enhancing techniques like CoinJoin [8], new techniques have been developed to avoid such false positives [12], and as such it has now been accepted as standard and incorporated into many tools for Bitcoin blockchain analytics.<sup>45</sup> Once addresses are

<sup>4</sup><https://www.chainalysis.com/>

<sup>5</sup><https://www.elliptic.co/>

clustered together in this manner, the entity can then further be identified using hand-collected tags that form a ground-truth dataset. We adopt both of these techniques in order to analyze the clusters formed by ShapeShift and Changelly in a variety of cryptocurrency blockchains, although as described in Section 7 we find them to be relatively unsuccessful in this setting.

In response to the rise of newer “privacy coins”, a recent line of research has also worked to demonstrate that the deployed versions of these cryptocurrencies have various properties that diminish the level of anonymity they achieve in practice. This includes work targeting Dash [10, 12], Monero [4, 7, 13, 24], and Zcash [6, 16].

In terms of Dash, its main privacy feature is similar to CoinJoin, in which different senders join forces to create a single transaction representing their transfer to a diverse set of recipients. Despite the intention for this to hide which recipient addresses belong to which senders, research has demonstrated that such links can in fact be created based on the value being transacted [10, 12]. Monero, which allows senders to hide which input belongs to them by using “mix-ins” consisting of the keys of other users, is vulnerable to de-anonymization attacks exploiting the (now-obsolete) case in which some users chose not to use mix-ins, or exploiting inferences about the age of the coins used as mix-ins [4, 7, 13, 24]. Finally, Zcash is similar to Bitcoin, but with the addition of a privacy feature called the shielded pool, which can be used to hide the values and addresses of the senders and recipients involved in a transaction. Recent research has shown that it is possible to significantly reduce the anonymity set provided by the shielded pool, by developing simple heuristics for identifying links between hidden and partly obscured transactions [6, 16].

## 3 Background

### 3.1 Cryptocurrencies

The first decentralized cryptocurrency, Bitcoin, was created by Satoshi Nakamoto in 2008 [14] and deployed in January 2009. At the most basic level, bitcoins are digital assets that can be traded between sets of users without the need for any trusted intermediary. Bitcoins can be thought of as being stored in a public key, which is controlled by the entity in possession of the associated private key. A single user can store their assets across many public keys, which act as pseudonyms with no inherent link to the user’s identity. In order to spend them, a user can form and cryptographically sign a transaction that acts to send the bitcoins to a recipient of their choice. Beyond Bitcoin, other platforms now offer more robust functionality. For example, Ethereum allows users to deploy *smart contracts* onto the blockchain, which act as stateful programs that can be triggered by transactions providing inputs to their functions.

In order to prevent double-spending, many cryptocurrencies are *UTXO-based*, meaning coins are associated not with

an address but with a uniquely identifiable UTXO (unspent transaction output) that is created for all outputs in a given transaction. This means that one address could be associated with potentially many UTXOs (corresponding to each time it has received coins), and that inputs to transactions are also UTXOs rather than addresses. Checking for double-spending is then just a matter of checking if an input is in the current UTXO set, and removing it from the set once it spends its contents.

### 3.2 Digital asset trading platforms

In contrast to a traditional (custodial) exchange, a digital asset trading platform allows users to move between different cryptocurrencies without storing any money in an account with the service; in other words, users keep their own money in their own accounts and the platform has it only at the time that a trade is being executed. To initiate such a trade, a user approaches the service and selects a supported input currency  $curIn$  (i.e., the currency from which they would like to move money) and a supported output currency  $curOut$  (the currency that they would like to obtain). A user additionally specifies a destination address  $addr_u$  in the  $curOut$  blockchain, which is the address to which the output currency will be sent. The service then presents the user with an exchange rate  $rate$  and an address  $addr_s$  in the  $curIn$  blockchain to which to send money, as well as a miner fee  $fee$  that accounts for the transaction it must form in the  $curOut$  blockchain. The user then sends to this address  $addr_s$  the amount  $amt$  in  $curIn$  they wish to convert, and after some delay the service sends the appropriate amount of the output currency to the specified destination address  $addr_u$ . This means that an interaction with these services results in two transactions: one on the  $curIn$  blockchain sending  $amt$  to  $addr_s$ , and one on the  $curOut$  blockchain sending (roughly)  $rate \cdot amt - fee$  to  $addr_u$ .

This describes an interaction with an abstracted platform. Today, the two best-known examples are ShapeShift and Changelly. Whereas Changelly has always required account creation, ShapeShift introduced this requirement only in October 2018. Each platform supports dozens of cryptocurrencies, ranging from better-known ones such as Bitcoin and Ethereum to lesser-known ones such as FirstBlood and Clams. In Section 4, we describe in more depth the operations of these specific platforms and our own interactions with them.

## 4 Data Collection and Statistics

In this section, we describe our data sources, as well as some preliminary statistics about the collected data. We begin in Section 4.1 by describing our own interactions with Changelly, a trading platform with a limited personal API. We then describe in Section 4.2 both our own interactions with ShapeShift, and the data we were able to scrape from their public API, which provided us with significant insight

into their overall set of transactions. Finally, we describe in Section 4.3 our collection of the data backing eight different cryptocurrencies.

### 4.1 Changelly

Changelly offers a simple API<sup>6</sup> that allows registered users to carry out transactions with the service. Using this API, we engaged in 22 transactions, using the most popular ShapeShift currencies (Table 1) to guide our choices for  $curIn$  and  $curOut$ .

While doing these transactions, we observed that they would sometimes take up to an hour to complete. This is because Changelly attempts to minimize double-spending risk by requiring users to wait for a set number of confirmations (shown to the user at the time of their transaction) in the  $curIn$  blockchain before executing the transfer on the  $curOut$  blockchain. We used this observation to guide our choice of parameters in our identification of on-chain transactions in Section 5.

### 4.2 ShapeShift

ShapeShift's API<sup>7</sup> allows users to execute their own transactions, of which we did 18 in total. As with Changelly, we were able to gain some valuable insights about the operation of the platform via these personal interactions. Whereas ShapeShift did not disclose the number of confirmations they waited for on the  $curIn$  blockchain, we again observed long delays, indicating that they were also waiting for a sufficient number.

Beyond these personal interactions, the API provides information on the operation of the service as a whole. Most notably, it provides three separate pieces of information: (1) the current trading rate between any pair of cryptocurrencies, (2) a list of up to 50 of the most recent transactions that have taken place (across all users), and (3) full details of a specific ShapeShift transaction given the address  $addr_s$  in the  $curIn$  blockchain (i.e., the address to which the user sent their coins).

For the trading rates, ShapeShift provides the following information for all cryptocurrency pairs ( $curIn, curOut$ ): the rate, the limit (i.e., the maximum that can be exchanged), the minimum that can be exchanged, and the miner fee (denominated in  $curOut$ ). For the 50 most recent transactions, information is provided in the form: ( $curIn, curOut, amt, t, id$ ), where the first three of these are as discussed in Section 3.2,  $t$  is a UNIX timestamp, and  $id$  is an internal identifier for this transaction. For the transaction information, when provided with a specific  $addr_s$ , ShapeShift provides the tuple (status, address, withdraw, inCoin, inType, outCoin, outType, tx, txURL, error). The status field is a flag that is

<sup>6</sup><https://api-docs.changelly.com/>

<sup>7</sup><https://info.shapeshift.io/api>

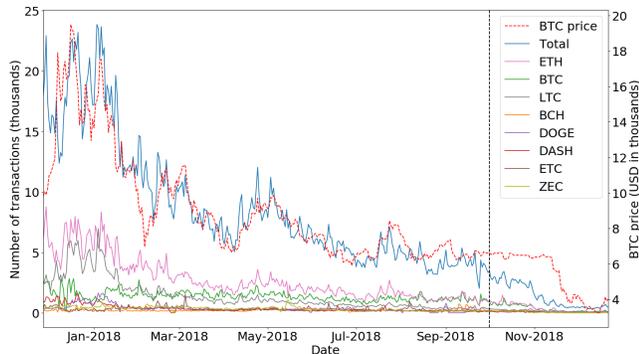

Figure 1: The total number of transactions per day reported via ShapeShift’s API, and the numbers broken down by cryptocurrency (where a transaction is attributed to a coin if it is used as either `curln` or `curOut`). The dotted red line indicates the BTC-USD exchange rate, and the horizontal dotted black line indicates when KYC was introduced into ShapeShift.

either `complete`, to mean the transaction was successful; `error`, to mean an issue occurred with the transaction or the queried address was not a ShapeShift address; or `no_deposits`, to mean a user initiated a transaction but did not send any coins. The error field appears when an error is returned and gives a reason for the error. The address field is the same address `addrs` used by ShapeShift, and `withdraw` is the address `addru` (i.e., the user’s recipient address in the `curOut` blockchain). `inType` and `outType` are the respective `curln` and `curOut` currencies and `inCoin` is the amt received. `outCoin` is the amount sent in the `curOut` blockchain. Finally, `tx` is the transaction hash in the `curOut` blockchain and `txURL` is a link to this transaction in an online explorer.

Using a simple Web scraper, we downloaded the transactions and rates every five seconds for close to thirteen months: from November 27 2017 until December 23 2018. This resulted in a set of 2,843,238 distinct transactions. Interestingly, we noticed that several earlier test transactions we did with the platform did not show up in their list of recent transactions, which suggests that their published transactions may in fact underestimate their overall activity.

#### 4.2.1 ShapeShift currencies

In terms of the different cryptocurrencies used in ShapeShift transactions, their popularity was distributed as seen in Figure 1. As this figure depicts, the overall activity of ShapeShift is (perhaps unsurprisingly) correlated with the price of Bitcoin in the same time period. At the same time, there is a decline in the number of transactions after KYC was introduced that is not clearly correlated with the price of Bitcoin (which is largely steady and declines only several months later).

ShapeShift supports dozens of cryptocurrencies, and in our data we observed the use of 65 different ones. The most commonly used coins are shown in Table 1. It is clear that Bitcoin

Currency	Abbr.	Total	<code>curln</code>	<code>curOut</code>
Ethereum	ETH	1,385,509	892,971	492,538
Bitcoin	BTC	1,286,772	456,703	830,069
Litecoin	LTC	720,047	459,042	261,005
Bitcoin Cash	BCH	284,514	75,774	208,740
Dogecoin	DOGE	245,255	119,532	125,723
Dash	DASH	187,869	113,272	74,597
Ethereum Classic	ETC	179,998	103,177	76,821
Zcash	ZEC	154,142	111,041	43,101

Table 1: The eight most popular coins used on ShapeShift, in terms of the total units traded, and the respective units traded with that coin as `curln` and `curOut`.

and Ethereum are the most heavily used currencies, which is perhaps not surprising given the relative ease with which they can be exchanged with fiat currencies on more traditional exchanges, and their rank in terms of market capitalization.

### 4.3 Blockchain data

For the cryptocurrencies we were interested in exploring further, it was also necessary to download and parse the respective blockchains, in order to identify the on-chain transactional behavior of ShapeShift and Changelly. It was not feasible to do this for all 65 currencies used on ShapeShift (not to mention that given the low volume of transactions for many of them, it would likely not yield additional insights anyway), so we chose to focus instead on just the top 8, as seen in Table 1. Together, these account for 95.7% of all ShapeShift transactions if only one of `curln` and/or `curOut` is one of the eight, and 60.5% if both are.

For each of these currencies, we ran a full node in order to download the entire blockchain. For the ones supported by the BlockSci tool [5] (Bitcoin, Dash and Zcash), we used it to parse and analyze their blockchains. BlockSci does not, however, support the remaining five currencies. For these we thus parsed the blockchains using Python scripts, stored the data as Apache Spark parquet files, and analyzed them using custom scripts. In total, we ended up working with 654 GB of raw blockchain data and 434 GB of parsed blockchain data.

## 5 Identifying Blockchain Transactions

In order to gain deeper insights about the way these trading platforms are used, it is necessary to identify not just their internal transactions but also the transactions that appear on the blockchains of the traded currencies. This section presents heuristics for identifying these on-chain transactions, and the next section explores the additional insights these transactions can offer.

Recall from Section 3.2 that an interaction with ShapeShift results in the deposit of coins from the user to the service on the `curln` blockchain (which we refer to as “Phase 1”), and

the withdrawal of coins from the service to the user on the curOut blockchain (“Phase 2”). To start with Phase 1, we thus seek to identify the deposit transaction on the input (curln) blockchain. Similarly to Portnoff et al. [15], we consider two main requirements for identifying the correct on-chain transaction: (1) that it occurred reasonably close in time to the point at which it was advertised via the API, and (2) that the value it carried was identical to the advertised amount.

For this first requirement, we look for candidate transactions as follows. Given a ShapeShift transaction with timestamp  $t$ , we first find the block  $b$  (at some height  $h$ ) on the curln blockchain that was mined at the time closest to  $t$ . We then look at the transactions in all blocks with height in the range  $[h - \delta_b, h + \delta_a]$ , where  $\delta_b$  and  $\delta_a$  are parameters specific to curln. We looked at both earlier and later blocks based on the observation in our own interactions that the timestamp published by ShapeShift would sometimes be earlier and sometimes be later than the on-chain transaction.

For each of our eight currencies, we ran this heuristic for every ShapeShift transaction using curln as the currency in question, with every possible combination of  $\delta_b$  and  $\delta_a$  ranging from 0 to 30. This resulted in a set of candidate transactions with zero hits (meaning no matching transactions were found), a single hit, or multiple hits. To rule out false positives, we initially considered as successful only ShapeShift transactions with a single candidate on-chain transaction, although we describe below an augmented heuristic that is able to tolerate multiple hits. We then used the values of  $\delta_b$  and  $\delta_a$  that maximized the number of single-hit transactions for each currency. As seen in Table 2, the optimal choice of these parameters varies significantly across currencies, according to their different block rates; typically we needed to look further before or after for currencies in which blocks were produced more frequently.

In order to validate the results of our heuristic for Phase 1, we use the additional capability of the ShapeShift API described in Section 4.2. In particular, we queried the API on the recipient address of every transaction identified by our heuristic for Phase 1. If the response of the API was affirmative, we flagged the recipient address as belonging to ShapeShift and we identified the transaction in which it received coins as the curln transaction. This also provided a way to identify the corresponding Phase 2 transaction on the curOut blockchain, as it is just the tx field returned by the API. As we proceed only in the case that the API returns a valid result, we gain ground-truth data in both Phase 1 and Phase 2. In other words, this method serves to not only validate our results in Phase 1 but also provides a way to identify Phase 2 transactions.

The heuristic described above is able to handle only single hits; i.e., the case in which there is only a single candidate transaction. Luckily, it is easy to augment this heuristic by again using the API. For example, assume we examine a BTC-ETH ShapeShift transaction and we find three candidate transactions in the Bitcoin blockchain after applying the

Currency	Parameters		Basic %	Augmented %
	$\delta_b$	$\delta_a$		
BTC	0	1	65.76	76.86
BCH	9	4	76.96	80.23
DASH	5	5	84.77	88.65
DOGE	1	4	76.94	81.69
ETH	5	0	72.15	81.63
ETC	5	0	76.61	78.67
LTC	1	2	71.61	76.97
ZEC	1	3	86.94	90.54

Table 2: For the selected (optimal) parameters and for a given currency used as curln, the percentage of ShapeShift transactions for which we found matching on-chain transactions for both the basic (time- and value-based) and the augmented (API-based) Phase 1 heuristic. The augmented heuristic uses the API and thus also represents our success in identifying Phase 2 transactions.

basic heuristic described above. To identify which of these transactions is the right one, we simply query the API on all three recipient addresses and check that the status field is affirmative (meaning ShapeShift recognizes this address) and that the outType field is ETH. In the vast majority of cases this uniquely identifies the correct transaction out of the candidate set, meaning we can use the API to both validate our results (i.e., we use it to eliminate potential false positives, as described above) and to augment the heuristic by being able to tolerate multiple candidate transactions. The augmented results for Phase 1 can be found in the last column of Table 2 and clearly demonstrate the benefit of this extra usage of the API. In the most dramatic example, we were able to go from identifying the on-chain transactions for ShapeShift transactions involving Bitcoin 65.75% of the time with the basic heuristic to identifying them 76.86% of the time with the augmented heuristic.

## 5.1 Accuracy of our heuristics

False negatives can occur for both of our heuristics when there are either too many or too few matching transactions in the searched block interval. These are more common for the basic heuristic, as described above and seen in Table 2, because it is conservative in identifying an on-chain transaction only when there is one candidate. This rate could be improved by increasing the searched block radius, at the expense of adding more computation and potentially increasing the false positive rate.

False positives can occur for both of our heuristics if someone sends the same amount as the ShapeShift transaction at roughly the same time, but this transaction falls within our searched interval whereas the ShapeShift one doesn’t. In theory, this should not be an issue for our augmented heuristic, since the API will make it clear that the candidate transaction

is not in fact associated with ShapeShift. In a small number of cases (fewer than 1% of all ShapeShift transactions), however, the API returned details of a transaction with different characteristics than the one we were attempting to identify; e.g., it had a different pair of currencies or a different value being sent. This happened because ShapeShift allows users to re-use an existing deposit address, and the API returns only the latest transaction using a given address.

If we blindly took the results of the API, then this would lead to false positives in our augmented heuristic for both Phase 1 and Phase 2. We thus ensured that the transaction returned by the API had three things in common with the ShapeShift transaction: (1) the pair of currencies, (2) the amount being sent, and (3) the timing, within the interval specified in Table 2. If there was any mismatch, we discarded the transaction. For example, given a ShapeShift transaction indicating an ETH-BTC shift carrying 1 ETH and occurring at time  $t$ , we looked for all addresses that received 1 ETH at time  $t$  or up to 5 blocks earlier. We then queried the API on these addresses and kept only those transactions which reported shifting 1 ETH to BTC. While our augmented heuristic still might produce false positives in the case that a user quickly makes two different transactions using the same currency pair, value, and deposit address, we view this as unlikely, especially given the relatively long wait times we observed ourselves when using the service (as mentioned in Section 4.2).

## 5.2 Alternative Phase 2 identification

Given that our heuristic for Phase 2 involved just querying the API for the corresponding Phase 1 transaction, it is natural to wonder what would be possible without this feature of the API, or indeed if there are any alternative strategies for identifying Phase 2 transactions. Indeed, it is possible to use a similar heuristic for identifying Phase 1 transactions, by first looking for transactions in blocks that were mined close to the advertised transaction time, and then looking for ones in which the amount was close to the expected amount. Here the amount must be estimated according to the advertised amt, rate, and fee. In theory, the amount sent should be  $\text{amt} \cdot \text{rate} - \text{fee}$ , although in practice the rate can fluctuate so it is important to look for transactions carrying a total value within a reasonable error rate of this amount.

When we implemented and applied this heuristic, we found that our accuracy in identifying Phase 2 transactions decreased significantly, due to the larger set of transactions that carried an amount within a wider range (as opposed to an exact amount, as in Phase 1) and the inability of this type of heuristic to handle multiple candidate transactions. More importantly, this approach provides no ground-truth information at all: by choosing conservative parameters it is possible to limit the number of false positives, but this is at the expense of the false negative rate (as, again, we observed in our own application of this heuristic) and in general it is not guaran-

teed that the final set of transactions really are associated with ShapeShift. As this is the exact guarantee we can get by using the API, we continue in the rest of the paper with the results we obtained there, but nevertheless mention this alternative approach in case this feature of the API is discontinued or otherwise made unavailable.

## 6 Tracking Cross-Currency Activity

In the previous section, we saw that it was possible in many cases to identify the on-chain transactions, in both the curln and curOut blockchains, associated with the transactions advertised by ShapeShift. In this section, we take this a step further and show how linking these transactions can be used to identify more complex patterns of behavior.

As shown in Figure 2, we consider these for three main types of transactions. In particular, we look at (1) *pass-through* transactions, which represent the full flow of money as it moves from one currency to the other via the deposit and withdrawal transactions; (2) *U-turns*, in which a user who has shifted into one currency immediately shifts back; and (3) *round-trip* transactions, which are essentially a combination of the first two and follow a user's flow of money as it moves from one currency to another and then back to the original one. Our interest in these particular patterns of behavior is largely based on the role they play in tracking money as it moves across the ledgers of different cryptocurrencies. In particular, our goal is to test the validity of the implicit assumption made by criminal usage of the platform — such as we examine further in Section 8 — that ShapeShift provides additional anonymity beyond simply transacting in a given currency.

In more detail, identifying pass-through transactions allows us to create a link between the input address(es) in the deposit on the curln blockchain and the output address(es) in the withdrawal on the curOut blockchain.

Identifying U-turns allows us to see when a user has interacted with ShapeShift not because they are interested in holding units of the curOut cryptocurrency, but because they see other benefits in shifting coins back and forth. There are several possible motivations for this: for example, traders may quickly shift back and forth between two different cryptocurrencies in order to profit from differences in their price. We investigate this possibility in Section 8.3. Similarly, people performing money laundering or otherwise holding “dirty” money may engage in such behavior under the belief that once the coins are moved back into the curln blockchain, they are “clean” after moving through ShapeShift regardless of what happened with the coins in the curOut blockchain.

Finally, identifying round-trip transactions allows us to create a link between the input address(es) in the deposit on the curln blockchain with the output address(es) in the later withdrawal on the curln blockchain. Again, there are many reasons why users might engage in such behavior, including

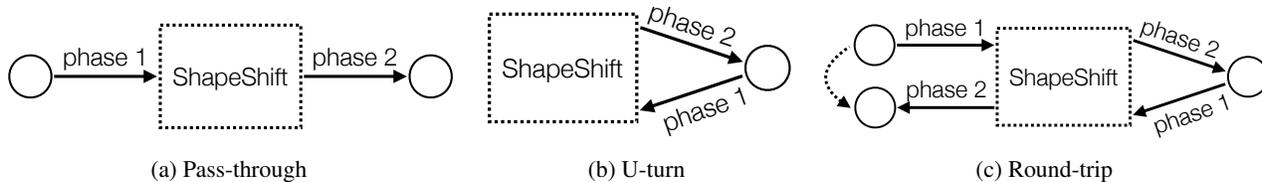

Figure 2: The different transactional patterns, according to how they interact with ShapeShift and which phases are required to identify them.

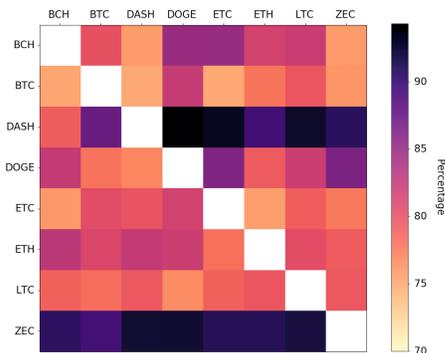

Figure 3: For each pair of currencies, the number of transactions we identified as being a pass-through from one to the other, as a percentage of the total number of transactions between those two currencies.

the trading and money laundering examples given above. As another example, if a curln user wanted to make an anonymous payment to another curln user, they might attempt to do so via a round-trip transaction (using the address of the other user in the second pass-through transaction), under the same assumption that ShapeShift would sever the link between their two addresses.

### 6.1 Pass-through transactions

Given a ShapeShift transaction from curln to curOut, the methods from Section 5 already provide a way to identify pass-through transactions, as depicted in Figure 2a. In particular, running the augmented heuristic for Phase 1 transactions identifies not only the deposit transaction in the curln blockchain but also the Phase 2 transaction (i.e., the withdrawal transaction in the curOut blockchain), as this is exactly what is returned by the API. As discussed above, this has the effect on anonymity of tracing the flow of funds across this ShapeShift transaction and linking its two endpoints; i.e., the input address(es) in the curln blockchain with the output address(es) in the curOut blockchain. The results, in terms of the percentages of all possible transactions between a pair (curln, curOut) for which we found the corresponding on-chain transactions, are in Figure 3.

The figure demonstrates that our success in identifying these types of transactions varied somewhat, and depended — not unsurprisingly — on our success in identifying transac-

tions in the curln blockchain. This means that we were typically least successful with curln blockchains with higher transaction volumes, such as Bitcoin, because we frequently ended up with multiple hits (although here we were still able to identify more than 74% of transactions). In contrast, the dark stripes for Dash and Zcash demonstrate our high level of success in identifying pass-through transactions with those currencies as curln, due to our high level of success in their Phase 1 analysis in general (89% and 91% respectively). In total, across all eight currencies we were able to identify 1,383,666 pass-through transactions.

### 6.2 U-turns

As depicted in Figure 2b, we consider a U-turn to be a pattern in which a user has just sent money from curln to curOut, only to turn around and go immediately back to curln. This means linking two transactions: the Phase 2 transaction used to send money to curOut and the Phase 1 transaction used to send money back to curln. In terms of timing and amount, we require that the second transaction happens within 30 minutes of the first, and that it carries within 1% of the value that was generated by the first Phase 2 transaction. This value is returned by the ShapeShift API in the outCoin field.

While the close timing and amount already give some indication that these two transactions are linked, it is of course possible that this is a coincidence and they were in fact carried out by different users. In order to gain additional confidence that it was the same user, we have two options. In UTXO-based cryptocurrencies (see Section 3.1), we could see if the input is the same UTXO that was created in the Phase 2 transaction, and thus see if a user is spending the coin immediately. In cryptocurrencies based instead on accounts, such as Ethereum, we have no choice but to look just at the addresses. Here we thus define a U-turn as seeing if the address that was used as the output in the Phase 2 transaction is used as the input in the later Phase 1 transaction.

Once we identified such candidate pairs of transactions (tx<sub>1</sub>, tx<sub>2</sub>), we then ran the augmented heuristic from Section 5 to identify the relevant output address in the curOut blockchain, according to tx<sub>1</sub>. We then ran the same heuristic to identify the relevant input address in the curOut blockchain, this time according to tx<sub>2</sub>.

In fact though, what we really identified in Phase 2 was not just an address but, as described above, a newly created

Currency	# (basic)	# (addr)	# (utxo)
BTC	36,666	565	314
BCH	2864	196	81
DASH	3234	2091	184
DOGE	546	75	75
ETH	53,518	5248	-
ETC	1397	543	-
LTC	8270	1429	244
ZEC	772	419	222

Table 3: The number of U-turns identified for each cryptocurrency, according to our basic heuristic concerning timing and value, and both the address-based and UTXO-based heuristics concerning identical ownership. Since Ethereum and Ethereum Classic are account-based, the UTXO heuristic cannot be applied to them.

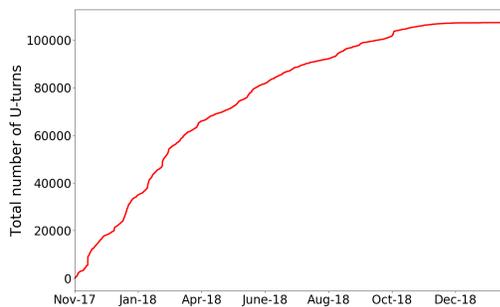

Figure 4: The total number of U-turns over time, as identified by our basic heuristic.

UTXO. If the input used in  $tx_2$  was this same UTXO, then we found a U-turn according to the first heuristic. If instead it corresponded just to the same address, then we found a U-turn according to the second heuristic. The results of both of these heuristics, in addition to the basic identification of U-turns according to the timing and amount, can be found in Table 3, and plots showing their cumulative number over time can be found in Figures 4 and 5. In total, we identified 107,267 U-turns according to our basic heuristic, 10,566 U-turns according to our address-based heuristic, and 1,120 U-turns according to our UTXO-based heuristic.

While the dominance of both Bitcoin and Ethereum should be expected given their overall trading dominance, we also observe that both Dash and Zcash have been used extensively as “mixer coins” in U-turns, and are in fact more popular for this purpose than they are overall. Despite this indication that users may prefer to use privacy coins as the mixing intermediary, Zcash has the highest percentage of identified UTXO-based U-turn transactions. Thus, these users not only do not gain extra anonymity by using it, but in fact are easily identifiable given that they did not change the address used in 419 out of 772 (54.24%) cases, or — even worse — immediately shifted back the exact same coin they received in 222 (28.75%) cases. In the case of Dash, the results suggest

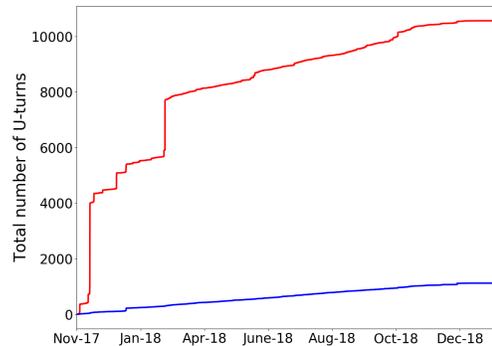

Figure 5: The total number of U-turns over time, as identified by our address-based (in red) and UTXO-based (in blue) heuristics.

something a bit different. Once more, the usage of a privacy coin was not very successful since in 2091 out of the 3234 cases the address that received the fresh coins was the same as the one that shifted it back. It was the exact same coin in only 184 cases, however, which suggests that although the user is the same, there is a local Dash transaction between the two ShapeShift transactions. We defer a further discussion of this asymmetry to Section 8.4, where we also discuss more generally the use of anonymity features in both Zcash and Dash.

Looking at Figure 5, we can see a steep rise in the number of U-turns that used the same address in December 2017, which is not true of the ones that used the same UTXO or in the overall number of U-turns in Figure 4. Looking into this further, we observed that the number of U-turns was particularly elevated during this period for four specific pairs of currencies: DASH-ETH, DASH-LTC, ETH-DASH, and LTC-ETH. This thus affected primarily the address-based heuristic due to the fact that (1) Ethereum is account-based so the UTXO-based heuristic does not apply, and (2) Dash has a high percentage of U-turns using the same address, but a much smaller percentage using the same UTXO. The amount of money shifted in these U-turns varied significantly in terms of the units of the input currency, but all carried between 115K and 138K in USD. Although the ShapeShift transactions that were involved in these U-turns had hundreds of different addresses in the curln blockchain, they used only a small number of addresses in the curOut blockchain: 4 addresses in Ethereum, 13 in Dash, and 9 in Litecoin. As we discuss further in Section 7.2, the re-use of addresses and the fact that the total amount of money (in USD) carried by the transactions was roughly the same indicates that perhaps a small group of people was responsible for creating this spike in the graph.

### 6.3 Round-trip transactions

As depicted in Figure 2c, a round-trip transaction requires performing two ShapeShift transactions: one out of the initial

currency and one back into it. To identify round-trip transactions, we effectively combine the results of the pass-through and U-turn transactions; i.e., we tagged something as a round-trip transaction if the output of a pass-through transaction from X to Y was identified as being involved in a U-turn transaction, which was itself linked to a later pass-through transaction from Y to X (of roughly the same amount). As described at the beginning of the section, this has the powerful effect of creating a link between the sender and recipient within a single currency, despite the fact that money flowed into a different currency in between.

In more detail, we looked for consecutive ShapeShift transactions where for a given pair of cryptocurrencies X and Y: (1) the first transaction was of the form X-Y; (2) the second transaction was of the form Y-X; (3) the second transaction happened relatively soon after the first one; and (4) the value carried by the two transaction was approximately the same. For the third property, we required that the second transaction happened within 30 minutes of the first. For the fourth property, we required that if the first transaction carried  $x$  units of `curln` then the second transaction carried within 0.5% of the value in the (on-chain) Phase 2 transaction, according to the `outCoin` field provided by the API.

As with U-turns, we considered an additional restriction to capture the case in which the user in the `curln` blockchain stayed the same, meaning money clearly did not change hands. Unlike with U-turns, however, this restriction is less to provide accuracy for the basic heuristic and more to isolate the behavior of people engaged in day trading or money laundering (as opposed to those meaningfully sending money to other users). For this pattern, we identify the input addresses used in Phase 1 for the first transaction, which represent the user who initiated the round-trip transaction in the `curln` blockchain. We then identify the output addresses used in Phase 2 for the second transaction, which represent the user who was the final recipient of the funds. If the address was the same, then it is clear that money has not changed hands. Otherwise, the round-trip transaction acts as a heuristic for linking together the input and output addresses.

The results of running this heuristic (with and without the extra restriction) are in Table 4. In total, we identified 95,547 round-trip transactions according to our regular heuristic, and identified 10,490 transactions where the input and output addresses were the same. Across different currencies, however, there was a high level of variance in the results. While this could be a result of the different levels of accuracy in Phase 1 for different currencies, the more likely explanation is that users indeed engage in different patterns of behavior with different currencies. For Bitcoin, for example, there was a very small percentage (1.2%) of round-trip transactions that used the same address. This suggests that either users are aware of the general lack of anonymity in the basic Bitcoin protocol and use ShapeShift to make anonymous payments, or that if they do use round-trip transactions as a form of money

Currency	# (regular)	# (same addr)
BTC	35,019	437
BCH	1780	84
DASH	3253	2353
DOGE	378	0
ETH	45,611	4085
ETC	1122	626
LTC	6912	2733
ZEC	472	172

Table 4: The number of regular round-trip transactions identified for each cryptocurrency, and the number that use the same initial and final address.

laundering they are at least careful enough to change their addresses. More simply, it may just be the case that generating new addresses is more of a default in Bitcoin than it is in other currencies.

In other currencies, however, such as Dash, Ethereum Classic, Litecoin, and Zcash, there were relatively high percentages of round-trip transactions that used the same input and output address: 72%, 56%, 40%, and 36% respectively. In Ethereum Classic, this may be explained by the account-based nature of the currency, which means that it is common for one entity to use only one address, although the percentage for Ethereum is much lower (9%). In Dash and Zcash, as we have already seen in Section 6.2 and explore further in Section 8.4, it may simply be the case that users assume they achieve anonymity just through the use of a privacy coin, so do not take extra measures to hide their identity.

## 7 Clustering Analysis

### 7.1 Shared ownership heuristic

As described in Sections 4.1 and 4.2, we engaged in transactions with both ShapeShift and Changelly, which provided us with some ground-truth evidence of addresses that were owned by them. We also collected three sets of tagging data (i.e., tags associated with addresses that describe their real-world owner): for Bitcoin we used the data available from WalletExplorer,<sup>8</sup> which covers a wide variety of different Bitcoin-based services; for Zcash we used hand-collected data from Kappos et al. [6], which covers only exchanges; and for Ethereum we used the data available from Etherscan,<sup>9</sup> which covers a variety of services and contracts.

In order to understand the behavior of these trading platforms and the interaction they had with other blockchain-based services such as exchanges, our first instinct was to combine these tags with the now-standard “multi-input” clus-

<sup>8</sup><https://www.walletexplorer.com/>

<sup>9</sup><https://etherscan.io/>

tering heuristic for cryptocurrencies [11, 17], which states that in a transaction with multiple input addresses, all inputs belong to the same entity. When we applied this clustering heuristic to an earlier version of our dataset [23], however, the results were fairly uneven. For Dogecoin, for example, the three ShapeShift transactions we performed revealed only three addresses, which each had done a very small number of transactions. The three Changelly transactions we performed, in contrast, revealed 24,893 addresses, which in total had received over 67 trillion DOGE. These results suggest that the trading platforms operate a number of different clusters in each cryptocurrency, and perhaps even change their behavior depending on the currency, which in turns makes it clear that we did not capture a comprehensive view of the activity of either.

More worrying, in one of our Changelly transactions, we received coins from a Ethereum address that had been tagged as belonging to HitBTC, a prominent exchange. This suggests that Changelly may occasionally operate using exchange accounts, which would completely invalidate the results of the clustering heuristic, as their individually operated addresses would end up in the same cluster as all of the ones operated by HitBTC. We thus decided not to use this type of clustering, and to instead focus on a new clustering heuristic geared at identifying common social relationships.

## 7.2 Common relationship heuristic

As it was clear that the multi-input heuristic would not yield meaningful information about shared ownership, we chose to switch our focus away from the interactions ShapeShift had on the blockchain and look instead at the relationships between individual ShapeShift users. In particular, we defined the following heuristic:

**Heuristic 7.1.** *If two or more addresses send coins to the same address in the curOut blockchain, or if two or more addresses receive coins from the same address in the curln blockchain, then these addresses have some common social relationship.*

The definition of a common social relationship is (intentionally) vague, and the implications of this heuristic are indeed less clear-cut than those of heuristics around shared ownership. Nevertheless, we consider what it means for two different addresses, in potentially two different blockchains, to have sent coins to the same address; we refer to these addresses as belonging in the *input* cluster of the output address (and analogously refer to the *output* cluster for an address sending to multiple other addresses). In the case in which the addresses are most closely linked, it could represent the same user consolidating money held across different currencies into a single one. It could also represent different users interacting with a common service, such as an exchange. Finally, it could simply be two users who do not know each other directly but

happen to be sending money to the same individual. What cannot be the case, however, is that the addresses are not related in any way.

To implement this heuristic, we parsed transactions into a graph where we defined a node as an address and a directed edge  $(u, v)$  as existing when one address  $u$  initiated a ShapeShift transaction sending coins to  $v$ , which we identified using the results of our pass-through analysis from Section 5. (This means that the inputs in our graph are restricted to those for which we ran Phase 1 to find the address, and thus that our input clusters contain only the top 8 currencies. In the other direction, however, we obtain the address directly from the API, which means output clusters can contain all currencies.) Edges are further weighted by the number of transactions sent from  $u$  to  $v$ . For each node, the cluster centered on that address was then defined as all nodes adjacent to it (i.e., pointing towards it).

Performing this clustering generated a graph with 2,895,445 nodes (distinct addresses) and 2,244,459 edges. Sorting the clusters by in-degree reveals the entities that received the highest number of ShapeShift transactions (from the top 8 currencies, per our caveat above). The largest cluster had 12,868 addresses — many of them belonging to Ethereum, Litecoin, and Dash — and was centered on a Bitcoin address belonging to CoinPayments.net, a multi-coin payment processing gateway. Of the ten largest clusters, three others (one associated with Ripple and two with Bitcoin addresses) are also connected with CoinPayments, which suggests that ShapeShift is a popular platform amongst its users.

Sorting the individual clusters by out-degree reveals instead the users who initiated the highest number of ShapeShift transactions. Here the largest cluster (consisting of 2314 addresses) was centered on a Litecoin address, and the second largest cluster was centered on an Ethereum address that belonged to Binance (a popular exchange). Of the ten largest clusters, two others were centered on Binance-tagged addresses, and three were centered on other exchanges (Freewallet, Gemini, and Bittrex). While it makes sense that exchanges typically dominate on-chain activity in many cryptocurrencies, it is somewhat surprising to also observe that dominance here, given that these exchanges already allow users to shift between many different cryptocurrencies. Aside from the potential for better rates or the perception of increased anonymity, it is thus unclear why a user wanting to shift from one currency to another would do so using ShapeShift as opposed to using the same service with which they have already stored their coins.

Beyond these basic statistics, we apply this heuristic to several of the case studies we investigate in the next section. We also revisit here the large spike in the number of U-turns that we observed in Section 6.2. Our hypothesis then was that this spike was caused by a small number of parties, due to the similar USD value carried by the transactions and by the re-use of a small number of addresses across Dash, Ethereum, and Lite-

coin. Here we briefly investigate this further by examining the clusters centered on these addresses.

Of the 13 Dash addresses, all but one of them formed small input and output clusters that were comprised of addresses solely from Litecoin and Ethereum. Of the 9 Litecoin addresses, 6 had input clusters consisting solely of Dash and Ethereum addresses, with two of them consisting solely of Dash addresses. Finally, of the 4 Ethereum addresses, all of them had input clusters consisting solely of Dash and Litecoin addresses. One of them, however, had a diverse set of addresses in its output cluster, belonging to Bitcoin, Bitcoin Cash, and a number of Ethereum-based tokens. These results thus still suggest a small number of parties, due to the tight connection between the three currencies in the clusters, although of course further investigation would be needed to get a more complete picture.

## 8 Patterns of ShapeShift Usage

In this section, we examine potential applications of the analysis developed in previous sections, in terms of identifying specific usages of ShapeShift. As before, our focus is on anonymity, and the potential that such platforms may offer for money laundering or other illicit purposes, as well as for trading. To this end, we begin by looking at two case studies associated with explicitly criminal activity and examine the interactions these criminals had with the ShapeShift platform. We then switch in Section 8.3 to look at non-criminal activity, by attempting to identify trading bots that use ShapeShift and the patterns they may create. Finally, in Section 8.4 we look at the role that privacy coins (Monero, Zcash, and Dash) play, in order to identify the extent to which the usage of these coins in ShapeShift is motivated by a desire for anonymity.

### 8.1 Starscape Capital

In January 2018, an investment firm called Starscape Capital raised over 2,000 ETH (worth 2.2M USD at the time) during their Initial Coin Offering, after promising users a 50% return in exchange for investing in their cryptocurrency arbitrage fund. Shortly afterwards, all of their social media accounts disappeared, and it was reported that an amount of ETH worth 517,000 USD was sent from their wallet to ShapeShift, where it was shifted into Monero [20].

We confirmed this for ourselves by observing that the address known to be owned by Starscape Capital participated in 192 Ethereum transactions across a three-day span (January 19-21), during which it received and sent 2,038 ETH; in total it sent money in 133 transactions. We found that 109 of these transactions sent money to ShapeShift, and of these 103 were shifts to Monero conducted on January 21 (the remaining 6 were shifts to Ethereum). The total amount shifted into Monero was 465.61 ETH (1388.39 XMR), and all of the money was shifted into only three different Monero addresses, of

which one received 70% of the resulting XMR. Using the clusters defined in Section 7.2, we did not find evidence of any other addresses (in any other currencies) interacting with either the ETH or XMR addresses associated with Starscape Capital.

### 8.2 Ethereum-based scams

EtherScamDB<sup>10</sup> is a website that, based on user reports that are manually investigated by its operators, collects and lists Ethereum addresses that have been involved in scams. As of January 30 2019, they had a total of 6374 scams listed, with 1973 associated addresses. We found that 194 of these addresses (9% of those listed) had been involved in 853 transactions to ShapeShift, of which 688 had a status field of `complete`. Across these successful transactions, 1797 ETH was shifted to other currencies: 74% to Bitcoin, 19% to Monero, 3% to Bitcoin Cash, and 1% to Zcash.

The scams which successfully shifted the highest volumes belonged to so-called trust-trading and MyEtherWallet scams. Trust-trading is a scam based on the premise that users who send coins prove the legitimacy of their addresses, after which the traders “trust” their address and send back higher amounts (whereas in fact most users send money and simply receive nothing in return). This type of scam shifted over 918 ETH, the majority of which was converted to Bitcoin (691 ETH, or 75%). A MyEtherWallet scam is a phishing/typosquatting scam where scammers operate a service with a similar name to the popular online wallet MyEtherWallet,<sup>11</sup> in order to trick users into giving them their account details. These scammers shifted the majority of the stolen ETH to Bitcoin (207 ETH) and to Monero (151 ETH).

Given that the majority of the overall stolen coins was shifted to Bitcoin, we next investigated whether or not these stolen coins could be tracked further using our analysis. In particular, we looked to see if they performed a U-turn or a round-trip transaction, as discussed in Section 6. We identified one address, associated with a trust-trading scam, that participated in 34 distinct round-trip transactions, all coming back to a different address from the original one. All these transactions used Bitcoin as `curOut` and used the same address in Bitcoin to both receive and send coins; i.e., we identified the U-turns in Bitcoin according to our address-based heuristic. In total, more than 70 ETH were circulated across these round-trip transactions.

### 8.3 Trading bots

ShapeShift, like any other cryptocurrency exchange, can be used by traders who wish to take advantage of the volatility in cryptocurrency prices. The potential advantages of doing this via ShapeShift, as compared with other platforms that

<sup>10</sup><https://etherscamdb.info/>

<sup>11</sup><https://www.myetherwallet.com/>

focus more on the exchange between cryptocurrencies and fiat currencies, are that (1) ShapeShift transactions can be easily automated via their API, and (2) a single ShapeShift transaction acts to both purchase desired coins and dump unwanted ones. Such trading usually requires large volumes of transactions and high precision on their the timing, due to the constant fluctuation in cryptocurrency prices. We thus looked for activity that involved large numbers of similar transactions in a small time period, on the theory that it would be associated primarily with trading bots.

We started by searching for sets of consecutive ShapeShift transactions that carried approximately the same value in curln (with an error rate of 1%) and involved the same currencies. When we did this, however, we found thousands of such sets. We thus added the extra conditions that there must be at least 15 transactions in the set that took place in a span of five minutes; i.e., that within a five-minute block of ShapeShift transactions there were at least 15 involving the same currencies and carrying the same approximate USD value. This resulted in 107 such sets.

After obtaining our 107 trading clusters, we removed transactions that we believed were false positives in that they happened to have a similar value but were clearly the odd one out. For example, in a cluster of 20 transactions with 19 ETH-BTC transactions and one LTC-ZEC transaction, we removed the latter. We were thus left with clusters of either a particular pair (e.g., ETH-BTC) or two pairs where the curOut or the curln was the same (e.g., ETH-BTC and ZEC-BTC), which suggests either the purchase of a rising coin or the dump of a declining one. We sought to further validate these clusters by using our heuristic from Section 7.2 to see if the clusters shared common addresses. While we typically did not find this in UTXO-based currencies (as most entities operate using many addresses), in account-based currencies we found that in almost every case there was one particular address that was involved in the trading cluster.

We summarize our results in Figure 6, in terms of the most common pairs of currencies and the total money exchanged by trading clusters using those currencies. It is clear that the most common interactions are performed between the most popular currencies overall, with the exception of Monero (XMR) and SALT. In particular, we found six clusters consisting of 17-20 transactions that exchanged BTC for XMR, and 13 clusters that exchanged BTC for SALT, an Ethereum-based token. The sizes of each trading cluster varied between 16 and 33 transactions and in total comprise 258 transactions, each of which shifted exactly 0.1 BTC. In total they originated from 514 different Bitcoin addresses, which may make it appear as though different people carried out these transactions. After applying our pass-through heuristic, however, we found that across all the transactions there were only two distinct SALT addresses used to receive the output. It is thus instead likely that this represents trading activity involving one or two entities.

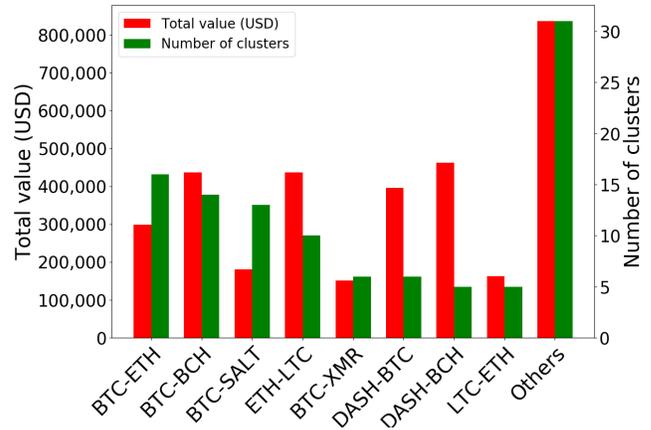

Figure 6: Our 107 clusters of likely trading bots, categorized by the pair of currencies they trade between and the total amount transacted by those clusters (in USD).

## 8.4 Usage of anonymity tools

Given the potential usage of ShapeShift for money laundering or other criminal activities, we sought to understand the extent to which its users seemed motivated to hide the source of their funds. While using ShapeShift is already one attempt at doing this, we focus here on the combination of using ShapeShift and so-called “privacy coins” (Dash, Monero, and Zcash) that are designed to offer improved anonymity guarantees.

In terms of the effect of the introduction of KYC into ShapeShift, the number of transactions using Zcash as curln averaged 164 per day the month before, and averaged 116 per day the month after. We also saw a small decline with Zcash as curOut: 69 per day before and 43 per day after. Monero and Dash, however, saw much higher declines, and in fact saw the largest declines across all eight cryptocurrencies. The daily average the month before was 136 using Monero as curln, whereas it was 47 after. Similarly, the daily average using it as curOut was 316 before and 62 after. For Dash, the daily average as curln was 128 before and 81 after, and the daily average as curOut was 103 before and 42 after.

In terms of the blockchain data we had (according to the most popular currencies), our analysis in what follows is restricted to Dash and Zcash, although we leave an exploration of Monero as interesting future work.

### 8.4.1 Zcash

The main anonymity feature in Zcash is known as the *shielded pool*. Briefly, transparent Zcash transactions behave just like Bitcoin transactions in that they reveal in the clear the sender and recipient (according to so-called *t-addresses*), as well as the value being sent. This information is hidden to various degrees, however, when interacting with the pool. In particular, when putting money into the pool the recipient is specified using a so-called *z-address*, which hides the recipient but still

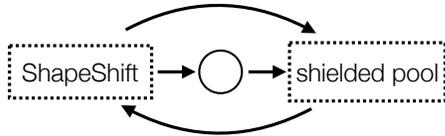

Figure 7: The three types of interactions we investigated between ShapeShift and the shielded pool in Zcash.

reveals the sender, and taking money out of the pool hides the sender (through the use of zero-knowledge proofs [2]) but reveals the recipient. Finally, Zcash is designed to provide privacy mainly in the case in which users transact *within* the shielded pool, which hides the sender, recipient, and the value being sent.

We considered three possible interactions between ShapeShift and the shielded pool, as depicted in Figure 7: (1) a user shifts coins directly from ShapeShift into the shielded pool, (2) a user shifts to a t-address but then uses that t-address to put money into the pool, and (3) a user sends money directly from the pool to ShapeShift.

For the first type of interaction, we found 29,003 transactions that used ZEC as curOut. Of these, 758 had a z-address as the output address, meaning coins were sent directly to the shielded pool. The total value put into the pool in these transactions was 6,707.86 ZEC, which is 4.3% of all the ZEC received in pass-through transactions. When attempting to use z-addresses in our own interactions with ShapeShift, however, we consistently encountered errors or were told to contact customer service. It is thus not clear if usage of this feature is supported at the time of writing.

For the second type of interaction, there were 1309 where the next transaction (i.e., the transaction in which this UTXO spent its contents) involved putting money into the pool. The total value put into the pool in these transactions was 12,534 ZEC, which is 8.2% of all the ZEC received in pass-through transactions.

For the third type of interaction, we found 111,041 pass-through transactions that used ZEC as curIn. Of these, 3808 came directly from the pool, with a total value of 22,490 ZEC (14% of all the ZEC sent in pass-through transactions).

Thus, while the usage of the anonymity features in Zcash was not necessarily a large fraction of the overall usage of Zcash in ShapeShift, there is clear potential to move large amounts of Zcash (representing over 10 million USD at the time it was transacted) by combining ShapeShift with the shielded pool.

### 8.4.2 Dash

As in Zcash, the “standard” transaction in Dash is similar to a Bitcoin transaction in terms of the information it reveals. Its main anonymity feature — *PrivateSend* transactions — are a type of CoinJoin [8]. A CoinJoin is specifically designed

to invalidate the multi-input clustering heuristic described in Section 7, as it allows multiple users to come together and send coins to different sets of recipients in a single transaction. If each sender sends the same number of coins to their recipient, then it is difficult to determine which input address corresponds to which output address, thus severing the link between an individual sender and recipient.

In a traditional CoinJoin, users must find each other in some offline manner (e.g., an IRC channel) and form the transaction together over several rounds of communication. This can be a cumbersome process, so Dash aims to simplify it for users by automatically finding other users for them and chaining multiple mixes together. In order to ensure that users cannot accidentally de-anonymize themselves by sending uniquely identifiable values, these *PrivateSend* transactions are restricted to specific denominations: 0.01, 0.1, 1, and 10 DASH. As observed by Kalodner et al. [5], however, the CoinJoin denominations often contain a fee of 0.0000001 DASH, which must be factored in when searching for these transactions. Our parameters for identifying a CoinJoin were thus that (1) the transaction must have at least three inputs, (2) the outputs must consist solely of values from the list of possible denominations (modulo the fees), and (3) and all output values must be the same. In fact, given how Dash operates there is always one output with a non-standard value, so it was further necessary to relax the second and third requirements to allow there to be at most one address that does not carry the specified value.

We first looked to see how often the DASH sent to ShapeShift had originated from a CoinJoin, which meant identifying if the inputs of a Phase 1 transaction were outputs from a CoinJoin. Out of 100,410 candidate transactions, we found 2,068 that came from a CoinJoin, carrying a total of 11,929 DASH in value (6.5% of the total value across transactions with Dash as curIn). Next, we looked at whether or not users performed a CoinJoin after receiving coins from ShapeShift, which meant identifying if the outputs of a Phase 2 transaction had been spent in a CoinJoin. Out of 50,545 candidate transactions, we found only 33 CoinJoin transactions, carrying a total of 187 DASH in value (0.1% of the total value across transactions using Dash as curOut).

If we revisit our results concerning the use of U-turns in Dash from Section 6.2, we recall that there was a large asymmetry in terms of the results of our two heuristics: only 5.6% of the U-turns used the same UTXO, but 64.6% of U-turns used the same address. This suggests that some additional on-chain transaction took place between the two ShapeShift transactions, and indeed upon further inspection we identified many cases where this transaction was a CoinJoin. There thus appears to have been a genuine attempt to take advantage of the privacy that Dash offers, but this was completely ineffective due to the use of the same address that both sent and received the mixed coins.

## 9 Conclusions

In this study, we presented a characterization of the usage of the ShapeShift trading platform over a thirteen-month period, focusing on the ability to link together the ledgers of multiple different cryptocurrencies. To accomplish this task, we looked at these trading platforms from several different perspectives, ranging from the correlations between the transactions they produce in the cryptocurrency ledgers to the relationships they reveal between seemingly distinct users. The techniques we develop demonstrate that it is possible to capture complex transactional behaviors and trace their activity even as it moves across ledgers, which has implications for any criminals attempting to use these platforms to obscure their flow of money.

## Acknowledgments

We would like to thank Bernhard Haslhofer and Rainer Stütz for performing the Bitcoin multi-input clustering using the GraphSense tool, and Zooko Wilcox, the anonymous reviewers, and our shepherd Matthew Green for their feedback. All authors are supported by the EU H2020 TITANIUM project under grant agreement number 740558.

## Abstract

The term “threat intelligence” has swiftly become a staple buzzword in the computer security industry. The entirely reasonable premise is that, by compiling up-to-date information about known threats (i.e., IP addresses, domain names, file hashes, etc.), recipients of such information may be able to better defend their systems from future attacks. Thus, today a wide array of public and commercial sources distribute threat intelligence data feeds to support this purpose. However, our understanding of this data, its characterization and the extent to which it can meaningfully support its intended uses, is still quite limited. In this paper, we address these gaps by formally defining a set of metrics for characterizing threat intelligence data feeds and using these measures to systematically characterize a broad range of public and commercial sources. Further, we ground our quantitative assessments using external measurements to qualitatively investigate issues of coverage and accuracy. Unfortunately, our measurement results suggest that there are significant limitations and challenges in using existing threat intelligence data for its purported goals.

## 1 Introduction

Computer security is an inherently adversarial discipline in which each “side” seeks to exploit the assumptions and limitations of the other. Attackers rely on exploiting knowledge of vulnerabilities, configuration errors or operational lapses in order to penetrate targeted systems, while defenders in turn seek to improve their resistance to such attacks by better understanding the nature of contemporary threats and the technical fingerprints left by attacker’s craft. Invariably, this means that attackers are driven to innovate and diversify while defenders, in response, must continually monitor for such changes and update their operational security practices accordingly. This dynamic is present in virtually every aspect of the operational security landscape, from anti-virus signatures to the configuration of firewalls and intrusion detection systems to incident response and triage. Common to all such reifications, however, is the process of monitoring for new data on attacker behavior

and using that data to update defenses and security practices. Indeed, the extent to which a defender is able to gather and analyze such data effectively defines a de facto window of vulnerability—the time during which an organization is less effective in addressing attacks due to ignorance of current attacker behaviors.

This abstract problem has given rise to a concrete demand for contemporary threat data sources that are frequently collectively referred to as *threat intelligence* (TI). By far the most common form of such data are so-called *indicators of compromise*: simple observable behaviors that signal that a host or network may be compromised. These include both network indicators such as IP addresses (e.g., addresses known to launch particular attacks or host command-and-control sites, etc.) and file hashes (e.g., indicating a file or executable known to be associated with a particular variety of malware). The presence of such indicators is a symptom that alerts an organization to a problem, and part of an organization’s defenses might reasonably include monitoring its assets for such indicators to detect and mitigate potential compromises as they occur.

While each organization naturally collects a certain amount of threat intelligence data on its own (e.g., the attacks they repel, the e-mail spam they filter, etc.) any single entity has a limited footprint and few are instrumented to carefully segregate crisp signals of attacks from the range of ambiguity found in normal production network and system logs. Thus, it is now commonly accepted that threat intelligence data procurement is a specialized activity whereby third-party firms, and/or collections of public groups, employ a range of monitoring techniques to aggregate, filter and curate quality information about current threats. Indeed, the promised operational value of threat intelligence has created a thriving (multi-billion dollar) market [43]. Established security companies with roots in anti-virus software or network intrusion detection now offer threat intelligence for sale, while some vendors specialize in threat intelligence exclusively, often promising coverage of more sophisticated threats than conventional sources.

Unfortunately, in spite of this tremendous promise, there has been little empirical assessment of threat intelligence data

or even a consensus about what such an evaluation would entail. Thus, consumers of **TI** products have limited means to compare offerings or to factor the cost of such products into any model of the benefit to operational security that might be offered.

This issue motivates our work to provide a grounded, empirical footing for addressing such questions. In particular, this paper makes the following contributions:

- ❖ We introduce a set of basic *threat intelligence metrics* and describe a methodology for measuring them, notably: **Volume, Differential Contribution, Exclusive Contribution, Latency, Coverage and Accuracy**.
- ❖ We analyze 47 distinct IP address **TI** sources covering six categories of threats and 8 distinct malware file hash **TI** sources, and report their metrics.
- ❖ We demonstrate techniques to evaluate the accuracy and coverage of certain categories of **TI** sources.
- ❖ We conduct the analyses in two different time periods two years apart, and demonstrate the strong consistency between the findings.

From our analysis, we find that while a few **TI** data sources show significant overlap, most do not. This result is consistent with the hypothesis advanced by [42] that different kinds of monitoring infrastructure will capture different kinds of attacks, but we have demonstrated it in a much broader context. We also reveal that underlying this issue are broader limitations of **TI** sources in terms of coverage (most indicators are unique) and accuracy (false positives may limit how such data can be used operationally). Finally, we present a longitudinal analysis suggesting that these findings are consistent over time.

## 2 Overview

The threat intelligence data collected for our study was obtained by subscribing to and pulling from numerous public and private intelligence sources. These sources ranged from simple blacklists of bad IPs/domains and file hashes, to rich threat intelligence exchanges with well labeled and structured data. We call each item (e.g., IP address or file hash) an *indicator* (after *indicator of compromise*, the industry term for such data items).

In this section we enumerate our threat intelligence sources, describe each source's structure and how we collected it, and then define our measurement metrics for empirically measuring these sources. When the source of the data is public, or when we have an explicit agreement to identify the provider, we have done so. However, in other cases, the data was provided on the condition of anonymity and we restrict ourselves to describing the nature of the provider, but not their identity. All of our private data providers were appraised of the nature of our research, its goals and the methodology that we planned to employ.

### 2.1 Data Set and Collection

We use several sources of **TI** data for our analysis:

**Facebook ThreatExchange (FB)** [17]. This is a closed-community platform that allows hundreds of companies and organizations to share and interact with various types of labeled threat data. As part of an agreement with Facebook, we collected all its data that it shared broadly. In subsequent analyses, sources with prefix "FB" indicate a unique contributor on the Facebook ThreatExchange.

**Paid Feed Aggregator (PA)**. This is a commercial paid threat intelligence data aggregation platform. It contains data collected from over a hundred other threat intelligence sources, public or private, together with its own threat data. In subsequent analyses all data sources with prefix "PA" are from unique data sources originating from this aggregator.

**Paid IP Reputation Service**. This commercial service provides an hourly-updated blacklist of known bad IP addresses across different attack categories.

**Public Blacklists and Reputation Feeds**. We collected indicators from public blacklists and reputation data sources, including well-known sources such as AlienVault [3], Badips [5], Abuse.ch [1] and Packetmail [28].

Threat Intelligence indicators include different types of data, such as IP address, malicious file hash, Domain, URL, etc. In this paper, we focus our analysis on sources that provide IP addresses and file hashes, as they are the most prevalent data types in our collection.

We collect data from all sources on an hourly basis. However, both the Facebook ThreatExchange and the Paid Feed Aggregator change their members and contributions over time, creating irregular collection periods for several of the sub-data sources. Similarly, public threat feeds had varying degrees of reliability, resulting in collection gaps. In this paper, we use the time window from **December 1, 2017 to July 20, 2018** for most of the analyses, as we have the largest number of active sources during this period. We eliminated duplicates sources (e.g., sources we collected individually and also found in the Paid Aggregator) and sub-sources (a source that is a branch of another source). We further break IP sources into separate categories and treat them as individual feeds, as shown in Section 3. This filtering leaves us with 47 IP feeds and 8 malware file hash feeds.

The ways each **TI** source collects data varies, and in some cases the methodology is unknown. For example, Packetmail IPs and Paid IP Reputation collect threat data themselves via honeypots, analyzing malware, etc. Other sources, such as Badips or the Facebook ThreatExchange, collect their indicators from general users or organizations—e.g., entities may be attacked and submit the indicators to these threat intelligence services. These services then aggregate the data and report it to their subscribers. Through this level of aggregation the precise collection methodologies and data providence can be lost.

## 2.2 Data Source Structure

TI sources in our corpus structure and present data in different ways. Part of the challenge in producing cross-dataset metrics is normalizing both the structure of the data as well as its *meaning*. A major structural difference that influences our analysis occurs between data sources that provide data in *snapshots* and data sources that provide *events*.

**Snapshot.** Snapshot feeds provide periodic snapshots of a set of indicators. More formally, a snapshot is a set of indicators that is a function of time. It defines, for a given point in time, the set of indicators that are members of the data source. Snapshot feeds imply *state*: at any given time, there is a set of indicators that are *in* the feed. A typical snapshot source is a published list of IPs periodically updated by its maintainer. For example, a list of command-and-control IP addresses for a botnet may be published as a snapshot feed subject to periodic updates.

All feeds of file hashes are snapshots and are *monotonic* in the sense that indicators are only added, not removed, from the feed. Hashes are a proxy for the file content, which does not change (malicious file content will not change to benign in the future).

**Event.** In contrast, event feeds report newly discovered indicators. More formally, an event source is a set of indicators that is a function of a time *interval*. For a given time interval, the source provides a set of indicators that were seen or discovered in that time interval. Subscribers of these feeds query data by asking for new indicators added in a recent time window. For example, a user might, once a day, request the set of indicators that appeared in the last 24 hours.

This structural difference is a major challenge when evaluating feeds comparatively. We need to normalize the difference to make a fair comparison, especially for IP feeds. From a TI consumer's perspective, an *event* feed does not indicate when an indicator will expire, so it is up to the consumer to act on the age of indicators. Put another way, the expiration dates of indicators are decided by how users query the feed: if a user asks for the indicators seen in the last 30 days when querying data, then there is an implicit 30-day valid time window for these indicators.

In this paper, we choose a 30-day valid period for all the indicators we collected from event feeds—the same valid period used in several snapshot feeds, and also a common query window option offered by event feeds. We then convert these event feeds into snapshot feeds and evaluate all of them in a unified fashion.

## 2.3 Threat Intelligence Metrics

The aim of this work is to develop *threat intelligence metrics* that allow a TI consumer to compare threat intelligence sources and reason about their fitness for a particular purpose. To this end, we propose six concrete metrics: *Volume*, *Differential contribution*, *Exclusive contribution*, *Latency*, *Accuracy* and *Coverage*.

◇ **Volume.** We define the *volume* of a feed to be the total number of indicators appearing in a feed over the measurement interval. Volume is the simplest TI metric and has an established history in prior work [21,23,24,30,35,36,42]. It is also useful to study the daily *rate* of a feed, which quantifies the amount of data appearing in a feed on a daily basis.

*Rationale:* To a first approximation, volume captures how much information a feed provides to the consumer. For a feed without false positives (see *accuracy* below), and if every indicator has equal value to the consumer, we would prefer a feed of greater volume to a feed of lesser volume. Of course, indicators do not all have the same value to consumers: knowing the IP address of a host probing the entire Internet for decades-old vulnerabilities is less useful than the address of a scanner targeting organizations in your sector looking to exploit zero-day vulnerabilities.

◇ **Differential contribution.** The *differential contribution* of one feed with respect to another is the number of indicators in the first that are not in the second during the same measurement period. We define differential contribution relative to the size of the first feed, so that the differential contribution of feed *A* with respect to feed *B* is  $\text{Diff}_{A,B} = |A \setminus B|/|A|$ . Thus,  $\text{Diff}_{A,B} = 1$  indicates that the two feeds have no elements in common, and  $\text{Diff}_{A,B} = 0$  indicates that every indicator in *A* also appears in *B*. It is sometimes useful to consider the complement of differential contribution, namely the normalized *intersection* of *A* in *B*, given by  $\text{Int}_{A,B} = |A \cap B|/|A| = 1 - \text{Diff}_{A,B}$ .

*Rationale:* For a consumer, it is often useful to know how many *additional* indicators a feed offers relative to one or more feeds that the consumer has already. Thus, if a consumer already has feed *A* and is considering paying for feed *B*, then  $\text{Diff}_{A,B}$  indicates how many new indicators feed *A* will provide.

◇ **Exclusive contribution.** The *exclusive contribution* of a feed with respect to a set of other feeds is the proportion of indicators unique to a feed, that is, the proportion of indicators that occur in the feed but no others. Formally, the exclusive contribution of feed *A* is defined as  $\text{Uniq}_{A,B} = |A \setminus \bigcup_{B \neq A} B|/|A|$ . Thus,  $\text{Uniq}_{A,B} = 0$  means that every element of feed *A* appears in some other feeds, while  $\text{Uniq}_{A,B} = 1$  means no element of *A* appears in any other feed.

*Rationale:* Like differential contribution, exclusive contribution tells a TI consumer how much of a feed is different. However, exclusive contribution compares a feed to all other feeds available for comparison, while differential contribution compares a feed to just another feed. From a TI consumer's perspective, exclusive contribution is a general measure of a feed's unique value.

◇ **Latency.** For an indicator that occurs in two or more feeds, its *latency* in a feed is the elapsed time between its first appearance in any feed and its appearance in the feed in question. In the feed where an indicator first appeared, its latency is zero. For all other feeds, the latency indicates how much later the

same indicators appears in those feeds. Taster’s Choice [30] referred to latency as *relative first appearance time*. (We find the term *latency* to be more succinct without loss of clarity.) Since latency is defined for one indicator, for a feed it makes sense to consider statistics of the distribution of indicator latencies, such as the median indicator latency.

*Rationale:* Latency characterizes how quickly a feed includes new threats: the sooner a feed includes a threat, the more effective it is at helping consumers protect their systems. Indeed, several studies report on the impact of feed latency on its effectiveness at thwarting spam [10, 32].

The metrics above are defined without regard for the *meaning* of the indicators in a feed. We can calculate the volume of a single feed or the differential contribution of one feed with respect to another regardless of what the feed purports to contain. While these metrics are easy to compute, they do little to tell us about the fitness of a feed for a particular purpose. For this, we need to consider the meaning or purpose of the feed data, as advertised by the feed provider. We define the following two metrics.

✧ **Accuracy.** The *accuracy* of a feed is the proportion of indicators in a feed that are correctly included in the feed. Feed accuracy is analogous to *precision* in Information Retrieval. This metric presumes that the description of the feed is well-defined and describes a set of elements that should be in the feed given perfect knowledge. In practice, we have neither perfect knowledge nor a perfect description of what a feed should contain. In some cases, however, we can construct a set  $A^-$  of elements that should definitely not be in a feed  $A$ . Then  $\text{Acc}_A \leq |A \setminus A^-|/|A|$ .

*Rationale:* The accuracy metric tells a **TI** consumer how many false positives to expect when using a feed, and, therefore, dictates how a feed can be used. For example, if a consumer automatically blocks all traffic to IP addresses appearing in a feed, then false positives may cause disruption in an enterprise by blocking traffic to legitimate sites. On the other hand, consumers may tolerate some false positives if a feed is only used to gain additional insight during an investigation.

✧ **Coverage.** The *coverage* of a feed is the proportion of the intended indicators contained in a feed. Feed coverage is analogous to *recall* in Information Retrieval. Like accuracy, coverage presumes that the description of the feed is sufficient to determine which elements should be in a feed, given perfect knowledge. In some cases, it is possible to construct a set  $A^+$  of elements that should be in a feed. We can then upper-bound the coverage  $\text{Cov}_A \leq |A|/|A^+|$ .

*Rationale:* For a feed consumer who aims to obtain complete protection from a specific kind of threat, coverage is a measure of how much protection a feed will provide. For example, an organization that wants to protect itself from a particular botnet will want to maximize its coverage of that botnet’s command-and-control servers or infection vectors.

In the following two sections, we use these metrics to evaluate two types of **TI**: IP address feeds and file hash feeds.

## 3 IP Threat Intelligence

One of the most common forms of **TI** are feeds of IP addresses considered malicious, suspicious, or otherwise untrustworthy. This type of threat intelligence dates back at least to the early spam and intrusion detection blacklists, many of which are still active today such as SpamhausSBL [40], CBL [8] and SORBS [39]. Here, we apply the metrics described above to quantify the differences between 47 different IP address **TI** feeds.

### 3.1 Feed Categorization

IP address **TI** feeds have different meanings, and, therefore, purposes. To meaningfully compare feeds to each other, we first group feeds into *categories* of feeds whose indicators have the same intended meaning. Unfortunately, there is no standard or widely accepted taxonomy of IP **TI** feeds. To group feeds into semantic categories, we use metadata associated with the feed as well as descriptions of the feed provided by the producer, as described below.

**Metadata.** Some feeds provide category information with each indicator as metadata. More specifically, all of the Paid Aggregator feeds, Alienvault IP Reputation and Paid IP Reputation include this category metadata. In this case, we use its pre-assigned category in the feed. Facebook ThreatExchange feeds do not include category information in the metadata, but instead provide a descriptive phrase with each indicator. We then derive its category based on the description.

**Feed description.** For feeds without metadata, we rely on online descriptions of each feed, where available, to determine its semantic category. For example, the website of feed Nothink SSH [27] describes that the feed reports brute-force login attempts on its corresponding honeypot, which indicates the feed belongs to brute-force category.

We grouped our IP feeds into categories derived from the information above. In this work, we analyze six of the most prominent categories:

- **Scan:** Hosts doing port or vulnerability scans.
- **Brute-force:** Hosts making brute force login attempts.
- **Malware:** Malware C&C and distribution servers.
- **Exploit:** Hosts trying to remotely exploit vulnerabilities.
- **Botnet:** Compromised hosts belonging to a botnet.
- **Spam:** Hosts that sent spam or should not originate email.

Table 1 lists the feeds, grouped by category, used in the rest of this section. The symbols ○ and △ before the feed name indicate whether the feed is a snapshot feed or an event feed, respectively (see Section 2.2). All data was collected during our measurement period, **December 1st, 2017 to July 20th, 2018**. Note that a few feeds, like Paid IP Reputation, appear in multiple categories. In these feeds, indicators are associated with different categories via attached metadata. We split these feeds into multiple virtual feeds each containing indicators belonging to the same category.

### 3.2 Volume

Volume is one of the oldest and simplest TI metrics representing how informative each data source is. Table 1 shows the total number of unique IP addresses collected from each feed during the measurement period, under column *Volume*. Feeds are listed in order of decreasing volume, grouped by category. The numbers we show are after the removal of invalid entries identified by the sources themselves. Column *Avg. Rate* shows the average number of new IPs we received per day, and *Avg. Size* lists the average daily working set size of each feed, that is, the average size of the snapshot.

◆ **Finding:** Feeds vary dramatically in volume. Within every category, big feeds can contain orders of magnitude more data than small feeds. For example, in the scan category, we saw over 361,004 unique IP addresses in DShield IPs but only 1,572 unique addresses in PA Analyst in the same time period. Clearly, volume is a major differentiator for feeds.

Average daily rate represents the amount of new indicators collected from a feed each day. Some feeds may have large volume but low daily rates, like Feodo IP Blacklist in the malware category. This means most indicators we get from that feed are old data present in the feed before our measurement started. On the other hand, the average rate of a feed could be greater than the volume would suggest, like Nothink SSH in the brute-force category. This is due to the fact that indicators can be added and removed multiple times in a feed. In general, IP indicators tend to be added in a feed only once: 37 among 47 IP feeds have over 80% of their indicators appearing only once, and 30 of them have this rate over 90%. One reason is that some snapshot feeds maintain a valid period for each indicator, as we found in all PA feeds where the expiration date of each indicator is explicitly recorded. When the same indicator is discovered again by a feed before its expiration time, the feed will just extend its expiration date, so this occurrence will not be captured if we simply subtract the old data from the newly collected data to derive what is added on a day. For event feeds and snapshot feeds in PA where we can precisely track every occurrence of each indicator, we further examined data occurrence frequency and still found that the vast majority of IPs in feeds only occurred once—an observation that relates to the dynamics of cyber threats themselves.

Nothink SSH, as we mentioned above, is a notable exception. It has over 64% of its indicators appearing 7 times in our data set. After investigating, we found that this feed posts all its previous data at the end of every month, behavior very likely due to the feed provider instead of the underlying threats.

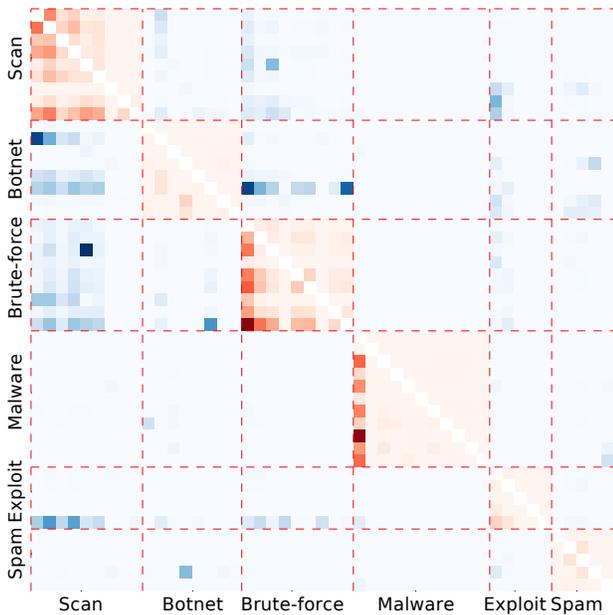

The working set size defines the daily average amount of indicators users need to store in their system to use a feed (the storage cost of using a feed). The average working set size is largely decided by the valid period length of the indica-

<sup>1</sup>This feed is aggregated by PA from Alienvault OTX, the Alienvault IP Reputation is the public reputation feed we collected from Alienvault directly. They are different feeds.

**Table 1.** IP TI feeds used in the study. A ○ denotes a *snapshot feed* and △ indicates an *event feed* (Section 2.2). *Volume* is the total number of IPs collected during our measurement period. *Exclusive* is the exclusive contribution of each feed (Section 3.4). *Avg. Rate* is the number of average daily new IPs added in the feed (Section 3.6), and *Avg. Size* is the average working set size of each feed (Section 3.2).

Feed	Volume	Exclusive	Avg. Rate	Avg. Size
<b>Scan Feeds</b>				
○ PA AlienVault IPs <sup>1</sup>	425,967	48.6%	1,359	128,821
△ DShield IPs	361,004	31.1%	1,556	69,526
○ PA Packetmail ramnode	258,719	62.0%	870	78,974
△ Packetmail IPs	246,920	48.6%	942	29,751
○ Paid IP Reputation	204,491	75.6%	1,362	8,756
○ PA Lab Scan	169,078	63.1%	869	9,775
○ PA Snort BlockList	19,085	96.3%	56	4,000
△ FB Aggregator <sub>1</sub>	6,066	71.3%	24	693
○ PA Analyst	1,572	34.5%	6.3	462
<b>Botnet Feeds</b>				
○ PA Analyst	180,034	99.0%	697	54,800
○ PA CI Army	103,281	97.1%	332	30,388
○ Paid IP Reputation	77,600	99.9%	567	4,278
○ PA Botscout IPs	23,805	93.8%	81	7,180
○ PA VoIP Blacklist	10,712	88.0%	40	3,633
○ PA Compromised IPs	7,679	87.0%	21	2,392
○ PA Blocklist Bots	4,179	80.7%	16	1,160
○ PA Project Honeybot	2,600	86.5%	8.5	812
<b>Brute-force Feeds</b>				
△ Badips SSH	542,167	84.1%	2,379	86,677
△ Badips Badbots	91,553	70.8%	559	17,577
○ Paid IP Reputation	89,671	52.8%	483	3,705
○ PA Brute-Force	41,394	92.1%	138	14,540
△ Badips Username Notfound	37,198	54.2%	179	3662.8
△ Haley SSH	31,115	43.6%	40	1,224
△ FB Aggregator <sub>2</sub>	22,398	77.3%	74	2,086
△ Nothink SSH	20,325	62.7%	224	12,577
△ Dangerrulez Brute	10,142	4.88%	37	1,102
<b>Malware Feeds</b>				
○ Paid IP Reputation	234,470	99.1%	1,113	22,569
△ FB Malicious IPs	30,728	99.9%	129	3,873
○ Feodo IP Blacklist	1,440	47.7%	1.3	1,159
○ PA Lab Malware	1,184	84.6%	3.5	366
△ Mal0de IP Blacklist	865	61.0%	2.9	86.6
○ PA Bambenek C2 IPs	785	92.1%	3.4	97.9
○ PA SSL Malware IPs	676	53.9%	2.9	84.0
○ PA Analyst	492	79.8%	2.1	149
○ PA Abuse.ch Ransomware	256	7.03%	1.6	117
○ PA Mal-Traffic-Anal	251	60.5%	0.9	72
○ Zeus IP Blacklist	185	49.1%	0.5	101
<b>Exploit Feeds</b>				
△ Badips HTTP	305,020	97.6%	1,592	22,644
△ Badips FTP	285,329	97.5%	1,313	27,601
△ Badips DNS	46,813	99.3%	231	4,758
△ Badips RFI	3,642	91.4%	16	104
△ Badips SQL	737	79.5%	4.4	99.2
<b>Spam Feeds</b>				
○ Paid IP Reputation	543,583	99.9%	3,280	6,551
△ Badips Postfix	328,258	90.5%	842	27,951
△ Badips Spam	302,105	89.3%	1,454	30,197
○ PA Botscout IPs	14,514	89.3%	49	4,390
○ Alienvault IP Reputation	11,292	96.6%	48	1,328

tors, controlled either by the feed (snapshot feeds) or the user (event feeds). The longer the valid period is, the larger the working set will be. Different snapshot feeds have different choices for this valid period: PA AlienVault IPs in the scan category sets a 90-day valid period for every indicator added to the feed, while PA Abuse.ch Ransomware uses a 30-day period. Although we do not know the data expiration mechanism used by snapshot feeds other than PA feeds, as there is no related information recorded, we can still roughly estimate this by checking the *durations* of their indicators—the time

**Figure 1.** Feed intersection for all IP feeds. Each row/column represents a feed, shown in the same order as Table 1. Darker (more saturated) colors indicate greater intersection.

between an indicator being added and being removed. Four Paid IP Reputation feeds have more than 85% of durations shorter than 10 days, while the one in the malware category has more than 40% that span longer than 20 days. Feodo IP Blacklist has over 99% of its indicators valid for our entire measurement period, while over 70% of durations in the Zeus IP Blacklist are less than 6 days. We did not observe a clear pattern regarding how each snapshot feed handles the expiration of indicators.

### 3.3 Differential Contribution and Intersection

The differential contribution metric measures the number of indicators in one feed that are not in another. Equivalently, we can consider the intersection of two feeds, which is the number of elements in one feed that are present in the other, normalized by the size of the first:  $|A \cap B|/|A|$ . Figure 1 shows the intersection relationship of all feeds in the study. Each cell in the matrix represents the number of elements in both feeds, normalized by the size of the feed spanning the rows on the table. That is,  $A$ , in the expression above, ranges over rows, and  $B$  over columns of the matrix. Darker (more saturated) colors indicate greater intersection. Comparisons of feeds within a category are shaded red and comparisons of feeds between different categories are shaded blue. Note that the matrix is asymmetric, because, in general,  $|A \cap B|/|A| \neq |A \cap B|/|B|$ . Elements of the matrix are in the same order as in Table 1.

◆ **Finding:** Feeds in scan and brute-force categories have higher pairwise intersections: Half of the pairwise intersection

rates in two categories are greater than 5%. The scan category has 29 out of 72 pairs (excluding self comparisons) with an intersection rate larger than 10%, and the same case occurred in 19 out of 72 pairs in the brute-force category.

On the other side, feeds in the botnet, exploit, malware and spam category do not share much data between each other: all 4 categories have more than three-quarters of pairwise intersection rates less than 1%. A few big feeds in these categories can share a significant amount of data with some small feeds in the same category—a characteristic that appears as a dark vertical line within its category in Figure 1. Paid IP Reputation in the malware category, for example, shares over 30% of 6 other malware feeds. But the intersections among the vast majority of feeds in these 4 categories are low. This finding is consistent with prior work [26, 42], but we provide a more comprehensive view regarding different categories.

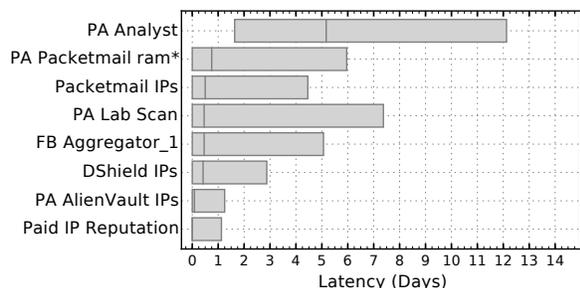

Figure 1 also shows the relation between feeds across different categories. We can clearly see a relation between scan and brute-force feeds: multiple scan feeds have non-trivial intersection with feeds in the brute-force category. In fact, 23.1% of all 760,263 brute-force IPs we collected are also included by scan feeds in our dataset. There are also three botnet feeds—PA CI Army, PA VoIP Blacklist and PA Compromised IPs—that have over 10% of its data shared with multiple feeds in the scan category.

### 3.4 Exclusive Contribution

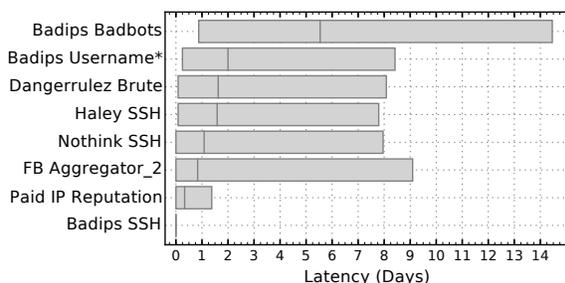

Exclusive contribution represents the number of indicators in a feed that are in no other feeds. We calculate each feed’s exclusive contribution among all the feeds in the same category, emphasizing their uniqueness regarding the scope of data they claim to report. Each feed’s exclusive contribution is presented in Table 1 in column *Exclusive*, calculated based on its volume.

◆ **Finding:** As we already observed in Section 3.3, botnet, exploit and spam feeds have relatively low pairwise intersections. Consequently, the feeds in these four categories have high exclusive contribution rates in general: the median exclusive contribution rates of these four categories are 90.9%, 97.5% and 90.5%, respectively. The malware category has a low median exclusive rate, since multiple small feeds have non-trivial intersection with the largest feed Paid IP Reputation, but the two largest feeds in malware both have a exclusive rate over 99%. Scan and brute-force feeds have more intersection within its category, and their exclusive rates are lower: 62.0% median rate in scan and 62.7% in brute-force, and the top two largest feeds in both categories have an exclusive rate below 85%.

If we assume a process where a feed is more likely to have popular elements, then smaller feeds would be subsumed by larger feeds. Yet, for some small feeds like Malc0de IP Blacklist in the malware and PA Project Honeykot in the botnet categories, even though they are several orders of magnitude smaller than the largest feeds in their categories, a significant

(a) Latency distribution in scan feeds

(b) Latency distribution in brute-force feeds

**Figure 2.** Distribution of indicators’ latency in scan and brute-force feeds. Each box shows the latency distribution of shared IPs in the feed calculated in hours from 25 percentile to 75 percentile, with the middle line indicating the median. (“Badips Username\*” here is the abbreviation for feed name Badips Username Notfound; “PA Packetmail Ram\*” for PA Packetmail Ramnode)

proportion of their indicators is still unique to the feed. When we aggregate the data in each category, 73% of all scan feed indicators are unique to a single feed and 88% of brute force feed indicators are unique to one feed. For other categories, over 97% of elements in the category are unique to a single feed. This result agrees with previous work that most data in threat intelligence feeds is unique [26, 42].

### 3.5 Latency

Feed latency measures how quickly a feed reports new threat indicators. The sooner a feed can report potential threats, the more valuable it is for consumers. The absolute latency of an indicator in a feed is the time from the beginning of the corresponding event until when the indicator shows up in the feed. However, it is difficult to know the actual time when an event begins from the threat intelligence data. Instead, we measure the *relative latency*, which is the delay of an indicator in one feed to be the time between its appearance in that feed and the first seen among all the feeds.

Relative latency can only be calculated for indicators that occur in at least two feeds. As discussed in Section 3.4, the number of common indicators in the botnet, malware, exploit and spam feeds is very low (fewer than 3% of elements occur in more than one feed). Relative latency calculated for these feeds is less meaningful. For this analysis, therefore, we focus

on scan and brute-force feeds.

Another issue is the time sensitivity of IP threats. An event that originated from an IP address, like scanning activity or a brute-force attack, will not last forever. If one scan feed reports an IP address today and another feed reports the same IP three months later, it would make little sense to consider them as one scanning event and label the second occurrence as being three months late. Unfortunately, there is no easy way we can clearly distinguish events from each other. Here we use a one-month window to restrict an event, assuming that the same attack from one source will not last for more than 30 days; although arbitrary, it provides a reasonably conservative threshold, and experimenting with other thresholds produced similar overall results. More specifically, we calculate relative latency by tracking the first occurrence of IPs in all feeds in a category, then recording the latency of the following occurrences while excluding ones that occur after 30 days. By just using the first appearance of each IP as the base, we avoid the uncertainty caused by multiple occurrence of indicators and different valid periods used among feeds.

Figures 2a and 2b show the relative latency distribution among feeds in the scan and brute-force categories, in hours. We focus on just those feeds that have over 10% of their data shared with others to ensure the analysis can represent the latency distribution of the overall feed. There is one feed in each category (PA Snort BlockList in scan and PA Brute-Force in brute-force) that is excluded from the figure.

◆ **Finding:** From the distribution boxes we can see that Paid IP Reputation in scan and Badips SSH in brute-force are the fastest feeds in their category, as they have the lowest median and 75th percentile latencies. On the other hand, PA Analyst in scan and Badips Badbots in brute-force are the slowest feeds. Figure 2a shows that all scan feeds except one have their 25th percentile latency equal to 0, indicating these feeds, across different sizes, all reported a significant portion of their shared data first. A similar case also happens in the brute-force category.

One may reasonably ask whether large feeds report data sooner than small feeds. The result shows that this is not always the case. FB Aggregator<sub>1</sub> is the second smallest feed in our scan category, yet it is no slower than several other feeds which have over 10 times of its daily rate. Badips Badbots, on the other hand, has the second largest rate in brute-force category, but it is slower than all the other feeds in the brute-force category. Feeds that are small in volume can still report a lot of their data first.

Another factor that could affect latency is whether feeds copy data from each other. For example, 93% of Dangerrulez Brute also appears in Badips SSH. If this is the case, we expect Dangerrulez Brute will be faster than Badips SSH on reporting their shared data. However, we compared the relative latency between just two feeds and found Badips SSH reported 88% of their shared indicators first. We further conducted this pairwise latency comparison between all feeds

**Table 2.** IP TI feeds accuracy overview. *Unrt* is fraction of unroutable addresses in each feed (Section 3.6). *Alexa Top* is the number of IPs intersected with top Alexa domain IP addresses, and *CDNs* is the number of IPs intersected with top CDN provider IP addresses.

<i>Feed</i>	<i>Added</i>	<i>Unrt</i>	<i>Alexa</i>	<i>CDNs</i>
<b>Scan Feeds</b>

PA Botscout IPs	11,358	0.06%	0	0
Alienvault IP Reputation	10,414	0.07%	63	1,040

in scan, brute-force and malware (since Paid IP Reputation shares non-trivial amount of data with a few small feeds in the malware category), and did not see a clear latency advantage between any two feeds. Note that this observation does *not* prove there is no data copying, since the shared data between two feeds might partially come from copying and partially from the feeds' own data collection. Furthermore, our latency analysis is at a one-hour granularity.

### 3.6 Accuracy

Accuracy measures the rate of false positives in a feed. A false positive is an indicator that data is labeled with a category to which it does not belong. For example, an IP address found in a scan feed that has not conducted any Internet scanning is one such false positive. As well, even if a given IP is in fact associated with malicious activity, if it is not unambiguously actionable (e.g., Google's DNS at 8.8.8.8 is used by malicious and benign software alike) then for many use cases it must also be treated as a false positive. False positives are problematic for a variety of reasons, but particularly because they can have adverse operational consequences. For example, one might reasonably desire to block all new network connections to and from IP addresses reported as hosting malicious activity (indeed, this use is one of the promises of threat intelligence). False positives in such feeds, though, could lead to blocking legitimate connections as well. Thus, the degree of accuracy for a feed may preclude certain use cases.

Unfortunately, determining which IPs belong in a feed and which do not can be extremely challenging. In fact, at any reasonable scale, we are unaware of any method for unambiguously and comprehensively establishing "ground truth" on this matter. Instead, in this section we report on a proxy for accuracy that provides a conservative assessment of this question. To wit, we assemble a *whitelist* of IP addresses that either should not reasonably be included in a feed, or that, if included, would cause significant disruption. We argue that the presence of such IPs in a feed are clearly false positives and thus define an upper bound on a feed's accuracy. We populate our list from three sources: unroutable IPs, IPs associated with top Alexa domains, and IPs of major content distribution networks (CDNs).

**Unroutable IPs.** Unroutable IPs are IP addresses that were not BGP-routable *when they first appeared* in a feed, as established by contemporaneous data in the RouteViews service [44]. While such IPs could have appeared in the source address field of a packet (i.e., due to address spoofing), it would not be possible to complete a TCP handshake. Feeds that imply that such an interaction took place should not include such IPs. For example, feeds in the Brute-force category imply that the IPs they contain were involved in brute-force login attempts, but this could not have taken place if the IPs are not routable. While including unroutable addresses in a feed is not, in itself, a problem, their inclusion suggests a quality control issue with the feed, casting shade on the validity of other indicators in the feed.

To allow for some delays in the feed, we check if an IP was routable at any time in the seven days prior to its first appearance in a feed, and if it had, we do not count it as unroutable. Table 2, column *Unrt*, shows the fraction of IP indicators that were not routable at any time in the seven days prior to appearing in the feed. This analysis is only conducted for the IPs that are added after our measurement started. The number of such IPs is shown in column *Added*,

and the unroutable fraction shown in *Unrt* is with respect to this number.

**Alexa.** Blocking access to popular Internet sites or triggering alarms any time such sites are accessed would be disruptive to an enterprise. For our analysis, we periodically collected the Alexa top 25 thousand domains (3–4 times a month) over the course of the measurement period [2]. To address the challenge that such lists can have significant churn [33], we restrict our whitelist to hold the *intersection* of all these top 25K lists (i.e., domains that were in the top 25K every time we polled Alexa over our 8-month measurement period), which left us with 12,009 domains. We then queried DNS for the A records, NS records and MX records of each domain, and collected the corresponding IP addresses. In total, we collected 42,436 IP addresses associated with these domains. We compute the intersection of these IPs with **TI** feeds and show the results in column *Alexa* in Table 2.

**CDNs.** CDN providers serve hundreds of thousands of sites. Although these CDN services can (and are) abused to conduct malicious activities [9], their IP addresses are not actionable. Because these are fundamentally shared services, blocking such IP addresses will also disrupt access to benign sites served by these IPs. We collected the IP ranges used by 5 popular CDN providers: AWS CloudFront [12], Cloudflare [11], Fastly [18], EdgeCast [16] and MaxCDN [25]. We then check how many IPs in **TI** feeds fall into these ranges. Column *CDNs* in Table 2 shows the result.

♦ **Finding:** Among the 47 feeds in the table, 33 feeds have at least one unroutable IP, and for 13 of them, over 1% of the addresses they contain are unrouteable. Notably, the Paid IP Reputation feed in the spam category has an unroutable rate over 78%. Although it is not documented, a likely explanation is that this feed may include unroutable IPs intentionally, as this is a known practice among certain spam feeds. For example, the Spamhaus DROP List [41] includes IP address ranges known to be owned or operated by malicious actors, whether currently advertised or not. Thus, for feeds that explicitly do include unroutable IPs, their presence in the feeds should not necessarily be interpreted as a problem with quality control.

We further checked feeds for the presence of any “reserved IPs” which, as documented in RFC 8190, are not globally routable (e.g., private address ranges, test networks, loopback and multicast). Indeed, 12 feeds reported at least one reserved IP, including four of the Paid IP Reputation feeds (excepting the spam category), six of the Badips feeds, and the FB Malicious IPs and DShield IPs feeds. Worse, the Paid IP Reputation feeds together reported over 100 reserved IPs. Since such addresses should never appear on a public network, reporting such IPs indicates that a feed provider fails to incorporate some basic sanity checks on its data.

There are 21 feeds that include IPs from top Alexa domains, as shown in column *Alexa* in Table 2. Among these IPs there are 533 A records, 333 IPs of MX records and 63 IPs of NS records. The overlapped IPs include multiple in-

stances from notable domains. For example, the IP addresses of [www.github.com](http://www.github.com) are included by Malc0de IP Blacklist. Paid IP Reputation in the malware category contains the IP address for [www.dropbox.com](http://www.dropbox.com). Alienvault IP Reputation contains the MX record of [groupon.com](http://groupon.com), and Badips SSH also contains the IP addresses of popular websites such as [www.bing.com](http://www.bing.com).

Most of the feeds we evaluated do not contain IPs in CDN ranges, yet there are a few (including multiple Paid IP Reputation feeds, Badips feeds and Alienvault IP Reputation) that have significant intersection with CDN IPs. Alienvault IP Reputation and Badips feeds primarily intersect with Cloudflare CDN, while most of the overlap in the Paid IP Reputation malware category overlaps with AWS CloudFront.

Overall, the rate of false positives in a feed is not strongly correlated with its volume. Moreover, certain classes of false positives (e.g., the presence of Top Alex IPs or CDN IPs) seem to be byproducts of how distinct feeds are collected (e.g., Badips feeds tend to contain such IPs, irrespective of volume). Unsurprisingly, we also could find not correlation between a feed’s latency and its accuracy.

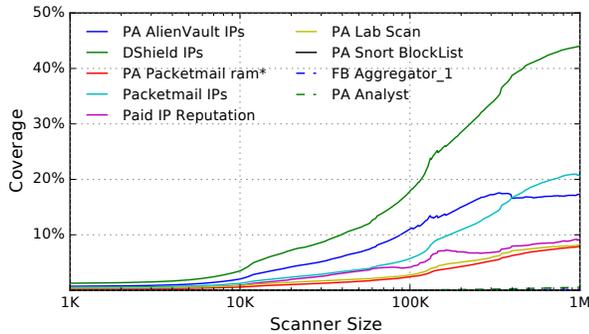

### 3.7 Coverage

The coverage metric provides a quantitative measure of how well a feed captures the intended threat. A feed with perfect coverage would include all indicators that belong in a category. Unfortunately, as discussed above, there is no systematic way for evaluating the exact accuracy or coverage of a feed since it is unrealistic to obtain ground truth of all threat activities on the Internet.

However, there are some large-scale threat activities that are well-collected and well-studied. One example is Internet scanning. Researchers have long been using “Internet telescopes” to observe and measure network scanning activities [6, 15, 29]. With a large telescope and well-defined scan filtering logic, one can obtain a comprehensive view of global scanning activities on the Internet.

To this end, we collected three months of traffic (from January 1st to March 31st 2018) using the UCSD network telescope [38], which monitors a largely quiescent /8 network comprising over 16 million IP addresses. We then used the default parameters of the Bro IDS [7] to identify likely scanning traffic, namely flows in which the same source IP address is used to contact 25 unique destination IP addresses on the same destination port/protocol within 5 minutes. Given the large number of addresses being monitored, any indiscriminate scanner observed by **TI** feeds will likely also be seen in our data. Indeed, by intersecting against this telescope data we are able to partially quantify the coverage of each **TI** scanning feed.

The scanners we collected from the telescope consist of 20,674,149 IP addresses. The total number of IPs in all the scan feeds during this period is 425,286, which covers only 1.7% (363,799 shared IPs) of all the telescope scan IPs. On the

**Figure 3.** The coverage of each feed on different sizes of scanners. Y axis is the proportion of scanners of a given size or larger that are covered by each feed.

other hand, telescope scanners intersect with 85% of all IPs in scan feeds. When looking at each feed, PA AlienVault IPs, DShield IPs Packetmail IPs, PA Lab Scan and PA Packetmail ramnode all have over 85% of their data intersected with telescope scanners; the other four, though, have less than 65% of their data shared (and the rate for PA Snort BlockList is only 8%).

To further understand how well each scan feed detects scanning activities, we measure how different sizes of scanners in the telescope are covered by each feed. Here, *scanner size* means how many IPs a scanner has scanned in the telescope within a day. Figure 3 shows the coverage rate of each feed over different sizes of scanners, ranging from 1,000 to 1 million. (There are 7,212,218 scanners from the telescope whose sizes are over 1K, 271,888 that are over 100K and 17,579 are over 1 million.)

◆ **Finding:** The union of all the scan IPs in the feeds covers less than 2% of the scanners collected by the telescope. Even if we only look at the scanners with sizes larger than 10,000, the overall coverage is still around 10%, suggesting the coverage capability of scan feeds is very limited. The graph shows that, as the scanner size increases, the coverage of each feed over the datasets also increases, and large feeds cover more percent of telescope scanners than small feeds. This trend aligns with the intuition that scan feeds tend to capture more extensive scanners.

It is surprising that the small scan feeds in our collection have a smaller percentage of their IPs shared with telescope scanners. This contradicts the idea that small feeds would contain a larger percentage of extensive scanners (that would most likely also be observed by the telescope).

## 4 File Hash Threat Intelligence

File hashes in a threat intelligence feed are indicators for malicious files. It is one of the most lightweight ways to mark files as suspicious. One can incorporate this data to block malicious downloads, malicious email attachments, and malware. Likewise, file hashes can be used to whitelist applications and

these feeds can be used to ensure malicious files do not appear in a customer’s whitelist. In this section we present our analysis on eight file hash feeds, also collected from December 1st, 2017 to July 20th, 2018. We use the same metrics defined in Section 2.3.

The file hash feeds we collected use a range of different hash functions to specify malicious files, including MD5, SHA1, SHA256 and SHA512 (and some feeds provided values for multiple different hash functions to support interoperability). Since most indicators in our dataset are MD5s, we have normalized to this representation by using other feeds and the VirusTotal service to identify hash aliases for known malicious files (i.e., which MD5 corresponds to a particular SHA256 value).

### 4.1 Volume

File hashes, unlike IP threat data, are not transient—a file does not change from malicious to benign—and thus a far simpler volume analysis is appropriate. We report volume as the number of new hashes that are added to each feed during our measurement period.

As seen in Table 3, we examine each feed’s volume and average daily rate. Like IP feeds, file hash feeds also vary dramatically in volume. The majority of the hashes are concentrated in three feeds: FB Malware, PA Malware Indicators, and PA Analyst, which also exhibit the highest daily rates. The other feeds are multiple order of magnitude smaller comparatively.

### 4.2 Intersection and Exclusive Contribution

As we mentioned earlier, to conduct intersection and exclusive analysis of file hash feeds, we need to convert indicators into the same hash type. Here we convert non-MD5 hashes into MD5s, using either metadata in the indicator itself (i.e., if it reports values for multiple hash functions) or by querying the source hash from VirusTotal [45] which reports the full suite of hashes for all files in its dataset. However, for a small fraction of hashes we are unable to find aliases to convert them to the MD5 representation and must exclude them from the analysis in this section. This filtering is reflected in Table 3, in which the Volume column represents the number of unique hashes found in each feed and the Converted column is the subset that we have been able to normalize to a MD5 representation.

◆ **Finding:** The intersections between hash feeds are minimal, even among the feeds that have multiple orders of magnitude differences in size. Across all feeds, only PA Analyst has relatively high intersections: PA Analyst shares 27% of PA OSINT’s MD5s and 13% of PA Twitter Emotet’s MD5s. PA Malware Indicators has a small intersection also with these two feeds. All other intersections are around or less than 1%. Consequently, the vast majority of MD5s are unique to one feed, as recorded in column *Exclusive* in Table 3. The “lowest” exclusivity belongs to PA Twitter Emotet and PA OSINT (still

**Table 3.** File hash feeds overview. The second column group presents feed volume, average daily rate, the number of converted MD5s (Section 4.2) and exclusive proportion. *Not in VT* is fraction of hashes that are not found in VirusTotal, *Not det.* the fraction of hashes that are found in VirusTotal but are not labeled as malicious by any products, and *Detected* the fraction that are found in VirusTotal and are labeled malicious by at least one product. Column *Not in SD* shows the fraction of hashes in a feed that are not in Shadowserver Bin Check. *In NSRL* and *In AppInfo* show the absolute number of hashes found in Shadowserver (Section 4.3). *Exclusive* is based on the MD5-normalized hashes counted under *Converted*. All the other percentages in the table are based on *Volume*.

Feed	Volume	Avg. Rate	Converted	Exclusive	Not in VT	Not det.	Detected	Not in SD	In NSRL	In AppInfo
FB Malware	944,257	4,070	944,257	>99.99%	37.41%	50.50%	12.09%	99.89%	442	706
PA Malware Indicators	39,702	171	39,702	98.73%	0.02%	0.04%	99.94%	>99.99%	2	0
PA Analyst	38,586	166	37,665	97.97%	4.26%	2.82%	92.92%	99.95%	8	19
PA Twitter Emotet	1,031	4.44	960	77.29%	11.74%	0.78%	87.49%	99.81%	0	2
PA OSINT	829	3.57	783	71.65%	19.06%	0.84%	80.10%	99.88%	1	0
PA Sandbox	298	1.28	115	95.65%	72.81%	0.34%	26.85%	100%	0	0
PA Abuse.ch	267	1.15	3	100%	98.88%	0.75%	0.37%	100%	0	0
PA Zeus Tracker	17	0.07	17	100%	88.24%	5.88%	5.88%	100%	0	0

77.29% and 71.65%, respectively). All other feeds showcase an over 95% exclusive percentage, demonstrating that most file hash feeds are distinct from each other.

Due to the different sources of malware between feeds, a low intersection is to be expected in some cases. For example, PA Twitter Emotet and PA Zeus Tracker should have no intersection, since they are tracking different malware strains. The other, more general feeds could expect some overlap, but mostly exhibit little to no intersection. Considering the sheer volume of the FB Malware feed, one might expect it would encapsulate many of the smaller feeds or at least parts of them. This is not the case, however, as FB Malware has a negligible intersection with all other feeds.

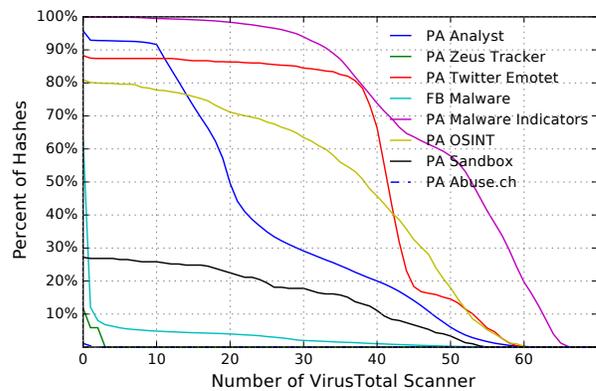

Due to the lack of intersection among the feeds, we omit the latency analysis of the hash feeds, as there is simply not enough intersecting data to conclude which feeds perform better with regards to latency.

### 4.3 Accuracy

Assessing the accuracy of file hash feeds presents a problem: there is no universal ground truth to determine if a file is malicious or benign. Thus, to gauge the accuracy of the feeds, we use two metrics: a check for malicious hashes against VirusTotal, and a check for benign hashes against Shadowserver’s Bin Check service. Note that all the percentages discussed below are based on the *Volume* of each feed.

#### 4.3.1 VirusTotal

VirusTotal is a service that is often used when analyzing malware to get a base of information about a suspected file. Anyone can upload a file to be scanned. Upon submission, these files will be scanned by more than 70 antivirus scanners, which creates a report on how many antivirus scanners mark it malicious, among other information. In this analysis, we query VirusTotal for the hashes in each file hash feed and then inspect the percent of hashes that are marked as malicious and how many AV scanners have recorded them. Due to the high volume of the FB Malware feed and the query rate limit of VirusTotal, we randomly sampled 80,000 hashes from the

**Figure 4.** VirusTotal detection distribution. Each point means the proportion of indicators (Y value) in a feed that is detected by *over X* number of AV scanners in VirusTotal.

feed for this analysis.

Table 3 shows a breakdown of the base detection rates for each feed from VirusTotal. As the PA feeds decrease in volume, the rates at which they are found in VirusTotal also decreases. The larger PA feeds have a much higher detection rate than their smaller counterparts. On the other hand, FB Malware only has 37% of its data detected by antivirus scanners and 50% in VirusTotal with no detection despite being the largest feed. This could indicate that FB Malware focuses on threats that specifically target Facebook and that are not as relevant to most VirusTotal users, such as malicious browser extensions [14, 20, 22]. This might undermine the limited coverage of VirusTotal as an oracle to detect targeted threats that are not of broader interest.

To further understand how the scanners in VirusTotal report the feed’s data, we plot a graph of what percentage of hashes in each feed are detected by how many VirusTotal scanners. As seen in Figure 4, four feeds have more than 50% of their samples detected by over 20 scanners. PA Malware Indicators and PA Twitter Emotet did not experience a large detection drop before 35 scanners, indicating that most indicators in the

two feeds are popular malicious files recognized by many AV vendors. While PA Sandbox has a large percent of its hashes not presented in VirusTotal, over 70% of its samples that are detected are marked by over 20 AV scanners, showcasing a high confidence detection.

### 4.3.2 Shadowserver

To more fully gauge the accuracy of the file hash feeds, we also examined how each feed measured against Shadowserver’s Bin Check Service [34]. The service checks file hashes against NIST’s National Software Registry List (NSRL) in addition to Shadowserver’s own repository of known software. Table 3 details how each feed compares with Shadowserver’s Bin Check service.

It might be expected that there would be no hash found with Shadowserver’s Bin Check service, but it is not the case. Some of the samples from the feeds that appear in Shadowserver are well known binaries such as versions of Microsoft Office products, Window’s Service Packs, calc.exe, etc. In the event malware injects itself into a running process, it remains plausible that some of these well-known binaries find their way into TI feeds from users wrongly attributing maliciousness. While FB Malware has over one thousand hashes in Shadowserver, this is not a widespread issue, as all feeds have <1% of their hashes contained within Shadowserver’s Bin Check service. This showcases that while there are a few exceptions, the feeds mostly do not contain well-known, benign files.

◆ **Finding:** Each PA feed has a negligible rate of occurrence within Shadowserver regardless of their VirusTotal detection, showing they do not contain generic false positives. Larger feeds exhibit high VirusTotal detection rates except for FB Malware, while small feeds have relatively low detection rates. This suggests that small hash feeds might focus more on specific malicious files that are not widely known. FB Malware has a low VirusTotal occurrence despite its size and has over one thousand hashes in Shadowserver, but its overall low percentage of hashes within Shadowserver indicates that it does not contain many known files and might have threats not typically recognized by VirusTotal’s scanners.

## 5 Longitudinal Comparison

In addition to the measurement period considered so far (December 1, 2017 to July 20, 2018), we also analyzed data from the same IP feeds from January 1, 2016 to August 31, 2016. These two measurement periods, 23 months apart, allow us to measure how these IP feeds have changed in two years. Table 4 summarizes the differences between these two measurement periods. In the table, 2018 represents the current measurement period and 2016 the period January 1, 2016 to August 31, 2016.

**Volume.** As shown in Table 4, feed volume has definitely changed after two years. Among 43 IP feeds that overlap both time periods, 21 have a higher daily rate compared with 2 years ago, 15 feeds have a lower rate, and 7 feeds do not

**Table 4.** Data changes in IP feeds compared against the ones in 2016, *Avg. Rate* shows the percentage of daily rate changed over the old feeds. The two columns under *Unrt* show the unroutable rates of feeds in 2016 and 2018 separately. The two columns under *CDN* present the number of IPs fall in CDN IP ranges in old and new data.

Feed	Avg. Rate	Unroutable		CDN	
		2016	2018	2016	2018
<b>Scan Feeds</b>

PA Botscout IPs	+18%	0.0%	0.06%	0	0
AlienVault IP Rep	+8%	0.57%	0.07%	479	1,040

change substantially (the difference is below 20%). Volume can change dramatically over time, such as PA AlienVault IPs in the scan category which is 13 times larger than before. On the other hand, a feed like PA Blocklist Bots is now over 90% smaller.

**Intersection and Exclusive Contribution.** Despite the volume differences, the intersection statistics between feeds are largely the same across two years, with feeds in scan and brute-force having high pairwise intersections and feeds in other categories being mostly unique. Certain specific pairwise relations also did not change. For example, Badips SSH still shared over 90% of data in Dangerrulez Brute back in

2016, and Paid IP Reputation in malware was still the only feed that has a non-trivial intersection with multiple small feeds. Again, most data was exclusive to each feed two years ago: Across all six categories more than 90% of the indicators are not shared between feeds.

**Latency.** The latency relationship between feeds was also similar: timely feeds today were also timely two years ago, and the same with tardy feeds.

**Accuracy.** Feeds have more unroutable IPs now than before as shown in Table 4: In 2016, 22 of the 43 IP feeds had at least 1 unroutable IP; four feeds had unroutable rates over 1%. When checking the intersection with popular CDNs, the feeds that contain IPs in CDN ranges two years ago are also the ones that have these IPs today.

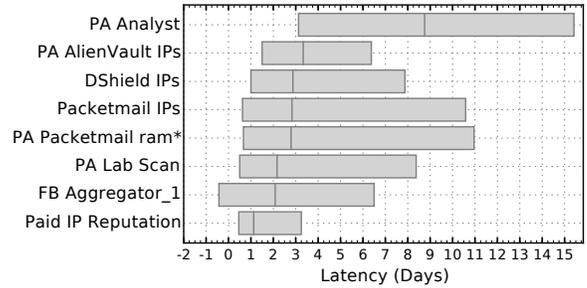

**Shared indicators 2016–2018.** We compared the data we collected from each feed in the two time periods, and found that 30 out of 43 feeds in 2018 intersect with their data from two years ago, and 9 feeds have an intersection rate over 10%. Three feeds in malware category, namely Feodo IP Blacklist, PA Abuse.ch Ransomware and Zeus IP Blacklist, have over 40% of their data shared with the past feed, meaning a large percent of C&C indicators two years ago are still identified by the feeds as threats today. Feeds in the botnet category, however, are very distinct from the past, with all feeds having no intersection with the past except Paid IP Reputation.

## 6 Absolute Latency

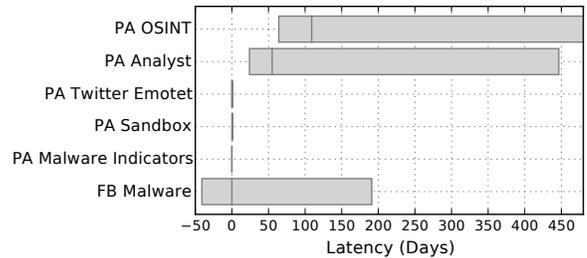

We defined our latency metric in this paper as relative latency between **TI** sources, since it is easy to compute and allows consumers to compare feeds to each other on this aspect. However, it is also critical to know about the absolute latency distribution of indicators. Absolute latency represents how fast a feed can actually report a threat, which directly decides the effectiveness of the data when used in a pro-active way. As we already discussed in Section 3.5, absolute latency is hard to measure, as we do not have ground truth of the underlying threat.

In Section 3.7, we used an Internet telescope as our approximation for ground truth to measure the coverage of scan feeds. In Section 4.3, we used VirusTotal as an oracle to measure the accuracy of file hash feeds. Although these sources are not real ground truth and it is unclear how far away they are, these large and well-managed sources can help us, to a certain extent, profile the performance of **TI** feeds. In this section, we use these two sources again to approximate the absolute latency of indicators in scan IP feeds and malicious file hash feeds.

More specifically, we measure the latency of IPs in scan feeds relative to the first occurrence time of the same IP in the scanners collected from the telescope. Considering the massive size of the telescope, it should presumably detect scanners much sooner after the scanning event actually happened. We measure latency of file hashes relative to the `first_seen` timestamps queried from VirusTotal. The `first_seen` times-

(a) Latency distribution in scan feeds relative to the Internet telescope

(b) Latency distribution in file hash feeds relative to VirusTotal

**Figure 5.** Distribution of indicators' latency in scan and file hash feeds. Note that the scan feeds' distribution are calculated in hour granularity while the file hash feeds' distribution are calculated in day granularity.

tamp represents the time when the corresponding file is first uploaded to VirusTotal. VirusTotal is a very popular service and it is a convention for many security experts to upload new malware samples to VirusTotal once they discovered them. Therefore, this timestamp roughly entails when the security community first noticed the malicious file and can be a good approximation for absolute latency.

Figure 5 show the latency distribution of each feed, using the same plotting convention as in Section 3.5. Some feeds are not shown in the figure as there are too little data points in those feeds to reason about distribution.

◆ **Finding:** Comparing Figure 5a to Figure 2a, we can see that the median latency of feeds are all larger. This is consistent with our assumption that a large sensor tends to receive indiscriminate scanners sooner. Scan feeds' median latency are one to three days relative to the Internet telescope, except PA Analyst, whose median latency is almost nine days. The order of median latency between feeds changed compared with Figure 2a, but since the original relative median latencies among scan feeds are very close, the new order here is more likely to be statistics variances. Also, note that although the PA AlienVault IPs seems much slower than it is in Figure 2a, its 75 percentile latency is still the second smallest one.

On the other hand, the latency distributions of hash feeds vary more dramatically. PA Malware Indicators, PA Sandbox and PA Twitter Emotet are almost as fast as VirusTotal: all three feeds have 25 percentile and median latency equal to

zero. PA OSINT and PA Analyst are comparatively much slower, and PA OSINT even has a 75 percentile latency of 1680 days. This might be because of the heterogeneous nature of malware feeds. The figure also shows that feed volumes do not imply their latency, as PA Analyst and FB Malware are much slower than the small hash feeds.

Figure 5 demonstrates that the Internet telescope and VirusTotal are indeed good approximations for absolute latency measurement, as most indicators in TI feeds are observed relatively later. However, every scan feed has over 2% of its indicators detected earlier than the telescope did. FB Aggregator<sub>1</sub> and DShield IPs even have over 10% of their indicators observed earlier. There is also a similar case in file hash feeds. This aligns with our observation in Section 3.5 that small feeds can still report a non-trivial amount of their data first. Another interesting observation is that both Facebook feeds, FB Aggregator<sub>1</sub> and FB Malware, have a large percent of their data observed earlier than the telescope or VirusTotal. This again suggests that Facebook (and its threat intelligence partners) might face more targeted threats, so those threats will be first observed by Facebook.

## 7 Discussion

### 7.1 Metrics Usage

Threat intelligence has many different potential uses. For example, analysts may consume threat data interactively during manual incident investigations, or may use it to automate the detection of suspicious activity and/or blacklisting. When not itself determinative, such information may also be used to *enrich* other data sources, informing investigations or aiding in automatic algorithmic interventions. We have introduced a set of basic threat intelligence metrics—volume, intersection, unique contribution, latency, coverage and accuracy—that can inform and quantify each of those uses. Depending on a number of factors, such as the intended use case and the cost of false positives and negatives, some of these metrics will become more or less important when evaluating a TI source. For example, a feed with poor accuracy but high coverage might be ideal when an analyst is using a TI source interactively during manually incident investigations (since in this case, the analyst, as a domain expert, can provide additional filtering of false positives). Similarly, latency might not be a critical metric in a retrospective use case (e.g., post-discovery breach investigation). However, if an organization is looking for a TI source where the IPs are intended to be added to a firewall’s blacklist then accuracy and latency should likely be weighted over coverage, assuming that blocking benign activity is more costly.

Another common real-world scenario is that a company has a limited budget to purchase TI sources and has a specific set of threats (i.e., botnet, brute-force) they are focused on mitigating. In such cases, the metrics we have described can be used directly in evaluating TI options, biasing towards

sources that maximize coverage of the most relevant threats while limiting intersection.

### 7.2 Data Labeling

Threat intelligence IP data carries different meanings. To properly use this data, it is critical to know what the indicators actually mean: whether they are Internet scanners, members of a botnet or malicious actors who had attacked other places before. We have attempted to group feeds by their intended meaning in our analysis.

However, this category information, which primarily comes from TI sources themselves, is not always available. Feeds such as Alienvault IP Reputation and Facebook Threat Exchange sources contain a significant number of indicators labeled “Malicious” or “Suspicious.” The meanings of these indicators are unclear, making it difficult for consumers to decide how to use the data and the possible consequences.

For feeds that provide category information, it is sometimes too broad to be meaningful. For example, multiple feeds in our collection simply label their indicators as “Scanner.” Network scanning can represent port scanning (by sending SYN packets), or a vulnerability scan (by probing host for known vulnerabilities). The ambiguity here, as a result of ad-hoc data labeling, again poses challenges for security experts when using TI data.

Recently, standard TI formats have been proposed and developed, notably IODEF [19], Cybox [13] and STIX [37], that try to standardize the threat intelligence presentation and sharing. But these standards focus largely on the data format. There is room to improve these standards by designing a standard *semantics* for threat intelligence data.

### 7.3 Limitations

There are several questions that our study does not address. We attempted to collect data from a diverse set of sources, including public feeds, commercial feeds and industrial exchange feeds, but it is inherently not comprehensive. There are some prohibitively expensive or publication-restricted data sources that are not available to us. More specialized measurement work should be done in the future to further analyze the performance of these expensive and exclusive data sources.

A second limitation is our visibility into how different companies use threat intelligence operationally. For a company, perhaps the most useful kind of metric measures how a threat intelligence source affects its main performance indicators as well as its exposure to risk. Such metrics would require a deep integration into security workflows at enterprises to measure the operation effect of decisions made using threat intelligence. This would allow CIOs and CSOs to better understand exactly what a particular threat intelligence product contributes to a company. As researchers, we do not use TI operationally. A better understanding of operational needs would help refine our metrics to maximize their utility for operations-driven consumers.

The third limitation is the lack of ground truth, a limitation shared by all the similar measurement work. It is simply very difficult to obtain the full picture of a certain category of threat, making it very challenging to precisely determine accuracy and coverage of feeds. In this study, we used data from an Internet telescope and VirusTotal as a close approximation. There are also a handful of cases where a security incident has been comprehensively studied by researchers, such as the Mirai study [4], and such efforts can be used to evaluate certain types of **TI** data. But such studies are few in number. One alternative is to try to establish the ground truth for a specific network. For example, a company can record all the network traffic going in and out of its own network, and identify security incidents either through its IDS system or manual forensic analysis. Then it can evaluate the accuracy and coverage of a **TI** feed under the context of its own network. This can provide a customized view of **TI** feeds.

## 8 Related Work

Several studies have examined the effectiveness of blacklist-based threat intelligence [23, 31, 32, 35, 36]. Ramachandran *et al.* [32] showed that spam blacklists are both incomplete (missing 35% of the source IPs of spam emails captured in two spam traps), and slow in responding (20% of the spammers remain unlisted after 30 days). Sinha *et al.* [36] further confirmed this result by showing that four major spam blacklists have very high false negative rates, and analyzed the possible causes of the low coverage. Sheng *et al.* [35] studied the effectiveness of phishing blacklists, showing the lists are slow in reacting to highly transient phishing campaigns. These studies focused on specific types of threat intelligence sources, and only evaluated their operational performance rather than producing empirical evaluation metrics for threat intelligence data sources.

Other studies have analyzed the general attributes of threat intelligence data. Pitsillidis *et al.* [30] studied the characteristics of spam domain feeds, showing different perspectives of spam feeds, and demonstrated that different feeds are suitable for answering different questions. Thomas *et al.* [42] constructed their own threat intelligence by aggregating the abuse traffic received from six Google services, showing a lack of intersection and correlation among these different sources. While focusing on broader threat intelligence uses, these studies did not focus on generalizable threat metrics that can be extended beyond the work.

Little work exists that defines a general measurement methodology to examine threat intelligence across a broad set of types and categories. Metcalf *et al.* [26] collected and measured IP and domain blacklists from multiple sources, but only focused on volume and intersection analysis. In contrast, we formally define a set of threat intelligence metrics and conduct a broad and comprehensive study over a rich variety of threat intelligence data. We conducted our measurement from the perspective of consumers of **TI** data to offer

guidance on choosing between different sources. Our study also demonstrated the limitation of threat intelligence more thoroughly, providing comprehensive characteristics of cyber threat intelligence that no work had addressed previously.

## 9 Conclusion

This paper has focused on the simplest, yet fundamental, metrics about threat intelligence data. Using the proposed metrics, we measured a broad set of **TI** sources, and reported the characteristics and limitations of **TI** data. In addition to the individual findings mentioned in each section, here we highlight the high-level lessons we learned from our study:

- **TI** feeds, far from containing homogeneous samples of some underlying truth, vary tremendously in the kinds of data they capture based on the particularities of their collection approach. Unfortunately, few **TI** vendors explain the mechanism and methodology by which their data are collected and thus **TI** consumers must make do with simple labels such as “scan” or “botnet”, coupled with inferences about the likely mode of collection. Worse, a significant amount of data does not even have a clear definition of category, and is only labelled as “malicious” or “suspicious”, leaving the ambiguity to consumers to decide what action should be taken based on the data.
- There is little evidence that larger feeds contain better data, or even that there are crisp quality distinctions between feeds across different categories or metrics (i.e., that a **TI** provider whose feed performs well on one metric will perform well on another, or that these rankings will hold across threat categories). How data is collected also does not necessarily imply the feeds’ attributes. For example, crowdsourcing-based feeds (e.g., Badips feeds), are not always slower in reporting data than the self-collecting feeds (like Paid IP Reputation).
- Most IP-based **TI** data sources are collections of singletons (i.e., that each IP address appears in at most one source) and even the higher-correlating data sources frequently have intersection rates of only 10%. Moreover, when comparing with broad sensor data in known categories with broad effect (e.g., random scanning) fewer than 2% of observed scanner addresses appear in most of the data sources we analyzed; indeed, even when focused on the largest and most prolific scanners, coverage is still limited to 10%. There are similar results for file hash-based sources with little overlap among them.

The low intersection and coverage of **TI** feeds could be the result of several non-exclusive possibilities. First is that the underlying space of indicators (both IP addresses and malicious file hashes) is large and each individual data source can at best sample a small fraction thereof. It is almost certain that this is true to some extent. Second, different collection

methodologies—even for the same threat category—will select for different sub distributions of the underlying ground truth data. Third, this last effect is likely exacerbated by the fact that not all threats are experienced uniformly across the Internet and, thus, different methodologies will skew to either favor or disfavor targeted attacks.

Based on our experience analyzing TI data, we try to provide several recommendations for the security community on this topic moving forward:

- The threat intelligence community should standardize data labeling, with a clear definition of what the data means and how the data is collected. Security experts can then assess whether the data fit their need and the type of action should be taken on this data.
- There are few rules of thumb in selecting among TI feeds, as there is not a clear correlation between different feed properties. Consumers need empirical metrics, such as those we describe, to meaningfully differentiate data sources, and to prioritize certain metrics based on their specific need.
- Blindly using TI data—even if one could afford to acquire many such sources—is unlikely to provide better coverage and is also prone to collateral damage caused by false positives. Customers need to be always aware of these issues when deciding what action should be taken on this data.
- Besides focusing on the TI data itself, future work should investigate the operational uses of threat intelligence in industry, as the true value of TI data can only be understood in operational scenarios. Moreover, the community should explore more potential ways of using the data, which will extend our understanding of threat intelligence and also influence how vendors are curating the data and providing the services.

There are many ways we can use threat intelligence data. It can be used to *enrich* other information (e.g., for investigating potential explanations of a security incident), as a probabilistic canary (i.e., identifying an overall site vulnerability via a single matching indicator may have value even if other attacks of the same kind are not detected) or in providing a useful source of ground truth data for supervised machine learning systems. However, even given such diverse purposes, organizations still need some way to prioritize which TI sources to invest in. Our metrics provide some direction for such choices. For example, an analyst who expects to use TI interactively during incident response would be better served by feeds with higher coverage, but can accommodate poor accuracy, while an organization trying to automatically label malicious instances for training purposes (e.g., brute force attacks) will be better served by the converse. Thus, if there is hope for demonstrating that threat intelligence can materially impact

operational security practices, we believe it will be found in these more complex uses cases and that is where future research will be most productive.

## 10 Acknowledgment

We would like to thank our commercial threat providers who made their data available to us and made this research possible. In particular, we would like to thank Nektarios Leontiadis and the Facebook ThreatExchange for providing the threat data that helped facilitate our study. We are also very grateful to Alberto Dainotti and Alistair King for sharing the UCSD telescope data and helping us with the analysis, Gautam Akiwate for helping us query the domain data, and Matt Jonkman. We are also grateful to Martina Lindorfer, our shepherd, and our anonymous reviewers for their insightful feedback and suggestions. This research is a joint work from multiple institutions, sponsored in part by DHS/AFRL award FA8750-18-2-0087, NSF grants CNS-1237265, CNS-1406041, CNS-1629973, CNS-1705050, and CNS-1717062.

## Abstract

Public vulnerability databases such as the Common Vulnerabilities and Exposures (CVE) and the National Vulnerability Database (NVD) have achieved great success in promoting vulnerability disclosure and mitigation. While these databases have accumulated massive data, there is a growing concern for their information quality and consistency.

In this paper, we propose an automated system VIEM to detect inconsistent information between the fully *standardized* NVD database and the *unstructured* CVE descriptions and their referenced vulnerability reports. VIEM allows us, for the first time, to quantify the information consistency at a massive scale, and provides the needed tool for the community to keep the CVE/NVD databases up-to-date. VIEM is developed to extract vulnerable software names and vulnerable versions from unstructured text. We introduce customized designs to deep-learning-based named entity recognition (NER) and relation extraction (RE) so that VIEM can recognize previous unseen software names and versions based on sentence structure and contexts. Ground-truth evaluation shows the system is highly accurate (0.941 precision and 0.993 recall). Using VIEM, we examine the information consistency using a large dataset of 78,296 CVE IDs and 70,569 vulnerability reports in the past 20 years. Our result suggests that inconsistent vulnerable software versions are highly prevalent. Only 59.82% of the vulnerability reports/CVE summaries strictly match the standardized NVD entries, and the inconsistency level increases over time. Case studies confirm the erroneous information of NVD that either overclaims or underclaims the vulnerable software versions.

## 1 Introduction

Security vulnerabilities in computer and networked systems are posing a serious threat to users, organizations, and nations at large. Unmatched vulnerabilities often lead to real-

world attacks with examples ranging from WannaCry ransomware that shut down hundreds of thousands of machines in hospitals and schools [20] to the Equifax data breach that affected half of America's population [21].

To these ends, a strong *community effort* has been established to find and patch vulnerabilities before they are exploited by attackers. The Common Vulnerabilities and Exposures (CVE) program [4] and the National Vulnerability Database (NVD) [11] are among the most influential forces. CVE is a global list/database that indexes publicly known vulnerabilities by harnessing the "the power of the crowd". Anyone on the Internet (security vendors, developers and researchers) can share the vulnerabilities they found on CVE. NVD is a more standardized database established by the U.S. government (*i.e.*, NIST). NVD receives data feeds from the CVE website and perform analysis to assign common vulnerability severity scores (CVSS) and other pertinent metadata [18]. More importantly, NVD standardizes the data format so that algorithms can directly process their data [12]. Both CVE and NVD play an important role in guiding the vulnerability mitigation. So far, over 100,000 vulnerabilities were indexed, and the CVE/NVD data stream has been integrated with hundreds of security vendors all over the world [10].

While the vulnerability databases are accumulating massive data, there is also a growing concern about the *information quality* [28, 42, 44]. More specifically, the information listed on CVE/NVD can be incomplete or outdated, making it challenging for researchers to reproduce the vulnerability [42]. Even worse, certain CVE entries contain erroneous information which may cause major delays in developing and deploying patches. In practice, industrial systems often use legacy software for a long time due to the high cost of an update. When a relevant vulnerability is disclosed, system administrators usually look up to vulnerability databases to determine whether their software (and which versions) need to be patched. In addition, CVE/NVD are serving as a key information source for security companies to assess the secu-

\*This work was done when Ying Dong studied at the Pennsylvania State University.

rity level of their customers. Misinformation on CVE/NVD could have left critical systems unpatched.

In this paper, we propose a novel system to automatically detect inconsistent information between the fully *standardized* NVD database and the *unstructured* CVE descriptions and their referenced vulnerability reports. Our system VIEM allows us, for the first time, to quantify the information consistency at a massive scale. Our study focuses on *vulnerable software versions*, which is one of the most important pieces of information for vulnerability reproduction and vulnerability patching. We face three main technical challenges to build VIEM. First, due to the high diversity of software names and versions, it is difficult to build dictionaries or regular expressions [30, 48, 59] to achieve high precision and recall. Second, the unstructured text of vulnerability reports and summaries often contain code, and the unique writing styles are difficult to handle by traditional natural language processing tools [22, 49, 50]. Third, we need to extract “*vulnerable*” software names and their versions, and effectively exclude the distracting items (*i.e.*, non-vulnerable versions).

**Our System.** To address these challenges, we build VIEM (short for Vulnerability Information Extraction Model) with a Named Entity Recognition (NER) model and a Relation Extraction (RE) model. The goal is to learn the patterns and indicators from the sentence structures to recognize the vulnerable software names/versions. Using “contexts” information, our model can capture previously unseen software names and is generally applicable to different vulnerability types. More specifically, the NER model is a recurrent deep neural network [36, 56] which pinpoints the relevant entities. It utilizes word and character embeddings to encode the text and then leverages a sequence-to-sequence bi-directional GRU (Gated Recurrent Unit) to locate the names and versions of the vulnerable software. The RE model is trained to analyze the relationships between the extracted entities to pair the vulnerable software names and their versions together. Finally, to generalize our model to handle different types of vulnerabilities, we introduce a transfer learning step to minimize the manual annotation efforts.

**Evaluation and Measurement.** We collect a large dataset from the CVE and NVD databases and 5 highly popular vulnerability reporting websites. The dataset covers 78,296 CVE IDs and 70,569 vulnerability reports across all 13 vulnerability categories in the past 20 years. For evaluation, we manually annotated a sample of 5,193 CVE IDs as the ground-truth. We show that our system is highly accurate with a precision of 0.941 and a recall of 0.993. In addition, our model is generalizable to all 13 vulnerability categories.

To detect inconsistencies in practice, we apply VIEM to the full dataset. We use NVD as the standard (since it is the last hop of the information flow), and examine the inconsistencies between NVD entries and the CVE entries/external sources. We have a number of key findings. First, the incon-

sistency level is very high. Only 59.82% of the external reports/CVE summaries have exactly the same vulnerable software versions as those of the standardized NVD entries. It’s almost equally common for an NVD entry to “overclaim” or “underclaim” the vulnerable versions. Second, we measure the consistency level between NVD and other sources and discover the inconsistency level increased over the past 20 years (but started to decrease since 2016). Finally, we select a small set of CVE IDs with highly inconsistent information to manually verify the vulnerabilities (including 185 software versions). We confirm real cases where the official NVD/CVE entries and/or the external reports falsely included non-vulnerable versions and missed truly vulnerable versions. Such information could affect systems that depend on NVD/CVE to make critical decisions.

**Applications.** Detecting information inconsistency is the *first step* to updating the outdated entries and mitigating errors in the NVD and CVE databases. There was no existing tool that could automatically extract vulnerable software names and versions from unstructured reports before. A key contribution of VIEM is to enable the possibility to continuously monitor different vulnerability reporting websites and periodically generate a “diff” from the CVE/NVD entries. This can benefit the community in various ways. For employees of CVE/NVD, VIEM can notify them whenever a new vulnerable version is discovered for an existing vulnerability (to accelerate the testing and entry updates). For security companies, VIEM can help to pinpoint the potentially vulnerable versions of their customers’ software to drive more proactive testing and patching. For software users and system administrators, the “diff” will help them to make more informed decisions on software updating. To facilitate future research and application development, we released our labeled dataset and the source code of VIEM<sup>1</sup>.

In summary, our paper makes three key contributions.

- *First*, we design and develop a novel system VIEM to extract vulnerable software names and versions from unstructured vulnerability reports.
- *Second*, using a large ground-truth dataset, we show that our system is highly accurate and generalizes well to different vulnerability types.
- *Third*, by applying VIEM, we perform the first large-scale measurement of the information consistency for CVE and NVD. The generated “diff” is helpful to drive more proactive vulnerability testing and information curation.

## 2 Background and Challenges

We first introduce the background of security vulnerability reporting, and describe the technical challenges of our work.

<sup>1</sup>[https://github.com/pinky/mm/inconsistency\\_detection](https://github.com/pinky/mm/inconsistency_detection)

## 2.1 Vulnerability Reporting

**CVE.** When people identify a new vulnerability, they can request a unique CVE-ID number from one of the CVE Numbering Authorities (CNAs) [5]. The *MITRE Corporation* is the editor and the primary CNA [19]. CNA will then do research on the vulnerability to determine the details and check if the vulnerability has been previously reported. If the vulnerability is indeed new, then a CVE ID will be assigned and the corresponding vulnerability information will be publicly released through the CVE list [4, 9].

The CVE list [4] is maintained by MITRE as a website on which the CVE team publishes a summary for each of the reported vulnerabilities. As specified in [8], when writing a CVE summary, the CVE team will analyze (public) third-party vulnerability reports and then include details in their description such as the name of the affected software, the vulnerable software versions, the vulnerability type, and the conditions/requirements to exploit the vulnerability.

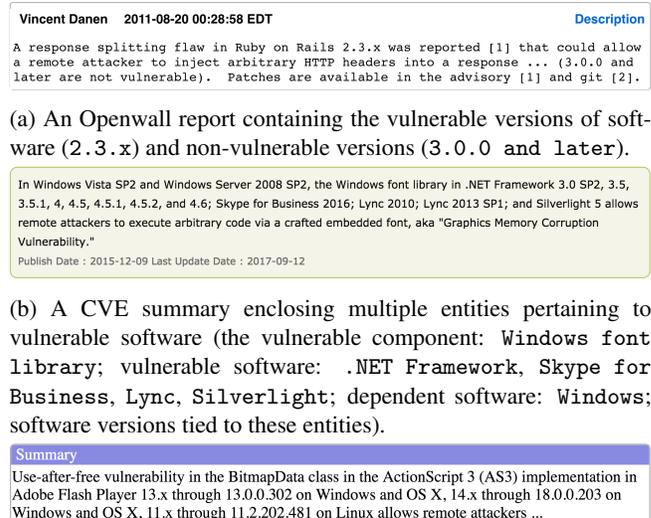

In addition to the summary, each CVE entry contains a list of external references. The external references are links to third-party technical reports or blog/forum posts that provide the needed information for the CVE team to craft the official vulnerability description [1]. The information on CVE can help software vendors and system administrators to pinpoint the versions of the vulnerable software, assess their risk level, and perform remediation accordingly.

**NVD.** NVD (National Vulnerability Database) is maintained by a different organization (*i.e.*, NIST) from that of CVE [3]. NVD is built fully synchronized with the CVE list. The goal is that any updates to CVE will appear immediately in NVD. After a new CVE ID appears on the CVE list, the NIST NVD team will first perform analysis to add enhanced information such as the severity score before creating the NVD entries [18].

Compared with CVE, NVD provides two additional features. First, NVD data entries are structured. The NIST NVD team would convert the unstructured CVE information into structured JSON or XML, where information fields such as vulnerable software names and versions are formatted and standardized based on the Common Weakness Enumeration Specification (CWE) [12]. Second, data entries are continuously updated. The information in NVD may be updated (manually) after the initial vulnerability reporting. For example, as time goes by, new vulnerable software versions may be discovered by NIST employees or outsiders, which will be added to the existing NVD entries [17].

## 2.2 Technical Challenges

CVE and NVD databases are primarily maintained by *manual efforts*, which leads to a number of important questions. First, given that a vulnerability may be reported and discussed in many different places, how complete is the infor-

(a) An Openwall report containing the vulnerable versions of software (2.3.x) and non-vulnerable versions (3.0.0 and later).

Figure 1: Examples of vulnerability descriptions and reports.

mation (*e.g.*, vulnerable software names and their versions) in the CVE/NVD database? Second, considering the continuous community effort to study a reported vulnerability, how effective is the current manual approach to keep the CVE/NVD entries up-to-date?

Our goal is to thoroughly understand the inconsistencies between external vulnerability reporting websites and the CVE/NVD data entries. According to the statistics from [6], the CVE list has archived more than 100,000 distinct CVEs (although certain CVE IDs were merged or withdrawn). Each CVE ID also has 5~30 external third-party reports. It is infeasible to extract such information manually. The main challenge is to automatically and accurately extract relevant information items from the unstructured reports.

Many existing NLP tools aim to extract relevant information from text (*e.g.*, [22, 49, 50, 53]). However, the unique characteristics of vulnerability reports impose significant challenges, making existing techniques inadequate. ❶ Previously unseen software emerges: the CVE list introduces new vulnerable software frequently, making it difficult to use a pre-defined dictionary to identify the names of all vulnerable software. As such, dictionary-based method is not suitable for this problem (*e.g.*, [30, 48]). ❷ Reports are unstructured: most CVE summaries and vulnerability reports are highly unstructured and thus simple regular-expression-based techniques (*e.g.*, [28, 59]) can be barely effective. ❸ Non-interested entities are prevalent: a vulnerability report usually encloses information about both vulnerable and non-vulnerable versions of software (see Figure 1a). Our goal is to extract “vulnerable” software names and versions while excluding information items related to non-vulnerable software. Techniques that rely on pre-defined rules would hardly

work here (e.g., [28, 55, 59]). ④ Multiple interested entities exist: the vulnerable software mentioned in a report usually refers to multiple entities (see Figure 1b) and the relationships of these entities are determined by the context of the report. This requirement eliminates techniques that lack the capability of handling multiple entities (e.g., [28, 32, 59]). ⑤ Vulnerability types are diverse: CVE covers a variety of vulnerability types, and each has its own characteristics in the descriptions. As a result, we cannot simply use techniques designed for certain vulnerability types. For example, a tool used by [59] is designed specifically for kernel memory corruption vulnerabilities. We tested it against our ground-truth dataset and did not receive satisfying results (the recall is below 40%).

### 3 The Design of VIEM

To tackle the challenges mentioned above, we develop an automated tool VIEM by combining and customizing a set of state-of-the-art natural language processing (NLP) techniques. In this section, we briefly describe the design of VIEM and discuss the reasons behind our design. Then, we elaborate on the NLP techniques that VIEM adopts.

#### 3.1 Overview

To pinpoint and pair the entities of our interest, we design VIEM to complete three individual tasks.

**Named Entity Recognition Model.** First, VIEM utilizes a state-of-the-art Named Entity Recognition (NER) model [36, 56] to identify the entities of our interest, *i.e.*, the name and versions of the vulnerable software, those of vulnerable components and those of underlying software systems that vulnerable software depends upon (see Figure 1b).

The reasons behind this design are twofold. First, an NER model pinpoints entities based on the structure and semantics of input text, which provides us with the ability to track down software names that have never been observed in the training data. Second, an NER model can learn and distinguish the contexts pertaining to vulnerable and non-vulnerable versions of software, which naturally allows us to eliminate non-vulnerable versions of software and pinpoint only the entities of our interest.

**Relation Extraction Model.** With the extracted entities, the next task of VIEM is to pair identified entities accordingly. As is shown in Figure 2, it is common that software name and version jointly occur in a report. Therefore, one instinctive reaction is to group software name and version nearby, and then deem them as the vulnerable software and version pairs. However, this straightforward approach is not suitable for our problem. As is depicted in Figure 1c, the vulnerable software name is not closely tied to all the vulnerable

versions. Merely applying the approach above, we might inevitably miss the versions of the vulnerable software.

To address this issue, VIEM first goes through all the possible combinations between versions and software names. Then, it utilizes a Relation Extraction (RE) model [38, 62] to determine the most possible combinations and deems them as the correct pairs of entities. The rationale behind this design is as follows. The original design of an RE model is not for finding correct pairs among entities. Rather, it is responsible for determining the property of a pair of entities. For example, assume that an RE model is trained to assign a pair of entities one of the following three properties – “*born in*”, “*employed by*” and “*capital of*”. Given two pairs of entities  $P_1 = (“Steve Jobs”, “Apple”)$  and  $P_2 = (“Steve Jobs”, “California”)$  in the text “*Steve Jobs was born in California, and was the CEO of Apple.*”, an RE model would assign the “*employed by*” to  $P_1$  and “*born in*” properties to  $P_2$ .

In our model, each of the possible version-and-software combinations can be treated as an individual pair of entities. Using the idea of the relation extraction model, VIEM assigns each pair a property, indicating the truthfulness of the relationship of the corresponding entities. Then, it takes the corresponding property as the true pairing. Take the case in Figure 2 for example, there are 4 entities indicated by 2 software (Microsoft VBScript and Internet Explorer) and 2 ranges of versions (5.7 and 5.8 and 9 through 11). They can be combined in 4 different ways. By treating the combinations as 4 different pairs of entities, we can use an RE model to assign a binary property to each of the combinations. Assuming that the binary property assigned indicates whether the corresponding pair of the entities should be grouped as software and its vulnerable versions, VIEM can use the property assignment as the indicator to determine the entity pairing. It should be noted that we represent paired entities in the Common Platform Enumeration (CPE) format [2]. For example, `cpe:/a:google:chrome:3.0.193.2:beta`, where `google` denotes the vendor, `chrome` denotes the product, `3.0.193.2` denotes the version number, and `beta` denotes the software update.

**Transfer Learning.** Recall that we need to measure vulnerability reports across various vulnerability types. As mentioned in §2.2, the reports of different vulnerability types do not necessarily share the same data distribution. Therefore, it is not feasible to use a single machine learning model to deal with all vulnerability reports, unless we could construct and manually annotate a large training dataset that covers all kinds of vulnerabilities. Unfortunately, there is no such labeled dataset available, and labeling a large dataset involves tremendous human efforts. To address this problem, VIEM takes the strategy of transfer learning, which learns the aforementioned NER and RE models using vulnerability reports in one primary category and then transfers their capability into other vulnerability categories. In this way, we can re-

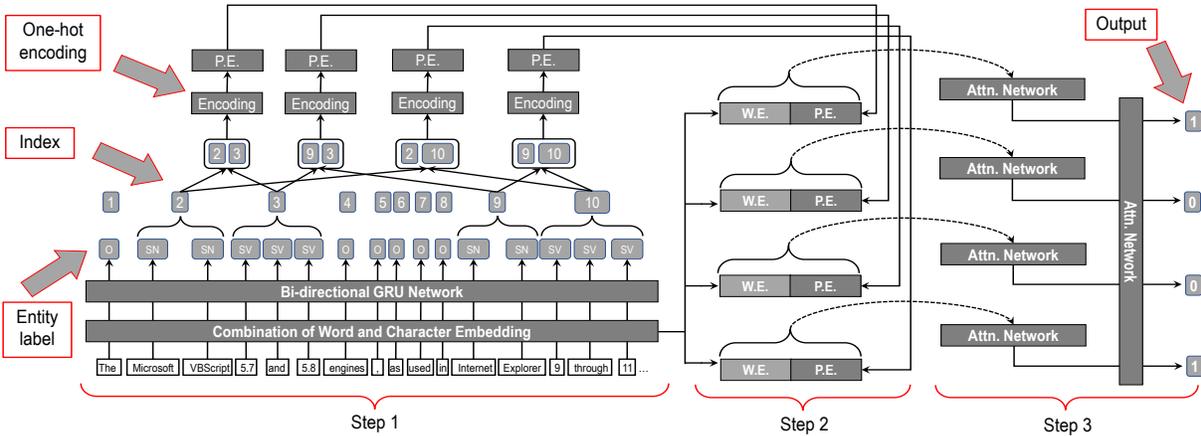

Figure 2: The RE model that pairs the entities of our interests through a three-step procedure. Here, the entities of our interest include software (Microsoft VBScript; Internet Explorer) as well as version range (5.7 and 5.8; 9 through 11). W.E. and P.E denote word and position embeddings, respectively.

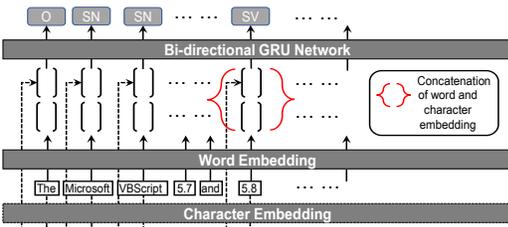

Figure 3: The NER model which utilizes both word and character embeddings to encode a target text and then a Bi-GRU network to assign entity labels to each word.

duce the efforts involved in data labeling, making VIEM effective for arbitrary kinds of vulnerability reports. More details of the transfer learning are discussed in §5.

### 3.2 Named Entity Recognition Model

We start by extracting named entities (vulnerable software names and versions) from the text. We develop our system based on a recent NER model [36,56]. On top of that, we integrate a gazetteer to improve its accuracy of extracting vulnerable software names. At the high level, the NER model first encodes a text sequence into a sequence of word vectors using the concatenation of word and character embeddings. This embedding process is necessary since a deep neural network cannot process text directly. Then taking the sequence of the word vectors as the input, the model predicts a label for each of the words in the sequence using a bi-directional Recurrent Neural Network. Below, we introduce the key technical details.

For word and character embeddings, the NER model first utilizes a standard word embedding approach [40] to encode each word as a vector representation. Then, it utilizes a Bi-directional Gated Recurrent United (Bi-GRU) network

to perform text encoding at the character level. As shown in Figure 3, the NER model concatenates these two embeddings as a single sequence of vectors and then takes it as the input for another Bi-GRU network.

Different from the aforementioned Bi-GRU network used for text embedding, the second Bi-GRU network is responsible for assigning labels to words. Recall that our task is to identify the entities of our interest which pertain to vulnerable software. As a result, we use the Bi-GRU network to pinpoint the words pertaining to this information. More specifically, we train this Bi-GRU network to assign each word with one of the following labels – ❶ SV (software version), ❷ SN (software name) and ❸ O (others) – indicating the property of that word. It should be noted that we assign the same SN label to vulnerable software, vulnerable component and the underlying software that vulnerable software is dependent upon. This is because this work measures version inconsistencies of all software pertaining to a vulnerability<sup>2</sup>.

Considering that the NER model may not perfectly track down the name of the vulnerable software, we further construct a gazetteer (*i.e.*, a dictionary consisting of 81,551 software mentioned in [10]) to improve the recognition performance of the NER model. To be specific, we design a heuristic approach to rectify the information that the NER model fails to identify or mistakenly tracks down. First, we perform a dictionary lookup on each of the vulnerability reports. Then, we mark dictionary words in that report as the software name, if the NER model has already identified at least one dictionary word as a software name. In this way, we can rectify some labels incorrectly identified. For example, in Figure 2, assume the NER model assigns the SN labels to words Microsoft VBScript and Explorer indicating the

<sup>2</sup>Vulnerable software names may include the names of vulnerable libraries or the affected operating systems. The names of vulnerable libraries and the affected OSes are also extracted by our tool.

software pertaining to the vulnerability. Through dictionary lookup, we track down software Internet Explorer in the gazetteer. Since the gazetteer indicates neither Internet nor Explorer has ever occurred individually as a software name, and they are the closest to the dictionary word Internet Explorer, we extend our label and mark the entire dictionary word Internet Explorer with an SN label and treat it as single software.

### 3.3 Relation Extraction Model

The relation extraction model was originally used to extract the relationships of two entities [41]. Over the past decade, researchers proposed various technical approaches to build highly accurate and computationally efficient RE model. Of all the techniques proposed, hierarchical attention neural networks [57] demonstrate better performance in many natural language processing tasks. For our system, we modify an existing hierarchical attention neural network to *pair* the extracted entities (*i.e.*, pairing vulnerable software names and their versions). More specifically, we implement a new *combined* word-level and sentence-level attention network in the RE model to improve the performance. In the following, we briefly introduce this model and discuss how we apply it to our problem. For more details about the RE model in general, readers could refer to these research papers [38, 57, 62].

As is depicted in Figure 2, the RE model pinpoints the right relationship between software name and version through a three-step procedure. In the first step, it encodes the occurrence of the software names as well as that of the version information, and then yields a group of position embeddings representing the relative distances from current word to the two named entities (*i.e.*, software name and version) in the same sentence [38]. To be specific, the RE model first indexes the sequence of the entity labels generated by the aforementioned NER model. Then, it runs through all the software names and versions in every possible combination, and encodes the combinations based on the indexes of the entity labels using one-hot encoding. With the completion of one-hot encoding, the RE model further employs a word embedding approach to convert the one-hot encoding into two individual vectors indicating the embeddings of the positions (see Figure 2).

In the second step, similar to the NER model, the RE model uses the same technique to encode text and transfers a text sequence into a sequence of vectors. Then, right behind the word sequence vectors, the RE model appends each group of the position embeddings individually. For example, in Figure 2, the NER model pinpoints two software names and two versions which form four distinct combinations (all the possible ways of pairing software names and versions). For each combination, the RE model appends the position embedding vector to the word embedding vector to form the input for the last step for performing classifications. In this

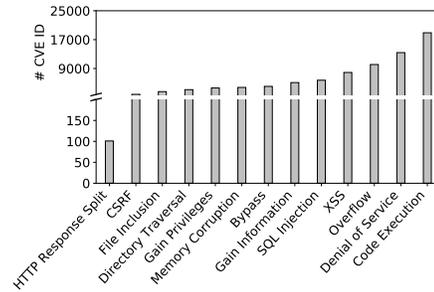

Figure 4: # of CVE IDs per vulnerability category.

example, four vectors are produced as the input, and each represents a possible software name-version pair.

In the last step, the RE model takes each sequence of vectors as the input for an attention-based neural network and outputs a vector indicating the new representation of the sequence. Then, as is illustrated in Figure 2, the RE model takes the output vectors as the input for another attention network, through which the RE model predicts which name-version pairing is most likely to capture the relationship between software name and its corresponding versions. Continue the example in Figure 2. The seq 1 and 4 are associated with a positive output, which indicates the legitimate pairing relationships of Microsoft VBScript 5.7 and 5.8 and Internet Explorer 9 through 11.

## 4 Dataset

To evaluate our system and detect real-world inconsistencies, we collected a large number of public vulnerability reports and CVE and NVD entries from the past 20 years. We sample a subset of these vulnerability reports for manual labeling (ground-truth) and use the labeled data to evaluate the performance of VIEM.

**CVE IDs.** We first obtain a list of CVE IDs from `cvedetails.com`, which divides the security vulnerabilities indexed in CVE/NVD database into 13 categories. To collect a representative dataset of publicly-reported vulnerabilities, we crawled the CVE IDs from January 1999 to March 2018 (over 20 years) of each vulnerability category. A CVE ID is the unique identifier for a publicly disclosed vulnerability. Even though the CVE website claimed that they have over 105,000 CVE IDs [6], many of the CVE IDs are either not publicly available yet, or have been merged or withdrawn. In total, we obtain 78,296 CVE IDs covering all 13 categories as shown in Figure 4. Each CVE ID corresponds to a short *summary* of the vulnerability as shown in Table 1.

**Vulnerability Reports.** The webpage of each CVE ID also contains a list of external references pointing to external reports. Our study focuses on 5 representative source websites to obtain the vulnerability reports referenced by the CVE, including ExploitDB [7], SecurityFocus [14], SecurityTracker [16], Openwall [13], and SecurityFocus Fo-

Dataset	CVE IDs	CVE Summaries (Unstructured)	NVD Entries (Structured)	Vulnerability Reports	Structured Reports		Unstructured Reports		
					SecTracker	SecFocus	ExploitDB	Openwall	SecF Forum
All	78,296	78,296	78,296	70,569	7,320	38,492	9,239	5,324	10,194
G-truth	5,193	5,193	0	1,974	0	0	785	520	669

Table 1: Dataset statistics.

rum [15]. Note that we treat SecurityFocus and SecurityFocus Forum as two different websites. SecurityFocus site only displays the “structured” information (*e.g.*, affected OS, software versions). SecurityFocus Forum (also called Bugtraq Mailing List) mainly contains “unstructured” articles and discussion threads between vulnerability reporters and software developers. Regarding the other three websites, SecurityTracker also contains well-structured information, while Openwall and ExploitDB<sup>3</sup> contain unstructured information. In total, we obtain 70,569 vulnerability reports associated with 56,642 CVE IDs. These CVE IDs cover 72.34% of all 78,296 public CVE IDs. This means 72.34% of the CVE IDs have a vulnerability report from one of the 5 source websites, confirming their popularity. There are 45,812 structured reports from SecurityTracker and SecurityFocus, and 24,757 unstructured reports from ExploitDB, Openwall, and SecurityFocus Forum.

**NVD Entries.** For each CVE ID, we also parse the JSON version of the NVD entries, which contains the structured data fields such as vulnerable software names and their versions. We obtain 78,296 NVD entries in total.

**Data Extraction and Preprocessing.** For *structured* reports, we directly parse the vulnerable software name and version information following the fixed format. For *unstructured* vulnerability reports and CVE summaries, we extract the text information, remove all the web links, and tokenize the sentences using the NLTK toolkit [24]. Note that we did not remove any stop words or symbols from the unstructured text, considering that they are often parts of the software names and versions.

**Ground-Truth Dataset.** To evaluate VIEM, we construct a “ground-truth” dataset by manually annotating the vulnerable software names and versions. As shown in Table 1, the ground-truth dataset contains only unstructured reports, covering 5,193 CVE IDs (the short summaries) and 1,974 unstructured reports. Some reports are referenced by multiple CVE IDs. We choose to label our own ground-truth dataset instead of using the structured data as the ground-truth, for two reasons. First, the structured data is not necessarily correct. Second, the NER model needs labels at the sentence level and the word level. The labels for the RE model represent the relationship between the extracted entities. The structured data cannot provide such labels.

<sup>3</sup>ExploitDB has some structured information such as the affected OS, but the vulnerable software version often appears in the titles of the posts and the code comments.

The 5,193 CVE IDs are not evenly sampled from different vulnerability categories. Instead, we sampled a large number of CVE IDs from one primary category and a smaller number of CVE IDs from the other 12 categories to evaluate model transferability. We choose memory corruption as the primary category for its severity and real-world impact (*e.g.*, Heartbleed, WannaCry). An analysis of the severity scores (CVSS) also shows that memory corruption vulnerabilities have the highest average severity score (8.46) among all the 13 categories. We intend to build a tool that at least performs well on memory corruption cases. Considering the high costs of manual annotation, we decide to label a large amount of data (3,448 CVE IDs) in one category (memory corruption), and only label a small amount of data (145 CVE IDs) for each of the other 12 categories. With this dataset, we can still apply transfer learning to achieve a good training result.

Given a document, we perform annotation in two steps. First, we manually label the *vulnerable software names* and *vulnerable software versions*. This step produces a ground-truth dataset to evaluate our NER model. Second, we manually *pair* the vulnerable software names with the versions. This step produces a ground-truth mapping to evaluate the RE model. We invited 6 lab-mates to perform the annotation. All the annotators have a bachelor or higher degree in Computer Science and an in-depth knowledge of Software Engineering and Security. Figure 2 shows an example. For the NER dataset, we label each word in a sentence by assigning one of the three labels: vulnerable software name (*SN*), vulnerable software version (*SV*)<sup>4</sup>, or others (*O*). Note that entities that are related to non-vulnerable software will be labeled as *O*. For the RE dataset, we pair *SN* and *SV* entities by examining all the possible pairs *within the same sentence*. Through our manual annotation, we never observe a vulnerable software name and its versions located in completely different sentences throughout the entire document.

## 5 Evaluation

In this section, we use the ground-truth dataset to evaluate the performance of VIEM. First, we use the dataset of memory corruption vulnerabilities to assess the system performance and fine-tune the parameters. Then, we use the data of the other 12 categories to examine the model transferability.

<sup>4</sup>For software versions, we treat keywords related to compatibility pack, service pack, and release candidate (*e.g.*, business, express edition) as part of the version. For versions that are described as a “range”, we include the conjunctions in the version labels.

Metric		w/o Gazetteer	w/ Gazetteer
Software Version	Precision	0.9880	0.9880
	Recall	0.9923	0.9923
Software Name	Precision	0.9773	0.9782
	Recall	0.9916	0.9941
Overall	Accuracy	0.9969	0.9970

Table 2: NER performance on “memory corruption” dataset.

## 5.1 Evaluating the NER and RE Model

To evaluate the NER and RE models, we use the *memory corruption* vulnerability reports and their CVE summaries (3,448 CVE IDs).

**NER Model.** Given a document, the NER model extracts the vulnerable software names and vulnerable versions. The extraction process is first at the *word level*, and then the consecutive words with the *SN* or *SV* label will be grouped into software names or software versions. We use three evaluation metrics on the word-level extraction: (1) *Precision* represents the fraction of the relevant entities over the extracted entities; (2) *Recall* represents the fraction of the relevant entities that are extracted over the total number of relevant entities; (3) *Overall accuracy* represents the fraction of the correct predictions over all the predictions. We compute the precision and recall for software name extraction and version extraction separately.

We split the ground-truth dataset with a ratio of 8:1:1 for training, validation, and testing. We use a set of default parameters, and later we show that our performance is not sensitive to the parameters. Here, the dimension of the pre-trained word embeddings is 300 (50 for character embeddings). To align our input sequences, we only consider the first 200 words per sentence. Empirically, we observe that the vast majority of sentences are shorter than 200 words. All the layers in the NER model are trained jointly except the word-level embedding weight  $W$  (using the FastText method). The default batch size is 50 and the number of epochs is 20. We use an advanced stochastic gradient descent approach Adam as the optimizer, which can adaptively adjust the learning rate to reduce the convergence time. We also adopt dropout to prevent overfitting.

We repeat the experiments 10 times by randomly splitting the dataset for training, validation, and testing. We show the average precision, recall, and accuracy in Table 2. Our NER model is highly accurate even without applying the gazetteer (*i.e.*, the dictionary). Both vulnerable software names and versions can be extracted with a precision of 0.978 and a recall of 0.991. In addition, we show that gazetteer can improve the performance of software name extraction as expected. After applying the gazetteer, the overall accuracy is as high as 0.9969. This high accuracy of NER is desirable because any errors could propagate to the later RE model.

We also observe that our NER model indeed extracts software names (and versions) that *never appear* in the train-

Metric	Ground-truth Software Name/Version as Input	NER Model’s Result as Input	
		w/o Gazetteer	w/ Gazetteer
Precision	0.9955	0.9248	0.9411
Recall	0.9825	0.9931	0.9932
Accuracy	0.9916	0.9704	0.9764

Table 3: RE performance on “memory corruption” dataset.

ing dataset. For example, after applying NER to the testing dataset, we extracted 205 unique software names, and 47 (22.9%) of them never appear in the training dataset. This confirms that the NER model has learned generalizable patterns and indicators to extract relevant entities, which allows the model to extract *previously unseen* software names.

**RE Model.** We then run experiments to first examine the performance of the RE model itself, and then evaluate the end-to-end performance by combining NER and RE. Similar as before, we split the ground-truth dataset with an 8:1:1 ratio for training, validation, and testing. Here, we set the dimension of the pre-trained word embeddings to 50. The dimension of position embeddings is 10. The default batch size is 80 and the number of epochs is 200. We set the number of bi-directional layers as 2. Like the NER model, our RE model also uses the pre-trained word embedding weight  $W$ . The position embedding weights (*i.e.*,  $W_s$  and  $W_v$ ) are randomly initialized and trained together with other parameters in the model.

First, we perform an experiment to evaluate the RE model alone. More specifically, we assume the named entities are already correctly extracted, and we only test the “pairing” process using RE. This assumes the early NER model has a perfect performance. As shown in Table 3, the RE model is also highly accurate. The model has a precision of 0.9955 and a recall of 0.9825.

Second, we evaluate the end-to-end performance, and use the NER’s output as the input of the RE model. In this way, NER’s errors may affect the performance of RE. As shown in Table 3, the accuracy has decreased from 0.9916 to 0.9704 (without gazetteer) and 0.9764 (with gazetteer). The degradation mainly happens in precision. Further inspection shows that the NER model has falsely extracted a few entities that are not software names, which then become the false input for RE and hurt the classification precision. In addition, the benefit of gazetteer also shows up after NER and RE are combined, bumping the precision from 0.9248 to 0.9411 (without hurting the recall). The results confirm that our model is capable of accurately extracting vulnerable software names and the corresponding versions from unstructured text.

**Baseline Comparisons.** To compare the performance of VIEM against other baselines, we apply other methods to the same dataset. First, for the NER model, we tested SemFuzz [59]. SemFuzz uses hand-built regular expressions to extract vulnerable software versions from vulnerability re-

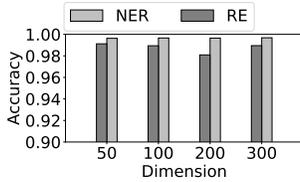

Figure 5: Word embedding dimension vs. accuracy.

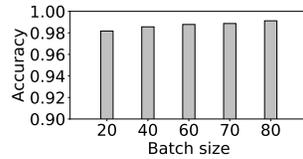

Figure 6: Batch size vs. RE model accuracy.

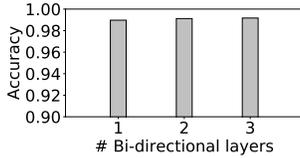

Figure 7: # network layers vs. RE model accuracy.

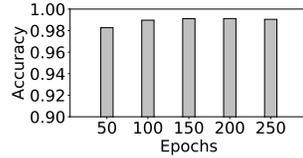

Figure 8: # Epochs vs. RE model accuracy.

ports. We find that SemFuzz achieves a reasonable precision (0.8225) but a very low recall (0.371). As a comparison, our precision and recall are both above 0.978. Second, for the end-to-end evaluation, we implemented a baseline system using off-the-shelf NLP toolkits. More specifically, we use the Conditional Random Field sequence model for extracting named entities. The model uses Stanford Part-Of-Speech tags [52] and other syntactic features. Then we feed the extracted entities to a baseline RE model that is trained with features from Stanford Neural Dependency Parsing [29]. The end-to-end evaluation returns a precision of 0.8436 and a recall of 0.8851. The results confirm the better performance of VIEM, at least for our application purposes (*i.e.*, processing vulnerability reports).

**Model Parameters.** The above results are based on a set of default parameters that have been fine-tuned based on the validation dataset. To justify our parameter choices, we change one parameter at a time and see its impact on the model. We perform this test on all parameters (*e.g.*, word embedding dimensions, batch sizes, network layers, epochs). The takeaway is that our model is not very sensitive to the parameter settings.

We pre-trained our own word embedding layer on the corpus built from all the unstructured reports in our dataset. We have tested two state-of-the-art methods Word2vec [39], and FastText [25]. We choose FastText since it gives a slightly higher accuracy (by 1%). Figure 5 shows the overall accuracy of FastText embeddings under different embedding dimensions. The results show that the performance is not sensitive to this parameter (as long as it is configured within a reasonable range). When training RE and NER, we need to set the batch size, the number of epochs, the number of bi-directional layers and the dimension of position embeddings in the neural networks. Again, we swap the parameters for RE and NER separately. For brevity, we only show the

Metric		Before Transfer		After Transfer	
		w/o Gaze	w/ Gaze	w/o Gaze	w/ Gaze
Software Version	Precision	0.8428	0.8467	0.9382	0.9414
	Recall	0.9407	0.9400	0.9410	0.9403
Software Name	Precision	0.8278	0.8925	0.9184	0.9557
	Recall	0.8489	0.9185	0.9286	0.9536

Table 4: Transfer learning result of NER model (average over 12 vulnerability categories).

results for the RE model in Figure 6–Figure 8. The results for the NER model are similar, which are shown in Appendix-A.

## 5.2 Evaluating Transfer Learning

Finally, we examine the generalizability of the model to other vulnerability categories. First, to establish a baseline, we *directly* apply the model trained with memory corruption dataset to other vulnerability categories. Second, we apply transfer learning, and retrain a dedicated model for each of the other vulnerability categories. We refer the two experiments as “before transfer” and “after transfer” respectively.

Transfer learning is helpful when there is not enough labeled data for each of the vulnerability categories. In this case, we can use the memory corruption classifier as the teacher model. By fine-tuning *the last layer* of the teacher model with the data of each category, we can train a series of category-specific classifiers. More specifically, we train a teacher model using all the ground-truth data from the memory corruption category (3,448 CVE IDs). Then we use the teacher model to train a new model for each of the 12 vulnerability categories. Given a target category (*e.g.*, SQL Injection), we split its ground-truth data with a ratio of 1:1 for training ( $T_{train}$ ) and testing ( $T_{test}$ ). The training data ( $T_{train}$ ) will be applied to the pre-trained teacher model to fine tune the final hidden layer. In this way, a new model that is specially tuned for “SQL Injection” reports is constructed. Finally, we apply this new model to the testing data ( $T_{test}$ ) to evaluate its performance.

The results are presented in Table 4 and Table 5. We find that the NER model is already highly generalizable before transfer learning. Transfer learning only introduces a small improvement in accuracy (from 0.987 to 0.994). Second, the RE model (trained on memory corruption data) has a clear degradation in performance when it is directly applied to other categories. The overall accuracy is only 0.876. After transfer learning, accuracy can be improved to 0.9044.

To confirm that transfer learning is necessary, we run an additional experiment by using all the ground-truth dataset from 13 categories to train a single model. We find that the end-to-end accuracy is only 0.883 which is lower than the transfer learning accuracy. The accuracy of certain categories clearly drops (*e.g.*, 0.789 for CSRF). This shows that the vulnerability reports of different categories indeed have different characteristics, and deserve their own models.

Metric	Before Transfer			After Transfer		
	G-truth as Input	NER Result as Input		G-truth as Input	NER Result as Input	
		w/o Gaze	w/ Gaze		w/o Gaze	w/ Gaze

## 6 Measuring Information Inconsistency

In this section, we apply VIEM to the full dataset to examine the information consistency. In particular, we seek to examine how well the structured NVD entries are matched up with the CVE entries and the referenced vulnerability reports. In the following, we first define the metrics to quantify consistency. Then we perform a preliminary measurement on the ground-truth dataset to estimate the measurement errors introduced by VIEM. Finally, we apply our model to the full dataset to examine how the consistency level differs across different vulnerability types and over time. In the next section (§7), we will perform case studies on the detected inconsistent reports, and examine the causes of the inconsistency.

### 6.1 Measurement Methodology

NVD database, with its fully *structured* and *standardized* data entries, makes it possible for automated information processing and intelligent mining. However, given that NVD entries are created and updated by manual efforts [18], we are concerned about its data quality, in particular, its ability to keep up with the most recent discoveries of vulnerable software and versions. To this end, we seek to measure the consistency of NVD entries with other information sources (including CVE summaries and external reports).

**Matching Software Names.** Given a CVE ID, we first match the vulnerable software names listed in the NVD database, and those from unstructured text. More specifically, let  $C = \{(N_1, V_1), (N_2, V_2), \dots, (N_n, V_n)\}$  be the vulnerable software name-version tuples extracted from the NVD, and  $C' = \{(N_1, V'_1), (N_2, V'_2), \dots, (N_m, V'_m)\}$  be the name-version tuples extracted from the external text. In our dataset, about 20% of the CVE IDs are associated with multiple software names. In this paper, we only focus on the *matched software names* between the NVD and external reports. Our matching method has the flexibility to handle the slightly different format of the same software name. We consider two names as a match if the number of matched words is higher or equal to the number of unmatched words. For example, “Microsoft Internet Explorer” and “Internet Explorer” are matched because there are more matched words than the unmatched one.

**Measuring Version Consistency.** Given a software name  $N_1$ , we seek to measure the consistency of the reported

Match	Memory Corruption			Avg. over 12 Other Categories		
	Matching Rate		Deviat.	Matching rate		Deviat.
	VIEM	G-truth		VIEM	G-truth	
Loose	0.8725	0.8528	0.0194	0.9325	0.9371	-0.0046
Strict	0.4585	0.4627	-0.0042	0.6100	0.6195	-0.0095

Table 6: Strict matching and loose matching results on the ground-truth dataset.

versions  $V_1$  and  $V'_1$ . We examine two types of matching. First, *strict matching* means  $V_1$  and  $V'_1$  exactly match each other ( $V_1 = V'_1$ ). Second, *loose matching* means one version is the other version’s superset ( $V_1 \subseteq V'_1$  or  $V_1 \supseteq V'_1$ ). Note that the loosely matched cases contain those that are strictly matched. Beyond loose matching, it means  $V_1$  and  $V'_1$  each contains some vulnerable versions that are not reported by the other (*i.e.*, conflicting information).

To perform the above matching procedure, we need to convert the text format of  $V_1$  and  $V'_1$  to a comparable format. In unstructured text, the software version is either described as a set of discrete values (*e.g.*, “version 1.1 and 1.4”) or a continuous range (*e.g.*, “version 1.4 and earlier”). For descriptions like “version 1.4 and earlier”, we first convert the text representation into a mathematical range. The conversion is based on a dictionary that we prepared beforehand. For example, we convert “... and earlier” into “ $\leq$ ”. This means “1.4 and earlier” will be converted into “ $\leq 1.4$ ”. Then, for “range” based version descriptions, we look up the CPE directory maintained by NIST [2] to obtain a list of all the available versions for a given software. This allows us to convert the “range” description (“ $\leq 1.4$ ”) into a set of discrete values  $\{1.0, 1.1, 1.2, 1.3, 1.4\}$ . After the conversion, we can determine if  $V_1$  and  $V'_1$  match or not.

If a CVE ID has more than one software names ( $k > 1$ ), we take a conservative approach to calculate the matching result. Only if all the  $k$  software version pairs are qualified as strict matching will we consider the report as a “strict match”. Similarly, only if all the pairs are qualified as loose matching will we label the report as “loose matching” report.

### 6.2 Ground-truth Measurement

Following the above methodology, we first use the ground-truth dataset to estimate the measurement error. More specifically, given all the ground-truth vulnerability reports and the CVE summaries, we use our best-performing model (with gazetteer and transfer learning) to extract the vulnerable software name-version tuples. Then we perform the strict and loose matching on the extracted entries and compare the matching rate with the ground-truth matching rate. The results are shown in Table 6.

We show that VIEM introduced a small deviation to the actual matching rate. For memory corruption vulnerabilities, our model indicates that 87.3% of the reports loosely match the NVD entries, and only 45.9% of the reports strictly

NVD data	
Software	Version
Mozilla Firefox	up to (including) 1.5
Netscape Navigator	up to (including) 8.0.40
K-Meleon	up to (including) 0.9
Mozilla Suite	up to (including) 1.7.12

CVE summary	
Software	Version
Mozilla Firefox	1.5
Netscape	8.0.4 and 7.2
K-Meleon	before 0.9.12

Figure 9: Example of underclaimed and overclaimed versions.

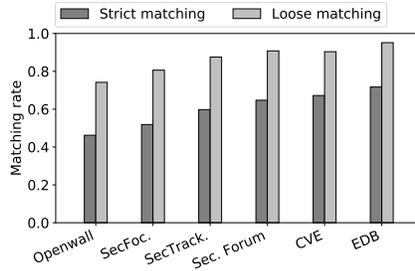

Figure 10: Matching rate for different information sources.

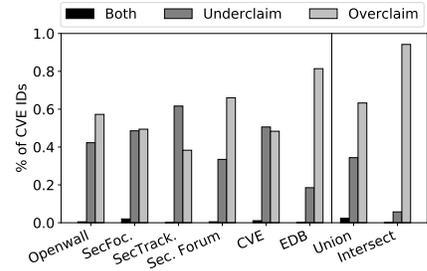

Figure 11: Breakdown of underclaimed and overclaimed cases.

match. The results are very close to the ground-truth where the matching rates are 85.3% and 46.3% respectively. For the rest of the 12 vulnerability categories, our model indicates that the loose matching rate is 93.3% and the strict matching rate is 61%. Again, the results are quite similar to the ground-truth (93.7% and 62%). The deviation from ground-truth ( $Rate_{estimated} - Rate_{groundtruth}$ ) is bounded within  $\pm 1.9\%$ . The results confirm that our model is accurate enough for the measurement.

### 6.3 Large-Scale Empirical Measurements

After the validation above, we then use the full ground-truth dataset to train VIEM and apply the model to the rest of the unlabeled and unstructured text (vulnerability reports and CVE summaries). Then we calculate the matching rate between the versions of NVD and those from external information sources (the CVE website and 5 external websites).

**Result Overview.** Across all 78,296 CVE IDs, we extract in total 18,764 unique vulnerable software names. These vulnerable software names correspond to 154,569 software name-version pairs from the CVE summaries, 235,350 name-version pairs from the external vulnerability reports, and 165,822 name-version pairs from NVD database. After matching the software names between NVD and other sources, there are 389,476 pairs left to check consistency.

At the name-version pair level, we find 305,037 strictly matching pairs (78.32%). This means about 22% of the name-version pairs from NVD do not match the external information sources. If we relax the matching condition, we find 361,005 loosely matched pairs (93.49%).

We then aggregate the matching results at the *report level*. Although the loose matching rate is still high (90.05%), the strict matching rate clearly decreases. Only 59.82% of the vulnerability reports/CVE summaries strictly match the NVD entries. This is because strictly matched reports require all the extracted versions to match those of NVD.

In order to understand how the level of consistency varies across different aspects, we next break down the results for more in-depth analyses.

**Information Source Websites.** Figure 10 shows the matching rates between the NVD entries and the 5 information websites and the CVE website. CVE has a relatively high matching rate (about 70% strict matching rate). This is not too surprising given that NVD is claimed to be synchronized with the CVE feed. More interestingly, we find that ExploitDB has an even higher matching rate with NVD. We further examine the *posting dates* of the NVD entries and the corresponding reports in other websites. We find that the vast majority (95.8%) of the ExploitDB reports were posted after the NVD entries were created. However, 81% of the ExploitDB reports were posted earlier than the reports in the other 4 websites, which might have helped to catch the attention of the NVD team to make an update.

**Overclaims vs. Underclaims.** For the loosely matched versions, the NVD entries may have overclaimed or underclaimed the vulnerable software versions with respect to the external reports. An example is shown in Figure 9 for CVE-2005-4134. Compared with CVE summary, NVD has *overclaimed* the vulnerable version for *Mozilla Firefox* and *Netscape Navigator*, given that NVD listed more vulnerable versions than CVE. On the contrary, for *K-Meleon*, NVD has *underclaimed* the vulnerable software version range.

Figure 11 shows the percentage of overclaimed and underclaimed NVD entries within the loosely matched pairs. “Strict-matched” pairs are not included in this analysis. We are not surprised to find NVD entries might overclaim. Given that NVD is supposed to search for different sources to keep the entries update-to-date, it is reasonable for the NVD entries to cover more vulnerable versions. Even if we take the union of the vulnerable versions across 5 websites and CVE, NVD is still covering more versions. The more interesting observation is that NVD has underclaimed entries compared to each of the external information sources. This suggests that NVD is either suffering from delays to update the entries or fails to keep track of the external information. Only a tiny portion of NVD entries contain both overclaimed and underclaimed versions (see the example in Figure 9).

**Examples of Conflicting Cases.** We then examined the conflicted pairs, and observed that a common reason for mis-

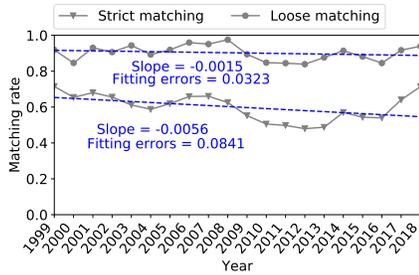

Figure 12: Matching rate over time: NVD vs. (CVE + 5 websites).

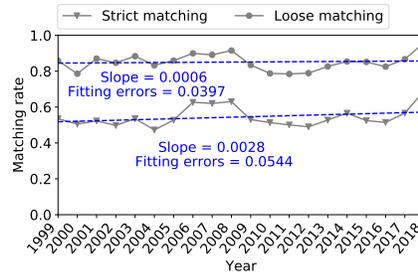

Figure 13: Matching rate over time: CVE vs. 5 websites.

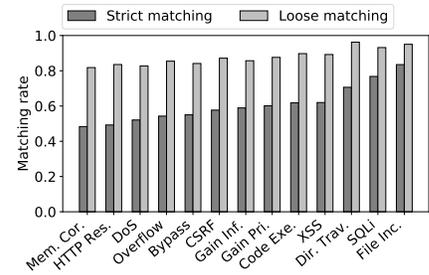

Figure 14: Matching rate for different vulnerability categories.

matching is *typos*. For example, under CVE-2008-1862, the versions listed on CVE and ExploitDB are both 0.22 and earlier for software *ExBB Italia*. However, the NVD version is slightly different “up to (including) 0.2.2”. Another example is CVE-2010-0364 where the software versions from NVD and CVE summary are both 0.8.6 for *Videolan VLC media player*. However, the information on SecurityFocus has a clear typo as 0.6.8.

In other cases, it is not clear whose information is correct. For example, sometimes the referenced vulnerable reports provide more detailed information than the CVE summary. For example, under CVE-2012-1173, the vulnerable version for *libtiff* is listed as 3.9.4 on NVD but SecurityTracker claims the vulnerable version should be 3.9.5. Under CVE-2000-0773, software *Bajie HTTP web server* is vulnerable for version 1.0 according to NVD. However, CVE lists version 0.30a and SecurityFocus lists 0.90, 0.92, 0.93. There is no way to determine the correctness of the contradicting information at the pure text level, but we argue that the value of such measurement results is to point out the cases that need validation and correction.

**Consistency Over Time.** Figure 12 shows the consistency level between NVD and the other 6 information sources (CVE and the 5 report websites) is decreasing over time. The strict matching rate has some fluctuation over time but still shows a decreasing trend. We perform a linear regression for both matching rates and find both have a negative slope (-0.0015 and -0.0056 respectively). The result suggests the overall consistency drops over time in the past 20 years. However, if we take a closer look at the recent three years (2016 to 2018), the consistency level is starting to increase, which is a good sign.

Figure 13 shows a different trend when we compare the consistency between CVE and the 5 external websites. The consistency level between CVE and external sites is relatively stable with a slight upward trend. We perform a linear regression for both matching rates which returns a positive slope (0.0006 and 0.0028 respectively). This suggests that CVE websites are getting better at summarizing the vulnerability versions.

**Types of Vulnerabilities.** As shown in Figure 14, we break down the results based on the vulnerability categories. While the loose matching rates are still similar (around 90%), there are clear differences in their strict matching rates. For example, “SQL Injection” and “File Inclusion” have the highest strict matching rate (over 75%), but categories such as “Memory Corruption” have a much lower strict matching rate (48%). Further manual examination suggests that memory corruption vulnerabilities are typically more complex than those under File Inclusion or SQL Injection, and thus require a longer time to reproduce and validate. As a result, it is not uncommon for NVD to miss newly discovered vulnerable versions over time.

**Inferring the Causes of Inconsistencies.** Finally, we attempt to infer the causes of inconsistencies by analyzing the NVD entry creation/update time with respect to the posting time of the external reports. More specifically, NVD maintains a “change history” for each CVE ID, which allows us to extract the entry creation time, and the time when new software versions are added/removed. Then we can compare it with the posting time of corresponding reports at the 5 websites. For this analysis, we randomly select 5,000 CVE IDs whose vulnerable versions in NVD are inconsistent with those of the 5 websites.

We find that 66.3% of the NVD entries have never been updated since they were created for the first time. This includes 5.8% NVD entries that were created before any of the 5 websites posted their reports. For example, for CVE-2006-6516, NVD claimed *KDPics* 1.16 was vulnerable in 2006. Later in 2010, SecurityFocus reported that both version 1.11 and version 1.16 were vulnerable. NVD has not added the new version 1.11 until today. For the much bigger portion (60.5%) of NVD entries, they were created when at least one of the external reports were already available. An example is CVE-2016-6855 as ExploitDB claimed *Eye of Gnome* 3.10.2 was vulnerable in August 2016. A month later, the NVD entry was created which did not include version 3.10.2. No update has been made since then.

For the rest of the 33.7% of the NVD entries, they have made at least one update to the vulnerable versions after the entry creation. For them, we compare the latest update time

CVE ID	Software	Vul. Versions Claimed by Different Sources	Majority Vote	Union	Ground truth	Versions Manually Tested	# Newly Detected Versions by Us (12)	# Overclaimed Reports (15)

Table 7: The summary of case study results. The number in parentheses denotes the total number of software versions.

and the posting time of the external reports at the 5 websites. We find all of the NVD entries made the latest update *after* the posting time of some of the external reports. Overall, these results suggest that the NVD team did not effectively include the vulnerable versions from the external reports, despite that the reports were already available at the time of the entry creation/update. The results in turn reflect the need of automatically monitoring different online sources and extracting vulnerable versions for more proactive version testing and entry updating.

## 7 Case Study

To demonstrate the real-world implications of our inconsistency measurement, we perform case studies. We randomly select 7 real-world vulnerabilities from the *mismatched cases* in our dataset. Then we attempt to manually reproduce the vulnerabilities of the related software under different versions. These vulnerabilities are associated with 7 distinct CVE IDs, covering 47 vulnerability reports in total. Note that for the case study, we not only included CVE summaries and the reports from the 5 websites, but considered all other source websites in the reference lists of these CVE IDs. For the software mentioned in these reports, we exhaustively gathered all the versions of these software programs and obtained 185 versions of software in total. We list the number of unique versions for each software in Table 7.

With the collected software, we examine the vulnerabilities in each version. We form a team of 3 security researchers

to manually analyze the source code of these software programs, and dynamically verify the reported vulnerabilities by manually crafting the PoC (proof-of-concept) input. The 185 software versions took us 4 months to fully verify.

The truly vulnerable versions are listed in the “ground-truth” column in Table 7. In total, out of the 185 software versions, we confirm that 64 versions are vulnerable. *12 of the truly vulnerable versions are discovered by us for the first time*, which have never been mentioned in existing vulnerability reports, or CVE/NVD entries.

### Observation 1. Erroneous Information Confirmed.

By comparing with the ground-truth vulnerable versions, we confirmed that most information sources including CVE and NVD have either missed real vulnerable versions or falsely included non-vulnerable versions. There are widespread and routine overclaims and underclaims. Given that many system administrators heavily rely on the information in vulnerability reports to assess the risk of their system and determine whether they need to upgrade their software, it is a big concern that the “underclaiming” problem could leave vulnerable software systems unpatched. The overclaims, on the other hand, could have wasted significant manual efforts from security analysts in performing risk assessments.

### Observation 2. Benefits and Limits of Majority Voting.

Given a vulnerability, if we take a majority voting among different information sources, we can diminish the “overclaiming” issue, which, however, amplifies the “underclaiming” issue. The result suggests that system administrators

and security analysts cannot simply utilize a majority voting mechanism to determine the risk of their software systems.

**Observation 3. Benefits and Limits of Union.** If we take a union set of all the claimed vulnerable versions, we can see the resulting vulnerable versions are having better coverage of the truly vulnerable versions. This indicates the benefit of broadly searching different online information sources and automatically extracting newly discovered vulnerable versions. While acknowledging the benefit, we also observe that the *union* approach is not perfect. First, the union set easily introduced overclaimed versions. Across all the vulnerabilities in Table 7, we find 15 external reports (not including NVD/CVE entries) where the claimed vulnerable versions turned out to be not vulnerable based on our tests (*i.e.*, overclaimed reports). Second, the union set sometimes fails to cover truly vulnerable versions. As shown in Table 7, we confirm 12 new vulnerable versions for CVE-2009-5018, CVE-2016-8676, and CVE-2016-9556. These vulnerable versions are discovered for the first time by us, by exhaustively testing all the available versions of the given software. In practice, our approach (testing all versions) is not scalable given the significant manual efforts required. To fully automate the vulnerability verification process is still an open challenge. Overall, the union approach at least helps to narrow down the testing space and improve the coverage of the truly vulnerable versions.

## 8 Discussion

**Key Insights.** The most important takeaway is NVD contains highly inconsistent information from external information sources and even the CVE list. The inconsistency involves both overclaiming and underclaiming problems. The implication is that system administrators or security analysts cannot simply rely on the NVD/CVE information to determine the vulnerable versions of the affected software. At the very least, browsing external vulnerability reports can help to better cover the *potentially vulnerable* versions.

Our system VIEM makes it possible to *automatically* keep track of the information of different sources to generate a “diff” from the NVD/CVE entries periodically. This allows employees of NIST NVD and MITRE CVE to get notified when new vulnerable versions are reported in external websites, and helps them to focus on the most inconsistent or outdated entries, which potentially accelerates vulnerability testing, entry updating, and software patching. This was not possible without VIEM. Although vulnerability testing and verification are still largely manual efforts (automatically verifying the correctness of the vulnerability information in reports is not yet possible, which is an open problem), our main contribution is that we enable the automation for the information collection and standardization process.

**Limitations.** Our study has a few limitations. First, we only focus on the 5 most popular source websites in order to make the data collection process manageable (each website needs its own crawler and content parser). We argue that the 5 websites are referenced by 72.34% of all CVE IDs, and the results are representative. Future work will seek to expand the scope of the measurements. Second, our definition of “vulnerable software” is relatively broad, including all different parts that are related to (or affected by) the vulnerability (*e.g.*, dependent libraries, OSes, components, functions). One way to improve our system is to further classify the different types of “software names” (*e.g.*, differentiating vulnerable applications and the affected OSes). Finally, the scale of our case study is still limited. The 185 software versions already cost months to manually verify, and it is difficult to increase the scale further.

## 9 Related Work

**NLP for Security.** Natural Language Processing (NLP) has been applied to address different security problems. For example, researchers apply NLP to extract malware detection features from researcher papers [63] or systematically collect cyber threat intelligence from technical blogs [27,37]. Another line of work applies text analysis to mobile apps to study permission abuse and user input sanitization [33, 35, 43, 45, 46]. Finally, NLP has been used to analyze API documentation and infer security policies [55, 61].

A more relevant line of works has employed NLP techniques to facilitate the identification and assessment of software bugs [47, 51, 54, 58]. A recent work [59] proposed a method to extract relevant information from CVE to facilitate vulnerability reproduction, with a specific focus on kernel vulnerabilities. Our work is the first to build customized NLP models to extract vulnerable software names and versions from CVE and vulnerability reports. We apply the model to systematically measure information consistency.

**Security Vulnerability Reports.** CVE and vulnerability reports have been studied in various contexts. Breu et al. [26] showed that the interaction between software developers and bug reporters can facilitate the remediation of software bugs. Guo et al. [34] found that vulnerabilities reported by professionals with high reputations usually get fixed quicker. Bettenburg et al. [23] discovered that additional information provided by duplicated vulnerability reports can help to resolve the problem more timely. Mu et al. [42] showed that the missing information in vulnerability reports could reduce the success rate of vulnerability reproduction. The authors of [42] only tested if one of the versions is vulnerable, and we need to test all the versions for a given software to obtain the ground-truth (§7). Zhang et al. [60] used NVD data for security risk assessment. Christey et al. [31] pointed out the biased statistics in CVE. Nappa et al. [44] found missing and

extraneous vulnerable versions in NVD data (for 1500 vulnerabilities) by comparing the NVD version with those of the product security advisories. Our work differs from previous works by focusing on the information consistency between *unstructured* information sources and CVE/NVD entries for a large number of vulnerabilities.

## 10 Conclusion

In this paper, we design and develop an automated tool VIEM to conduct a large-scale measurement of the information consistency between the structured NVD database and unstructured CVE summaries and external vulnerability reports. Our results demonstrate that inconsistent information is highly prevalent. In-depth case studies confirm that the NVD/CVE database and third-party reports have either missed truly vulnerable software versions or falsely included non-vulnerable versions. The erroneous information could leave vulnerable software unpatched, or increase the manual efforts of security analysts for risk assessment. We believe there is an emerging need for the community to systematically rectify inaccurate claims in vulnerability reports.

## Acknowledgments

We would like to thank our shepherd Giancarlo Pellegrino and the anonymous reviewers for their helpful feedback. We also want to thank Dongliang Mu and Jing Wang for their insightful suggestions. This project was supported in part by CSC scholarship, National Key Research and Development Program of China (2016YFB0800703), Chinese National Natural Science Foundation (U1836210), and NSF grants (CNS-1750101, CNS-1717028, CNS-1718459). ### A Model Parameters

The have tested the model performance with respect to different parameter settings for the NER model and the RE model. Figure 15 shows the RE model performance under different position embedding dimensions. Figure 16 to Figure 18 show the NER model performance under different batch sizes, the number of network layers, and the number of epochs. The result shows that our model is not very sensitive to parameter settings.

## Abstract

Recent years have witnessed the rise of Internet-of-Things (IoT) based cyber attacks. These attacks, as expected, are launched from compromised IoT devices by exploiting security flaws already known. Less clear, however, are the fundamental causes of the pervasiveness of IoT device vulnerabilities and their security implications, particularly in how they affect ongoing cybercrimes. To better understand the problems and seek effective means to suppress the wave of IoT-based attacks, we conduct a comprehensive study based on a large number of real-world attack traces collected from our honeypots, attack tools purchased from the underground, and information collected from high-profile IoT attacks. This study sheds new light on the device vulnerabilities of today's IoT systems and their security implications: ongoing cyber attacks heavily rely on these known vulnerabilities and the attack code released through their reports; on the other hand, such a reliance on known vulnerabilities can actually be used against adversaries. The same bug reports that enable the development of an attack at an exceedingly low cost can also be leveraged to extract vulnerability-specific features that help stop the attack. In particular, we leverage Natural Language Processing (NLP) to automatically collect and analyze more than 7,500 security reports (with 12,286 security critical IoT flaws in total) scattered across bug-reporting blogs, forums, and mailing lists on the Internet. We show that signatures can be automatically generated through an NLP-based report analysis, and be used by intrusion detection or firewall systems to effectively mitigate the threats from today's IoT-based attacks.

## 1 Introduction

The pervasiveness of Internet-of-Things (IoT) systems, ranging from cameras, routers, and printers to various home automation, industrial control and medical systems, also brings

in new security challenges: they are more vulnerable than conventional computing systems. IoT systems may fall into an adversary's grip once their vulnerabilities are exposed. Indeed, recent years have seen a wave of high-profile IoT related cyber attacks, with prominent examples including IoT Reaper [25], Hajime [24], and Mirai [41]. Particularly, compromised IoT systems are becoming the mainstay for today's botnets, playing a central role in recent distributed denial-of-service attacks and other cybercrimes [39]. An example is Mirai, which involved hundreds of thousands of IoT devices and generated an attack volume at 600 Gbps, overwhelming Krebs on Security, OVH, and Dyn. It does not come as a surprise that these devices are reported to be hacked all through known vulnerabilities, including those caused by misconfiguration or mismanagement, just like unpatched servers and personal computers that are routinely exploited [42]. Still less clear, however, are the fundamental causes for this trend of malicious activities that are disproportionately related to IoT systems and these vulnerable devices' impact upon the cybercrime ecosystem.

**Understanding the perilous IoT world.** More specifically, we raise the following questions: Why are IoT devices more favorable to cybercriminals than other Internet hosts? How important are known vulnerabilities to the ongoing attacks on IoT systems? Is there an effective defense to mitigate ongoing attacks? The answers to these questions are critical for seeking an effective means to thwart the wave of malicious attacks that increasingly rely on a large number of vulnerable IoT devices. Finding these answers, however, is by no means trivial due to the challenges in (1) recovering disclosed IoT vulnerabilities from a large number of vulnerability reports scattered around forums, mailing lists, and blogs, and (2) collecting artifacts from the cybercrime underground to study how known flaws are utilized and how significant they are to ongoing criminal activities.

To understand how cybercriminals use these known vulnerabilities, we set up honeypots to collect the data of real-world IoT exploits and also analyzed four popular attack toolkits. From the adversary's end, our study shows that today's IoT

\*Work was done while visiting Indiana University Bloomington.

†Corresponding author

‡Institute of Information Engineering

attacks almost *exclusively* use known vulnerabilities for exploitation. Specifically, among 81 different exploit scripts recovered from our honeypots, we found that 78 of them are on our vulnerability list. Also, each of the four attack toolkits we studied incorporates the exploits on at least 34 vulnerabilities, with all of them on our list. More importantly, we have evidence that an adversary extensively leverages the exploit code released together with the vulnerability reports, and in most cases, directly copies the code or slightly adjusts it. More than 80% of the IoT-related reports come with working attack methods. Given our observations that *most of* IoT vulnerabilities can be exploited to attack target devices (compared with only 5% exploitable ones in Linux kernel vulnerabilities [43]), it is apparent that the cost for attacking IoT systems today is *exceedingly low*.

**Automated protection generation.** On the other hand, we show that adversaries' indulgence in such low-hanging fruits can actually be used against themselves. Specifically, the reliance on known vulnerabilities means that a large attack surface would be closed once these problems have been fixed. Interestingly, this turns out to be completely feasible, due to the simplicity of the problems and the availability of the vulnerability disclosure and attack code that carries all the information we need to fix the reported flaws. Based on this observation, we developed a framework, called *IoTShield*, which utilizes Natural-Language Processing (NLP) to automatically evaluate the content of vulnerability reports. In particular, IoTShield is based upon a set of automatic content analysis techniques that accurately discover IoT-related vulnerability disclosures from a large number of vulnerability reports published at different sources.

Using the approaches above, we automatically analyzed 430,000 vulnerability reports and discovered more than 7,500 IoT reports in the past 20 years. Then, IoTShield extracts key knowledge from these reports to automatically generate *vulnerability-specific* signatures, which can be used by existing intrusion detection systems (IDSes) or web application firewalls (WAFs) to screen the traffic received by IoT devices under protection. We validated the efficacy of IoTShield over 178,778 traces harvested by our honeypots, as well as 11,602 traces of eight real devices, including both attack and legitimate traffic. Furthermore, we evaluated the effectiveness of IoTShield over a long-time (more than one year) traffic captured in an industrial control system's human machine interface (HMI) Honeypot. The evaluation results show that IoTShield achieves a high precision (above 97%) and a very low false positive rate with minor performance impact.

**Contributions.** The major contributions of this work are outlined as follows:

- *New discovery.* Leveraging the collected traces of real-world IoT exploits and analysis results from popular attack toolkits, we bring to light new observations, including the adversary's exclusive use of known flaws and published code. These

observations demonstrate that IoT devices are indeed more vulnerable, less patchable, and easier to attack than traditional Internet hosts, elucidating the ongoing cybercrime trend that heavily relies on these devices.

- *New defense.* More importantly, these findings also present us with an opportunity that could lead to the immediate defeat of most attack vectors in today's IoT-related attacks. We demonstrate that from the same sources adversaries use to build their exploits, vulnerability signatures can be *automatically* generated using NLP, and be quickly deployed to shield IoT devices from malicious attacks. Given the adversary's dependence on these known vulnerabilities, we believe that this simple, low cost yet effective defense will significantly raise the bar for future IoT-related attacks.

**Roadmap.** The rest of the paper is organized as follows. Section 2 presents the background and our threat model. Section 3 describes our new understandings on IoT vulnerabilities and real-world threats to IoT devices. Section 4 introduces the automated protection generation to defend against IoT attacks. Sections 5 and 6 present the implementation and evaluation of our automated protection generation, respectively. Section 7 discusses the limitations of this study and mitigation. Section 8 surveys related work, and finally, Section 9 concludes the paper.

## 2 Background

**IoT vulnerability life cycle.** Usually, an IoT device's vulnerability is a loophole in its firmware that enables an attacker to circumvent the deployed security measures [57]. Such a vulnerability has a life cycle with distinct phases characterized by its discovery, disclosure, exploitation, and patching. The first phase starts when the vulnerability is discovered by a vendor, a hacker, or a third-party security researcher. The security risk becomes particularly high if it is first found by hackers. The next phase is the public disclosure of the vulnerability by those who discover it, and is supposed to be done through a coordinated process [22], during which the vulnerability information is kept confidential allowing vendors to create a patch. However, this procedure is not always followed. Actual real-world disclosures could happen in different ways through sources across the Internet, including personal blogs, public forums, and security mailing lists. Once publicly disclosed, the information about a vulnerability is freely available to anyone. Thus, the level of security risk further increases as the hacker community is active in developing and releasing zero-day exploits [40]. From our observations, about 80% of IoT vulnerability reports are released together with exploitable methods, which can be readily utilized by hackers.

Even worse, a vendor may not provide any security updates or patches in response to a disclosure, even though it is supposed to do so. Also, even with the patches available, it is not uncommon that many users of the affected IoT devices do not

install them, given the complicated procedure (for ordinary users) to patch the firmware.

The life cycle of an IoT vulnerability ends when all IoT users install the patch to fix the vulnerability. However, even if an IoT device has a serious security vulnerability and vendors have released the patch, some users have no capability of updating patches in a timely manner due to their limited knowledge. From our observations, the life cycle of some IoT vulnerabilities lasts more than five years, during which these problems can be exploited at any time.

**Signature-based IDS.** An intrusion detection system (IDS) monitors a network or a system for malicious activities or policy violations. These systems can be signature-based or anomaly-based. Signature-based detection leverages known patterns (signatures) of malicious code or operations to identify malicious activities, while anomaly-based detection captures deviations from a system’s normal profile. The focus of our protection is to provide automatic signature generation for the signature-based detection systems, such as Snort [37].

Signatures can be used to describe a specific attack on a vulnerability or model the vulnerability itself. The latter, which provides comprehensive protection against *all* related attacks on the weakness, is called a *vulnerability-specific* signature. Such a signature is typically created through manual analysis of a vulnerability. In our study, however, we found that the rich information about IoT vulnerabilities from various sources (blogs, mailing lists, and forums) can actually be leveraged to *automatically* generate such a signature, using NLP techniques.

**Natural language processing.** Our research utilizes various NLP techniques to analyze the text content of various vulnerability reports. A spell-checking [1] is used to filter out documents irrelevant to IoT. Regular expression based pattern matching is utilized to identify the vulnerability reports related to IoT. Further, semantic consistency analysis is used to examine the extracted IoT entities. To generate a vulnerability-specific signature, in-depth understanding of the vulnerability semantics is needed and can be achieved by using a grammatical dependency parser [51], which provides a representation of grammatical relations between words in a sentence.

**Threat model.** In this work, we consider an adversary who attempts to exploit the security flaws disclosed in a vulnerability report to compromise remote, Internet-connected IoT devices. For this purpose, the adversary can compromise the remote IoT devices and use them to launch malicious attacks. In particular, we focus on Internet-connected IoT devices (e.g., IP cameras, routers, and printers) that expose their attack surfaces on the Internet. Accordingly, adversaries can exploit those devices’ security flaws remotely, and gain unauthorized control of those vulnerable devices (e.g., a compromised IoT device may become a botnet node).

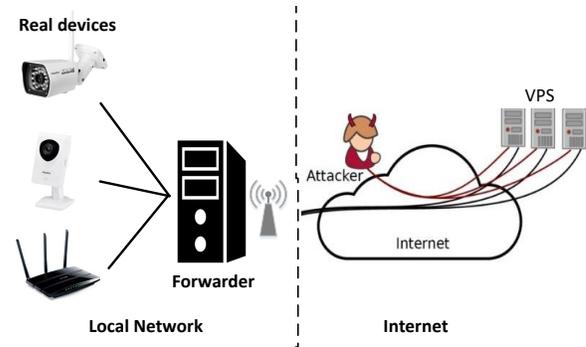

Figure 1: The infrastructure of our real device honeypots.

### 3 Understanding Real-World Threats

To understand how IoT vulnerabilities are exploited by adversaries, we deployed honeypots, analyzed underground attack toolkits, and studied prior attack reports. Here we elaborate our findings.

#### 3.1 Honeypot

Our honeypots include real IoT devices and simulated devices for collecting real-world attack activities.

**Real device honeypot.** We deployed eight vulnerable IoT devices (three routers and five cameras) as honeypots from May 2018 to June 2018. These devices and their corresponding vulnerabilities are listed in Table 1. We chose these devices because they are typical IoT systems being exploited in various real-world attacks [41].

Figure 1 illustrates our honeypot system’s infrastructure. To increase these devices’ IP diversity, we rented Virtual Private Servers (VPSes) across different countries as relay hosts for each IoT device. Whenever an attacker connects to a VPS, we redirect this request to the corresponding IoT device and forward its response back to the attacker.

More specifically, we use the reverse SSH tunneling [33] to bridge the gap between the IoT devices behind NAT and VPSes. For this purpose, we set up a persistent SSH tunnel from our device to its corresponding VPS, which is configured with the SSH port forwarding command [38] to send the traffic received from the VPS’ public IP on the HTTP port to FORWARD\_PORT (pointing to the IoT device). For devices not supporting the SSH protocol, we set up a PC as FORWARD\_PORT, passing the received traffic to the device.

**Simulated honeypot.** To study the attacks on more vulnerable devices, we also deployed four simulated IoT honeypots from May 2018 to July 2018<sup>1</sup> across two countries (Canada and the United States) and four cities (Buffalo, Los Angeles,

<sup>1</sup>The timeline for simulated honeypot data collection is not consistent with that of the real device honeypot, due to the data loss caused by a mis-configuration event in our real device honeypot.

**Table 1:** IoT device honeypot.

Products	Vulnerabilities
Linksys	Multiple XSS [10]
WVC54GCA	Absolute path traversal [12] Stored passwords/keys [13] Directory traversal (adm/file.cgi) [11]
TP-Link	Authentication bypass [19]
TL-SC3171G	OS Command injection [14] Hard-coded credentials [15] Unauthenticated file uploads [16] Unauthenticated firmware upgrades [17]
Dahua IPC-HF2100	Hard-coded Credentials [18]
D-Link DIR-645	Authentication Bypass [21]
TVT TD-9436T	Command execution [32]
Easyn Model:10D	Unreported 0-day
TP-link TL-WAR458L	Remote command execution [20]
TP-Link TL-WR941N	Backdoor [8]

Canyon Country, and Beauharnois), which cover more than 2,000 devices and 23 vulnerabilities.

The settings of these simulators are listed in Table 2. The Avtech honeypot covers 14 vulnerabilities, such as authentication bypass and command injection, which affect all Avtech devices (i.e., IP camera, NVR, and DVR) and firmware versions. The “GoAhead webs” honeypot simulates the GoAhead IP camera using a GoAhead-webs HTTP server. The honeypot covers seven critical vulnerabilities, such as the backdoor account and the pre-auth information leakage. Particularly, the latter is found in more than 1,250 different camera models. This enables us to significantly increase the number of vulnerable devices in our study.

Specifically, each honeypot is an HTTP server (on Apache), whose default configurations (such as default page and HTTP response header/body) have been modified to simulate real devices. If a honeypot finds an IP address that attempts to connect to our honeypot, it records the request packets from the IP and their timestamps before sending back “200 OK” and redirecting all HTTP requests to our main page. Note that some attacks may first send a harmless request to identify their target devices. In this case, returning a “200 OK” often triggers follow-up attack behaviors. Also, all of our simulators are indexed as real IoT devices in Shodan [59], and so they can be discovered from the device search engine.

**Analysis.** From May to July in 2018, our honeypots gathered 190,380 HTTP requests from 47,089 IPs across 175 countries. We analyzed these traffic traces as follows: first we removed those confirmed to be legitimate, including legitimate login attempts, the requests like “GET /”, and other ordinary HTTP GET requests; then we scanned the traces for attack attempts by searching the exploit code in our vulnerability dataset and further looking for the common attack traffic patterns, such as the presence of SQL commands and various execution commands (e.g., “cmd=/usr/bin/telnetd”). In this way, we identified nearly 2,000 IoT exploit attempts from 60 different countries, with an average of 38 attacks per day.

**Table 2:** Four simulated honeypots.

Name	Vulnerability	Affected products
D-link SOAP [23]	command injection	at least 12 products
GoAhead webs [27]	7 CVEs	1,250 affected models
JAWS [30]	command injection	all DVR running JAWS
Avtech [4]	14 vulnerabilities	all Avtech devices

**Table 3:** Traffic analysis of deployed honeypots.

	Real devices	Simulated honeypots
Malicious (Targeted)	20	~300
Malicious (Blind-scanned)	121	~1,560
Benign	11,451	176,764
Unknown	10	~154
Total	11,602	178,778

Table 3 presents the results in detail: for the real device honeypot, 141 unique attacks with 26 different scripts were captured, and 1,860 unique attacks through 81 attack scripts were found from our simulated honeypots. About 164 *unknown* requests still cannot be confirmed to be legitimate or malicious.

Analyzing these attacks (2,001 in total), we found that about 320 of them aimed at the honeypot (real or simulated) devices, while about 1,681 targeted the devices whose types are not covered in any honeypots. On one hand, this indicates that an adversary may blindly conduct an attack without first identifying the device type. On the other hand, this implies that our honeypots have a wide-spectrum attack coverage, not limited by the types of devices deployed at honeypots. More importantly, there are only 164 unknown requests observed by our honeypots. Even if we *conservatively* assume that all unknown requests originate from individual malicious attacks that exploit unknown security flaws, less than 10% (164 vs 2,001) of the total attacks exposed to our honeypots are such unknown attacks. In other words, more than 90% of malicious attacks exploit the *known* vulnerabilities. This observation is consistent with our analysis of underground attack toolkits (see Section 3.2).

Most commonly exploited vulnerabilities found in our study include unauthenticated command injection and information disclosure. These flaws can be easily attacked by sending a simple HTTP request to the vulnerable device to gain full control of the device. An intriguing observation is that 96% of the IoT attacks use the same or similar scripts included in the vulnerability reports we collected. For example, an attacker compromised our device TVT TD-9436T through a command execution vulnerability by using the exact same code documented in the report [32]. In another exploit (i.e., /board.cgi?cmd=/usr/sbin/telnetd) [28] on the same vulnerability location “board.cgi”, the only change found in the attack code was an adjustment of a parameter from “/usr/sbin/telnetd” to the Linux command “cat+/etc/passwd”.

**Table 4:** Underground IoT attack tools.

Name	Vulnerabilities
IPCAM exploits	Pre-Auth Info Leak
Huawei Exploits	Command Execution
iotNigger	Netis Backdoor
Brickerbot	More than 30 vulnerabilities

**Table 5:** Known IoT attack activities.

Name	Vulnerabilities	Year
IOT Reaper [25]	10 vulnerabilities	2017
Hajime [24]	at least 3 vulnerabilities	2016
Satori [34]	2 vulnerabilities	2018
Brickerbot [6]	21 vulnerabilities	2017
Masuta [26]	bypass & command execution	2018
Amnesia [3]	remote code execution	2017

### 3.2 Artifacts from Other Sources

To validate the findings made from the honeypots, we further analyzed four underground attack toolkits and six well-documented IoT botnets, which are elaborated below.

**Underground attack tools.** In this work, we searched popular underground marketplaces (such as openbazaar and dream-market) by using a set of keywords related to attack toolkits (such as IoT malware names listed in Table 12 of Appendix), in an attempt to find the posts selling such tools. Once the posts were discovered, we contacted the sellers and purchased the tools. Altogether, we obtained four such tools with their source code (see Table 4), including Brickerbot, a variation for the one used in the famous Brickerbot attack [6].

By analyzing their code, we again found that *all* vulnerabilities they exploit are known ones, and their attack scripts are *all* copied from the vulnerability reports with minor changes (e.g., C&C server IP) to customize for specific attack campaigns. More specifically, from these tools, we identified 99 different attack scripts related to 34 vulnerabilities. Those vulnerabilities are all recorded in our dataset. Among the 99 attack scripts, three of them are exactly the same as those documented, while the remaining 96 all have small changes. As an example in Table 4, the Huawei exploit on an arbitrary command execution vulnerability apparently comes from exploits-db (<https://www.exploit-db.com/exploits/43414/>), with only its Linux command (e.g., “ls”) changed to a new one (e.g., communicate with a specific remote server). Again, this confirms what we observed by analyzing our honeypot data: most IoT attacks utilize known vulnerabilities and even the attack code provided in the vulnerability reports, which on the other hand could be leveraged to quickly suppress this emerging attack wave.

**Known attacks.** Finally, we analyzed some well-known, well-documented IoT botnets that were recently reported (Table 5) to understand whether mostly known vulnerabilities and docu-

mented attack scripts were indeed used. These botnets were all aimed at the security flaws that affect many different products (like IoT Reaper) or those widely deployed on the Internet (like Masuta). Some of them (IoT Reaper and Amnesia) also focus on the vulnerabilities without patches.

Once again, we found that all the vulnerabilities exploited in these attacks are also included in the reports gathered in our research, and all the scripts attacking these flaws are the copies or variations of the code in the reports. For example, IoT Reaper attacks 37 vulnerabilities documented by 10 different reports: 10 for remote command execution, at least 24 not on any CVE and 7 without patches. Note that *all* these attacks took place *after* the disclosure of related vulnerabilities. For instance, IoT Reaper was brought to light in 2017, while the flaw it uses, Linksys E1500/E2500 vulnerabilities, was made public in 2013.

## 4 Automated Vulnerability-specific Signature Generation

As mentioned earlier, the IoT vulnerability ecosystem has a serious problem: the attack scripts are often publicly available in the vulnerability reports, making those known vulnerabilities easy to exploit. Such a problem has led to the spree of large-scale IoT based attacks in recent years, which almost exclusively exploit known flaws.

In the meantime, the adversary’s reliance on the well-documented vulnerabilities also presents a new opportunity for mitigating such threats. From the same vulnerability reports, vulnerability-specific information can be extracted to form a protection strategy that stops all attacks on the vulnerability. In our research, we developed IoTShield, an automatic tool that collects IoT vulnerability reports from the Internet, analyzes the content of the IoT vulnerability reports, and recovers key knowledge to generate *vulnerability-specific* signatures, with their qualities determined by the comprehensiveness of the reports. These signatures can be easily deployed to existing intrusion detection systems (IDSes) or web application firewalls (WAFs) to detect exploit attempts on the target device from the traffic it receives. In the following, we elaborate on this approach.

### 4.1 Overview and Data

Collecting IoT vulnerability reports from Internet and extracting vulnerability-specific knowledge from the collected IoT vulnerability reports for signature generation is a non-trivial task, with unique technical challenges. First, a large number of vulnerability reports are scattered around forums, mailing lists, and blogs with different format written by different people. It is difficult to identify IoT vulnerability reports from other documents. Second, such identified IoT vulnerability reports describe security flaws in natural language, which makes a large-scale discovery of vulnerability information difficult.

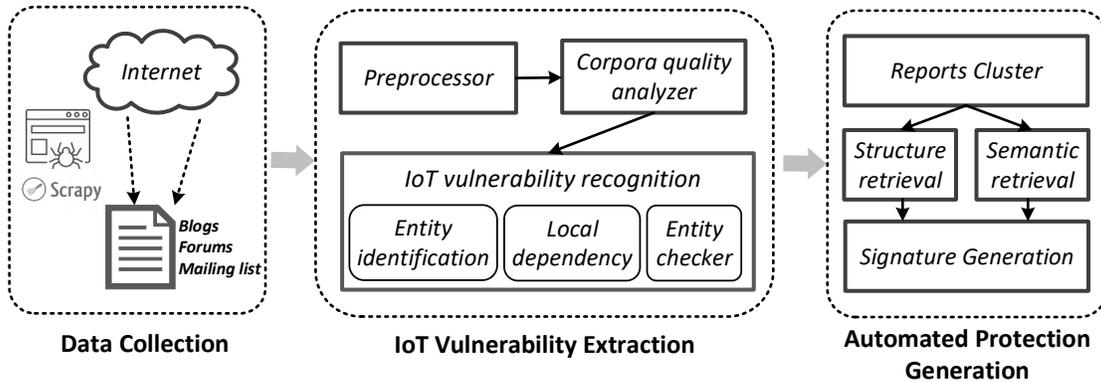

Figure 2: The architecture of IoTShield.

Third, identifying critical elements for a signature requires domain-specific knowledge to carefully distinguish between exploit-specific information and vulnerability-specific information. To address these challenges, in IoTShield, we use an IoT vulnerability extractor to remove irrelevant content and identify key information of IoT security flaws. After the collection of IoT vulnerability reports, we extract the semantics of vulnerability descriptions and other structured information (e.g., attack scripts) from the vulnerability reports. The descriptions here provide information about all circumstances under which a vulnerability can be exploited (e.g., all related parameters and locations), which enables us to leverage the attack surface observed from an attack script or other structured information like traffic logs to stop other attacks. A problem is that some of the vulnerability reports do not have vulnerability descriptions or structured information. Later we discuss how we handle this issue (see Section 4.3).

**Architecture.** Figure 2 illustrates the architecture of IoTShield, which has three major components: (1) data collection, (2) IoT vulnerability extraction, and (3) automated protection generation. Data collection is used to gather vulnerability reports from the Internet. The IoT vulnerability extraction is used to extract IoT vulnerability information from a large number of documents, including forums, blogs, and mailing lists. More specifically, we crawled popular online sources for bug disclosure and further ran a corpora quality analyzer to filter out the documents that are irrelevant to vulnerability reports. For the remaining documents, we used a recognizer to identify IoT vulnerability reports and extracted key information, such as their types, affected products, CVE numbers, authors, and published dates. This information will serve as the description for the later signature generation stage. Once given a set of IoT vulnerability reports, IoTShield first clusters the reports describing the same vulnerability together, and then utilizes NLP to discover the vulnerability semantics (e.g., vulnerability type, location, and parameters) from the descriptions. Then, it extracts the structured information (e.g., traffic logs, scripts, and Linux commands) to create an exploit

(or PoC) template and find illegal parameters (e.g., those used to inject commands). After that, the signature generation component utilizes the vulnerability location and parameters to identify all related attack surfaces, which helps to determine all parameters for the template that can also lead to exploits. The parameters and template here form the signature. Finally, IoTShield automatically transforms the signature into the format used in existing IDSes or WAFs (the prototype built in our research outputs a Snort signature [37]) for a fast deployment.

**Dataset.** As mentioned earlier, we ran our crawler across the vulnerability reporting websites listed in Table 6, including forums ([seclists.org/fulldisclosure](https://seclists.org/fulldisclosure)), mailing lists ([seclists.org/bugtraq](https://seclists.org/bugtraq)), personal blogs/advisories ([pierrekim.github.io](https://pierrekim.github.io)), research team advisories ([coresecurity.com](https://coresecurity.com)), and vulnerability archive websites ([packetstormsecurity.com](https://packetstormsecurity.com)). These sources were collected from the external references included in CVEs, among which we selected the most frequently used ones. From these sources, we further manually picked out those related to IoT vulnerabilities, like [seclists.org](https://seclists.org), and added them to the list, which also includes some research groups' websites known to report security vulnerabilities.

## 4.2 IoT Vulnerability Extraction

**Preprocessing.** Over the documents collected by the crawler, our IoT vulnerability extraction component removes the textual information irrelevant to vulnerabilities, such as advertisements, pictures, dynamical scripts, and navigation bar, while keeping the main content of each webpage with document URLs, document titles, authors, and publication dates. Since different websites have different templates and HTML structures, we manually analyzed each of them (13 vulnerability reporting sites in total, see Table 6) to identify useful content.

**Corpora quality analyzer.** After the preprocessing, we still need to filter out the documents irrelevant to IoT vulnerability reports, which is done as follows:

- *The percentage of dictionary words.* We removed the documents whose content contains mostly (above 82% in our research) dictionary words, which are recognized by enchant library [1], since a real vulnerability report always includes a significant amount of non-text information, like vulnerable paths and functions, PoC or scripts, etc. Otherwise, the text looks more like a survey article, white paper or notification.
- *The number of hyperlinks.* In general, a vulnerability report, particularly for IoT, is not supposed to include too many hyperlinks. Otherwise, it could be a summary for all the vulnerabilities disclosed, instead of a specific report with detailed vulnerability information. Thus, we discarded the documents with more than 25 hyperlinks.
- *Threshold justification.* The two threshold values above (i.e., 82% and 25) are based on our empirical experience, for the purpose of filtering out most non-IoT vulnerability reports with little collateral damage. To justify our threshold configuration, we attempt to estimate the possibility of a real IoT vulnerability report being wrongly discarded. To this end, we randomly sampled 100 documents being discarded and then manually examined whether there is any wrongly discarded case (i.e., a real IoT vulnerability report but discarded as non-IoT). What we found is that all of the sampled documents are irrelevant to IoT vulnerability reports (neither related to IoT vulnerability nor containing any vulnerability details). In the other words, no real IoT case exists among these 100 randomly sampled documents that are discarded as non-IoT. This implies that our empirical threshold configuration is very effective to filter out non-IoT vulnerability reports.

**IoT vulnerability recognition.** For the remaining documents, we further ran a recognizer to discover IoT vulnerability reports and extract key information (i.e., device type, vendor name, and vulnerability type). The retrieval of the vulnerability information is modeled as a named entity recognition problem [52] in NLP. More specifically, we first attempted to identify four IoT vulnerability-related entities, including device types, vendors, product names, and vulnerability types, and then utilize the dependency relationship across them to confirm the presence of vulnerability-related

**Table 7:** Context textual terms.

Entity	Context terms
	camera, ipcam, netcam, cam, dvr, router
Device Type	nvr, nvs, video server, video encoder, video recorder diskstation, rackstation, printer, copier, scanner switches, modem, switch, gateway, access point
Vendor	1,552 vendor names
Product	[A-Za-z]+[-]?[A-Za-z!]*[0-9]+[-]?[-]?[A-Za-z0-9] *^[0-9]2,4[A-Z]+
Vuln type	733 CWE, 88 abbreviations
Version	(?:version[:. ]*(\w- \w.- +) ve?r?s?i?o?n?s?[:. ]*(\d- \w.- +)
CVE	CVE-[0-9]{4}-[0-9]{4,}

descriptions. Given the uniqueness of the descriptions, we adopted a set of IoT-specific recognition techniques to retrieve them, as elaborated on below.

To identify these individual entities, we utilized keyword and regular expression based matching. For device types, vendor names, and vulnerability types, we used a set of keywords, as illustrated in Table 7: whenever a single word in the category (device type, vendor name, or vulnerability type) is found, we believe that its corresponding entity exists. These keywords are from the features of real-world devices. Specifically, we collected all common device types, including routers, cameras, modems, and printers, and found vendor names from Wikipedia. We also gathered vulnerability types from the Common Weakness Enumeration (CWE), which is a community-developed list of common software security weaknesses [9]. Further, we added to the list common acronyms of these vulnerabilities, such as CSRF and RCE. For product names, we built regular expressions to identify each entity, due to the large volume and difficulty of enumeration. These expressions are listed in Table 7.

In this way, our approach can identify all IoT vulnerability-related documents. However, given the pervasiveness of such entities (e.g., the term “switch” also appears in the documents unrelated to IoT flaws), using them alone could introduce a large number of false positives. To address this issue, we leveraged the dependency among these entities to ensure the correct recognition of these vulnerabilities.

Intuitively, when these entities are indeed used to describe an IoT vulnerability, they do not independently occur. Instead, they come together to present a concept. This implies the existence of dependency among them. In particular, the term for the vendor entity precedes the product entity or the device-type entity: e.g., D-Link DIR-600 or Foscam IPcamera. Also, the document needs to contain the vulnerability type, e.g., command injection. Using these rules, we can piece together these entities, linking IoT products to vulnerabilities. However, there are still several cases satisfying the rules above but as non-IoT device entities, such as “NAI NAI-0020” and “EE

Thomson TWG850 Wireless Router Multiple Vulnerabilities
Foscam IP Cameras Multiple Cross Site Request Forgery Vulnerabilities
Belkin Router N150 - Path Traversal Vulnerability
Dlink DIR-601 Command injection in ping functionality
Squirrelmail 1.4.22 Remote Code Execution
New Linux kernel 2.6.8 packages fix several vulnerabilities
Cisco Ironport Appliances - Privilege Escalation Vulnerability

**Figure 3:** Examples of the IoT vulnerability entities (first four) and non-IoT vulnerability entities (last three).

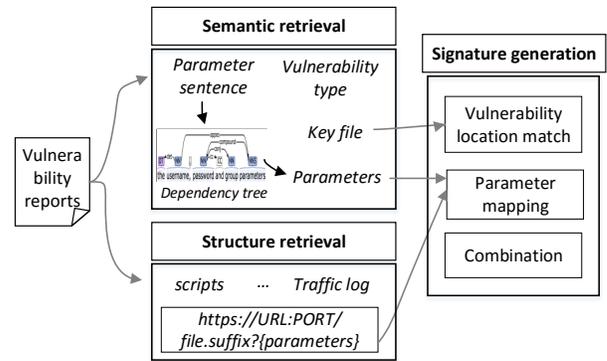

13EFF4”. To suppress false positives, we further investigate the results by using an entity checker. More specifically, in the entity checker, we search for the extracted entities (e.g., D-Link DIR-600) in Google, and then calculate the cosine similarity between the extracted entities and the title of the search results. If the similarity is extremely low (e.g., 0.08), we regard the extracted entity as a non-IoT device.

Figure 3 shows examples of IoT vulnerabilities (the first four) and other vulnerabilities (the last three) in vulnerability reports. For each vulnerability extracting from the preprocessing stage, we used the keyword matching to identify the device type (e.g., router), vendor (e.g., Belkin), and vulnerability type (e.g., path traversal). Then, we used the regular expression based matching to extract product information (e.g., N150). After that, we checked if the extracted entities are combined to present a IoT vulnerability concept via local dependency and entity checker. For example, three entities “Belkin”, “router”, and “N150” together describe an IoT device. As we can see from Figure 3, the first four always include the affected IoT products (e.g., D-Link DIR-600) and the vulnerability types (e.g., command injection), while the latter three do not. Once such a report is found, our approach further extracts the firmware version and CVE number from its content when such information exists, for the follow-up analysis. The regular expressions for identifying these entities are also listed in Table 7.

### 4.3 Automatic Defense Rule Generation

After the IoT vulnerability recognition, we identified the entities (i.e., device types, vendors, product names, and vulnerability types) from the IoT vulnerability reports. These entities are then used to cluster IoT vulnerability reports describing the same IoT vulnerability. Then, given each cluster, we extracted the vulnerability semantics (e.g., vulnerability location<sup>2</sup> and exploit parameters) and other structured information (e.g., attack scripts) from the vulnerability reports. This generation process, as shown in Figure 4, enables us to leverage the attack surface to generate a vulnerability-specific signature.

<sup>2</sup>A vulnerability location is where flaws exist, such as “command injection in PwdGrp.cgi”, “PwdGrp.cgi” is the vulnerability location.

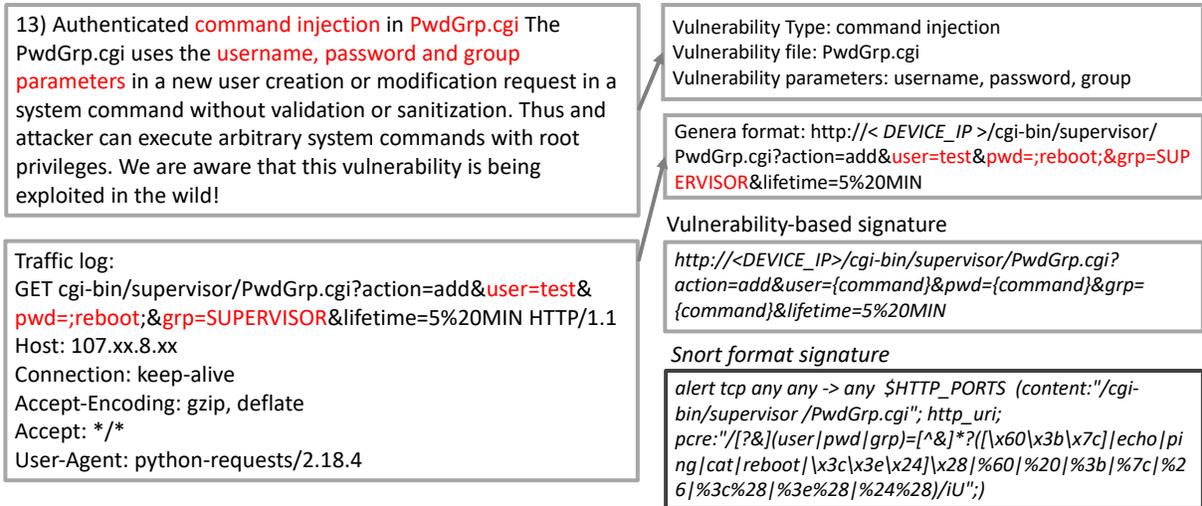

**Figure 4:** The architecture of signature generation.

Figure 5 presents an example, showing how we generate a signature from an extracted IoT vulnerability report. On the top-left of the figure is the vulnerability description. The bottom-left is the content of the structured information, which is a traffic log for an exploit on this vulnerability. IoTShield first locates the vulnerability semantics in the description. For instance, the sentence “command injection in PwdGrp.cgi” indicates that the vulnerability type is “command injection” and the affected location is “PwdGrp.cgi”, together with the vulnerable parameters from another sentence “the username, password, and group parameters”. Then, IoTShield parses the structured information (e.g., the traffic logs), and discovers the path of the vulnerable CGI “/cgi-bin/supervisor/PwdGrp.cgi” and the parameter used for command injection “pwd = ;reboot;”, from the command indicator “;” and the list of legitimate commands.

Further, from the sentence about other vulnerable parameters “the username, password, and group parameters” (from the description), we can now infer that the same injection can also happen on “usr” and “grp”, but not on the parameters “action” and “lifetime”. In this way, we can build a vulnerability-specific signature for the injection flaw, and then transform it into the Snort format (based on vulnerability type) as presented in Figure 5. Here we elaborate on the individual components of IoTShield.

**Report clustering.** There are some different blogs describing the same vulnerability, and these reports may describe the vulnerability from different aspects. So, we need to cluster these reports together to form a complete vulnerability report before the rule generation stage. The challenge is that although two reports describe the same vulnerability, they may have different formats with different hash values. Our solution is to use the entities (i.e., device types, vendors, product names, and vulnerability types), which are recognized from IoT vulnerability reports, to cluster IoT vulnerability reports that describe the same IoT vulnerability.

Note that report clustering aims to supplement the missing information of a vulnerability report (e.g., missing script code or missing vulnerability description). There rarely exist

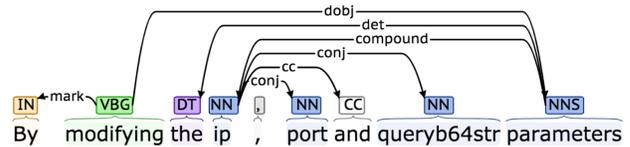

**Figure 5:** Example of vulnerability-specific signature generation from a vulnerability report.

different vulnerabilities with same device type, vendor, product name, and vulnerability type. However, even different vulnerabilities are clustered together, we can extract signatures for each vulnerability when matching the template (see Section 4.3)

**Semantic and structured information retrieval.** We first utilized NLP techniques to analyze the vulnerability descriptions to find vulnerability semantics, including vulnerability type, location, and short sentences with exploit parameters. Our approach is based on the observation that the semantic information of interest is presented through a relatively stable grammatical structure. Specifically, we utilized the vulnerability type list in Section 4.2 to determine the type of the problem documented and the regular expressions to find the vulnerability location, which should be a web content file, such as “.htm”, “.cgi”, “.php”, “.asp”, and “.html”. When it comes to vulnerability parameters, our approach locates the sentences containing the keyword “parameter”, “variable”, “action”, or “function”, and leverages the grammatical relationship among these words and the values of the parameters to find them. For this purpose, we constructed a dependency tree using the Stanford Dependency Parser [51] to parse the whole sentence and then extract the nouns as the targeted terms to inspect their relationship with the keywords. These terms are considered to be parameters if they have a non-“nmod” relation<sup>3</sup> with the keyword, or have a “conj” relation<sup>4</sup> with an identified parameter. An example is shown in Figure 6.

Further, we used the regular expressions (listed in Table 13 of Appendix) to locate different kinds of the structured information, including the PoC using Linux commands (curl and wget), PoC URL, PoC HTML scripts, and PoC traffic log, etc. For each type of the structured information, we built a parser

**Figure 6:** The dependency tree of a sentence with vulnerability parameters.

to transform it into a general template:

`http://HOST:PORT/file.suffix?{parameters}`,

where HOST is the device’s IP address, port is the application layer server port (default is 80), file.suffix is the vulnerability location, and {parameters} is the key-value format that includes the parameters used for the vulnerability file in the exploits. For each item in {parameters}, IoTShield checks whether it carries any illegal values like injected Linux command or Java scripts. Note that not all vulnerabilities need parameters, such as some information disclosure weaknesses, which could be exploited by simply requesting the vulnerable location. In this way, our approach acquires the semantic and structured information from the vulnerability reports.

**Signature generation.** After discovering vulnerability information from the reports, IoTShield utilizes it to build a signature. Specifically, we first compared the vulnerability location (recovered from the description) and “file.suffix” in the template (from the structured information); if matched, we believed that the semantic information (including vulnerability types and parameters) would be about the flaw modeled by the template (e.g., that attacked by the script). Then, based on the vulnerability type, we decided whether to ignore the parameter part of the template, since some vulnerabilities do not need parameters to exploit (e.g., information disclo-

<sup>3</sup>One element serves as a nominal modifier for the other.

<sup>4</sup>Two elements are connected by a coordinating conjunction.

sure and directory traversal). For the vulnerability types that do not need parameters to exploit (e.g., directory traversal (“./../etc/passwd”) in D-Link routers [CVE-2018-10822]), we ignore the parameter part. As of all the vulnerability types in our data, information disclosure and directory traversal are the only two typical vulnerability types not requiring a parameter to exploit. For those vulnerabilities that need parameters, IoTShield generalizes the parameter field in the template with those collected from the description. In this way, we built a vulnerability-specific signature. An example is shown in Figure 5.

A problem with this simple signature generation process is that the semantic information and the structured information may not always match in an exact fashion. For example, in Figure 5, the vulnerability parameters in the vulnerability description are presented in the natural language (i.e., username, password, and group) while they are abbreviated in the structured information (i.e., user, pwd, and grp). To address this problem, we manually collected a list mapping individual keywords to their corresponding abbreviations used in Linux, such as grp for group, for translating natural language terms into parameters in a signature.

Another issue is that, as mentioned earlier, some vulnerability reports do not contain both vulnerability descriptions and structured information; or vulnerability descriptions do not contain all vulnerability semantics. Next, we discuss how to handle them.

- *Vulnerability description only.* Without structured information, all we can get are just the vulnerability type, locations, and parameters. The parameters, however, can be less reliable due to the abbreviations they could have, which we cannot see. Therefore, we can only generate signatures for some vulnerabilities: those in which the knowledge of the vulnerability location alone (e.g., “PwdGrp.cgi”) is enough for protection. Examples of such flaws include information disclosure and directory traversal, e.g., for an information disclosure problem, a request for /QIS\_wizard.htm is sufficient for signature generation.

- *Structured information only.* Without vulnerability description, we cannot produce a generalized, vulnerability-specific signature. However, we can still utilize the structured information to build an exploit-specific signature to defeat the attack script described in a vulnerability report. As found in our measurement study (Section 3), today’s IoT attacks often utilize these published scripts. These signatures can still contribute to the detection of many ongoing attacks, though they can be evaded once an adversary is willing to make more effort to better understanding the flaws he attacks. It is important to note that some level of generalization is still possible here; for example, once a parameter recovered from an attack script is found to contain a Linux command, we can add other commands commonly used in attacks to the parameter list for signature generation.

## 5 Implementation and Deployment

### 5.1 Implementation

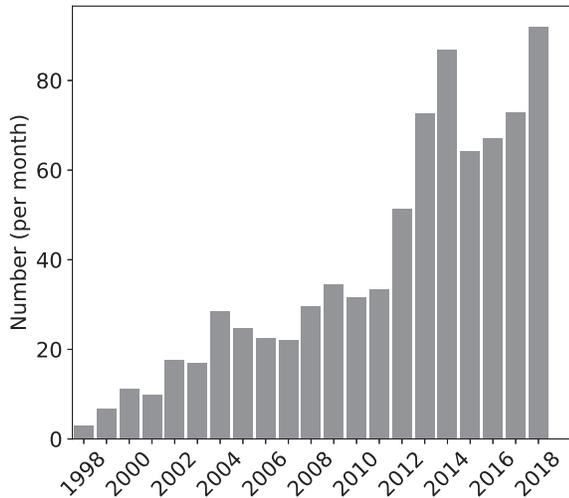

We implemented a prototype system of IoTShield, which includes a set of building blocks. Here we briefly describe the system’s nuts and bolts, and then show how they are assembled into the prototype system.

**Nuts and bolts.** Our prototype system was built upon three key functional components: *report crawler*, *vulnerability extractor*, and *rule generator*. Those components are extensively used across the whole system, and they were implemented as follows.

- The report crawler fetches the vulnerability reports from the Internet using wget and the scrapy crawling framework [36]. Specifically, for some websites that are well archived (e.g., [seclists.org/fulldisclosure](http://seclists.org/fulldisclosure)), we used “wget -mirror” to download their pages recursively (i.e., crawl the websites as deep as possible). For other websites, we used the scrapy crawling framework to crawl the whole websites. Since websites sometimes have crawling restrictions (e.g., [packetstorm.com](http://packetstorm.com) has a rate limit and [s3curity.de](http://s3curity.de) requires a cookie in the header of each request), our crawler simulates browser behaviors to mitigate those restrictions. It utilizes different user-agents for each request and sleeps for a random period of time after sending out multiple requests; additionally, once an access fails, a new attempt will be made later, after all pending requests in the current waiting queue have been delivered.
- The vulnerability extractor was implemented by 2,300 lines of python code. The Beautiful Soup Python library [5] was used to parse the vulnerability reports to extract main contents. The NLTK [29] package was used to split sentences, stem words, remove stop words, etc. The Aho–Corasick algorithm [2] is a string-searching algorithm to speed up the entity identification stage. A scikit-learn [35] library was used to calculate the TF-IDF (Term Frequency-Inverse Document Frequency) cosine similarity in the entity checker.
- The rule generator was implemented by 1,500 lines of Python code. We used a Simhash Algorithm [31] to detect near-duplicates, and the Stanford dependency parser [51] to establish the dependency tree.

### 5.2 Deployment

IoTShield can be deployed in two modes: coarse-grained and fine-grained. In the coarse-grained mode, all the generated rules are used in the IDS system, regardless of device types. All the rules are used to inspect the network traffic. This mode is easy to deploy but may have some false positives, since some rules can be device-specific. Also, in the coarse-grained mode, we suggest not to use the rules generated from descriptions only. This is because when ignoring device type, the rules generated from descriptions only may lead some false

**Figure 7:** Vulnerability disclosure trend.

positives. For example, for a report describing an information disclosure vulnerability at the file of “/new/index.htm” in Merit Lilin IP Cameras, with description only, we generate a signature to block the traffic that attempts to extract information from the file of “/new/index.htm”. However, such a scenario (retrieving the file of “/new/index.htm”) may also occur in normal web servers and cause false positives. In the fine-grained mode, we take the network environments into account and deploy rules for given device types. For example, if there are just D-link devices in the local network, we only deploy the rules to protect D-link vulnerabilities. More specifically, in the fine-grained mode, IoTShield first analyzes the network traffic or actively probes the network to identify device types (e.g., models and brands) and their IP addresses. This step can be achieved by using a device list in the monitored network or using the device fingerprinting method proposed in [47]. After that, a signature selection process will be conducted to select the corresponding signatures, given the current device types in the network.

## 6 Evaluation

### 6.1 Effectiveness

To validate the efficacy of IoTShield, we first manually checked the extracted IoT vulnerabilities and obtained some basic statistics of them. Then, we used two different traffic traces to evaluate the effectiveness of generated signatures.

**Vulnerability extractor.** We randomly sampled 200 reports from those identified for manual validation and achieved a precision of 94%. In total, we collected 7,514 IoT vulnerability reports from 0.43 million articles (Table 6). These reports disclose 12,286 IoT vulnerabilities, with roughly 1.6 each on average. Figure 7 shows the average number of IoT vul-

**Table 8:** List of top 10 vendors and device types of affected devices.

Device Vendor	Num	Device Type	Num
Cisco	1,264	router	3,700
D-Link	988	switch	1,422
Linksys	539	camera	1,248
Netgear	522	firewall	1,101
HP	485	gateway	1,032
Symantec	299	modem	843
TP-Link	255	access point	478
Zyxel	229	printer	408
Huawei	195	nas	338
Asus	180	scanner	176

**Table 9:** List of top 10 vulnerability types.

	Vulnerability type	Num
1	Denial of service	975
2	CSRF	902
3	Buffer overflow	869
4	Command injection	806
5	XSS	775
6	Authentication bypass	763
7	Command execution	458
8	Information disclosure	407
9	Directory traversal	307
10	Privilege escalation	276

nerabilities disclosed per month from 1998 to 2018. We can see that the number of disclosures has increased since 1998, and this increasing trend has further sped up since 2012 and slowed down since 2014, but it peaked in 2018 when about 90 IoT vulnerabilities per month were disclosed.

These IoT vulnerabilities are related to device types and vendors. We found that the distribution of vulnerabilities among IoT vendors follows a long-tail: nearly 60% of vulnerable devices are from the top 10 vendors with the most security flaws. Table 8 lists the vulnerability distribution over these 10 device types and vendors. As we can see here, routers, switches, and cameras, which are perceived to be the most common IoT devices, also have the most vulnerabilities. In addition, the vendors responsible for the most vulnerabilities (i.e., Cisco, D-Link, and linksys) are all reputable and have the largest market shares.

Table 9 further lists the top 10 vulnerability types in our dataset. The majority of them are remotely exploitable (e.g., buffer overflow, denial-of-service, CSRF command injection, and authentication bypass), which could be easily used to compromise IoT devices. Moreover, cross-site scripting (XSS), command injection and command execution are commonly used by IoT malware to execute commands on a compromised device as a botnet node.

**Table 10:** Effectiveness of IoTShield.

Dataset	Precision	Recall	False Positive Rate
Real devices	97%	83%	0.01%
Honeypot	98%	93%	0.06%

**Rule generation effectiveness.** We first evaluated our IoTShield prototype on 190K HTTP requests collected from IoT devices and honeypots, using a Macbook Pro with 2.6GHz Intel Core i7 and 16GB of memory. Again, all signatures generated were in the Snort format.

Our HTTP requests include those gathered from real-device honeypots and those from the simulators. In our experiments, we labeled IoT device traffic as described in Section 3.1. Those traces include 178,778 HTTP requests received by the simulators, which are related to 141 attack activities generated by 26 unique attack scripts, and the rest is benign traffic. The remaining data come from the real-device honeypots, as described in Section 3.1, including 11,602 HTTP requests in 1,860 attacks generated by 81 unique attack scripts.

We evaluated the effectiveness of IoTShield using precision, recall, and the false positive rate (FPR). Precision is defined as  $|TP|/|FP + TP|$ , recall is  $|TP|/|TP + FN|$ , and FPR is  $|FP|/|FP + TN|$ , where TP is the number of true positives, FN is the number of false negatives, FP is the number of false positives, and TN is the number of true negatives. Table 10 presents the experimental results. Over the traces received by the simulators, the precision of our automatically generated signatures is 98%, the recall is 93%, and the FPR is 0.06%. Over the requests gathered from the real devices, our signatures can achieve a 97% precision, 83% recall, and 0.01% FPR.

We further used a long-time traffic captured in an industrial control system’s HMI honeypot for the evaluation of IoTShield. The simulated industrial control system’s HMI honeypot is used to monitor the attack traffic with a blind scanning and attack. The duration was from October 2017 to November 2018 across from seven different cities. By replaying the traffic, IoTShield reported 7,396 alerts of exploiting the HMI system. By manually checking the 7,396 alerts, we confirmed that about 6,705 alerts were indeed IoT attacks. The rest of the alerts were confirmed to have attacked other vulnerabilities on common web servers. For instance, “/level/77/exec/show/config/cr”, is found in exploit-db as a script to evade detection of HTTP attacks via non-standard “%u” Unicode encoding of ASCII characters in the requested URL. [7].

## 6.2 Performance

**Signature generation.** To understand the performance of IoTShield, we conducted experiments to measure the time cost of

**Table 11:** Running time at different stages.

Stage	Running time (s)	Percentage
Data collection	0.386	51%
IoT vulnerability extraction	0.154	21%
Rule generation	0.210	28%
Overall	0.750	100%

processing vulnerability reports at each individual stage: data collection, IoT vulnerability extraction, and automated rule generation. The IoTShield prototype runs on a commercial desktop computer (Ubuntu 18.04, 8GB of memory, 64-bit OS, with 4-core Intel(R) Core(TM) i7-4790 CPU @ 3.60GHz), indicating that the CPU and memory requirements of IoTShield can be easily met. The IoTShield process runs in a single thread. Table 11 lists the average time cost of each stage of IoTShield for one rule generation. The acquisition of vulnerability reports from the Internet takes 0.386 seconds (51%). Note that this stage requires message transmissions, and the time cost is dependent upon the network conditions. The IoT vulnerability extraction takes 0.154 seconds (21%), while the rule generation costs more time, 0.21 seconds (28%), due to the fact that it needs to establish the dependency tree of the sentence with vulnerability parameters. Overall, the time cost of IoTShield for automatic rule generation is low in practice, and we could further reduce the time cost by running it in multiple threads. The results indicate that IoTShield is efficient and can be easily scaled to a desirable level to handle the massive amounts of vulnerabilities online with a timely update of the defense rules.

**Rule inspection.** To further evaluate the performance of IoTShield in practice, we ran it as one component of an IDS for processing the real-world traffic captured on the edge router of a research institution, which consists of more than 100,000 Internet devices. The amount of traffic is about 53G, and the duration of this traffic collection is about two hours. We replayed the traffic to Snort with and without IoTShield. For the Snort without IoTShield, it costs 426.28 seconds to inspect all the collected packets; for the Snort with IoTShield, it only adds 0.13 seconds for rule inspection over the entire 53G of data, showing that IoTShield induces little overhead to IDSes for online data processing.

## 7 Discussion

**Limitation.** In the data collection, we crawled 13 different websites retrieving 0.4 million reports, and we plan to keep a periodic update in the future. However, we acknowledge that our methods cannot exhaustively collect all IoT vulnerabilities in the wild. Although we believe that we have collected the majority of IoT vulnerabilities in public, other methods

for data collection could also be considered to collect those vulnerabilities recorded in less popular websites, such as personal blogs or social networking logs. For example, since IoT vulnerabilities are usually targeted for some specific devices, we will search product names combined with vulnerability types as query keywords in search engines to crawl more reports.

In addition, although we did observe that the majority (80%) of the malicious HTTP requests are from blind scanings, not targeted at specific IoT devices, we acknowledge that the traffic logs collected by the honeypots could be biased, due to the IoT device types in the honeypots and deployment time periods of the honeypots. Ideally, IoTShield could be deployed in ISPs for a large-scale and real-scenario evaluation. However, we were unable to access ISP data. Alternatively, we performed a real-scenario evaluation based on the traffic we captured from edge routers of a research institution, whose data size is about 114G and the duration is about 12 hours. In this experiment, IoTShield only produced two false positive alerts; considering the substantial data size, the FPR is close to zero.

Since IoTShield deals with generally uncoordinated sources of vulnerability information, it may sometimes face incomplete source information (missing both vulnerability descriptions and structured information, or vulnerability descriptions not containing all vulnerability semantics), even we have used report clustering to supplement the missing information. As mentioned in Section 4.3, we indeed take the problem of incomplete information into serious considerations. For structured information only (about 9% observed in our dataset), we generate an exploit-specific signature that can contribute to the detection of many ongoing attacks. However, we acknowledge that we may miss some exploit variants, which leads to the decrease of recall. For vulnerability description only (about 20% observed in our dataset), we use vulnerability location alone (e.g., “PwGrp.cgi”) as signature for some specific vulnerabilities, which may lead to the increase of false positive rate. In this way, IoTShield can only generate signatures for limited vulnerability types (e.g., information disclosure and directory traversal). A natural follow-up step is to investigate the missing information and explore a systematic information supplement method. We will leave this as our future work.

Also, IoTShield cannot handle the exploits in some specific program languages, and its processing capability is limited to traffic logs, scripts, Linux commands, etc. This is because IoTShield cannot easily generate the general exploit template to identify vulnerability locations and parameters in a different program language. In our future work, we plan to develop a simulation system to execute these programs and generate the attack traffic. Thus, we will be able to produce the attack script in the traffic format (e.g., HTTP request) for whichever program language is used. Moreover, although we did observe a few IoT vulnerabilities in other application layer protocols,

our defense only targets HTTP vulnerabilities, which cover most (90%) of the IoT vulnerabilities we observed in the honeypots and vulnerability reports. In our future work, we plan to cover more vulnerabilities, which exploit other application layer protocols, by extracting vulnerability semantic and structure information based on individual application layer protocol’s domain knowledge.

**Mitigation.** Based on the results of our measurement study, we have identified several potentially effective mitigation strategies to restrain the fast-growing IoT-based attacks. In our study, we observed a large number of vulnerability reports in the wild, which are missed by vendors but exploited by attackers. We also observed the heterogeneity of IoT devices. IoT devices usually do not have an automatic update mechanism and are maintained by device users who may lack security awareness. Thus, the mitigation of an IoT-based attack requires a collaboration among users, vendors, and security researchers.

First, vendors should provide an official vulnerability report platform, and reply to vulnerability reports in a timely manner. In this work, we observed a relatively short duration of public disclosure: report authors usually disclosed the bugs after contacting vendors three times if no reply is received. In addition, vendors are expected to provide technical support for their discontinued products, especially those devices that are still widely used. Since most users lack security awareness, a vendor should increase efforts to avoid misconfiguration and notify these users about updating their devices in a more effective fashion (e.g., using an automatic update mechanism). Second, the authors of vulnerability reports should follow the guidelines for vulnerability reporting, such as a coordinated disclosure. We observed that at least 2,000 vulnerabilities were released before the vendors provided patches. Even worse, some report authors released a disclosure without attempting to contact the vendors or CVE. Finally, device users should pay more attention to the device configuration (e.g., default password) and quickly update vulnerable firmware when a new version becomes available.

**Ethical issues.** One ethical concern is the way by which the security reports were gathered, i.e., scraping various websites. We deployed certain mechanisms to bypass rate limiting and authentication. However, our process follows the robot exclusion protocol (robots.txt) of websites and causes no harm to them or their users. Another ethical concern is that we purchased attack tools on the black market. In our research, we consulted with our Institutional Review Board (IRB) (though no IRB review is required) and legal consul to ensure that the purchase has been done within the legal and ethical boundaries. The purchases did not violate any law and regulation. Also during the process, we refrained from gathering any information not supposed to collect, such as identity-related data.

## 8 Related Work

**Vulnerability-specific signature generation.** Cui et al. [46] presented a system for automatically generating a vulnerability-specific signature (or data patch) for an unknown vulnerability, given a zero-day attack instance. Their system injects the softwares/real devices to generate the variants of attack instances. However, it cannot be easily applied for the IoT vulnerability-specific signature generation, due to the large amount of different IoT device vulnerabilities being covered. Wang et al. [60] proposed a vulnerability-specific network filter, Shield, at an end-system to prevent known vulnerability exploits. Shield requires a manually-generated policy to describe the vulnerability. Specially, it requires a fairly deep understanding of the protocol over which the vulnerability is exploited. It is not acceptable for the IoT vulnerability signature generation, due to the significant amount of manual efforts to generate policies for each IoT device. Brumley et al. [44] proposed data-flow analysis techniques for automatically generating vulnerability-specific signatures. However, it cannot be deployed in IoT vulnerability signature generation, due to the lack of source code. By contrast, IoTShield analyzes the content of more than 7,500 IoT vulnerability reports and recovers key knowledge to generate vulnerability-specific signatures.

**NLP for vulnerability assessment.** Pandita et al. [54] used NLP techniques to analyze Android APP descriptions and API documents for determining unnecessary permissions. Sabottke et al. [55] explored the vulnerability-related information disseminated on Twitter and provided an early warning for the existence of real-world exploits by tweets. Liao et al. [50] presented a novel technique for automatic Indicator-of-Compromise extraction from unstructured text. You et al. [61] proposed leveraging vulnerability-related text (CVE reports and Linux git logs) to guide Linux kernel vulnerability fuzzing. Zhu et al. [62] mined Android documents and security literature to generate features for detecting Android malware. Caselli et al. [45] proposed to automatically mine parameter configuration rules of network control systems (e.g., BACnet-based building automation systems) from system specifications. In contrast to these previous works, we utilize a set of IoT vulnerability reports' syntax features to discover vulnerability-specific knowledge for IDS signature generation to protect IoT from being attacked.

**Vulnerability-related measurement.** Shahzad et al. [58] conducted a large-scale study on the software vulnerability life-cycle based on public vulnerability databases. They utilized association rule mining to extract the relationship between the representative exploitation behavior of hackers and the patching behavior of vendors. Nappa et al. [53] presented a systematic study of patch deployment in client-side vulnerabilities, in order to analyze how users deploy patches. They

found that the patch mechanism has an important impact upon the patch deployment rate. Li et al. [48] performed an extensive study on the effectiveness of vulnerability notifications, with the aim of illuminating which fundamental aspects of notifications have the greatest impact. Li et al. [49] conducted a large-scale empirical study of security patches based on the open-source software projects. They sought to identify the differences between security and non-security bug fixes. Sarabi et al. [56] studied the vulnerability patching by analyzing vulnerabilities across four software products. Their focus is mainly on how individual behaviors influence the security state of an end-host. In contrast to previous works focusing on vulnerabilities in CVE or NVD, our work extensively studies the IoT-related vulnerabilities that are from a large number of vulnerability reports scattered around forums, mailing lists, and blogs, and we further explore the effectiveness of using such reports for IoT vulnerability defense.

## 9 Conclusion

To understand how cybercriminals launch IoT-related attacks, we leveraged honeypots to collect the traces of real-world IoT exploits and analyzed four popular attack toolkits. Our research sheds light on a largely overlooked cause of the pervasiveness of IoT attacks in recent years: IoT vulnerabilities are publicly available and easy to exploit, and today's IoT attacks almost exclusively use known vulnerabilities for mounting malicious attacks. More importantly, our findings lead to the design of IoTShield, a simple yet effective IoT vulnerability-specific signature generation system for intrusion detection. IoTShield first collects 430,000 vulnerability reports from the past 20 years and identifies content of 7,500 IoT vulnerability reports. IoTShield then retrieves key knowledge to generate vulnerability-specific signatures. These signatures can be easily deployed at existing intrusion detection systems or web application firewalls to detect exploit attempts on a target IoT device. Therefore, IoTShield significantly raises the bar for future IoT attacks to succeed.

## Acknowledgments

We are grateful to our shepherd Adwait Nadkarni and anonymous reviewers for their insightful feedback. ## Abstract

Despite the fact that cyberattacks are constantly growing in complexity, the research community still lacks effective tools to easily monitor and understand them. In particular, there is a need for techniques that are able to not only track how prominently certain malicious actions, such as the exploitation of specific vulnerabilities, are exploited in the wild, but also (and more importantly) how these malicious actions factor in as attack steps in more complex cyberattacks. In this paper we present ATTACK2VEC, a system that uses temporal word embeddings to model how attack steps are exploited in the wild, and track how they evolve. We test ATTACK2VEC on a dataset of billions of security events collected from the customers of a commercial Intrusion Prevention System over a period of two years, and show that our approach is effective in monitoring the emergence of new attack strategies in the wild and in flagging which attack steps are often used together by attackers (e.g., vulnerabilities that are frequently exploited together). ATTACK2VEC provides a useful tool for researchers and practitioners to better understand cyberattacks and their evolution, and use this knowledge to improve situational awareness and develop proactive defenses.

## 1 Introduction

Modern cyberattacks have reached high levels of complexity. An attacker who is trying to compromise a computer system has to perform a number of *attack steps* to achieve her goal [16], including reconnaissance (i.e., identifying weaknesses on the victim machine), the actual exploitation, and installing mechanisms to ensure persistence (e.g., installing a remote access trojan (RAT) on the machine [10]). Moreover, getting access to the victim machine might not be enough for attackers to achieve what they want, therefore they might have to perform additional attack steps (e.g., exploiting another vulnerability to escalate privileges [36]). Additionally, for each of the attack steps that compose the attack, attackers have a choice of executing a variety of malicious actions

(e.g., exploiting different known vulnerabilities on the victim system), depending on the exploits that they have available, on the software configuration of the victim machine, and on its security hygiene (i.e., which known vulnerabilities on it have not been patched).

Previous research studied how attack steps (e.g., specific Common Vulnerabilities and Exposures (CVEs) being exploited) evolve and are used in isolation [5, 33, 39]. While doing so is useful to understand how prominently certain attack steps are exploited in the wild, it does not tell us anything on *how* these attack steps are used as part of complex cyberattacks. Instead, looking at attack steps in relation to each other can provide researchers and practitioners with invaluable insights into the *modus operandi* of attackers, highlighting important trends in the way attacks are conducted. In this paper, we define the sequence of attack steps that are commonly performed together with an attack step of interest as its *context*.

Understanding the context in which a vulnerability is exploited in the wild as well as detecting when this context suddenly changes can be very useful for researchers, to better understand the modus operandi of attackers, to improve situational awareness in organizations, and to develop more proactive defenses. For example, when a new CVE is published, attackers will start attempting to exploit it, and in this process they will first try a number of strategies. Eventually, once an attacker will succeed in developing an attack that reliably compromises machines, we will observe this strategy being consistently exploited in the wild, potentially because this consolidated attack was commoditized and added to an exploit kit for multiple attackers to use [12]. This information is useful for defenders, since it allows to design better mitigation strategies that take into account the entire attack, and it can possibly also be used for attack attribution, since the same attacker often uses similar strategies to carry out their attacks [38].

However, attack strategies are not stable over time, because new defenses might be deployed that make them ineffective (e.g., vulnerabilities getting patched), or simply because the

attackers might develop more efficient strategies. Looking at the context of an attack step (e.g., a particular CVE) can help identifying these sudden changes in the way attacks are performed, and prompt proactive defenses. For example, a number of systems have been proposed that use supervised learning to detect attacks [4, 13, 14, 41]. These systems typically need periodic retraining due to the fact that the evolution of attacks over time makes the model that the system was trained on obsolete [18]. Having a system able to track significant changes in the context associated to a security event could be used to perform a timely retraining of such systems.

To model the context of an attack step, in this paper we adapt techniques that have been proposed in the area of natural language processing. Word embeddings [30, 35] are a powerful tool for modeling relationships between words. This technique represents words with low-dimensional vectors based on the surrounding words that appear in the same sentence (i.e., the context). These vectors are able to capture the context of a word and its relationship with the other words, allowing researchers to understand the way in which words are used in various types of language (e.g., on social media [8]). In a similar way, we can calculate the embedding of an attack step by considering the entire attack sequence as a sentence, and each step as a word. Upon encoding the relationship between attack steps within the vector space, we can quantitatively study the attack steps appearing in similar contexts in the latent space and understand them in a more meaningful and measurable way.

As a proxy for the attack steps performed by attackers in the wild, we use the security alerts generated by a commercial Intrusion Prevention System (IPS), collected over a period of two years. Throughout this observation period, we collect 102 snapshots on a weekly basis. Each snapshot contains over 190 million alerts collected from tens of millions unique machines. Each alert is indicative of the attack step that is performed by an attacker, and our dataset contains over 8k possible alert types, spanning from port scans to exploits for specific CVEs. Similar data was used in our previous work, which showed that, although a proxy (e.g., they can only monitor attacks for which a detection signature exists), these alerts are useful to study the behavior of attackers in the wild [40]. In the remainder of the paper, we define each alert generated by the IPS a *security event*.

We implement our approach in a system, ATTACK2VEC. Our system takes a stream of security events and computes their context by using temporal word embeddings. By running ATTACK2VEC on our data, we show that our approach is able to effectively monitor how security events are exploited in the wild. For example, we can identify when a certain CVE starts getting exploited, when its exploitation becomes stable, and when attackers change strategy in exploiting it. By leveraging the similarity between the context of different security events, we can infer which events are often used as part of the same malicious campaign, and this allows us to identify emerging

attacks in a more timely manner than the state of the art. For example, we were able to identify a variant of the Mirai botnet that was scanning the Internet attempting to exploit a CVE relative to Apache Struts, together with IoT-related exploits over 72 weeks before this variant was officially identified. These findings show that ATTACK2VEC can be an effective tool for researchers and practitioners who need to understand how security events are exploited in the wild and react to sudden changes.

In summary, this paper makes the following contributions:

- We show that temporal word embeddings are an effective way to study how attack steps are exploited in the wild and how they evolve.
- We show how ATTACK2VEC can be used to understand the emergence, the evolution, and the characteristics of attack steps in relation to the wider context in which they are exploited.
- We discuss how ATTACK2VEC can be effectively used to identify emerging attack campaigns several weeks before they are publicly disclosed.

## 2 Motivation

This paper presents the first approach to characterize not only single security events, but the context in which they are used in the wild. The problem of characterizing the evolution of security events, however, is a complex one and presents multiple challenges. To illustrate its complexity, consider the real-world example in Figure 1, showing several machines undergoing two coordinated attacks across time,  $C_1$  and  $C_2$ . Both attacks leverage the attack step  $e_{11}$ , “CVE-2018-7602 Drupal core RCE.”  $C_1$ :  $\{e_4, e_{10}, e_{11}, e_{12}\}$  mainly functions as a reconnaissance attack including “Joomla JCE security bypass and XSS vulnerabilities” ( $e_4$ ), “Wordpress RevSlider/ShowBiz security byPass” ( $e_{10}$ ) and “Symposium plugin shell upload” ( $e_{12}$ ), together with  $e_{11}$ .  $C_2$ :  $\{e_7, e_5, e_{11}, e_6\}$ , is an attack targeted at the Drupal ecosystem, consisting of “phpMyAdmin RFI CVE-2018-12613” ( $e_7$ ), “Drupal SQL Injection CVE-2014-3704” ( $e_5$ ), and “Apache Flex BlazeDS RCE CVE-2017-3066” ( $e_6$ ), and the aforementioned  $e_{11}$ . Our goal is to develop a system that allows to automatically analyze the context in which  $e_{11}$  is exploited, and identify changing trends.

The first challenge that we can immediately notice from Figure 1 is that even though the machines at a certain timestamp are going through the same type of attack (e.g.,  $C_1$  at  $t_i$ ), there are no obvious event relationships reflected in the telemetry recorded by the IPS due to noise (e.g., other security events not related to the coordinated attack observed, or certain events relating to the coordinated attack being not observed). If we take the IPS data recorded at timestamp  $t_i$ , it is not trivial to understand how  $e_{11}$  is leveraged by the attackers by directly inspecting the security events, what attack vectors

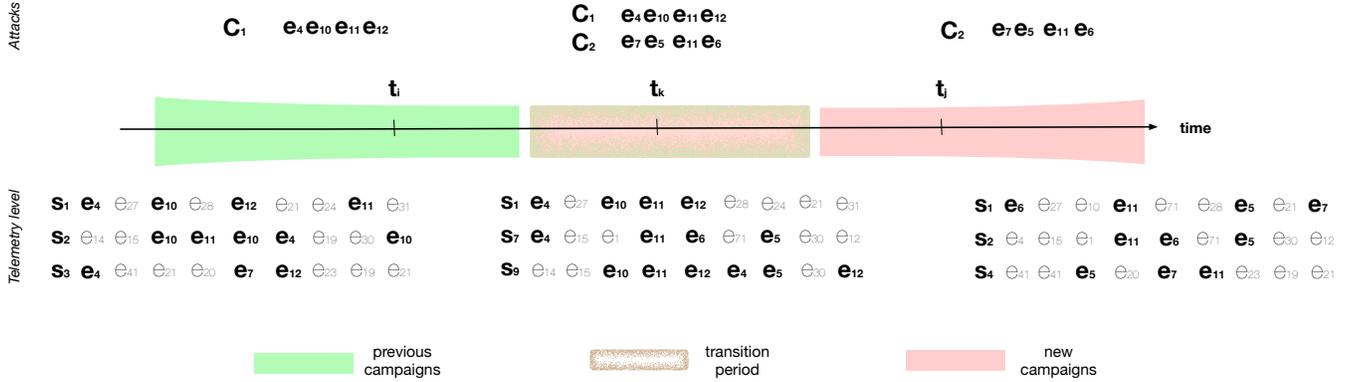

Figure 1: A real-world example of security event evolution. Over time,  $e_{11}$  evolves from being an “add-on” reconnaissance vector to part of a targeted attack on the Drupal ecosystem.

are used together with  $e_{11}$ , etc. Additionally, it is worth noting that not all security events may be observed in a given observation period. For example,  $e_7$  is not observed until timestamp  $t_j$ .

The second challenge is that attacks change over time, consequently, the context of a security event and its relationship with other attack steps may drift. It is possible that  $C_1$  and  $C_2$  can be operated by the same attackers, and that at some point they changed their attack scripts to leverage newly disclosed vulnerabilities (i.e., , phpMyAdmin RFI CVE-2018-12613 ( $e_7$ )). As we can see in Figure 1, from timestamp  $t_i$  to  $t_j$  attack  $C_1$  gradually migrated to or was replaced by attack  $C_2$ . However, it is difficult to determine if these new relationships (e.g.,  $e_{11}$  starting to appear in close proximity of  $e_5$ ) at timestamp  $t_k$  with respect to those of timestamp  $t_i$  are due to noise or are actually indicators of a change in the way  $e_{11}$  is being used in the wild. Considering all these temporal factors, it is desirable to have a model that is able to understand the context of a security event and its changes over time, and whose output can be quantitatively measured and studied. This is what ATTACK2VEC aims to do.

**Problem formulation.** We formalize our temporal security event evolution approach as follows. A security event  $e_i \in \mathcal{E}$  is a timestamped observation recorded at timestamp  $i$ , where  $\mathcal{E}$  denotes the set of all unique events and  $|\mathcal{E}|$  denotes the size of  $\mathcal{E}$ . A security event sequence observed in an endpoint  $s_j$  is a sequence of events ordered by their observation time,  $s_j = \{e_1^{(j)}, e_2^{(j)}, \dots, e_l^{(j)}\}$ . Let  $\mathcal{S}_t = \{s_1^t, \dots, s_i^t, \dots, s_z^t\}$  denote the set of the security events from  $z$  endpoints during the  $t$ -th observation period. Finally we denote  $\mathcal{S} = \{\mathcal{S}_1, \dots, \mathcal{S}_t, \dots, \mathcal{S}_T\}$ ,  $t = 1, \dots, T$ , as the total security events over time  $T$ . It is worth noting that not all security events may be observed in a given  $\mathcal{S}_t$ . For example, security events associated with CVEs reported in 2018 are not present in the set of security events collected in 2017. Our goal is to find a mapping function  $\mathcal{M}(e_i, \mathcal{S}, T) \rightarrow \{\eta_{e_i}^t\}$ , where  $t = 1, \dots, T$  and  $\eta_{e_i}^t \in \mathbb{R}^d$ ,  $d \ll |\mathcal{E}|$  denotes a  $d$ -dimensional vector representation of the security

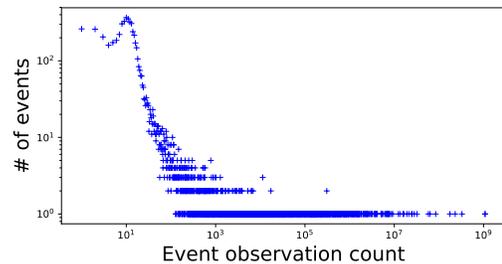

Figure 2: The distribution of events in our IPS security event dataset follows a power-law, much like the distribution of words in natural language, confirming the appropriateness of word embeddings to study the evolution of the use of security events over time.

event  $e_i$  at timestamp  $t$ . In the next section, we describe the data used in this paper in more detail. Then, in Section 4 we describe the methodology used by ATTACK2VEC.

### 3 Dataset

**Data origin.** As a proxy for the attack steps performed by miscreants in the wild, we use security event data collected from Symantec’s intrusion prevention system (IPS). The company offers end users to explicitly opt in to its data sharing program to help improving its detection capabilities. To preserve the anonymity of users, endpoint identifiers are anonymized and it is not possible to link the collected data back to the users that originated it. Meta-information associated with a security event is recorded when the product detects network-level or system-level activity that matches a predefined signature (i.e., a security event).

**Data collection.** To thoroughly investigate security event evolution, we collected 102 days (one observation day per week for 102 consecutive weeks) of data between December 1, 2016 and November 08, 2018. From this data we extract the

following information: anonymized machine ID, timestamp, security event ID, event description, system actions, etc. On average, we collect 190 million security events collected from tens of millions unique machines per day. These security events were then reconstructed on a per machine basis and sorted chronologically. Note that for privacy reasons we use the anonymized endpoint ID to reconstruct a series of security events detected in a given machine and discard it after the reconstruction process is done. In total, the monitored machines generated 8,087 unique security events over the 102 observation days.

**Data Limitations.** It is important to note that the security event data is collected passively. That is, these security events are recorded only when corresponding attack signatures are triggered. Any events preemptively blocked by other security products cannot be observed. Additionally, any events that did not match the predefined signatures are also not observed. Hence the findings in this paper reflect security event evolution observed by Symantec’s IPS, and the data can only be considered as a proxy for the actual attacker behavior in the wild. For example, we are unable to trace how zero day attacks are exploited in the wild [5]. However, as we show in Section 5 this data still allows ATTACK2VEC to identify meaningful trends in how security events are used and evolve. Additionally, ATTACK2VEC could be applied to any dataset with similar characteristics (i.e., a sequence of security events). Another limitation is that our dataset is composed of weekly snapshots, and we are therefore unable to characterize the evolution of security events that are faster than that. While this could prevent us from detecting quick anomalies in the way security events are used (i.e., those that go back to “normal” in a matter of a few days), this data is still representative enough to identify long term trends. We provide a more detailed discussion on the limitations of our data in Section 6.

**Appropriateness for word embeddings.** As we mentioned, the word embedding techniques used by ATTACK2VEC come from the natural language processing field. Word frequency in natural language follows a power-law distribution, and techniques from language modeling account for this distributional behavior. For these techniques to be appropriate to our data, therefore, it is ideal that our security events follow a similar distribution. Figure 2 shows that the events in our dataset indeed follows a power-law distribution. This similarity forms a solid theoretical foundation for us to use word embedding techniques to encode latent forms of security events, by considering sequences of security events in the IPS logs as short sentences and phrases in a special language. In the next section, we describe how ATTACK2VEC builds temporal embeddings from a sequence of security events in detail.

## 4 Methodology

In this section we first define the context window used in this work. We then formalize the techniques used to generate

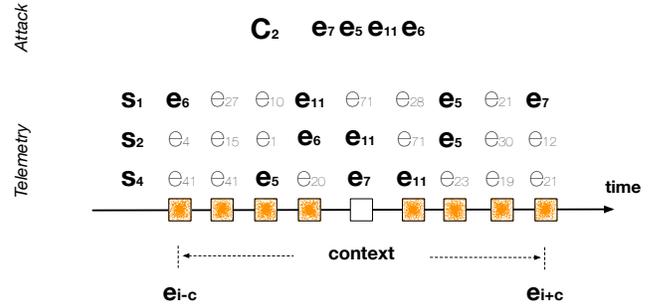

Figure 3: Illustration of context window ( $c = 4$ ).

vector embeddings of security events. Finally, we describe ATTACK2VEC’s architecture.

### 4.1 Context Window

Previous research made several interesting observations that different attack vectors are often packed together by attackers for a given period of time. For example, Kwon *et al.* [21] observed that silent delivery campaigns exhibit synchronized activity among a group of downloaders or domains and access the same set of domains to retrieve payloads within a short bounded time period. Shen *et al.* [40] pointed out that some machines may potentially observe different attacks from various adversary groups happening at the same time, and one coordinated attack may be observed by different machines. On the defense side (i.e., IPS telemetry), we consequently observe that related security events co-occur within a context (i.e., the sequence of attack steps that are commonly performed together with an attack step of interest). Note that this context can be defined as a time window [21] or a rollback window [40].

In this paper, we define the context as a sliding window, denoted as  $c$ , centering around a given security event  $e_i$  (see Figure 3). The purpose of using this symmetric context window is to deal with the noise incurred by concurrency at the telemetry level (see Section 2). For example, given a real-world coordinated attack  $e_7, e_5, e_{11}, e_6$  (highlighted in bold in Figure 3), each endpoint may observe the attack vectors in different order (e.g.,  $e_7$  and  $e_5$  may switch orders), attack vectors might be diluted by other unrelated security events (e.g.,  $e_{71}$  observed between  $e_6$  and  $e_5$  in  $s_2$ ), or certain security events are not observed, for example because they have been blocked by other security products before the IPS was able to log them (e.g.,  $e_6$  not observed in  $s_4$ ). The proposed context window mechanism is able to capture the events surrounding a given security event (i.e., before and after), minimizing the impact of noise incurred by concurrency.

## 4.2 Temporal Security Event Embedding

The proposed temporal security event embedding is adapted from dynamic word embeddings by Yao *et al.* [48]. We use pointwise mutual information (PMI), a popular measure for word associations, to calculate weights between two security events given a contextual window  $c$  and an observation period  $t$ . PMI measures the extent to which the events co-occur more than by chance or are independent. The assumption is that if two events co-occur more than expected under independence there must be some kind of relationship between them. For each  $t$ -th observation period, we build a  $|\mathcal{E}| \times |\mathcal{E}|$  PMI matrix, where a PMI value between  $e_i$  and  $e_j$  is defined as follows.

$$\begin{aligned} PMI_t(e_i, e_j, c, \mathcal{S}) &= \max\left(\log\left(\frac{p_t(e_i, e_j)}{p_t(e_i)p(e_j)}\right), 0\right), \\ p_t(e_i, e_j) &= \frac{W(e_i, e_j)}{|\mathcal{S}_t|}, \\ p_t(e_i) &= \frac{W(e_i)}{|\mathcal{S}_t|}, \end{aligned} \quad (1)$$

where  $W(e_i)$  and  $W(e_j)$  respectively count the occurrences of security events  $e_i$  and  $e_j$  in  $\mathcal{S}_t$ , and  $W(e_i, e_j)$  counts the number of times  $e_i$  and  $e_j$  co-occur within a context window (see Figure 3, Section 4.1) in  $\mathcal{S}_t$ . Note that when  $W(e_i, e_j)$ , the number of times  $e_i$  and  $e_j$  co-occurring in a given contextual window is small,  $\log\left(\frac{p_t(e_i, e_j)}{p_t(e_i)p(e_j)}\right)$  can be negative and affects the numerical stability. Therefore, we only keep the positive values in Eq 1 (see [22]).

Following the definition of  $PMI_t$ , the security event embedding  $H(t)$ , e.g.,  $\eta_{e_i}^t \in H(t)$ , at  $t$ -th observation time is defined as a factorization of  $PMI_t(c, \mathcal{S})$ ,

$$H(t)H(t)^T \approx PMI_t(c, \mathcal{S}). \quad (2)$$

The denser representation  $H(t)$  reduces the noise [37] and is able to capture events with high-order co-occurrence (i.e., that appear in similar contexts) [30, 35]. These characteristics enable us to use word embedding techniques to encode latent forms of security events, and interpret the security event evolution in a meaningful and measurable way. Note that Li *et al.* [25] and Levy *et al.* [22] have theoretically proven that the skip-gram negative sampling (SGNS) used by the word2vec model can be viewed as explicitly (implicitly) factorizing a word co-occurrence matrix. We refer interested readers to [22, 25] for theoretical proofs.

Across time  $T$ , we also require that  $\eta_{e_i}^t \approx \eta_{e_i}^{t+1}$ . This means that the same security event should be placed in the same latent space so that their changes across time can be reliably studied. This requirement roots upon a practical implication. For example, a security event was observed after its associated CVE was disclosed. Its embeddings must therefore approximately stay the same before the disclosure date. Otherwise,

we would observe unwanted embedding changes and invalidate the findings. To this end, Yao *et al.* [48] identified the solution of the following joint optimization problem as the temporal embedding results. Note that throughout this section,  $\|\cdot\|$  denotes squared Frobenius norm of a vector.

$$\begin{aligned} \min_{H(1), \dots, H(T)} & \frac{1}{2} \sum_{t=1}^T \|PMI_t(c, \mathcal{S}) - H(t)H(t)^T\|_2 \\ & + \frac{\alpha}{2} \sum_{t=1}^T \|H(t)\|^2 + \frac{\beta}{2} \sum_{t=1}^T \|H(t-1) - H(t)\|^2, \end{aligned} \quad (3)$$

where  $\alpha$  and  $\beta$  are parameters respectively regularizing  $H(t)$ , and making sure that  $H(t-1)$  and  $H(t)$  are aligned (i.e., embeddings should be close if their associated contexts don't change between subsequent times.). In this way, all embeddings across time  $T$  are taken into consideration. At the same time, this method can accommodate extreme cases such as the one in which security event  $e_i$  is not observed in  $(\mathcal{S})_t$  since the optimization is applied across all time slices in Eq 3. We refer interested readers to [48] for theoretical proofs and empirical comparison studies with other state-of-the-art embedding approaches. Following [48], we use grid search to identify the best parameters and experimentally set  $\alpha = 10$ ,  $\beta = 40$ ,  $c = 8$ ,  $d = 50$  and run 5 epochs for all the evaluations throughout our paper.

## 4.3 ATTACK2VEC Architecture

The architecture and workflow of ATTACK2VEC is depicted in Figure 4. Its operation consists of three phases: ① data collection and preprocessing, ② temporal event embedding, and ③ event tracking and monitoring.

**Data collection and preprocessing (①).** ATTACK2VEC takes the security event stream generated by endpoints (e.g., computers that installed an IPS). The goal of the data collection and preprocessing module is to prepare the data for the temporal event embedding method detailed in Section 4.2. ATTACK2VEC then consumes this timestamped security event data generated from millions of machines that send back their activity reports. The collection and preprocessing module reconstructs the security events observed on a given machine  $s_j$  as a sequence of events ordered by timestamps, in the format of  $s_j = \{e_1^{(j)}, e_2^{(j)}, \dots, e_l^{(j)}\}$ . The output of the data collection and preprocessing module is  $\mathcal{S}_t = \{s_1^t, \dots, s_l^t, \dots, s_z^t\}$  where  $z$  denotes the number of machines.

**Temporal event embedding (②).** The core operation of ATTACK2VEC is embedding these security events into a low dimensional space over time. This phase takes  $\mathcal{S}$  as input and encodes latent forms of security events, by considering sequences of security events in the IPS logs as short sentences and phrases in a special language. In this way, each security

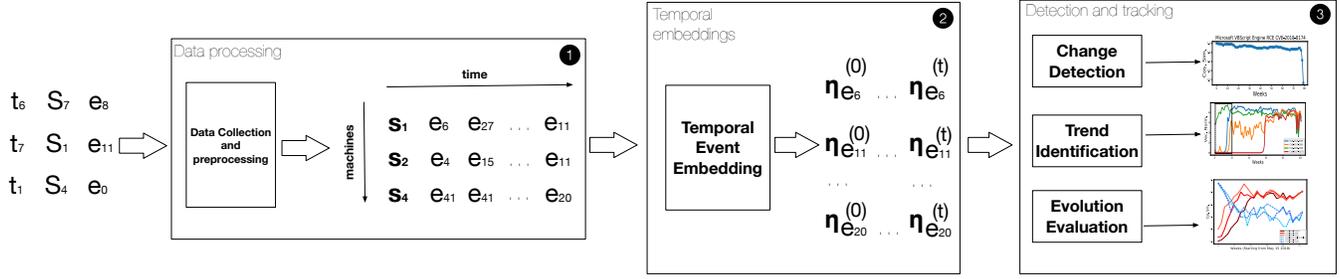

Figure 4: ATTACK2VEC's Architecture.

event, at a timestamp  $t$ , is represented by a  $d$ -dimensional vector representation  $\eta_{e_i}^t$ , and later aligned across time.

**Detection and monitoring (⊗).** Once the security events are encoded in low-dimensional space, ATTACK2VEC is able to use various metrics (Section 5.1) to detect changes (Section 5.2), identify event trends (Section 5.3), and monitor how security events are exploited in the wild (Section 5.4) in a measurable and quantifiable way.

## 5 Evaluation

In this section, we provide a thorough evaluation of temporal event embeddings and ATTACK2VEC. We designed a number of experiments that allow us to answer the following questions:

- Can we use the temporal embeddings calculated by ATTACK2VEC to identify changes in how a security event is used in the wild (see Section 5.2)? To this end, we need our temporal embeddings to present high fidelity over time. The rationale behind this question is that the same security event should be placed in the same latent space by the proposed temporal event embedding method (see Section 4). Their changes across time can be reliably studied (see Section 5.6).
- Can we leverage temporal embeddings to identify trends in the use of security events (see Section 5.3)? The rationale behind this evaluation is that embedding vector norms across time should be more robust to the changes than word frequency which is static (i.e., calculated at a specific point of time) and sporadic.
- Can we leverage temporal embeddings to meaningfully understand the evolution of security events, and monitor how security events are exploited in the wild (see Section 5.4)?

In the following, we first define the metrics used by our evaluation. We then proceed to show that ATTACK2VEC is effective in answering these three research questions, and discuss the performance of our approach, showing that ATTACK2VEC is able to process a day of data within minutes. Finally, we

present further evaluation of ATTACK2VEC, showing an end-to-end case on how our system can be used to assess the evolution in the use of a specific vulnerability in the wild.

### 5.1 Evaluation Metric

We use *cosine similarity* as the distance metric to quantify the temporal embedding changes at time  $t$  in the latent space. That is, for any two embeddings (i.e.,  $\eta_{e_i}^{(t)}$  and  $\eta_{e_j}^{(t)}$ ), the similarity is measured as

$$\text{similarity}(\eta_{e_i}^{(t)}, \eta_{e_j}^{(t)}) = \frac{\eta_{e_i}^{(t)T} \eta_{e_j}^{(t)}}{\|\eta_{e_i}^{(t)}\|_2 \|\eta_{e_j}^{(t)}\|_2}. \quad (4)$$

Note that in this paper the cosine similarity is used in positive space, where the outcome is bounded in  $[0, 1]$ . That is, two vectors with the same orientation have a cosine similarity of 1 (most similar), two vectors oriented at  $90^\circ$  relative to each other have a similarity of 0 (not similar).

Following Eq 4, we denote the *neighborhood* of a security event embedding  $e_i^{(t)}$  as  $\mathcal{N}(e_i^{(t)})$ , and accordingly defined as

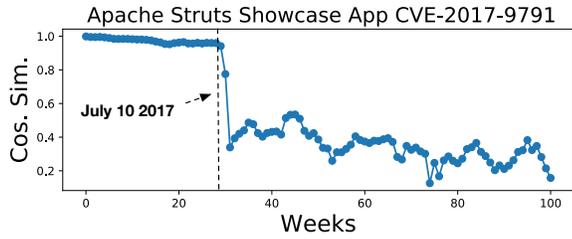

$$\mathcal{N}(e_i^{(t)}) = \text{argsort}_{e_j^{(t)}}(\text{similarity}(e_i^{(t)}, e_j^{(t)})). \quad (5)$$

$\mathcal{N}(e_i^{(t)})$  enables us to use temporal embeddings to discover and analyze how different security events are used together with  $e_i$ . We use  $\mathcal{N}_k(e_i^{(t)})$  to denote the top  $k$  closest neighbors of  $e_i$ . As we show in Section 5.4, this can be used to identify security events that are frequently used together as part of a multi-step attack.

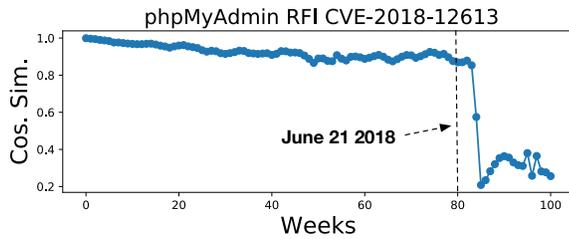

We also use a *weighted drift* metric to measure a security event *relative* changes. This metric is defined in Eq 6 as

$$\text{weighted\_drift}(e_i) = \text{argsort}_t \left( \frac{\|\eta_{e_i}^{(t-1)}, \eta_{e_i}^{(t)}\|}{\sum_{e \in \mathcal{E}} \|\eta_e^{(t-1)}, \eta_e^{(t)}\|} \right). \quad (6)$$

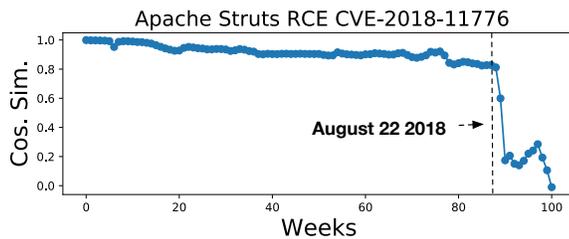

Eq 6 normalizes a security event's embedding change by the sum of all security event changes within that observation period. This metric enables us to measure how a security event changes comparing to the other security events within a given observation point.

(a) CVE-2017-9791 disclosure date: July 10 2017

(b) CVE-2018-12613 disclosure date: June 21 2018

(c) CVE-2018-11776 disclosure date: August 22 2018

Figure 5: Temporal embedding results of “Apache Struts Showcase App CVE-2017-9791” (5a), “phpMyAdmin RFI CVE-2018-12613” (5b), and “Apache Struts RCE CVE-2018-11776” (5c). The cosine similarities of the CVE embeddings are stable before they are publicly disclosed, and decline swiftly after the disclosure.

## 5.2 Change Detection

One of the key practical questions when evaluating the temporal security event embeddings built by ATTACK2VEC is determining the fidelity of the embedding results over time. In this paper, fidelity refers to the condition that the same security event should be placed in the same latent space. That is, if the frequency and the contexts of a security event between subsequent time slices don’t change, its latent embedding should stay the same. This consistency allows the change to be reliably detected. This requirement lays the foundation to quantitatively study their changes. The concept of fidelity is different from the stability term used in previous research approaches in which stability was used to evaluate how classifiers perform after certain period of time. Bearing this difference in mind, we use the following two criteria to evaluate the fidelity of temporal embeddings and show how ATTACK2VEC can faithfully capture both single event usage

change and global changes:

- **criterion a.** The cosine similarity of the event embeddings must be stable when an event usage does not change between subsequent time slices.
- **criterion b.** The cosine similarity of these embeddings should change swiftly if these events are used in different attacks or emerge as a new attack vector.

It is important to note that while these criteria are helpful in demonstrating the power of word embeddings extracted by ATTACK2VEC, they are self-referential and not in themselves sufficient to validate the effectiveness of our approach.

**Single event change detection.** To evaluate whether our two criteria hold for our dataset, we use three CVEs, “Apache Struts Showcase App CVE-2017-9791” (Figure 5a), “phpMyAdmin RFI CVE-2018-12613” (Figure 5b), and “Apache Struts RCE CVE-2018-11776” (Figure 5c). These CVEs were disclosed between 2017 and 2018. Regarding the aforementioned two evaluation criteria, these vulnerabilities were not disclosed in 2016, and therefore they did not have a matching signature in the IPS from which we collected our data. Thus, they form a good baseline for temporal fidelity evaluation. We therefore expect the following properties to hold:

**response to a.** Before a vulnerability was disclosed, its corresponding signature does not exist hence its non-existent context should stay the same until timestamp  $t$ . That is, if the vulnerability’s disclosure date is  $t$ ,  $similarity(\eta_{e_i}^{(0)}, \eta_{e_i}^{(z)})$ , where  $z \in (0, t]$ , should be stable.

**response to b.** After the disclosure date, the cosine similarity values of its embeddings should change swiftly. The justification is obvious. If attackers start exploiting a vulnerability, its corresponding security event moves away from its non-existent context and such drift leads to embedding changes.

For each CVE, we calculate the cosine similarity between each event’s current representation (i.e., at timestamp  $t$ ) and its *original* representation (i.e., at timestamp 0, on December 1 2016) over our observation period (i.e.,  $similarity(\eta_{e_i}^{(0)}, \eta_{e_i}^{(t)})$ , where  $t = 1..T$ . See Eq 4). The results are shown in Figure 5. As we can observe, the temporal embeddings of CVE-2017-9791, CVE-2018-12613 and CVE-2018-11776 are stable across time and their cosine similarity values are above 0.9 before their respective disclosure dates (see **criterion a**). The way to interpret **criterion a** is that before a vulnerability is disclosed, its corresponding signature does not exist, and therefore its context is *non-existing*. As such, this context should remain constant until the vulnerability starts being exploited in the wild. Figure 5a shows that the cosine similarity between the embeddings of CVE-2017-9791 calculated daily and the original one recorded on

day 0 is stable and above 0.95 before July 10 2017, which is when the vulnerability was disclosed. Note that the similarity is not strictly 1.0 because of marginal deviation incurred by joint optimization across time slices (see Eq 3). Nevertheless, the high similarity before the disclosure date shows that ATTACK2VEC obtains correct temporal embeddings. After their public disclosure of each CVE, on the other hand, we expect the context in which each vulnerability is exploited to quickly change. This can be measured by ATTACK2VEC with the fact that the cosine similarity values of CVE-2017-9791, CVE-2018-12613, and CVE-2018-11776 decline quickly and move away from the original non-existing context built for those CVEs (see **criterion b**). This phenomenon exemplifies that the temporal embeddings capture the changes in the context in which a security event is used.

It is also worth noting that the temporal embeddings of CVE-2018-11776 show an immediate change after disclosure, while those of CVE-2018-12613 are slightly delayed for a couple of weeks (i.e., CVE-2018-12613 was officially published on June 21 2018 and the embedding starts to drift on July 12 2018). This phenomenon, i.e., the gap between public disclosure dates and real world exploits was well discussed in Sabottke *et al.* [39], and ATTACK2VEC allows to easily observe it.

The temporal embeddings generated by ATTACK2VEC not only allow us to identify when a vulnerability starts being exploited in the wild, but also how these event embeddings change after the disclosure date. To monitor and evaluate these changes, instead of comparing the context of a security event with the one extracted from the first day of observation, we compare the cosine similarity of the contexts extracted on subsequent time slices – between each event’s current representation (i.e., at timestamp  $t$ ) and its previous representation (i.e., at timestamp  $t - 1$ ). In short, we calculate  $similarity(\eta_{e_i}^{(t)}, \eta_{e_i}^{(t-1)})$  (see Eq 4), which enables us to capture how the context of each event evolves between two subsequent observations. If the use of an event remains stable, the cosine similarity between  $\eta_{e_i}^{(t)}$  and  $\eta_{e_i}^{(t-1)}$  will remain high. If, on the other hand, the event experiences a sudden change in the way it is used in the wild, then its context will also significantly change and the cosine similarity with the previous observation will suddenly decrease, allowing an analyst to identify the point in time in which this change happened. To demonstrate this, we reuse the security event “Apache Struts Showcase App CVE-2017-9791” from earlier in this section. We calculate the cosine similarity between subsequent snapshots, where  $t_0$  starts from July 10 2017 (the public disclosure date). This evolution is depicted in Figure 6.

We can observe the following: ❶ The cosine similarity values decline for the first three weeks. This phenomenon implies that CVE-2017-9791 started being exploited in different attacks after its disclosure date, with attackers trying different strategies to reliably exploit this vulnerability. ❷ the cosine similarity increases between the 3rd week and the 10th week.

This phenomenon implies that CVE-2017-9791 became being exploited in less diversified attacks, indicating that attackers were converging towards a stable way to exploit the CVE. ❸ The cosine similarity stabilizes after the 10th week, which means that CVE-2017-9791 started being exploited in a *stable* context. This could indicate that attackers weaponized the CVE into a reliable attack, and possibly developed methods to exploit it at scale (e.g., by including it in an exploit kit). Later in the timeline, we can see other changes in the way in which attacks are exploited, but after each sudden change we observe a stabilization in how the CVE is exploited, indicating that attackers keep the same modus operandi over long periods of time.

A possible concern is that the changes in context identified by ATTACK2VEC might be due to noise and not representative of actual changes in the modus operandi of attackers. To demonstrate that this is not the case, we use the event co-occurrence matrix  $PMI_t(c, \mathcal{S})$  as defined in Section 4. This matrix captures the co-occurrence of any two events within the context window. For each observation time  $t$ , we select the top events that co-occurred with CVE-2017-9791 to better understand the phenomenon. If the changes in the use of a CVE identified by ATTACK2VEC are meaningful, we expect the co-occurrence matrix on that day to suddenly change, but to later stabilize and remain similar over time. For the first three weeks after disclosure in Figure 6 (❶), CVE-2017-9791 was used in conjunction with known attack vectors such as Apache Struts RCE CVE-2013-2251, HTTP Apache Tomcat UTF-8 dir traversal CVE-2008-2938, and malicious OGNL expression upload. By the third week, while some attack vectors were still associated with CVE-2017-9791, the vulnerability gradually started being used together with more recent server attack vectors (e.g., Apache Struts RCE CVE-2016-3087) and application vulnerabilities (e.g., WebNMS RCE CVE-2016-6603 and Web CMS Think PHP RCE). After ❷, CVE-2017-9791 started being used consistently with the aforementioned attack vectors and with several additional attack vectors (e.g., Apache Struts dynamic method invocation RCE CVE-2016-3081, Drupal PHP RCE, and generic PHP REC) Once CVE-2017-9791 reached ❸, its usage patterns became reasonably stable. Note that small fluctuations still happen when new Apache Struts related vectors were disclosed and exploited (e.g., Apache Struts CVE-2017-9805 (week 11), CVE-2017-12611 (week 15) and CVE-2017-12617 (week 21), and temporary withdrawn of CVE-2017-12617 (around week 45) in the attacks. These changes are reliably detected by ATTACK2VEC.

In summary, our method is able to capture changes in the security event embeddings with high fidelity.

**Global change detection.** Recall that temporal event embeddings are the solution of a joint optimization problem across all time slices (see Section 4). Therefore, such embeddings not only encode their respective usage and context in a given time slice, but also its history across all time slices. In this

Table 1: Top 5 events with most usage changes in selective dates.

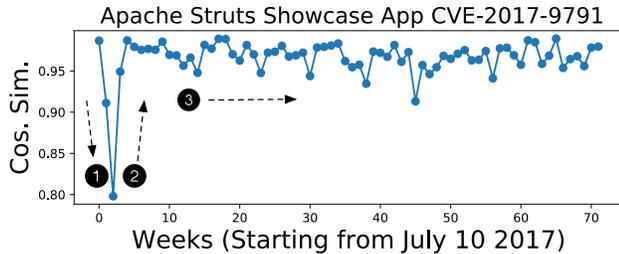

Figure 6: Temporal embedding result of Apache Struts Showcase App CVE-2017-9791. Cosine similarity values for each plot is calculated as  $similarity(\eta_{e_i}^{(t-1)}, \eta_{e_i}^{(t)})$  (i.e., cosine similarity between subsequent time slices), where  $t$  starts from July 10 2017 (the public disclosure date).

section, we show how to leverage the temporal embeddings generated by ATTACK2VEC to find times where we observe an anomalous high number of changes in the use of multiple security events.

ATTACK2VEC computes a list of changes for each security event  $e_i$  in all time slices using the weighted drift metric (see Eq 6). We use this to identify the observation periods in which many security events exhibit most usage changes. These points are interesting candidates for scrutiny for security analysts, since multiple changes in word embeddings might indicate the emergence of new pervasive attacks. Note that we remove all the security events with less than 100 observations in 2 years time (see Section 6 for a rationale for this). Figure 7 shows a histogram of the time slices in which security event usage changes most. As we can see, we observe 34 security events with most usage changes between October 11 and October 18 2018. We selectively list the top 5 events with most usage changes in different dates (see Table 1). These changes demonstrate how security event evolve over the time. For example, at the beginning of 2017, we can observe many changes relating to exploits affecting routers. This can be an indicator of a large attack campaign targeting such devices unfolding. Across time, more attacks change over fake tech support websites, coinminer and content management systems. This context information is usually for analysts to improve situational awareness and be promptly warned about emerging attacks.

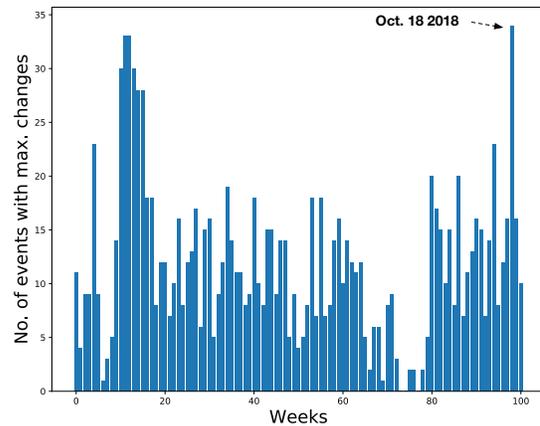

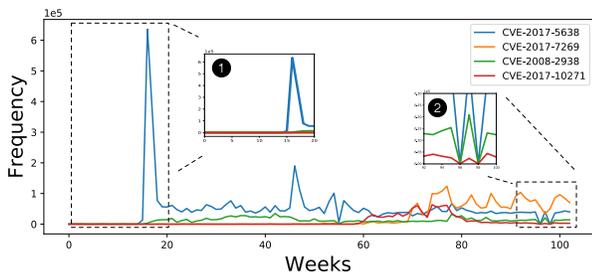

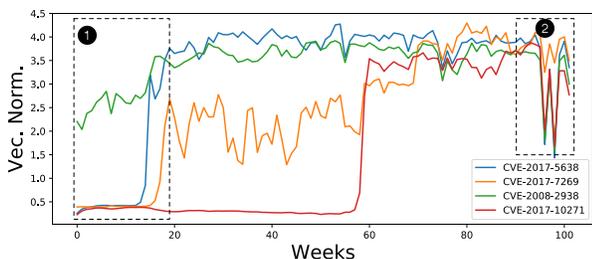

Figure 7: Summary of the security event changes between December 1 2016 and November 15 2018.

### 5.3 Trend Identification

One *de facto* method used in empirical studies [5, 24, 32, 46] to analyze temporal usage changes is leveraging frequencies to reveal patterns. That is, previous approaches often start by determining the occurrence frequency of events across the data, and using the event frequency time series as a criterion to reveal the significance of these events. Despite its straightforwardness in analyzing and visualizing temporal data, one drawback of this approach is that frequencies are prone to noise because they are only counted at a specific timestamp. Another drawback of using temporal frequency, especially in practical analysis, is that it is more difficult to compare two time series when they are both trending but at a different magnitude, and a sudden spike in the occurrence of one security event might make it difficult to identify other important events that are not happening as frequently. To demonstrate this problem, we use four popular remote Web server attack vectors (see Figure 8a). We can observe in Figure 8a (inset 1), that Apache Struts CVE-2017-5638 (blue line) was overwhelmingly exploited by attackers after it was disclosed. Its preponderant usage overshadows (see the zoom region inset 1 in Figure 8a) the other popular remote Web server attack vectors (e.g., HTTP Apache Tomcat UTF-8 Dir

(a)

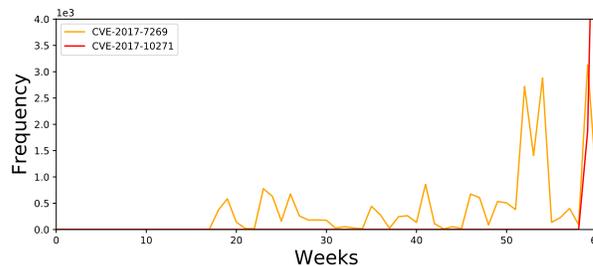

(b)

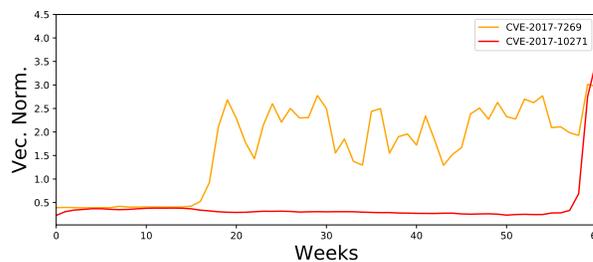

Figure 8: Event frequencies (8a) and event embedding vector norms (8b). We select four CVEs relating to different Web services to demonstrate the robustness of temporal event embedding in trend changes (CVE-2008-2938 in green line, CVE-2017-5638 in blue line, CVE-2017-10271 in red line, and CVE-2017-7269 in orange line). The dashed box highlights the observation period discussed in Section 5.3.

Traversal CVE-2008-2938) when using event frequency time series to comparatively study attack vector popularity.

In the rest of this section, we demonstrate that the word embeddings calculated by ATTACK2VEC are more robust than temporal frequencies to reveal trend changes. Recall the definition of  $PMI_i(c, S)$  (defined in Section 4). It contains information from  $W(e_i, e_j)$ , the number of times  $e_i$  and  $e_j$  co-occurring in a given contextual window, and  $W(e_i)$  and  $W(e_j)$  respectively count the occurrences of security events  $e_i$  and  $e_j$ . The norms of word embeddings  $\eta_{e_i}$ , as a consequence of matrix factorization of  $PMI_i(c, S)$ , grow with word frequency and are averaged by their contexts. Therefore, we can leverage these norms to identify event usage trends. We compare temporal frequencies (Figure 8a) to the embedding vector norm (Figure 8b) in the context of trend identification. It is straightforward to see that the security event “Apache Struts CVE-2017-5638” was predominantly leveraged by the attackers for a short period of time. As we said, such sudden spike makes other trendy CVEs used at that same period of time less detectable (Figure 8a). However, we can see that the temporal event embeddings (Figure 8b) reveal the real patterns behind the frequencies, and are able to capture trends more reliably. For example, we can clearly see in Figure 8b that CVE-2008-2938 (“HTTP Apache Tomcat UTF-8 Dir Traversal,” green

(a)

(b)

Figure 9: Comparison study of CVE-2017-7269 (orange line) and CVE-2017-10271 (red line). ATTACK2VEC can trace the emerging popularity of CVE-2017-7269 even though it is barely observable in Figure 8.

line in Figure 8a) is a persistent vector used by the attackers. This was not observable in Figure 8a because CVE-2017-5638 dominates during that period of time. Nevertheless, it is worth noting that we study the independent popularity of these attack vectors and reveal their underlying usage trend beneath the event frequency time series. Hence in this paper we do not intend to study how such attack vectors influence each other. It is coincidental that the red (CVE-2017-10271) and green (CVE-2008-2938) lines show a similar vector norm shift. In fact, these vector norm shifts were incurred by their similar usage changes (e.g., dropping close to zero) during the same period (see inset 2, Figure 8a). ATTACK2VEC still preserves the trends of red (CVE-2017-10271) and green (CVE-2008-2938) lines (i.e., larger than zero) in this extreme case and their respective vector norms become stable immediately after.

Our temporal embedding can also capture how two CVEs, CVE-2017-10271 (“Oracle WebLogic RCE,” red line in Figure 8a) and CVE-2017-7269 (“Buffer overflow in the ScStoragePathFromUrl function in the WebDAV service in IIS 6.0,” orange line in Figure 8a) gradually emerge as a trendy attack vector over time. That is, both CVE-2017-10271 (red line) and CVE-2017-7269 (orange line), before their disclosure dates (May 27, 2017 and Oct 17, 2017), are flat. This proves that ATTACK2VEC faithfully captures their non-existent trend. After their disclosure, ATTACK2VEC is able to correctly keep track of their trends. For example, in Figure 9 we show that

Drupal core RCE (CVE-2018-7602)	
May 15 2018	Nov. 08 2018
Joomla JCE Vulnerability	phpMyAdmin RFI (CVE-2018-12613)
Wordpress RevSlider/ShowBiz Bypass (CVE-2014-9735)	Drupal SQL Injection (CVE-2014-3704)
WordPress Symposium Plugin Shell Upload	Adobe Flex BlazeDS RCE (CVE-2017-3066)

Table 2: Top 3 security events associated with CVE-2018-7602 at the beginning (May 15 2018) and the end (November 18 2018) of our time span.

our approach can reliably trace the trends of CVE-2017-7269 (orange line) from approximately week 19 in the figure. Although its usage (e.g., frequency) is less observable than CVE-2008-2938 and CVE-2017-5638 during the same period of time (see Figure 8), its emerging trend is still recognized by the increase in vector norm as we can see in Figure 9b. Additionally, despite the five times of frequency difference between its initial disclosure (week 19 in Figure 9a) and later weeks (after week 51 in Figure 9a), ATTACK2VEC captures the trend changes with a small fluctuation of less than 0.6. ATTACK2VEC also reliably captures CVE-2017-10271 (red line) non-existent trend before its public disclosure.

## 5.4 Event Evolution

Another useful functionality for which ATTACK2VEC can be used is understanding how attacks evolve in the wild, and in particular monitoring which attack steps are often performed together by attackers. In a nutshell, security events that are often used together will have similar contexts. Identifying events with such similar contexts could help detecting emerging threats such as new botnets scanning for specific vulnerabilities (e.g., Mirai or WannaCry) or new exploit kits that are probing for specific weaknesses in victim systems [3, 33].

To evaluate ATTACK2VEC’s capability of tracking the evolution of security event contexts over time in relation to each other we use the same CVE from Section 2, “Drupal core RCE (CVE-2018-7602).” This CVE is for a highly critical remote code execution (RCE) vulnerability that exists within multiple subsystems of Drupal 7.x and 8.x, enabling attackers to compromise a machine running a Drupal website. This vulnerability was first disclosed on April 23 2018, and we observe its activities in the our data starting from May 15 2018. Due to its high severity, it is interesting to see how such a critical vulnerability was exploited in different contexts across time.

We use Eq 5 to identify the top 3 security events associated with CVE-2018-7602 at the beginning and the end of our time span. These events are the ones that have the closest context to CVE-2018-7602, and are therefore used in association with it. Table 2 shows a detailed description of these events. It is interesting to note that the top 3 attack vectors used together with CVE-2018-7602 at the beginning resemble a reconnaissance attack aiming at all three major content management systems - Joomla, Wordpress, and Drupal. Toward the end of the time

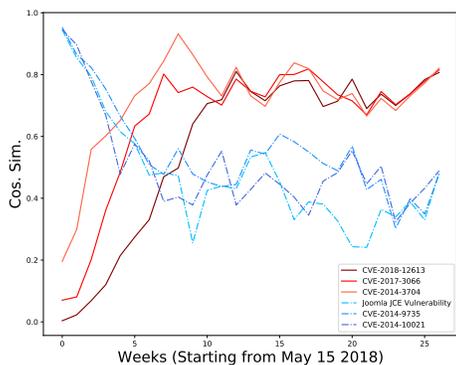

span, however, we notice that CVE-2018-7602 migrates to be part of a more specific multi-step attack, aiming at the ecosystem surrounding the Drupal CMS - php (phpMyAdmin), SQL (Drupal SQL Injection), and Flex (BlazeDS RCE).

Leveraging Eq 4, we show in Figure 10a that the temporal security event embedding computed by ATTACK2VEC can meaningfully capture the aforementioned usage changes across time. “Joomla JCE Vulnerability,” CVE-2014-9735, CVE-2014-10021 (blue dashed lines), and CVE-2018-12613, CVE-2017-3066, CVE-2014-3704 (red solid lines) respectively are the top three closest security events associated with “Drupal core RCE (CVE-2018-7602)” at the beginning (end) of the observation span (starting from May 15 2018). We can clearly see that the red lines are rising (i.e., these security events are used more closely with CVE-2018-7602), and the blue lines are moving away from CVE-2018-7602. In general, we can see that the attackers change their modus operandi, using CVE-2018-7602 as part of a more targeted attack on Drupal, 8 weeks after its initial observation in the telemetry data. This can be indicative of the old reconnaissance campaign fading and of the new one more targeted towards Drupal emerging, or of an attacker changing their behavior. Note that such usage changes can be automatically detected using various change point detection algorithms [2].

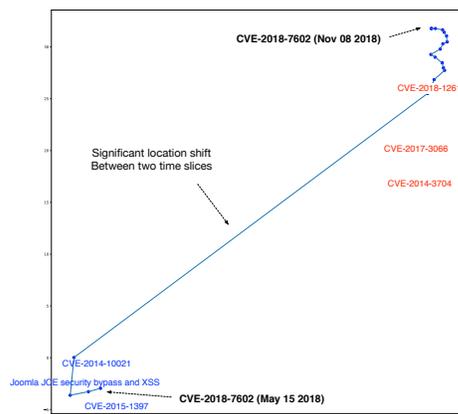

**Trajectory visualization.** The trajectory of a security event in the embedded latent space can assist security analysts to understand its context changes over time. To show this, we collect the top  $k$  security events associated with CVE-2018-7602 using Eq 5 in each time slice to form our trajectory data  $D_{e_i} = \{\mathcal{N}_k(e_i^{(t)})\}$ , where  $t$  starts from May 15, 2018. We accordingly plot the 2-D t-SNE projection of the temporal embeddings of CVE-2018-7602 (and the aforementioned security events) in Figure 10b to visualize its context change over time. In Figure 10b, each blue dot represents the 2-D location in the latent space at a given timestamp. We can observe a considerable drift in Figure 10b between the fourth and the fifth blue dot. This is correlated to the trend we observed in Figure 10a. The top 3 security events associated with CVE-2018-7602 at the beginning and the end of our time span are closer to the respectively locations in Figure 10b. Note that such changes in Figure 10b can be quantitatively detected as these locations are bounded in a Euclidean space.

## 5.5 System Performance

ATTACK2VEC is implemented in Python 3.7.3 and tested on a server with dual Xeon E5-2630 CPUs and 256GB memory running Ubuntu Linux 14.04. In this setup, ATTACK2VEC takes 859.86 seconds to construct the PPMI matrices for all 102 snapshots. Once the PPMI matrices are constructed, ATTACK2VEC takes 3014.18 seconds per epoch to optimize the temporal embeddings (see Section 4). We empirically run 5 epochs for ATTACK2VEC to reach the optimum embedding results. This leads to approximately 4.18 hours for

(a) Joomla JCE Vulnerability, CVE-2014-9735, CVE-2014-10021 (blue dashed lines) and CVE-2018-12613, CVE-2017-3066, CVE-2014-3704 (red solid lines) respectively are the top three closest security events associated with Drupal core RCE (CVE-2018-7602) at the beginning (end) of the observation span (starting from May 15 2018).

(b) Temporal t-SNE trajectory of Drupal core RCE (CVE-2018-7602). The significant shift in this figure can be indicative of the old reconnaissance campaign fading and of the new one more targeted towards Drupal emerging, or of an attacker changing their behavior.

Figure 10: Drupal core RCE (CVE-2018-7602) Evolution between May 15 2018 and November 8 2018.

Apache Struts Jakarta Multipart parser RCE (CVE-2017-5638)	
Mar. 23 2017	Nov. 08 2018
WifiCam Authentication Bypass	Malicious OGNL Expression Upload
CCTV-DVR Remote Code Execution	Apache Struts CVE-2017-12611
ZyNOS Information Disclosure	Malicious Serialized Object Upload

Table 3: Top 3 security events associated with CVE-2017-5638 at the beginning (March 9 2017) and the end (November 8 2018) of our time span.

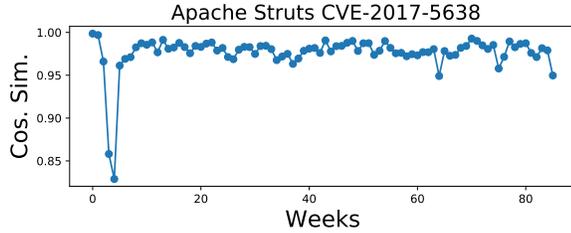

ATTACK2VEC to generate final temporal embeddings for all 8,087 security events across 102 snapshots. This enables us to deploy ATTACK2VEC to understand the long term evolution of different security events at scale by security analysts.

## 5.6 End-to-end Evaluation of ATTACK2VEC

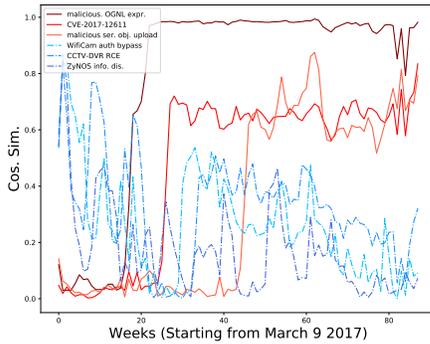

In the previous sections we evaluated the ability of ATTACK2VEC to study various aspects of how a security event is exploited in the wild. We envision that ATTACK2VEC could be used by security analysts to understand the evolution of the use of a security event (e.g., a vulnerability) over time. In this section we provide an end-to-end example to show how an analyst could be using our tool to better understanding the context surrounding a security vulnerability and its evolution. To this end, we study the evolution of the security event “Apache Struts Jakarta Content-Type RCE (CVE-2017-5638),” a remote code execution vulnerability targeting Apache Struts. This vulnerability is classified by NVD as a critical bug with CVSS score 10.0, and was the culprit of the Equifax data

breach [11].

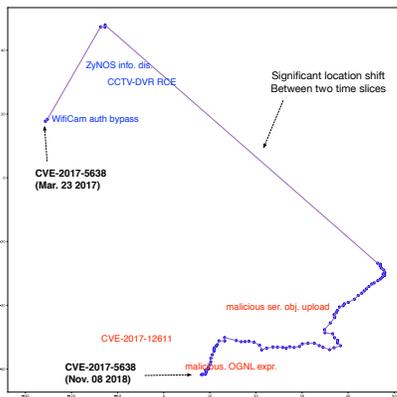

Figure 11a shows that CVE-2017-5638 experienced a change in the way it is being exploited between April 5, 2017 and April 13, 2017. ATTACK2VEC is able to identify this change in the way the vulnerability is exploited, and an analyst could easily identify this. We then want to understand what these two contexts looked like, and evaluate whether this information can help us understand the types of attacks that CVE-2017-5638 was used in. To this end we perform the analysis described in Section 5.4, whose results are shown in Figure 11b. In particular, we trace the top three security events with the closest context to CVE-2017-5638 at the beginning and at the end of our analysis period (see Table 3 for a detailed description of these events). The top 3 security events tightly associated with CVE-2017-5638 at the beginning of our observation span are IoT specific attack vectors. Figure 11b shows that these three IoT attack vectors maintain similar contexts to CVE-2017-5638 for approximately 10 weeks, indicating that the four vulnerabilities were frequently exploited together in the wild as part of a multi-step attack. Later in the analysis period (starting from May 8, 2017) we see that this attack is substituted by another attack that is targeted at the Apache Struts ecosystem, consisting of Malicious OGNL expression upload, CVE-2017-12611 and Malicious Serialized Object Upload. Figure 11c shows a similar pattern, with CVE-2017-5638 migrating from being close to the IoT security events to the Apache Struts related ones. This information could inform an analyst about the change in which CVE-2017-5638 was

(a) Temporal embedding result of Apache Struts Jakarta Multipart parser RCE (CVE-2017-5638). Cosine similarity values for each plot is calculated as  $similarity(\eta_{e_i}^{(t-1)}, \eta_{e_i}^{(t)})$ , where  $t$  starts from March 9 2017.

(b) WifiCam Authentication Bypass, CCTV-DVR Remote Code Execution, ZyNOS Information Disclosure (blue dashed lines) and Malicious OGNL expression upload, CVE-2017-12611 and Malicious Serialized Object Upload (red solid lines) are the top three closest security events associated with CVE-2017-5638 at the beginning (end) of the observation span (starting from March 9 2017), respectively.

(c) Temporal t-SNE trajectory of Apache Struts Jakarta Multipart parser RCE (CVE-2017-5638).

Figure 11: Apache Struts Jakarta Multi- part parser RCE (CVE-2017-5638) evolution between March 9 2017 and November 8 2018.

exploited in the wild, switching from an attack step as part of an IoT-centered attack to part of an attack centered around Apache Struts.

To further evaluate the accuracy of the embeddings calculated by ATTACK2VEC, and the meaningfulness of our analysis, we further investigate the contexts calculated at the beginning of our analysis period, when CVE-2017-5638 was exploited in conjunction with IoT-related vulnerabilities. To this end, we retrieve the remote IP addresses from which the security events originated on selected dates. We find that in many cases these four (including CVE-2017-5638) security events were generated from connections originating from the same IP addresses (for example, 701 unique IP addresses on March 23 2018), indicating that the relation depicted by the context is not an artifact of ATTACK2VEC, but it is indeed a large scale attack performed by the same malicious actors. These IP addresses were often located in residential ISPs, indicating a potential botnet infection.

We later found confirmation that a variant of the Mirai IoT malware was active during that period and was explicitly exploiting CVE-2017-5638, “WifiCam auth bypass,” “CCTV-DVR RCE,” and “ZyNOS information disclosure,” the same vulnerabilities picked up by ATTACK2VEC as being related (see Table 3) [1]. This shows that ATTACK2VEC can help identifying complex attacks in an effective way. An additional advantage of our approach is that our system was able to flag this attack as emerging in the wild 72 weeks before it was actually discussed by security researchers, highlighting the potential of the use of temporal embeddings for early warning and situational awareness.

## 6 Limitations and Discussion

**Rare events.** The temporal security event embedding used in this paper builds on top of event frequency and event co-occurrence (see Section 4). By design the learned temporal event embeddings are biased towards word frequency per observation time. When analyzing the security events using the proposed method, we need to pay attention to the events that appear less frequently. Broadly speaking, these rare events can be grouped into two categories - i) the new security events associated with recently disclosed vulnerabilities and ii) those rarely observed in the IPS. For the new events, their corresponding disclosure dates are good indicators when interpreting the embedding results. For the events that rarely observed, frequency and popularity are two good reference points when interpreting the embedding results. Take “CVE-2018-0101 (Cisco Adaptive Security Appliance (ASA) RCE vulnerability)” for example (see Figure 12). ATTACK2VEC faithfully identifies its changes over time (see Figure 12a). However, when referring to event frequency (see Figure 12b), we can see that these changes do not represent that the attackers are changing their attack campaign strategy. Moreover, it is important to notice that our proposed system is robust

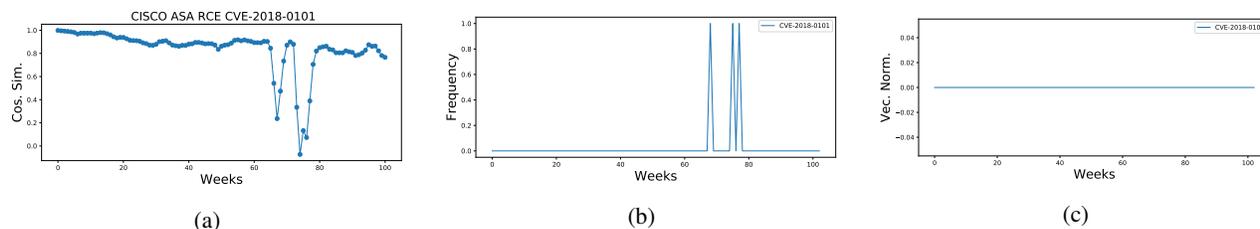

Figure 12: Rare event CVE-2018-0101 (Cisco Adaptive Security Appliance (ASA) RCE vulnerability).

and can correctly indicate that such event is not actively being exploited by attackers (see Figure 12c), and therefore the changes flagged at the previous steps are spurious.

**Distraction from attackers.** Our proposed temporal event embedding may be subject to distraction from malicious attackers, leading to inaccurate insights. For example, attackers could generate large amounts of fake events by targeting a considerable number of machines (e.g., hundreds of thousands) over a certain period of time (e.g., weeks). However, we argue that this would make the attackers more visible to the security companies who could track such malicious activities and block them accordingly. Additionally, such distraction operations would not bring financial incentive to the attackers. Note that once they switch back to real campaigns, our method would faithfully capture the new trend.

**Limitations.** ATTACK2VEC relies on a dataset of pre-labeled security events to generate insights and understand their evolution. An inherent limitation of this type of data is that an event can be detected only if it belongs to a known attack vector. If, for example, a new zero-day vulnerability started being exploited in the wild, this would not be reflected in the data until its signature is created. Our method is data-driven hence it can not deduce insights before an event was detected. However, such delay can be reduced since security companies typically use threat intelligence systems and employ human specialists to analyze intrusion data identifying new attack trends. We refer interested readers to Bilge *et al.* [5] for a detailed study on zero-day vulnerabilities.

## 7 Related Work

### 7.1 Embedding Applications in Security

Xu *et al.* [47] proposed to use network-based graph embedding to accomplish cross-platform binary code similarity detection task. The authors adopted the structure2vec approach to effectively compute embedding vectors for the control flow graph of binary functions. This allows for efficient similarity detection by comparing the embeddings for two functions. Song *et al.* [42] propose DeepMem, a graph-based deep learning approach to automatically generate abstract representations for kernel objects and recognize these objects from raw memory dumps. The key idea is building a memory graph and embed the graph nodes into a low-dimensional vector space

using a node’s actual content and the embeddings of its four kinds of neighboring nodes. These embeddings are then used as features for classification. Ding *et al.* [9] developed an assembly code representation learning model called Asm2Vec. The key idea is to encode assembly code syntax and control flow graph into a feature vector. At the query/estimation stage, the previously unknown assembly code is encoded into a lower-dimensional vector and compared using cosine similarity. Li *et al.* [23] introduced a data poisoning attack on matrix factorization. The authors demonstrated that, with the full knowledge of the learner, several attacks can be achieved.

### 7.2 Other Related Work

**Concept drift.** Concept drift refers to the phenomenon that the statistical properties of the target variable change over time. Such causes less accurate predictions across time. Within the context of security research, Maggi *et al.* [27] addressed concept drift in Web application security, while Kantchelian *et al.* [20] discussed adversarial drift. In recent years, Jordaney *et al.* [18] proposed Transcend, a statistical framework to identify aging classification models. The authors used a statistical comparison of samples seen during deployment with those used to train the model, thereby building metrics for prediction quality. They then combine both decision assessment (i.e., the robustness of the prediction results) and alpha assessment (i.e., the quality of the non-conformity measure) to detect concept drift.

**Empirical studies on cyberattacks.** Bilge *et al.* [5] conducted a systematic study of the characteristics of zero-day attacks through the data collected from 11 million endpoints. Nappa *et al.* [32] conducted a systematic analysis of the patching process of 1,593 vulnerabilities in 10 client-side applications over 5 year time, especially on measuring the patching delay and several patch deployment milestones for each vulnerability. Nayak *et al.* [33] carried an empirical study on vulnerability using field data and proposed several count-based metrics for attack surface evaluation. Vervier *et al.* [46] analyzed 18 months of data collected by an infrastructure specifically built to address BGP hijacks. The author characterized the BGP hijacks in this longitudinal study and provide a thorough investigation and validation of the candidate malicious BGP hijacks. Li *et al.* [24] conducted a large-scale empirical study of security patches that affected 862 open-

source projects.

**Vulnerability prediction.** Vulnerability prediction techniques learn the attack history from previous events (e.g., historical compromise data) and use the acquired knowledge to predict future ones. What learned in the history can offer insights to evolution and is therefore relevant to our work. Sabottke *et al.* [39] conducted a quantitative and qualitative exploration of the vulnerability-related information disseminated on Twitter. The authors built a twitter-based exploit detector, which was capable of providing early warnings for the existence of real-world exploits. Similarly, Bozorgi *et al.* [6] showed how to train linear support vector machines (SVMs) that predict whether and how soon a vulnerability is likely to be exploited (i.e., predict time to exploit). Recently, Shen *et al.* [40] demonstrated that recurrent neural networks (RNNs) can be leveraged to predict the specific steps (i.e., vulnerability that may be exploited) that would be taken by an adversary when performing an attack. Liu *et al.* [26] explored the effectiveness of forecasting security incidents. This study collected 258 externally measurable features about an organization's network covering two main categories: mismanagement symptoms (e.g., misconfigured DNS) and malicious activities (e.g., spam, scanning activities originated from this organization's network). Based on the data, the study trained and tested a Random Forest classifier on these features, and are able to achieve with 90% True Positive (TP) rate, 10% False Positive (FP) rate and an overall accuracy of 90% in forecasting security incidents. In summary, these approaches learn the attack history from previous events (e.g., historical compromise data) and use the acquired knowledge to predict future ones. They don't provide thorough investigations on how security events evolve over time.

**Alert correlation.** Alert correlation [7, 45] refers to a process that analyzes the alert logs produced by IDS and forms higher-level information on attempted intrusions. Once alerts are correlated among multiple monitors, the results can provide IDS a holistic view of the network monitored. A lot of work has been done in this areas such CRIM [7], DIDMA [19], ACARM [44], INDRA [17], etc. Vasilomanolakis *et al.* [45] summarized the current state of the art in the area of distributed and collaborative intrusion detection. In contrast to this previous work, this paper focuses on understanding the emergence, the evolution, and the characteristics of attack steps in relation to the wider context in which they are exploited.

**Automated causality analysis.** Causality is an orthogonal but interesting problem relating to ATTACK2VEC. Hercule [34] uses tainted path  $s$  from  $t$  to model the causality. SteamSpot [28] uses a new similarity function to compare graphs and builds information flow graph clusters to detect anomalies. NoDoze [15] builds provenance graph of a given event and use a novel diffusion algorithm to efficiently propagate and aggregate the anomalous scores. HOLMES [31] also leverages provenance graph and identify APT attacks

via information flow graphs. Conversely, our goal is to provide a reliable new method for analyzing attack trends than frequency analysis.

**Closest work.** One of the closest work to this paper is DarkEmbed [43]. It used paragraph vector to learn low dimensional distributed representations, i.e., embeddings, of dark-web/deepweb discussions. These embeddings effectively captured the meaning of these discussions and their other characteristics, such as language, and indicator words. DarkEmbed then trained a classifier to recognize posts discussing vulnerabilities that would be exploited in the wild. DarkEmbed is essentially a NLP analysis. Different from DarkEmbed, our work focuses on using representation vectors to parameterize the conditional probabilities of security events in the context of other events, and study how these security events evolve from a temporal perspective. Another closest work is [29]. The authors carried out a longitudinal analysis of a large corpus of cyber threat descriptions. It quantifies the severity and types (e.g., worms, viruses and trojans) of 12,400 threats detected by Symantec's AV and 2,700 attacks detected by Symantec's IPS. Different from [29], our work focuses on how the security events evolve and monitor how security events are exploited in the wild from real-world intrusion prevention data.

## 8 Conclusion

In this paper, we showed that techniques that were developed in the area of natural language processing can be used to effectively model and monitor the evolution of cyberattacks. To demonstrate this, we developed ATTACK2VEC, a tool that leverages word embeddings to understand the context in which attack steps are exploited. We showed that ATTACK2VEC is effective in flagging changes in the way attacks unfold. In future work we plan to investigate how the use of ATTACK2VEC could make the work of security analysts easier in studying emerging attacks.

# Leaky Images: Targeted Privacy Attacks in the Web

Cristian-Alexandru Staicu  
*Department of Computer Science*  
*TU Darmstadt*

Michael Pradel  
*Department of Computer Science*  
*TU Darmstadt*

## Abstract

Sharing files with specific users is a popular service provided by various widely used websites, e.g., Facebook, Twitter, Google, and Dropbox. A common way to ensure that a shared file can only be accessed by a specific user is to authenticate the user upon a request for the file. This paper shows a novel way of abusing shared image files for targeted privacy attacks. In our attack, called *leaky images*, an image shared with a particular user reveals whether the user is visiting a specific website. The basic idea is simple yet effective: an attacker-controlled website requests a privately shared image, which will succeed only for the targeted user whose browser is logged into the website through which the image was shared. In addition to targeted privacy attacks aimed at single users, we discuss variants of the attack that allow an attacker to track a group of users and to link user identities across different sites. Leaky images require neither JavaScript nor CSS, exposing even privacy-aware users, who disable scripts in their browser, to the leak. Studying the most popular websites shows that the privacy leak affects at least eight of the 30 most popular websites that allow sharing of images between users, including the three most popular of all sites. We disclosed the problem to the affected sites, and most of them have been fixing the privacy leak in reaction to our reports. In particular, the two most popular affected sites, Facebook and Twitter, have already fixed the leaky images problem. To avoid leaky images, we discuss potential mitigation techniques that address the problem at the level of the browser and of the image sharing website.

## 1 Introduction

Many popular websites allow users to privately share images with each other. For example, email services allow attachments to emails, most social networks support photo sharing, and instant messaging systems allow files to be sent as part of a conversation. We call websites that allow users to share images with each other *image sharing services*.

This paper presents a targeted privacy attack that abuses a vulnerability we find to be common in popular image sharing services. The basic idea is simple yet effective: An attacker can determine whether a specific person is visiting an attacker-controlled website by checking whether the browser can access an image shared with this person. We call this attack *leaky images*, because a shared image leaks the private information about the victim's identity, which otherwise would not be available to the attacker. To launch a leaky images attack, the attacker privately shares an image with the victim through an image sharing service where both the attacker and the victim are registered as users. Then, the attacker includes a request for the image into the website for which the attacker wants to determine whether the victim is visiting it. Since only the victim, but no other user, is allowed to successfully request the image, the attacker knows with 100% certainty whether the victim has visited the site.

Beyond the basic idea of leaky images, we describe three further attacks. First, we describe a targeted attack against groups of users, which addresses the scalability issues of the single-victim attack. Second, we show a pseudonym linking attack that exploits leaky images shared via different image sharing services to determine which user accounts across these services belong to the same individual. Third, we present a scriptless version of the attack, which uses only HTML, and hence, works even for users who disable JavaScript in their browsers.

Leaky images can be (ab)used for targeted attacks in various privacy-sensitive scenarios. For example, law enforcement could use the attack to gather evidence that a suspect is visiting particular websites. Similarly but perhaps less noble, a governmental agency might use the attack to deanonymize a political dissident. As an example of an attack against a group, consider deanonymizing reviewers of a conference. In this scenario, the attacker would gather the email addresses of all committee members and then share leaky images with each reviewer through some of the various websites providing that service. Next, the attacker would embed a link to an external website into a paper under review, e.g.,

Table 1: Leaky images vs. related web attacks. All techniques assume that the victim visits an attacker-controlled website.

Threat	Who can attack?	What does the attacker achieve?	Usage scenario
Tracking pixels	Widely used ad providers and web tracking services	Learn that user visiting site A is the same as user visiting site B	Large-scale creation of low-entropy user profiles
Social media fingerprinting	Arbitrary website provider	Learn into which sites the victim is logged in	Large-scale creation of low-entropy user profiles
Cross-site request forgery	Arbitrary website provider	Perform side effects on a target site into which the victim is logged in	Abuse the victim's authorization by acting on her behalf
Leaky images	Arbitrary website provider	Precisely identify the victim	Targeted, fine-grained deanonymization

a link to a website with additional material. If and when a reviewer visits that page, while being logged into one of the image sharing services, the leaky image will reveal to the attacker who is reviewing the paper. The prerequisite for all these attacks is that the victim has an account at a vulnerable image sharing service and that the attacker is allowed to share an image with the victim. We found at least three highly popular services (Google, Microsoft Live, and Dropbox) that allow sharing images with any registered user, making it straightforward to implement the above scenarios.

The leak is possible because images are exempted from the same-origin policy, and because image sharing services authenticate users through cookies. When the browser makes a third-party image request, it attaches the user's cookie of the image sharing website to it. If the decision of whether to authorize the image request is cookie-dependent, then the attacker can infer the user's identity by observing the success of the image request. Related work discusses the dangers of exempting JavaScript from the same-origin policy [24], but to the best of our knowledge, there is no work discussing the privacy implications of observing the result of cross-origin requests to privately shared images.

Leaky images differ from previously known threats by enabling arbitrary website providers to precisely identify a victim (Table 1). One related technique are tracking pixels, which enable tracking services to determine whether two visitors of different sites are the same user. Most third-party tracking is done by a few major players [13], allowing for regulating the way these trackers handle sensitive data. In contrast, our attack enables arbitrary attackers and small websites to perform targeted privacy attacks. Another related technique is social media fingerprinting, where the attacker learns whether a user is currently logged into a specific website.<sup>1</sup> In contrast, leaky images reveal not only whether a user is logged in, but precisely which user is logged in. Leaky images resemble cross-site request forgery (CSRF) [33], where a malicious website performs a request to a target site on behalf of the user. CSRF attacks typically cause side effects on the server, whereas our attack simply retrieves an image.

<sup>1</sup>See <https://robinlinus.github.io/socialmedia-leak/> or <https://browserleaks.com/social>.

We discuss in Section 5 under what conditions defenses proposed against CSRF, as well as other mitigation techniques, can reduce the risk of privacy leaks due to leaky images.

To understand how widespread the leaky images problem is, we study 30 out of the 250 most popular websites. We create multiple user accounts on these websites and check whether one user can share a leaky image with another user. The attack is possible if the shared image can be accessed through a link known to all users sharing the image, and if access to the image is granted only to certain users. We find that at least eight of the 30 studied sites are affected by the leaky images privacy leak, including some of the most popular sites, such as Facebook, Google, Twitter, and Dropbox. We carefully documented the steps for creating leaky images and reported them as privacy violations to the security teams of the vulnerable websites. In total, we informed eight websites about the problem, and so far, six of the reports have been confirmed, and for three of them we have been awarded bug bounties. Most of the affected websites are in the process of fixing the leaky images problem, and some of them, e.g., Facebook and Twitter, have already deployed a fix.

In summary, this paper makes the following contributions:

- We present leaky images, a novel targeted privacy attack that abuses image sharing services to determine whether a victim visits an attacker-controlled website.
- We discuss variants of the attack that aim at individual users, groups of users, that allow an attacker to link user identities across image sharing services, and that do not require any JavaScript.
- We show that eight popular websites, including Facebook, Twitter, Google, and Microsoft Live are affected by leaky images, exposing their users to be identified on third-party websites.
- We propose several ways to mitigate the problem and discuss their benefits and weaknesses.

## 2 Image Sharing in the Web

Many popular websites, including Dropbox, Google Drive, Twitter, and Facebook, enable users to upload images and to

share these images with a well-defined set of other users of the same site. Let  $i$  be an image,  $U$  be the set of users of an image sharing service, and let  $u_{owner}^i \in U$  be the owner of  $i$ . By default,  $i$  is not accessible to any other users than  $u_{owner}^i$ . However, an owner of an image can share the image with a selected subset of other users  $U_{shared}^i \subseteq U$ , which we define to include the owner itself. As a result, all users  $u \in U_{shared}^i$ , but no other users of the service and no other web users, have read access to  $i$ , i.e., can download the image via a browser.

**Secret URLs** To control which users can access an image, there are several implementation strategies. One strategy is to create a *secret URL* for each shared image, and to provide this URL only to users allowed to download the image. In this scenario, there is a set of URLs  $L^i$  ( $L$  stands for “links”) that point to a shared image  $i$ . Any user who knows a URL  $l^i \in L^i$  can download  $i$  through it. To share an image  $i$  with multiple users, i.e.,  $|U_{shared}^i| > 1$ , there are two variants of implementing secret URLs. On the one hand, each user  $u$  may obtain a personal secret URL  $l_u^i$  for the shared image, which is known only to  $u$  and not supposed to be shared with anyone. On the other hand, all users may share the same secret URL, i.e.,  $L^i = \{l_{shared}^i\}$ . A variant of secret URLs are URLs that expire after a given amount of time or after a given number of uses. We call these URLs session URLs.

**Authentication** Another strategy to control who accesses an image is to authenticate users. In this scenario, the image sharing service checks for each request to  $i$  whether the request comes from a user in  $U_{shared}^i$ . Authentication may be used in combination with secret URLs. In this case, a user  $u$  may access an image  $i$  only if she knows a secret URL  $l^i$  and if she is authenticated as  $u \in U_{shared}^i$ . The most common way to implement authentication in image sharing services are cookies. Once a user logs into the website of an image sharing service, the website stores a cookie in the user’s browser. When the browser requests an image, the cookie is sent along with the request to the image sharing service, enabling the server-side of the website to identify the user.

**Image Sharing in Practice** Different real-world image sharing services implement different strategies for controlling who may access which image. For example, Facebook mostly uses secret URLs, which initially created confusion among users due to the apparent lack of access control<sup>2</sup>. Gmail relies on a combination of secret URLs and authentication to access images attached to emails. Deciding how to implement image sharing is a tradeoff between several design goals, including security, usability, and performance. The main advantage of using secret URLs only is that third-party content delivery networks may deliver images, without

<sup>2</sup><https://news.ycombinator.com/item?id=13204283>

any cross-domain access control checks. A drawback of secret URLs is that they should not be used over non-secret channels, such as HTTP, since these channels are unable to protect the secrecy of requested URLs. The main advantage of authentication is to not require links to be secret, enabling them to be sent over insecure channels. On the downside, authentication-based access control makes using third-party content delivery networks harder, because cookie-based authentication does not work across domains.

**Same-Origin Policy** The same-origin policy regulates to what extent client-side scripts of a website can access the document object model (DOM) of the website. As a default policy, any script loaded from one origin is not allowed to access parts of the DOM loaded from another origin. Origin here means the URI scheme (e.g., *http*), the host name (e.g., *facebook.com*), and the port number (e.g., 80). For example, the default policy implies that a website *evil.com* that embeds an `iframe` from *facebook.com* cannot access those parts of the DOM that have been loaded from *facebook.com*. There are some exceptions to the default policy described above. One of them, which is crucial for the leaky images attack, are images loaded from third parties. In contrast to other DOM elements, a script loaded from one origin can access images loaded from another origin, including whether the image has been loaded at all. For the above example, *evil.com* is allowed to check whether an image requested from *facebook.com* has been successfully downloaded.

### 3 Privacy Attacks via Leaky Images

This section presents a series of attacks that can be mounted using leaky images. At first, we describe the conditions under which the attack is possible (Section 3.1). Then, we present a basic attack that targets individual users (Section 3.2), a variant of the attack that targets groups of users (Section 3.3), and an attack that links identities of an individual registered at different websites (Section 3.4). Next, we show that the attack relies neither on JavaScript nor CSS, but can be performed by a purely HTML-based website (Section 3.5). Finally, we discuss how leaky images compare to previous privacy-related issues, such as web tracking (Section 3.6).

#### 3.1 Attack Surface

Our attack model is that an attacker wants to determine whether a specific victim is visiting an attacker-controlled website. This information is important from a privacy point of view and usually not available to operators of a website. An operator of a website may be able to obtain some information about clients visiting the website, e.g., the IP and the browser version of the client. However, this information is limited, e.g., due to multiple clients sharing

Table 2: Conditions that enable leaky image attacks.

Authenti- cation (e.g., cookies)	URL of image		
	Publicly known	Secret URL shared among users	Per-user secret URL
Yes	(1) Leaky image	(2) Leaky image	(3) Secure
No	(4) Irrelevant	(5) Secure	(6) Secure

the same IP or the same browser version, and often insufficient to identify a particular user with high confidence. Moreover, privacy-aware clients may further obfuscate their traces, e.g., by using the Tor browser, which hides the IP and other details about the client. Popular tracking services, such as Google Analytics, also obtain partial knowledge about which users are visiting which websites. However, the use of this information is legally regulated, available to only a few tracking services, and shared with website operators only in anonymized form. In contrast, the attack considered here enables an arbitrary operator of a website to determine whether a specific person is visiting the website.

Leaky image attacks are possible whenever all of the following four conditions hold. First, we assume that the attacker and the victim are both users of the same image sharing service. Since many image sharing services provide popular services beyond image sharing, such as email or a social network, their user bases often cover a significant portion of all web users. For example, Facebook announced that it has more than 2 billion registered users<sup>3</sup>, while Google reported to have more than 1 billion active Gmail users each month<sup>4</sup>. Moreover, an attacker targeting a specific victim can simply register at an image sharing service where the victim is registered. Second, we assume that the attacker can share an image with the victim. For many image sharing services, this step involves nothing more than knowing the email address or user name of the victim, as we discuss in more detail in Section 4. Third, we assume that the victim visits the attacker-controlled website while the victim’s browser is logged into the image sharing service. Given the popularity of some image sharing services and the convenience of being logged in at all times, we believe that many users fulfill this condition for at least one image sharing service. In particular, in Google Chrome and the Android operating system, users are encouraged immediately after installation to login with their Google account and to remain logged in at all times.

The fourth and final condition for leaky images concerns the way an image sharing service determines whether a request for an image is from a user supposed to view that image. Table 2 shows a two-dimensional matrix of possible

<sup>3</sup><https://techcrunch.com/2017/06/27/facebook-2-billion-users/>

<sup>4</sup><https://www.businessinsider.de/gmail-has-1-billion-monthly-active-users-2016-2>

implementation strategies, based on the description of secret URLs and authentication-based access control in Section 2. In one dimension, a website can either rely on authentication or not. In the other dimension, the site can make an image available through a publicly known URL, a secret URL shared among the users allowed to access the image, or a per-user secret URL. Out of the six cases created by these two dimensions, five are relevant in practice. The sixth case, sharing an image via a publicly known URL without any authentication, would make the image available to all web users, and therefore is out of the scope of this work. The leaky image attack works in two of the five possible cases in Table 2, cases 1 and 2. Specifically, leaky images are enabled by sites that protect shared images through authentication and that either do not use secret URLs at all or that use a single secret URL per shared image. Section 4 shows that these cases occur in practice, and that they affect some of today’s most popular websites.

### 3.2 Targeting a Single User

After introducing the prerequisites for leaky images, we now describe several privacy attacks based on them. We start with a basic version of the attack, which targets a single victim and determines whether the victim is visiting an attacker-controlled website. To this end, the attacker uploads an image  $i$  to the image sharing service and therefore becomes the owner of the image, i.e.,  $u_{attacker} = u_{owner}^i$ . Next, the attacker configures the image sharing service to share  $i$  with the victim user  $u_{victim}$ . As a result, the set of users allowed to access the image is  $U_{shared}^i = \{u_{attacker}, u_{victim}\}$ . Then, the attacker embeds a request for  $i$  into the website  $s$  for which the attacker wants to determine whether the victim is visiting the site. Because images are exempted from the same-origin policy (Section 2), the attacker-controlled parts of  $s$  can determine whether the image gets loaded successfully and report this information back to the attacker. Once the victim visits  $s$ , the image request will succeed and the attacker knows that the victim has visited  $s$ . If any other client visits  $s$ , though, the image request fails because  $s$  cannot authenticate the client as a user in  $U_{shared}^i$ . We assume that the attacker does not visit  $s$ , as this might mislead the attacker to believe that the victim is visiting  $s$ .

Because the authentication mechanism of the image sharing service ensures that only the attacker and the victim can access the image, a leaky image attack can determine with 100% accuracy whether the targeted victim has visited the site. At the same time, the victim may not notice that she was tracked, because the image can be loaded in the background.

For example, Figure 1 shows a simple piece of HTML code with embedded JavaScript. The code requests a leaky image, checks whether the image is successfully loaded, and sends this information back to the attacker-controlled web

```

1 <script>
2 window.onload = function() {
3   var img = document.getElementById("myPic");
4   img.src = "https://imgsharing.com/leakyImg.png";
5   img.onload = function() {
6     httpReq("evil.com", "is the target");
7   }
8   img.onerror = function() {
9     httpReq("evil.com", "not the target");
10  }
11 }
12 </script>
13 <img id="myPic">

```

Figure 1: Tracking code included in the attacker’s website.

server via another HTTP request. We assume `httpReq` is a method that performs such a request using standard browser features such as `XMLHttpRequest` or `innerHTML` to send the value of the second argument to the domain passed as first argument. Alternatively to using `onload` to detect whether the image has been loaded, there are several variations, which, e.g., checking the width or height of the loaded image. As we show below (Section 3.5), the attack is also possible within a purely HTML-based website, i.e., without JavaScript.

The described attack works because the same-origin policy does not apply to images. That is, the attacker can include a leaky image through a cross-origin request into a website and observe whether the image is accessible or not. In contrast, requesting an HTML document does not cause a similar privacy leak, since browsers implement a strict separation of HTML coming from different origins. A second culprit for the attack’s success is that today’s browsers automatically include the victim’s cookie in third-party image requests. As a result, the request passes the authentication of the image sharing service, leaking the fact that the request comes from the victim’s browser.

### 3.3 Targeting a Group of Users

The following describes a variant of the leaky images attack that targets a group of users instead of a single user. In this scenario, the attacker considers a group of  $n$  victims and wants to determine which of these victims is visiting a particular website.

As an example, consider a medium-scale spear phishing campaign against the employees of a company. After preparing the actual phishing payload, e.g., personalized emails or cloned websites, the attacker may include a set of leaky images to better understand which victims interact with the payload and in which way. In this scenario, leaky images provide a user experience analysis tool for the attacker.

A naive approach would be to share one image  $i_k$  ( $1 \leq k \leq n$ ) with each of the  $n$  victims. However, this naive ap-

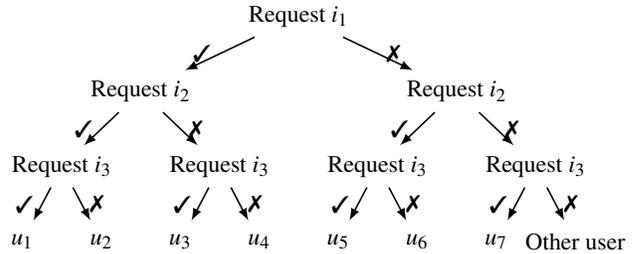

Figure 2: Binary search to identify individuals in a group of users  $u_1$  to  $u_7$  through requests to leaky images  $i_1$  to  $i_3$ .

proach does not scale well to larger sets of users: To track a group of 10,000 users, the attacker needs 10,000 shared images and 10,000 image requests per visit of the website. In other words, this naive attack has  $\mathcal{O}(n)$  complexity, both in the number of leaky images and in the number of requests. For the above example, this naive way of performing the attack might raise suspicion due to the degraded performance of the phishing site and the increase in the number of network requests.

To efficiently attack a group of users, an attacker can use the fact that image sharing services allow sharing a single image with multiple users. The basic idea is to encode each victim with a bit vector and to associate each bit with one shared image. By requesting the images associated with each bit, the website can compute the bit vector of a user and determine if the user is among the victims, and if yes, which victim it is. This approach enables a binary search on the group of users, as illustrated in Figure 2 for a group of seven users. The website includes code that requests images  $i_1$ ,  $i_2$ , and  $i_3$ , and then determines based on the availability of the images which user among the targeted victims has visited the website. If none of the images is available, then the user is not among the targeted victims. In contrast to the naive approach, the attack requires only  $\mathcal{O}(\log(n))$  shared images and only  $\mathcal{O}(\log(n))$  image requests, enabling the attack on larger groups of users.

In practice, launching a leaky image attack against a group of users requires sharing a set of images with different subsets of the targeted users. This process can be automated, either through APIs provided by image sharing services or through UI-level web automation scripts. However, this process will most likely be website-specific which makes it expensive for attacking multiple websites at once.

### 3.4 Linking User Identities

The third attack based on leaky images aims at linking multiple identities that a single individual has at different image sharing services. Let  $siteA$  and  $siteB$  be two image sharing services, and let  $u_{siteA}$  and  $u_{siteB}$  be two user accounts, registered at the two image sharing services, respectively. The

```

1 <!-- Three users (u1, u2, u3) have access to two
2 images (i1, i2) as follows: u1 to (i1);
3 u2 to (i2); u3 to (i1, i2) -->
4 <object data="leaky-domain.com/i1.png">
5   <object data="evil.com?info=not_i1?sid=2342"/>
6 </object>
7 <object data="leaky-domain.com/i2.png">
8   <object data="evil.com?info=not_i2?sid=2342"/>
9 </object>
10
11 <object data="leaky-domain.com/invalidImg.png">
12   <object data="leaky-domain.com/invalidImg2.png">
13     <object data="leaky-domain.com/invalidImg3.png">
14       <object data="evil.com?info=loaded?sid=2342"/>
15     </object>
16   </object>
17 </object>

```

Figure 3: HTML-only variant of the leaky image group attack. All the `object` tags should have the `type` property set to `image/png`.

attacker wants to determine whether  $u_{siteA}$  and  $u_{siteB}$  belong to the same individual. For example, this attack might be performed by law enforcement entities to check whether a user account that is involved in criminal activities matches another user account that is known to belong to a suspect.

To link two user identities, the attacker essentially performs two leaky image attacks in parallel, one for each image sharing service. Specifically, the attacker shares an image  $i_{siteA}$  with  $u_{siteA}$  through one image sharing service and an image  $i_{siteB}$  with  $u_{siteB}$  through the other image sharing service. The attacker-controlled website requests both  $i_{siteA}$  and  $i_{siteB}$ . Once the targeted individual visits this site, both requests will succeed and establish the fact that the users  $u_{siteA}$  and  $u_{siteB}$  correspond to the same individual. For any other visitors of the site, at least one request will fail because the two requests only succeed if the browser is logged into both user accounts  $u_{siteA}$  and  $u_{siteB}$ .

The basic idea of linking user accounts generalizes to more than two image sharing services and to user accounts of more than a single individual. For example, by performing two attacks on groups of users, as described in Section 3.3, in parallel, an attacker can establish pairwise relationships between the two groups of users.

### 3.5 HTML-only Attack

The leaky image attack is based on the ability of a client-side website to request an image and to report back to the attacker-controlled server-side whether the request was successful or not. One way to implement it is using client-side JavaScript code, as shown in Figure 1. However, privacy-aware users may disable JavaScript completely or use a security mechanism that prevents JavaScript code from reading details about images loaded from different domains.

We present a variant of the leaky image attack implemented using only HTML code, i.e., without any JavaScript or CSS. The idea is to use the `object` HTML tag, which allows a website to specify fallback content to be loaded if there is an error in loading some previously specified content.<sup>5</sup> When nesting such `object` elements, the browser first requests the resource specified in the outer element, and in case it fails, it performs a request to the inner element instead. Essentially, this behavior corresponds to a logical *if-not* instruction in pure HTML which an attacker may use to implement the leaky image attack.

Figure 3 shows an example of this attack variant. We assume that there are three users  $u_1$ ,  $u_2$ , and  $u_3$  in the target group and that the attacker can share leaky images from `leaky-domain.com` with each of them. The comment at the beginning of Figure 3 specifies the exact sharing configuration. We again need  $\log(n)$  images to track  $n$  users, as for the JavaScript-based attack against a group of users (Section 3.3). We assume that the server-side generates the attack code upon receiving the request, and that the generated code contains a session ID as part of the reporting links pointing to `evil.com`. In the example, the session ID is 2342. Its purpose is to enable the server-side code to link multiple requests coming from the same client.

The main insight of this attack variant is to place a request to the attacker's domain as fallbacks for leaky image requests. For example, if the request to the leaky image  $i_1$  at line 4 fails, a request is made to `evil.com` for an alternative resource in line 5. This request leaks the information that the current user cannot access  $i_1$ , i.e., `info=not_i1`. By performing similar requests for all the leaky images, the attacker leaks enough information for precisely identifying individual users. For example, if in a given session, `evil.com` receives `not_i1`, but not `not_i1`, the attacker can conclude that the user is  $u_2$ . Because the server-side infers the user from the absence of requests, it is important to ensure that the current tracking session is successfully completed before drawing any conclusions. Specifically, we must ensure that the user or the browser did not stop the page load before all the nested `object` tags were evaluated. One way to ensure this property is to add a sufficiently high number of nested requests to non-existent images in lines 11 to 13 followed by a request that informs the attacker that the tracking is completed, in line 14. The server discards every session that does not contain this last message.

As a proof of concept, we tested the example attack and several variants of it in the newest Firefox and Chrome browsers and find the HTML-only attack to work as expected.

<sup>5</sup><https://html.spec.whatwg.org/multipage/iframe-embed-object.html#the-object-element>

## 3.6 Discussion

**Tracking pixels** Leaky images are related to the widely used tracking pixels, also called web beacons [14, 8, 47], but both differ regarding who learns about a user’s identity. A tracking pixel is a small image that a website  $s$  loads from a tracker website  $s_{track}$ . The image request contains the user’s cookie for  $s_{track}$ , enabling the tracker to recognize users across different page visits. As a result, the tracking service can analyze which pages of  $s$  users visit and show this information in aggregated form to the provider of  $s$ . If the tracker also operates services where users register, it can learn which user visits which site. In contrast, leaky images enable the operator of a site  $s$  to learn that a target user is visiting  $s$ , without relying on a tracker to share this information, but by abusing an image sharing service. As for tracking pixels, an attacker can deploy leaky image attacks with images of 1x1 pixel size to reduce its impact on page loading time.

**Fingerprinting** Web fingerprinting techniques [12, 29, 10, 22, 1, 2, 30] use high-entropy properties of web browsers, such as the set of installed fonts or the size of the browser window, to heuristically recognize users. Like fingerprinting, leaky images aim at undermining the privacy of users. Unlike fingerprinting, the attacks presented here enable an attacker to determine specific user accounts, instead of recognizing that one visitor is likely to be the same as another visitor. Furthermore, leaky images can determine a visitor’s identity with 100% certainty, whereas fingerprinting heuristically relies on the entropy of browser properties.

**Targeted attacks versus large-scale tracking** Leaky images are well suited for targeted attacks [37, 6, 26, 16], but not for large-scale tracking of millions of users. One reason is that leaky images require the attacker to share an image with each victim, which is unlikely to scale beyond several hundreds users. Another reason is that the number of image requests that a website needs to perform increases logarithmically with the number of targeted users, as discussed in Section 3.3. Hence, instead of aiming at large-scale tracking in the spirit of tracking pixels or fingerprinting, leaky images are better suited to target (sets of) individuals. However, this type of targeted attacks is reported to be increasingly popular, especially when dealing with high-value victims [37].

## 4 Leaky Images in Popular Websites

The attacks presented in the previous section make several assumptions. In particular, leaky images depend on how real-world image sharing services implement access control for shared images. To understand to what extent popular websites are affected by the privacy problem discussed in this paper, we systematically study the prevalence of leaky

images. The following presents our methodology (Section 4.1), our main findings (Section 4.2), and discusses our ongoing efforts toward disclosing the detected problems in a responsible way (Section 4.3).

### 4.1 Methodology

**Selection of websites** To select popular image sharing services to study, we examined the top 500 most popular websites, according to the “Top Moz 500” list<sup>6</sup>. We focus on websites that enable users to share data with each other. We exclude sites that do not offer an English language interface and websites that do not offer the possibility to create user accounts. This selection yields a list of 30 websites, which we study in more detail. Table 3 shows the studied websites, along with their popularity rank. The list contains all of the six most popular websites, and nine of the ten most popular websites. Many of the analyzed sites are social media platforms, services for sharing some kind of data, and communication platforms.

**Image sharing** One condition for our attacks is that an attacker can share an image with a victim. We carefully analyze the 30 sites in Table 3 to check whether a site provides an image sharing service. To this end, we create multiple accounts on each site and attempt to share images between these accounts using different channels, e.g., chat windows or social media shares. Once an image is shared between two accounts, we check if the two accounts indeed have access to the image. If this requirement is met, we check that a third account cannot access the image.

**Access control mechanism** For websites that act as image sharing services, we check whether the access control of a shared image is implemented in a way that causes leaky images, as presented in Table 2. Specifically, we check whether the access to a shared image is protected by authentication and whether both users access the image through a common link, i.e., a link known to the attacker. A site that fulfills also this condition exposes its users to leaky image attacks.

### 4.2 Prevalence of Leaky Images in the Wild

Among the 30 studied websites, we identify a total of eight websites that suffer from leaky images. As shown in Table 3 (column “Leaky images”), the affected sites include the three most popular sites, Facebook, Twitter, and Google, and represent over 25% of all sites that we study. The following discusses each of the vulnerable sites in detail and explains how an attacker can establish a leaky image with a target user. Table 4 summarizes the discussion in a concise way.

<sup>6</sup><https://moz.com/top500>

**Facebook** Images hosted on Facebook are in general delivered by content delivery networks not hosted at the facebook.com domain, but, e.g., at fbcdn.net. Hence, the fact that facebook.com cookie is not sent along with requests to shared images disables the leaky image attacks. However, we identified an exception to this rule, where a leaky image can be placed at [https://m.facebook.com/photo/view/\\_full/\\_size/?fbid=xxx](https://m.facebook.com/photo/view/_full/_size/?fbid=xxx). The fbid is a unique identifier that is associated with each picture on Facebook, and it is easy to retrieve this identifier from the address bar of an image page. The attacker must gather this identifier and concatenate it with the leaky image URL given above. By tweaking the picture’s privacy settings, the attacker can control the subset of friends that are authorized to access the image, opening the door for individual and group attacks. A prerequisite of creating a leaky image on Facebook is that the victim is a “friend” of the attacker.

**Twitter** Every image sent in a private chat on Twitter is a leaky image. The victim and the attacker can exchange messages on private chats, and hence send images, if one of them checked “Receive direct messages from anyone” in their settings or if one is a follower of the other. An image sent on a private chat can only be accessed by the two participants, based on their login state, i.e., these images are leaky images. The attacker can easily retrieve the leaky image URL from the conversation and include it in another page. A limitation of the attack via Twitter is that we are currently not aware of a way of sharing an image with multiple users at once.

**Google** We identified two leaky image channels on Google’s domains: one in the thumbnails of Google Drive documents and one in Google Hangouts conversations. To share documents with the victim, an attacker only needs the email address of the victim, while in order to send Hangouts messages, the victim needs to accept the chat invitation from the attacker. The thumbnail-based attack is more powerful since it allows to easily add and remove users to the group of users that have access to an image. Moreover, by unselecting the “Notify people” option when sharing, the victim users are not even aware of this operation. An advantage of the Hangouts channel, though, is that the victim has no way to revoke its rights to the leaky image, once the image has been received in a chat, as opposed to Drive, where the victim can remove a shared document from her cloud.

**Wordpress** To create a leaky image via Wordpress, the attacker needs to convince the victim to become a reader of his blog, or the other way around. Once this connection is established, every image posted on the shared private blog is a leaky image between the two users. Fulfilling this strong prerequisite may require non-trivial social engineering.

**GitHub** Private repositories on GitHub enable leaky images. Once the victim and the attacker share such a repository, every committed image can be accessed through a link in the web interface, e.g., <https://github.com/johndoe/my-awesome-project/raw/master/car.jpg>. Only users logged into GitHub who were granted access to the repository *my-awesome-project* can access the image. To control the number of users that have access to the image, the attacker can remove or add contributors to the project.

**Dropbox** Every image uploaded on Dropbox can be accessed through a leaky image endpoint by appending the HTTP parameter `d1=1` to a shared image URL. Dropbox allows the attacker to share such images with arbitrary email addresses and to fine-tune the permissions to access the image by including and excluding users at any time. Once the image is shared, our attack can be successfully deployed,

Table 4: Leaky images in popular websites, the attack’s preconditions, the image sharing channel and the implemented authentication mechanism as introduced in Table 2

Domain	Prerequisites	Image sharing channel	Authentication mechanism
facebook.com	Victim and attacker are "friends"	Image sharing	(5), (2)
twitter.com	Victim and attacker can exchange messages	Private message	(2)
google.com	<i>None</i>	Google Drive document	(3), (2)
		Private message	
wordpress.com	Victim is a viewer of the attacker’s private blog	Posts on private blogs	(2)
github.com	Victim and attacker share a private repository	Private repository	(3), (2)
dropbox.com	<i>None</i>	Image sharing	(3), (6), (2)
live.com	<i>None</i>	Shared folder on OneDrive	(3), (2)
skype.com	Victim and attacker can exchange messages	Private message	(2)

without requiring the victim to accept the shared image. However, the victim can revoke its rights to access an image by removing it from the “Sharing” section of her account.

**Live.com** Setting up a leaky image on One Drive, a cloud storage platform available on a live.com subdomain, is very similar to the other two file sharing services that we study, Google Drive and Dropbox. The attacker can share images with arbitrary email addresses and the victim does not need to acknowledge the sharing. Moreover, the attacker can easily deploy a group attack due to the ease in changing the group of users that have access to a particular image.

**Skype** In the Skype web interface, every image sent in a chat is a leaky image. Note that most of the users probably access the service through a desktop or mobile standalone client, hence the impact of this attack is limited to the web users. Moreover, Skype automatically logs out the user from time to time, limiting the time window for the attack.

Our study of leaky images in real-world sites enables several observations.

**Leaky images are prevalent** The first and perhaps most important observation is that many of the most popular websites allow an attacker to create leaky images. From an attacker’s point of view, a single leaky image is sufficient to track a user. If a victim is registered as a user with at least one of the affected image sharing services, then the attacker can create a user account at that service and share a leaky image with the victim.

**Victims may not notice sharing a leaky image** Several of the affected image sharing services enable an attacker to share an image with a specific user without any notice given to the user. For example, if the attacker posts an image on her Facebook profile and tweaks the privacy settings so that only the victim can access it, then the victim is not informed in any way. Another example is Google Drive, which allows sharing files with arbitrary email addresses while instructing the website to not send an email that informs the other user.

**Victims cannot “unshare” a leaky image** For some services, the victim gets informed in some way that a connection to the attacker has been established. For example, to set up a leaky image on Twitter, the attacker needs to send a private message to the victim, which may make the victim suspicious. However, even if the victim knows about the shared image, for most websites, there is no way for a user to revoke its right to access the image. Specifically, let’s assume the victim receives a cute cat picture from a Google Hangouts contact. Let us now assume that the victim is aware of the leaky image attack and that she suspects the sender of the image tracking her. We are not aware of any way in which the victim can revoke the right to access the received image.

**Image sharing services use a diverse mix of implementation strategies** Secret URLs and per-user authenticated URLs are widely implemented techniques that protects against our attack. However, many websites use multiple such strategies and hence, it is enough if one of the API endpoints uses leaky images. Identifying this endpoint is often a hard task: for example, in the case of Facebook, most of the website rigorously implements secret URLs, but one API endpoint belonging to a mobile subdomain exposes leaky images. After identifying this endpoint we realized that it can be accessed without any problem from a desktop browser as well, enabling all the attacks we describe in Section 3.

**The attack surface varies from site to site** Some but not all image sharing services require a trust relation between the attacker and the victim before a leaky image can be shared. For example, an attacker must first befriend a victim on Facebook before sharing an image with the victim, whereas no such requirement exists on Dropbox or Google Drive. However, considering that most users have hundreds of friends on social networks, there is a good chance that a trust channel is established before the attack starts. In the case of Wordpress the prerequisite that the “victim is a viewer of the attacker’s private blog” appears harder to meet and may require advanced social engineering. Nonetheless, we believe that such leaky images may still be relevant in certain targeted attacks.

Moreover, three of the eight vulnerable sites allow attackers to share images with arbitrary users, without any prerequisite sites (Table 4).

Since our study of the prevalence of leaky images is mostly manual, we cannot guarantee that the 22 sites for which we could not create a leaky image are not affected by the problem. For some sites, though, we are confident that they are not affected, as these sites do not allow users to upload images. A more detailed analysis would require in-depth knowledge of the implementation of the studied sites, and ideally also access to the server-side source code. We hope that our results will spur future work on more automated analyses that identify leaky images.

### 4.3 Responsible Disclosure and Feedback from Image Sharing Services

After identifying image sharing services that suffer from leaky images, we contacted their security teams to disclose the problem in a responsible way. Between March 26 and March 29, 2018, we sent a detailed description of the general problem, how the specific website can be abused to create leaky images, and how it may affect the privacy of users of the site. Most security teams we contacted were very responsive and eager to collaborate upon fixing the issue.

**Confirmed reports** The last three columns of Table 3 summarize how the security teams of the contacted companies reacted to our reports. For most of the websites, the security teams confirmed that the reported vulnerability is worth fixing, and at least six of the sites have already fixed the problem or have decided to fix it. In particular, the top three websites all confirmed the reported issue and all have been working on fixing it. Given the huge user bases of these sites and the privacy implications of leaky images for their users, this reaction is perhaps unsurprising. As another sign of appreciation of our reports, the authors have received bug bounties from (so far) three of the eight affected sites.

**Dismissed reports** Two of our reports were flagged as false positives. The security teams of the corresponding websites replied by saying that leaky images are a “desired behavior” or that the impact on privacy of their user is limited. Comparing Table 3 with Table 4 shows that the sites that dismiss our report are those where the prerequisites for creating a leaky image are harder to fulfill than for the other sites: Creating a leaky image on GitHub requires the attacker and the victim to share a private repository, and Wordpress requires that the victim is a viewer of the attacker’s private blog. While we agree that the attack surface is relatively small for these two sites, leaky images may nevertheless cause surprising privacy leaks. For example, an employee

might track her colleagues or even her boss if their company uses private GitHub repositories.

**Case study: Fix by Facebook** To illustrate how image sharing services may fix a leaky images problem, we describe how Facebook addressed the problem in reaction to our report. As mentioned earlier, Facebook employs mostly secret URLs and uses content delivery networks to serve images. However, we were able to identify a mobile API endpoint that uses leaky images and redirects the user to the corresponding content delivery network link. This endpoint is used in the mobile user interface for enabling users to download the full resolution version of an image. The redirection was performed at HTTP level, hence it resulted in a successful image request when inserted in a third-party website using the `<a>` HTML tag. The fix deployed by Facebook was to perform a redirection at JavaScript level, i.e. load an intermediate HTML that contains a JavaScript snippet that rewrites `document.location.href`. This fix enables a benign user to still successfully download the full resolution image through a browser request, but disables third-party image inclusions. However, we believe that such a fix does not generalize and cannot be deployed to the other identified vulnerabilities. Hence, we describe alternative ways to protect against a leaky image attacks in Section 5.

**Case study: Fix by Twitter** A second case study of how websites can move away from leaky images comes from Twitter that changed its API<sup>7</sup> in response to our report<sup>8</sup>. First, they disabled cookie-based authentication for images. Second, they changed the API in a way that image URLs are only delivered on secure channels, i.e., only authenticated HTTPS requests. Last, Twitter also changed the user interface to only render images from strangers when explicit consent is given. Essentially, Twitter moved from implementation strategy (2) to (5) in Table 2 in response to our report.

Overall, we conclude from our experience of disclosing leaky images that popular websites consider it to be a serious privacy problem, and that they are interested in detecting and avoiding leaky images.

## 5 Mitigation Techniques

In this section, we describe several techniques to defend against leaky image attacks. The mitigations range from server-side fixes that websites can deploy, over improved privacy settings that empower users to control what is shared with them, to browser-based mitigations.

<sup>7</sup><https://twitter.com/TwitterAPI/status/1039631353141112832>

<sup>8</sup><https://hackerone.com/reports/329957>

## 5.1 Server-Side Mitigations

The perhaps easiest way to defend against the attack presented in this paper is to modify the server-side implementation of an image sharing service, so that it is not possible anymore to create leaky images. There are multiple courses of actions to approach this issue.

First, a controversial fix to the problem is to disable authenticated image requests altogether. Instead of relying on, e.g., cookies to control who can access an image, an image sharing service could deliver secret links only to those users that should access an image. Once a user knows the link she can freely get the image through the link, independent of whether she is logged into the image sharing service or not. This strategy corresponds to case 5 in Table 2. Multiple websites we report about in Table 3 implement such an image sharing strategy. The most notable examples are Facebook, which employs this technique in most parts of their website, and Dropbox, which implements this technique as part of their link sharing functionality. The drawback of this fix is that the link’s secrecy might be compromised in several ways outside of the control of the image sharing service: by using insecure channels, such as HTTP, through side-channel attacks in the browser, such as cache attacks [20], or simply by having the users handle the links in an insecure way because they are not aware of the secrecy requirements.

Second, an alternative fix is to enforce an even stricter cookie-based access control on the server-side. In this case, the image sharing service enforces that each user accesses a shared image through a secret, user-specific link that is not shared between users. As a result, the attacker does not know which link the victim could use to access a shared image, and therefore the attacker cannot embed such a link in any website. This implementation strategy corresponds to case 3 in Table 2. On the downside, implementing this defense may prove challenging due to the additional requirement of guaranteeing the mapping between users and URLs, especially when content delivery networks are involved. Additionally, it may cause a slowdown for each image request due to the added access control mechanism.

Third, one may deploy mitigations against CSRF.<sup>9</sup> One of them is to use the `origin` HTTP header to ensure that the given image can only be embedded on specific websites. The `origin` HTTP header is sent automatically by the browser with every request, and it precisely identifies the page that requests a resource. The server-side can check the request’s `origin` and refuse to respond with an authenticated image to unknown third-party request. For example, `facebook.com` could refuse to respond with a valid image to an HTTP request with the `origin` set to `evil.com`. However, this mitigation cannot defend against tracking code injected into a trusted domain. For example, until recently Facebook al-

lowed users to post custom HTML code on their profile page. If a user decides to insert leaky image-based tracking code on the profile page, to be notified when a target user visits the profile page, then the CSRF-style mitigation does not prevent the attack. The reason for this is that the request’s `origin` would be set to `facebook.com`, and hence the server-side code will trust the page and serve the image.

Similarly, the server-side can set the `Cross-Origin-Resource-Policy` response header on authenticated image requests and thus limit which websites can include a specific image. Browsers will only render images for which the `origin` of the request matches the `origin` of the embedding website or if they correspond to the same site. This solution is more coarse-grained than the previously discussed `origin` checking since it does not allow for cross-origin integration of authenticated images, but it is easier to deploy since it only requires a header set instead of a header check. The `From-Origin` header was proposed for allowing a more fine-grained integration policy, but to this date there is no interest from browser vendors side to implement such a feature.

Another applicable CSRF mitigation is the `SameSite` cookie attribute. When set to “strict” for a cookie, the attribute prevents the browser from sending the cookie along with cross-site requests, which effectively prevents leaky images. However, the “strict” setting may be too strict for most image sharing services, because it affects all links to the service’s website. For example, a link in a corporate email to a private GitHub project or to a private Google Doc would not work anymore, because when clicking the link, the session cookie is not sent along with the request. The less restrictive “lax” setting of the `SameSite` attribute does not suffer from these problems, but it also does not prevent leaky images attacks, as it does not affect GET requests.

A challenge with all the described server-side defenses is that they require the developers to be aware of the vulnerability in the first place. From our experience, a complex website may allow sharing images in several ways, possibly spanning different UI-level user interactions and different API endpoints supported by the image sharing service. Since rigorously inspecting all possible ways to share an image is non-trivial, we see a need for future work on automatically identifying leaky images. At least parts of the methodology we propose could be automated with limited effort. To check whether an image request requires authentication, one can perform the request in one browser where the user is logged in, and then try the same request in another instance of the browser in “private” or “incognito” mode, i.e., without being logged in. Comparing the success of the two requests reveals whether the image request relies in any form of authentication, such as cookies. Automating the rest of our methodology requires some support by image sharing services. In particular, automatically checking that a leaky image is accessible only by a subset of a website’s users, requires APIs

<sup>9</sup>[https://www.owasp.org/index.php/Cross-Site\\_Request\\_Forgery\\_\(CSRF\)\\_Prevention\\_Cheat\\_Sheet](https://www.owasp.org/index.php/Cross-Site_Request_Forgery_(CSRF)_Prevention_Cheat_Sheet)

to handle user accounts and to share images between users.

Despite the challenges in identifying leaky images, we believe that server-side mitigations are the most straightforward solution, at least in the short term. In the long term, a more complete solution would be desirable, such as those described in the following.

## 5.2 Browser Mitigations

The current HTTP standard does not specify a policy for third-party cookies<sup>10</sup>, but it encourages browser vendors to experiment with different such policies. More precisely, the current standard lets the browser decide whether to automatically attach the user's cookie to third-party requests. Most browsers decide to attach third-party cookies, but there are certain counter-examples, such as the Tor browser. In Tor, cookies are sent only to the domain typed by the user in the address bar.

Considering the possible privacy implications of leaky images and other previously reported tracking techniques [8], one possible mitigation would be that browsers specify as default behavior to not send cookies with third-party (image) requests. If this behavior is overwritten, possibly using a special HTTP header or tag, the user should be informed through a transparent mechanism. Moreover, the user should be offered the possibility to prevent the website from overwriting the default behavior. We believe this measure would be in the spirit of the newly adopted European Union's General Data Protection Regulation which requires *data protection by design and by default*. However, such an extreme move may impact certain players in the web ecosystem, such as the advertisement ecosystem. To address this issue, advertisers may decide to move towards safer distribution mechanisms, such as the one popularized by the Brave browser.

An alternative to the previously discussed policy is to allow authenticated image requests, but only render them if the browser is confident that there are no observable differences between an authenticated request and a non-authenticated one. To this end, the browser could perform two image requests instead of one: one request with third-party cookies and one request without. If the browser receives two equivalent responses, it can safely render the content, since no sensitive information is leaked about the authenticated user. This solution would still allow most of the usages of third-party cookies, e.g. tracking pixels, but prevent the leaky image attack described here. A possible downside might be the false positives due to strategy (3) in Table 2, but we hypothesize that requests to such images rarely appear in benign third-party image requests. A second possible drawback of this solution may be the increase in web traffic and the potential performance penalties. Future work should test the benefits of this defense and the cost imposed by the additional image request.

<sup>10</sup><https://tools.ietf.org/html/rfc6265#page-28>

To reduce the cost imposed by an additional image request, a hybrid mechanism could disable authenticated image requests by default, and allow them only for the resources specified by a CSP directive. For the allowed authenticated images, the browser deploys the double image requests mechanism described earlier. We advocate this as our preferred browser-level defense since it can also defend against other privacy attacks, e.g. reading third-party image pixels through a side channel [21], while still permitting benign uses.

Similarly to ShareMeNot [32], one can also implement a browser mechanism in which all third-party image requests are blocked unless the user authorizes them by providing explicit consent. To release the burden from the user, a hybrid mechanism can be deployed in which the website requires authenticated requests only for a subset of images for which the user needs to provide consent.

Another solution for when third-party cookies are allowed is for browsers to implement some form of information flow control to ensure that the fact whether a third-party request was successfully loaded or not, cannot be sent outside of the browser. A similar approach is deployed in *tainted canvas*<sup>11</sup>, which disallows pixel reads after a third-party image is painted on the canvas. Implementing such an information flow control for third-party images may, however, be challenging in practice, since the fact whether an image has successfully loaded or not can be retrieved through multiple side channels, such as the `object` tag or by reading the size of the contained div.

The mechanisms described in this section vary both in terms of implementation effort required for deploying them and in terms of their possible impact on the existing state of the web, i.e., incompatibility with existing websites. Therefore, to aid the browser vendors to take an informed decision, future work should perform an in-depth analysis of all these defenses in terms of usability, compatibility and deployment cost, in the style of Calzavara et al. [9], and possibly propose additional solutions.

## 5.3 Better Privacy Control for Users

A worrisome finding of our prevalence study is that a user has little control over the image sharing process. For example, for some image sharing services, the user does not have any option to restrict which other users can privately share an image with her. In others, there is no way for a user to revoke her right to access a specific image. Moreover, in most of the websites we analyzed, it is difficult to even obtain a complete list of images privately shared with the current account. For example, a motivated user who wants to obtain this list must check all the conversations in a messaging platform, or all the images of all friends on a social network.

<sup>11</sup><https://html.spec.whatwg.org/multipage/canvas.html#security-with-canvas-elements>

We believe that image sharing services should provide users more control over image sharing policies, to enable privacy-aware users to protect their privacy. Specifically, a user should be allowed to decide who has the right to share an image with her and she should be granted the right to revoke her access to a given image. Ideally, websites would also offer the user a list of all the images shared with her and a transparent notification mechanism that announces the user when certain changes are made to this list. Empowering the users with these tools may help mitigate some of the leaky image attacks by attracting user's attention to suspicious image sharing, allowing users to revoke access to leaky images.

The privacy controls for web users presented in this section will be useful mostly for advanced users, while the majority of the users are unlikely to take advantage of such fine-grained controls. Therefore, we believe that the most effective mitigations against leaky images are at the server side or browser level.

## 6 Related Work

Previous work shows risks associated with images on the web, such as malicious JavaScript code embedded in SVGs [17], image-based fingerprinting of browser extensions [35], and leaking sensitive information, such as the gender or the location of a user uploading an image [11]. This work introduces a new risk: privacy leaks due to shared images. Lekies et al. [24] describe privacy leaks resulting from dynamically generated JavaScript. The source of this problem is the same as for leaky images: both JavaScript code and images are excepted from the same-origin policy. While privacy leaks in dynamic JavaScript reveal confidential information about the user, such as credentials, leaky images allow for tracking specific users on third-party websites. Heiderich et al. [18] introduce a scriptless, CSS-based web attacks. The HTML-only variant of leaky images does not rely on CSS and also differ in the kinds of leaked information: While the attack by Heiderich et al. leaks content of the current website, our attacks leak the identity of the user.

Wondracek et al. [46] present a privacy leak in social networks related to our group attack. In their work, the attacker neither has control over the group structure nor can she easily track individuals. A more recent attack [41] deanonymizes social media users by correlating links on their profiles with browsing histories. In contrast, our attack does not require such histories. Another recent attack [44] retrieves sensitive information of social media accounts using the advertisement API provided by a social network. However, their attack cannot be used to track users on third-party websites.

Cross-Site Request Forgery (CSRF) is similar in spirit to leaky image attacks: both rely on the fact that browsers send cookies with third-party requests. For CSRF, this behavior results in an unauthorized action on a third-party website, whereas for leaky images, it results in deanonymizing

the user. Existing techniques for defending [5] and detecting [31] CSRF partially address but do not fully solve the problem of leaky images (Section 5).

Browser fingerprinting is a widely deployed [1, 2, 30] persistent tracking mechanism. Various APIs have been proposed for fingerprinting: user agent and fonts [12], canvas [29, 10], ad blocker usage, and WebGL Renderer [22]. Empirical studies [12, 22] suggest that these technique have enough entropy to identify most of the users, or at least, to place a user in a small set of possible users, sometimes even across browsers [10]. The leaky image attack is complementary to fingerprinting, as discussed in detail in Section 3.6.

Another web tracking mechanism is through third-party requests, such as tracking pixels. Mayer and Mitchell [27] describe the tracking ecosystem and the privacy costs associated with these practices. Lerner et al. [25] show how tracking in popular websites evolves over time. Several other studies [42, 47, 13, 32, 8, 14] present a snapshot of the third-party tracking on the web at various moments in time. One of the recurring conclusion of these studies was that few big players can track most of the traffic on the Internet. We present the first image-based attack that allows a less powerful attacker to deanonymize visitors of a website.

Targeted attacks or advanced persistent threats are an increasingly popular class of cybersecurity incidents [37, 26]. Known attacks include spear phishing attacks [6] and targeted malware campaigns [26, 16]. Leaky images adds a privacy-related attack to the set of existing targeted attacks.

Several empirical studies analyze different security and privacy aspects of websites in production: postMessages [36], cookie stealing [4, 34], credentials theft [3], cross-site scripting [28, 23], browser fingerprinting [30, 1], deployment of CSP policies [45], and ReDoS vulnerabilities [38]. User privacy can also be impacted by security issues in browsers, such as JavaScript bindings bugs [7], micro-architectural bugs [20], and insufficient isolation of web content [19]. Neither of these studies explores privacy leaks caused by authenticated cross-origin image requests.

Van Goethem et al. [43] propose the use of timing channels for estimating the file size of a cross-origin resource. One could combine leaky images with such a channel to check if a privately shared image is accessible for a particular user, enabling the use of leaky images even if the browser would block cross-origin image requests. One difference between our attack and theirs is that leaky images provide 100% certainty that a victim has visited a website, which a probabilistic timing channel cannot provide.

Several researchers document the difficulty of notifying the maintainers of websites or open-source projects about security bugs in software [24, 40, 39]. We experienced quick and helpful responses by all websites we contacted, with an initial response within less than a week. One reason for this difference may be that we used the bug bounty channels provided by the websites to report the problems [15, 48].

## 7 Conclusions

This paper presents leaky images, a targeted deanonymization attack that leverages specific access control practices employed in popular websites. The main insight of the attack is a simple yet effective observation: Privately shared resources that are exempted from the same origin policy can be exploited to reveal whether a specific user is visiting an attacker-controlled website. We describe several flavors of this attack: targeted tracking of single users, group tracking, pseudonym linking, and an HTML-only attack.

We show that some of the most popular websites suffer from leaky images, and that the problem often affects any registered users of these websites. We reported all the identified vulnerabilities to the security teams of the affected websites. Most of them acknowledge the problem and some already proceeded to fixing it. This feedback shows that the problem we identified is important to practitioners. Our paper helps raising awareness among developers and researchers to avoid this privacy issue in the future.

### Acknowledgments

Thanks to Stefano Calzavara and the anonymous reviewers for their feedback on this paper. This work was supported by the German Federal Ministry of Education and Research and by the Hessian Ministry of Science and the Arts within CRISP, by the German Research Foundation within the ConcSys and Perf4JS projects, and by the Hessian LOEWE initiative within the Software-Factory 4.0 project.

## Abstract

Click is the prominent way that users interact with web applications. For example, we click hyperlinks to navigate among different pages on the Web, click form submission buttons to send data to websites, and click player controls to tune video playback. Clicks are also critical in online advertising, which fuels the revenue of billions of websites. Because of the critical role of clicks in the Web ecosystem, attackers aim to intercept genuine user clicks to either send malicious commands to another application on behalf of the user or fabricate realistic ad click traffic. However, existing studies mainly consider one type of click interceptions in the cross-origin settings via iframes, *i.e.*, clickjacking. This does not comprehensively represent various types of click interceptions that can be launched by malicious third-party JavaScript code.

In this paper, we therefore systematically investigate the click interception practices on the Web. We developed a browser-based analysis framework, OBSERVER, to collect and analyze click related behaviors. Using OBSERVER, we identified three different techniques to intercept user clicks on the Alexa top 250K websites, and detected 437 third-party scripts that intercepted user clicks on 613 websites, which in total receive around 43 million visits on a daily basis.

We revealed that some websites collude with third-party scripts to hijack user clicks for monetization. In particular, our analysis demonstrated that more than 36% of the 3,251 unique click interception URLs were related to online advertising, which is the primary monetization approach on the Web. Further, we discovered that users can be exposed to malicious contents such as scamware through click interceptions. Our research demonstrated that click interception has become an emerging threat to web users.

## 1 Introduction

Clicking an HTML element is the primary way that users interact with web applications. We click hyperlinks to navigate among different documents that are interconnected through

the hyperlinks on the Web. We click form submission buttons (*e.g.*, the Facebook like button and the Twitter tweet button) to share data with websites and other people on the Internet. We click custom user interface components (*e.g.*, the video or audio player controls) to command various web applications.

Since clicks are important in modern web applications, attackers have launched UI redressing attacks, namely Clickjacking [26], to hijack user clicks. In particular, malicious websites trick a user into clicking components (*e.g.*, a Facebook like button) different from what the user perceives to click, in order to send commands on behalf of the user to the different application they secretly embed (typically in an iframe tag). To defend against Clickjacking, a rich collection of works has been proposed, which has shown great performance [1, 3, 10, 15, 29, 30].

Clicks are also critical in one pervasive application—online display advertising, which powers billions of websites on the Internet. The publisher websites earn a commission when a user clicks an advertisement they embed from an online advertising network (ad network in short). However, the ad click-through rate is usually very low, *e.g.*, around 2% in business-to-consumer banner ads [18]. To increase revenue that can be made through ad clicks, malicious websites have used bots to automatically and massively send fake click traffic to the ad networks, which is known as ad click fraud [5, 22, 27]. To combat against click frauds, ad networks have developed advanced techniques to determine the authenticity of click traffic [2, 6, 9, 38]. Consequently, traditional bot-based ad click fraud has then become less effective.

Instead of relying on click bots, attackers recently started to *intercept and redirect* clicks or page visits from real users to fabricate realistic ad clicks. First, they infect a victim user's computer with malware to either force or trick a user into submitting an ad click. For example, some "browser redirect viruses" modify a user's default search engine to a malicious one, redirecting the user to an advertiser's page when the user clicks a search result [19]. Second, malicious third-party iframes can automatically redirect users to an ad page. Similarly, a user's current tab may be automatically redirected

to unintended destinations when a script opens a new tab upon click. Google recently released a new version of the Chrome browser to automatically prevent these two types of automatic redirects [8]. Nevertheless, Chrome still cannot detect and prevent other possible ways to intercept user clicks, including but not limited to links modified by third-party scripts, third-party contents disguised as first-party contents, and transparent overlays.

A systematic study on click interceptions is necessary to deeply understand this emerging threat to web users. We aim to develop a system to automatically detect such practices on the Web, and investigate what kinds of techniques are exploited and who are involved in. We first design and develop a system to detect various techniques employed by JavaScript to intercept user clicks. Using this system, we then perform a large-scale measurement with the goal of finding out those practitioners that hijack links and deceive user clicks. Finally, we analyze our measurement results, and explore the intents and consequences hidden behind the click interception practices.

However, it is challenging to perform the aforementioned systematic study because of the dynamic and event-driven characteristics of web applications. First, JavaScript code can be dynamically loaded. Statically analyzing the HTML source code is insufficient to cover all scripts that can intercept user clicks. Second, hyperlinks can be dynamically created and modified by any scripts. To pinpoint the scripts truly accountable for the interception, we need to re-engineer a browser to differentiate the actions of different scripts in runtime. Third, JavaScript can dynamically bind a URL to user click on an arbitrary HTML element through event listeners (handlers). Monitoring hyperlink creation and modification is insufficient to catch all the click interception practices. Last but not least, a web page may contain a large number of event handlers that respond to user clicks. To perform a large-scale comprehensive study, we have to efficiently interact with all those event handlers.

To tackle the challenges mentioned above, we design our analysis framework by customizing an open-sourced Web browser. We first mediate all JavaScript accesses to hyperlinks in a web page in the browser's renderer. In this way, we can identify the *initiator* of the URL associated with each hyperlink. Second, we monitor the creation and execution of JavaScript objects so that we can track down the *provenance* of dynamic inline JavaScript code. Third, we monitor all event handlers registered on every HTML element and hook navigation-related JavaScript APIs. With this design, we can develop an automated approach to monitor the event handlers accordingly, and determine if an event handler might be used to hijack user clicks. Last but not least, we derive the navigation URL without really firing the navigation that is initiated by a user click. This allows us to interact with all the click event handlers in an efficient way. It also helps us understand the reason why a particular user click is of the

interest of a script.

In this work, we developed OBSERVER, a prototype of the aforementioned analysis framework by customizing and extending the Chromium browser. Using this framework, we performed a large-scale data crawling on the Alexa top 250K websites. We discovered that 437 third-party scripts exhibited the activities of intercepting user clicks on 613 websites. They combined receive 43 million visits on a daily basis. In particular, we observed that some scripts tricked users into clicking their carefully crafted contents, which were usually disguised as first-party contents, or intentionally implemented as barely visible elements covering first-party elements. In addition, we revealed that these third-party scripts intercepted user clicks in order to monetize user clicks, which is a new practice we observe as committing ad click frauds. It is worth noting that we will make our implementation publicly available.

In summary, this paper makes the following contributions.

- We design and develop OBSERVER, a framework for studying click interception practices. This facilitates our capability in automatically detecting a wide range of click interception cases on various websites.
- We perform a large-scale measurement study to explore and understand how attackers manipulate web pages in the wild and thus intercept user clicks.
- We characterize the activities of click interceptions on top Alexa websites and discover the intents and consequences hidden behind the activities of click interception.

## 2 Related Work

In this section, we introduce existing studies about how attackers intercept user clicks or generate fake clicks, and how to detect and prevent such attempts. We also explain other studies analyzing how JavaScript libraries are included and what their behaviors are.

**Clickjacking.** Clickjacking, also known as UI redressing, is a popular attack designed to trick a victim into doing some tasks on another website the user has logged in, bypassing the same-origin policy. It is one type of *inter-page* click interception in which a malicious *first-party website* tricks a victim into clicking components in another website loaded in an *iframe*. For example, a malicious website could load a specific page of a target website via an invisible *iframe*, and place it on top of a crafted object that looks benign and independent to the target page. The malicious website then can trick a victim into unintentionally clicking the target page via the crafted object to activate some operations defined in that page. Framebusting [29–31] is a well-known defense to prevent clickjacking by disallowing untrusted websites to load specified pages via an *iframe*. However, framebusting is incompatible with third-party mashup or other techniques that demand cross-origin framing [15]. Rather, other studies

including ClickIDS [3] and InContext [10] rely on human perception to verify whether a click was intended by a user. Akhawe *et al.* [1], however, identified that such mechanisms are not comprehensive or suffer from an unacceptable usability cost.

Our research complements these studies by investigating new practices of *intra-page* click interception by *third-party scripts*, which intercept a victim’s clicks on components (including iframes) within the same page/frame. Further, we demonstrate that the scripts can use hyperlinks, event listeners, and visual deceptions, to intercept user clicks.

**Link Hijacking.** Link hijacking is an attack to modify the destination of links on websites. Nikiforakis *et al.* [24] investigated ad-based URL shortening services and discovered link hijacking by an embedded third-party iframe on a “waiting page” through automatic tab redirects, which the new Chrome browser can prevent [8]. Our research demonstrates a new form of link hijacking that modifies all first-party hyperlinks before the user even clicks them, and shows our system can automatically detect them.

**Visual Deception.** Prior works have studied how visual deceptive contents can be used to intercept user clicks. Duman *et al.* [7] studied trick banners (*e.g.*, download buttons) that look similar to first-party contents, and further proposed a defense based on a supervised classifier. Rafique *et al.* [28] discovered overlay ads and invisible banners in free live-streaming services. Note that our research does not focus on a specific category of visual deceptive contents or services. Moreover, OBSERVER is able to distinguish deceptive contents created by *different scripts* because of its provenance tracking capability, allowing us to detect the real culprits.

**Click Fraud and Click Spam.** Click fraud and click spam are attempts to raise revenue by submitting fake ad clicks to an ad network. In traditional click fraud, attackers usually operate a botnet to fabricate a large number of ad clicks automatically to an ad network. For example, Pearce *et al.* [27] estimated that the ZeroAccess click-fraud botnet incurred advertising losses on the order of \$100,000 per day. In click spam, unethical content publishers or ad injection attackers [32, 37] either trick the users into clicking ads, or use malware to click ads on behalf of the users. Click spams could even lead victim users to malicious ads [16, 37, 39]. Defenses against click fraud and click spam mostly aim to distinguish fake clicks from real clicks by analyzing their patterns [5, 6, 12, 17, 21, 22, 38]. Thus, attackers try to make their click traffic look as benign as possible. For example, some attacks hijack real human clicks through rogue DNS servers and redirect them to ad networks [2]. We discover that the click interception techniques we identify have already been used by attackers for generating realistic click traffic in the wild.

**JavaScript Inclusion and Behavior Analysis.** Numerous researchers have analyzed the behavior of third-party JavaScript libraries and how they are included. Nikiforakis *et*

*al.* [23] investigated the Alexa Top 10K websites to discover how many remote JavaScript libraries they include and from which library hosting servers they include the scripts. They also assessed the security of those hosting servers to infer whether they could serve malicious JavaScript code. Lauinger *et al.* [14] and Retire.js [25] studied the semantics of JavaScript libraries, by considering whether hosted JavaScript libraries are outdated or have known vulnerabilities. Systems like EvilSeed [11] and Revolver [13] focus on detecting malicious web pages using content or code similarities. Also, ScriptInspector [40] inspects API calls from third-party scripts to study how they interact with critical resources, such as the DOM, local storage and network. It is able to detect suspicious third-party scripts that violate some access policies. These studies, however, rely on the origin of a JavaScript script to determine whether it is a first-party or third-party script. This implies that they cannot properly handle the situation where a website includes JavaScript libraries from their subdomains or other domains, and from other CDNs (§4.2). Furthermore, unlike ScriptInspector, OBSERVER can track the dynamic creation of JavaScript objects and DOM elements such that it can accurately attribute hyperlink modifications and event listener registrations.

### 3 Overview of OBSERVER

In this section, we present OBSERVER, an analysis framework that is designed to comprehensively log all potential click-interception-related events performed by JavaScript code in a best-effort manner. OBSERVER focuses on three fundamental actions that JavaScript code might rely on to intercept clicks: 1) *modifying* an existing hyperlink in a page; 2) *creating* a new hyperlink in a page; and 3) *registering* an event handler to an HTML element to hook a user click. Whenever OBSERVER identifies any of such actions, it *tags* the corresponding element with the unique identifier of the script that *initiates* the action. Further, OBSERVER logs the reaction (*i.e.*, *navigation*) of a page after it *intentionally* clicks a hyperlink or an element associated with an event handler in the page, to know the URLs to which a click interceptor aims to lead a user.

In the following, we first demonstrate our threat model (§3.1). We then describe how OBSERVER monitors the JavaScript accesses to HTML anchor elements (§3.2), and how it tracks the dynamic creation of HTML anchor elements and HTML script elements (§3.3). Further, we show how OBSERVER hooks several APIs to catch navigation-related JavaScript event listeners (§3.4). Finally, we detail our prototype implementation based on the Chromium browser (§3.5).

#### 3.1 Threat Model

In our threat model, we consider only click interception activities performed by *third-party* scripts as malicious. Although first-party websites might exhibit similar activities to intercept

user clicks, we do not consider them as malicious, because they have the full privilege to control their own applications. Nevertheless, OBSERVER can comprehensively collect all data related to click interception.

## 3.2 Recording Accesses to HTML Anchor Elements

Modifying a hyperlink in a web page is one of the most explicit methods to intercept and navigate a user click into a different URL rather than the original one. OBSERVER aims to record any accesses to all hyperlinks in a web page to detect any such attempts. In HTML, a hyperlink is defined with an anchor element (*i.e.*, an `<a>` tag), and its `href` attribute specifies the associated destination URL. Thus, by monitoring and recording which script modifies the `href` attribute of an `<a>` tag, OBSERVER is able to recognize a script's potential click interception.

JavaScript can modify the `href` attribute through DOM APIs in several ways. We use the keyword `a` to represent an HTML Anchor Element object and the keyword `url` to represent a URL string in the following examples. First, a script can directly assign a new value to the attribute as in `a.href = url`; or in `a.attributes["href"] = url`; Second, it may also call the `setAttribute()` API as in `a.setAttribute("href", url)` to perform a similar operation. Note that developers may leverage APIs defined in some third-party JavaScript libraries, *e.g.*, jQuery, to change the attribute. OBSERVER can cover all these wrapper libraries because they would still need to call the above APIs defined in the DOM standard, which is implemented by all browsers to ensure cross-browser compatibility.

OBSERVER hooks all these DOM APIs to monitor modifications to the `href` attribute of `<a>` tags in the DOM. Specifically, it intercepts any call to such an API. Once intercepted, it inspects the current JavaScript call stack to reason about the origin of API invocation. It locates the bottom JavaScript frame in the call stack to find the JavaScript function that initiates the API call.

**Script Identification.** To attribute the API access to a specific script, we need to obtain the identity of the accessing JavaScript code. OBSERVER assigns a `scriptId` to each script object to uniquely identify it in the JavaScript runtime. In HTML, JavaScript code is usually enclosed between `<script>` and `</script>` tags as an inline script, or stored in an external JavaScript file and loaded with `<script>` tags as an external script. Each `<script>` tag is compiled into an individual JavaScript object in the JavaScript engine. There are also other types of inline JavaScript code. For example, JavaScript code can be written as the on-event listener attributes of HTML elements. This kind of inline scripts that are not wrapped within a `<script>` tag are also compiled into separate JavaScript objects, which are identified by the unique `scriptIDs`.

OBSERVER associates the `scriptId` of a script with its `sourceURL`, which is the URL the browser uses to load the remote JavaScript code. The `sourceURL` of an inline script, however, is empty. Instead, we use the URL of the embedding frame, *i.e.*, the URL that the browser uses to load the HTML document into the embedding frame, as the `sourceURL` of *static* inline scripts. However, inline scripts can also be created on-the-fly by JavaScript. We will discuss how we attribute a DOM access to a dynamic inline script in §3.3.2. Besides the `scriptId`, we also record the row number, column number, and name of the function in the accessing script in a *shadow* data store associated with the element. It is worth noting that JavaScript code cannot modify the shadow data store because it is a C++ data structure that is not writable on the JavaScript side.

## 3.3 Tracking Dynamic Element Creation

Dynamically creating a new hyperlink in a web page is another method to intercept a user click. In short, OBSERVER considers direct and indirect approaches that a script can exploit to achieve this goal: 1) creating a hyperlink and 2) creating a script that creates a hyperlink.

### 3.3.1 HTML Anchor Elements

JavaScript code can dynamically create any HTML elements, including an anchor element, in a web page. Specifically, JavaScript can insert a new `<a>` tag into the DOM tree of a web page through APIs such as `document.write("<a>...</a>")` and `document.createElement("a")`. A script can even replace the entire element with a new element by changing the `outerHTML` attribute of it, *e.g.*, `a.outerHTML = '<a href="' + url + "'>...</a>'`. These techniques could be exploited by scripts as another way to intercept user clicks instead of modifying existing hyperlinks. Thus, OBSERVER needs to track the dynamic creation of `<a>` tags in the browser.

OBSERVER attaches a *shadow initiator* attribute to each anchor element in the DOM tree to represent the creator of the object. The initiator attribute is the `scriptId` of the script that creates the corresponding element. OBSERVER assigns a special initiator value—`0`, which represents the owner of a document—to all static elements that are built by the browser parser. The static `<a>` tags are the *first-party* hyperlinks. OBSERVER intercepts all the element creation APIs in the web browser to find the initiating JavaScript frame in the call stack. The `scriptId` of the initiating script is used as the initiator of the dynamically created elements (hyperlinks). OBSERVER would also record any accesses to the `href` attribute of the dynamically created anchor elements.

### 3.3.2 JavaScript

JavaScript code can also be dynamically generated in web applications, just like HTML elements. Specifically, as one class

of HTML elements, new `<script>` elements can be dynamically created by JavaScript using the same APIs for creating elements. OBSERVER aims to assign unique identifies to all of such dynamically created scripts. If an external script file is loaded from a remote host into a dynamically inserted `<script>` element, getting its identity is not different from getting the sourceURL of one static `<script>` element. Some strings can also be dynamically parsed as inline JavaScript code if they are defined as inline event handlers or passed in the call of APIs like `window.eval("...")`.

However, it is not straightforward to tell the identity of a dynamically generated inline script because its sourceURL is blank. To overcome this difficulty, OBSERVER hooks the APIs that are used to generate dynamic scripts. It saves the sourceURL of the JavaScript code that calls the script generation API as the sourceURL of the newly generated inline script. To distinguish the dynamically generated script, or the *child* script (either an inline script or an external script), from the generating script, or the *parent* script (the one that generates the script), OBSERVER records the scriptID of the parent script as the `parentScriptID` attribute of the child script. The `parentScriptID` of all scripts that are initially statically embedded by the document owner is set to `0`. This allows us to construct a script dependency graph in the analysis.

OBSERVER also logs all accesses to any inline on-event handlers of any DOM object as it does with the `href` attribute of `<a>` elements. It finds the last script that sets an inline on-event handler as its parent script and derives the sourceURL from it. If no such an entry can be found, OBSERVER sets the script that creates the receiver object as its parent script.

### 3.4 Monitoring JavaScript Event Listeners

Instead of modifying or creating hyperlinks, a script can register an event listener or handler to an HTML element. The event handler is asynchronously executed whenever there is a user click on the element. In particular, a script may open an arbitrary URL in a new browser window/tab, or send an HTTP request in the background, when a user clicks any element it listens for. Therefore, OBSERVER aims to monitor all event listeners registered by JavaScript code in a page to identify whether they will navigate a user to a different URL according to a user click.

OBSERVER first monitors event listener registration by hooking the `addEventListener()` API and monitoring accesses to the on-event listeners, to identify the scripts that are interested in user interactions. It then intercepts any click-related user events (*e.g.*, `click` and `mousedown`) when they are fired in the web browser and detects the event target element in the DOM tree. Since a script may not necessarily initiate a page navigation in its event handler (*e.g.*, an analytic script), OBSERVER filters those scripts by hooking several APIs that can be used for starting a navigation, *e.g.*, `window.open('...')`, `window.location = '...'`; *etc.* OBSERVER

detects the bottom frame in the JavaScript call stack and further constructs and logs the navigation URL in these APIs in the shadow data store of the target element.

One challenge we met in our design is that one event handler can be activated multiple times. In the DOM, the events are propagated in three phases: capturing, target, and bubbling. For example, in the capturing phase, an event is propagated from the root node in the DOM tree—the `<html>` node, then through any intermediate parent nodes, before finally reaching the target node. An event handler registered in the capturing phase at the `<html>` tag will always be triggered whenever any of its child elements is clicked<sup>1</sup>. To avoid activating such event listeners multiple times, OBSERVER would skip calling an event listener at a node if the `Event.currentTarget` object (*i.e.*, the current node) is different from the `Event.target` object in event propagation. We further set a flag in OBSERVER to abort all page navigations, including those caused by clicking the `<a>` tags, after the navigation URLs are saved in the logs. This enables us to efficiently interact with all elements in a web page without really visiting the linked URLs.

### 3.5 Implementation

We implement a prototype of OBSERVER in the Chromium browser (version 64.0.3282.186). We will release our prototype implementation as an open source software. We implement OBSERVER in a full-fledged browser to escape any artificial result that might be caused by using a simpler and uncommon user agent. We add several custom attributes (*e.g.*, `initiator`, `accessLog`, `scriptID`, `parentScriptID`, `sourceURL`) to the `Node`<sup>2</sup> objects to save the monitoring data. All these custom attributes can be read but not written by JavaScript for further analysis. For performance concerns, we implement a lazy update mechanism for setting the above attributes. The values of these attributes are kept in the hidden attribute members of the modified C++ classes. They are updated in the DOM tree only when the attributes are first accessed by JavaScript.

We hook the above DOM APIs by inserting custom monitoring code in the C++ implementation of the V8 binding layer between the V8 JavaScript engine and the DOM implementation in WebKit. The custom monitoring code identifies the JavaScript caller by fetching the `scriptID` of the bottom frame in the JavaScript call stack. It appends the logs of accesses to the `href` attribute and the inline on-event handlers to the hidden `accessLog` attribute of the corresponding DOM object. The code sets the `initiator` attribute of an anchor element when it is created by either JavaScript code or the browser parser. Furthermore, the `sourceURL` and `parentScriptID`

<sup>1</sup>An event handler registered in the bubbling phase at a parent node may not be activated because the event propagation can be stopped by some other event handler registered at its child node.

<sup>2</sup>Node is the base class of HTML elements in WebKit.

tID of all scripts are stored with a `<script>` object. We further store the scriptID in the sourceURL dictionary at the global Document object.

The prototype of OBSERVER can comprehensively log all click-interception-related events. In the browser, a click-driven navigation can be started by the built-in default event handler of anchor elements (hyperlinks) and the developer-defined event handlers, which we have introduced in §3.2 and §3.4. OBSERVER ensures complete mediation of element accesses and event handler registrations in the C++ implementation of the corresponding DOM APIs (including the built-in default event handler), which cannot be bypassed by any JavaScript code. In other words, the browser must go through the underlying C++ APIs and our monitoring code when JavaScript code accesses any hyperlink or registers an EventListener to any HTML element.

## 4 Methodology

In order to study the click interception problems in the wild, we perform a large-scale data crawling of the Alexa top 250K websites. We describe our data collection method in §4.1, how we determine the owner and privilege of JavaScript code as well as HTML elements in §4.2, and finally how we detect three classes of click interception in §4.3.

### 4.1 Data Collection

We use the OBSERVER prototype to collect data for investigating the click interception problem. In particular, we aim to identify all hyperlinks and scripts that react on user clicks, and the destination URLs that the browser would visit after the clicks. We leverage the Selenium WebDriver Python binding to automatically drive OBSERVER and interact with the web page it renders. To this end, we run our analysis framework on a 64 core CPU Linux server and collect data from the Alexa top 250K websites.

We collect data in two phases for each web page: 1) collecting *default data* right after page rendering; and 2) collecting *reaction data* by interacting with a rendered page. In each page navigation, we first asks OBSERVER to wait for a page to be completely rendered by the browser for up to 45 seconds. After that, we insert a script into the page to traverse the DOM tree in pre-order to collect all the data OBSERVER has logged with each element. In addition, we log for each element several display properties (*e.g.*, width, height, position, opacity, *etc.*) to study additional tricks that may be used to intercept user clicks (*e.g.*, some third-party contents overlap with or appear similar to first-party contents). We then save a snapshot of the current DOM tree into an external HTML file as well as a full-page screenshot for further analysis.

Next, we interact with a rendered page to collect data about how the page reacts to our clicks, such as navigation and DOM modification. We disable the navigation flag in OBSERVER

to deactivate real navigations that may be caused by event handlers or hyperlinks. We then automatically click all elements in the DOM tree through Selenium to trigger the click event listeners and hyperlink navigations to collect navigation logs. For each navigation triggered by a click, we log the information regarding the navigation URL, the clicked element, and, if exist, the corresponding event listeners and scripts that initiate the navigation. In addition, we traverse the DOM tree again, as we do in the first phase, to identify whether scripts update the DOM elements due to user clicks.

### 4.2 Third-party Content Detection

In this section, we explain our techniques to distinguish first-party scripts/contents from third-party scripts/contents, which is necessary to detect click interceptions driven by third-party scripts. A naïve technique that merely relies on the exact origin of scripts is not enough because a website frequently loads its own scripts from its subdomains, its different domains, and domains operated by others such as content delivery network (CDN) services. For example, the main page of <https://www.google.com/> includes scripts from its subdomain [apis.google.com](https://apis.google.com) and its CDN domain [gstatic.com](https://gstatic.com). If we use only origin information, we may misidentify these scripts as third-party scripts. We aim to solve this problem using *domain substring matching* and *DNS record matching*.

Domain substring matching is a heuristic technique to infer that a remote script is a first-party script if the remote script's domain name is similar to the current page's domain name. It first checks whether the main domain names of a remote script and the current page are the same while excluding domain suffixes. For example, a script loaded from <https://apis.google.com/> on <https://www.google.co.jp/> is determined as a first-party script because its main domain name excluding the suffix *com* is *google*, which is identical to that of the current page excluding the suffix *co.jp*. Second, it tests whether the proper subdomain name of a remote script consists of the main domain name of the current page without suffixes, to come up with CDN practices that maintain custom subdomain names for individual websites. For example, a script loaded from <https://static-global-s-msn-com.akamaized.net/> on <https://www.msn.com/> are inferred as a first-party script because the proper subdomain name *static-global-s-msn-com* contains the main domain name *msn*. We do realize that our technique has limitations, which we will discuss in §6.

DNS record matching leverages several DNS records to decide whether two distinct domains are operated by the same organization. Specifically, we inspect the DNS SOA records [36] and the DNS NS records [34] of the two hostnames (domain names). An SOA record includes the email address used to register the domain. Many organizations would use the same email address to register multiple domains. For instance, the SOA email addresses of [google.com](https://google.com) and [gstatic.com](https://gstatic.com) are both *dns-admin@google.com*. However, there are also exceptions.

Different organizations may use the same Managed DNS providers [35] to register domains. Accordingly, their SOA same email addresses are identical. For example, both [dropbox.com](https://dropbox.com) and [bitbucket.org](https://bitbucket.org) use `awsdns-hostmaster@amazon.com` as their SOA email address.

We address this limitation by further examining if the name server (NS) records of a script/URL and the first-party web page have an intersection. Specifically, we use the *domain name* instead of the full hostname of a NS, because one domain may use several NSs from a large pool. If the first-party domain name is found in a common NS, we mark the external script as a first-party script. For instance, both [gstatic.com](https://gstatic.com) and [google.com](https://google.com) use NSs `nsX.google.com`, where *X* is a numeric value. Therefore, we determine the two domains belong to the same organization because they have a common NS domain name—`google.com`, and an identical SOA email address. Note that we exclude all common NSs that are operated by any known managed or dynamic DNS providers.

**Dynamic Element.** Recognizing the sources of dynamic elements is also important to identify cross-party accesses. We classify dynamic elements into two groups based on which parties their initiating scripts belong to. This allows us to distinguish first-party contents from third-party contents.

## 4.3 Click Interception Detection

Normally, a user may explicitly click a hyperlink to navigate to another web page, or click some components such as images or buttons to interact with the current web page. However, some scripts may deliberately intercept a user's clicks to override the default action that the user may expect. Furthermore, a user could also be fooled by a script into clicking some components she/he would not click. We designate such undesired click manipulation caused by privilege abuse as **click interception** in web applications. As discussed earlier, we do not consider click interceptions exhibited by first-party scripts as malicious.

Based on how a user click could be manipulated, we categorize click interception into three classes—interception by hyperlinks, interception by event handlers, and interception by visual deception. In particular, a script can intercept user click by 1) using an existing hyperlink or creating a new hyperlink; 2) registering a click event handler with an element; and 3) manipulating the UI to deceive a user into clicking elements controlled by the script.

In the following, we explain the methods to detect the three classes of click interception. Specifically, we leverage the *navigation URL* and the *navigation APIs*<sup>3</sup> (§3.4), and the display properties of the element (§4.1).

<sup>3</sup>The default event handler of `<a>` tags is also considered as one API.

### 4.3.1 Interception by Hyperlinks

In general, a script can intercept user clicks with hyperlinks in two ways: modifying one existing (first-party) hyperlink, and adding one hyperlink to a huge element.

**Modifying Existing Hyperlinks.** A *third-party* script can intercept a user's click through a *first-party* hyperlink by overwriting the `href` attribute. A *third-party* script might also employ a similar approach to intercept a user's click on *another third-party* hyperlink. Therefore, we search in the `href` attribute log of an anchor element the last script that modifies its value. If a (different<sup>4</sup>) *third-party* script is found, the script is marked as one click interception script. We use the technique in §4.2 to determine if the script and the anchor element belong to the same organization. A *third-party* script might also intercept a user's click through attaching an event listener to a *first-party* hyperlink, which we discuss in the following section. Note that although a *first-party* script may modify a *third-party* hyperlink, we think this is legitimate because the first party as the owner of the web page is entitled to include or remove any third-party contents.

**Creating Huge Hyperlinks.** A script can trick users into clicking its hyperlink by enclosing a huge clickable element. In particular, it can enclose a significant part of its web page within one `<a>` tag such that a click on any of the enclosed contents would result in a page navigation that is controlled by it. Therefore, we also check the size of an anchor element relative to the browser window<sup>5</sup>. Specifically, we use 75% as the threshold to detect the suspicious huge hyperlinks that can be used to intercept user clicks. According to our knowledge, most (but not all) links on the web are relatively small compared to the browser window. Therefore, we think 75% is a reasonably large threshold to help quickly identify the suspicious ones. Further, we exclude any hyperlinks pointing to a first party navigation URL, because the first party has the right to use huge hyperlinks in its own pages.

### 4.3.2 Interception by Event Handlers

The event handlers are the second technique that a script can use to intercept user clicks. However, a script listening for user click may not necessarily navigate the user to another URL. For instance, an analytic script may observe user clicks to determine and log only user engagement within the current page. We leverage the navigation-related APIs to solve this problem.

To start a new navigation, a developer needs to either call the `window.open()` API or change the `location` of the current frame. The two JavaScript DOM APIs are implemented by the C++ methods `LocalDOMWindow::open()` and `Location::SetLocation()` in WebKit, respectively. For each element, we

<sup>4</sup>We use the term a *different script* to represent a script of a different organization in the rest of the paper.

<sup>5</sup>We used 1024px x 768px as the browser window size in our experiments.

examine if the two C++ methods are (indirectly) called upon a click on the element. We then extract the navigation URLs from the associated logs.

### **Third-party Interception Scripts using Event Handlers.**

We determine a *third-party* script as a click interception script if it (indirectly) calls either one of the above two C++ methods in its click event listener that is added to a *first-party* element. We name such a click event listener as a *navigation event listener*. Similarly, if such a navigation event handler is added to a *third-party* element created by the script of a different organization, the third-party script implementing the event handler is also determined as a click interception script.

**Intercepting Huge Elements with Event Handlers.** We use the same 75% relative size threshold to detect suspicious huge elements that are registered with a *third-party navigation event handler* and can be used to intercept user clicks. We also filter the elements that are associated with a first-party navigation URL.

### **4.3.3 Interception by Visual Deception**

Third party scripts can also intercept a user's clicks through visual implementation tricks to deceive a user. In particular, the third-party contents are designed in some way such that a user is likely to click. We do not consider first-party contents with similar characteristics malicious because the first-party websites have the complete freedom to design their contents.

This last click interception category could be controversial in our opinion, as some third-party developers may argue that they *do not intend to deceive the end users*. Nevertheless, we still classify such practices as click interception (but not necessarily malicious) because the users *can be deceived through the visual tricks*.

We have identified two possible visual deceptions—mimicry, and transparent overlay. We detect these visual deceptive tricks for each *group of third-party elements*, which are the largest sub DOM tree that consists of only elements of the same third-party script (organization).

**Mimicry.** Some third-party script would deliberately decorate its elements such that they are almost visually indistinguishable from first-party contents. A user might consequently click these mimic elements. However, the imitating elements are usually not exact copies of some first-party elements. As a result, we cannot use pixel-wise comparison to detect such mimic elements.

We utilize the structural information as well as the display properties of a third-party element group to detect mimicry. Specifically, we compute the relative size of media contents, *e.g.*, images, videos, and iframes, in a *group of third-party elements*, as well as the size of the largest container of them. We then compute the same metrics for any *group of first-party elements* whose root node is a sibling (neighbor) to that of the third-party element group. Next, we calculate a similarity score between the two groups of elements using: 1) the CSS

class names of the two root nodes, which are primarily used to describe the representations of HTML elements; 2) the numbers of each kind of media tags, which indicate how media contents are implemented; and 3) the relative sizes of media contents in two groups and the sizes of the largest container nodes, which represent the visual layout of an element group.

We set a threshold learned from our training phase to keep only third-party element groups that are very similar to some first-party element groups. Note that we compute the similarity scores using the display property data before we click the elements to find the elements whose default representation is likely to fool a user. We do acknowledge that there are other features (*e.g.*, the DOM tree structure, color histogram) that may better determine the similarity. However, we find the ones that we select work well in our manual test over a small set of samples. We plan to leverage more sophisticated techniques (*e.g.*, image classification [7]) in our future work.

**Transparent Overlay.** A third-party script can inject contents that partially overlap with or completely cover first-party contents. In the case that some first-party contents are completely covered, the user might not notice their existence and treat the covering third-party contents as first-party ones. Further, a script can make some of its elements barely visible by setting a small value to their *opacity* style property. Subsequently, a user's click could be delivered to these “hidden” elements when the user is intending to click some other elements beneath them. We detect transparent overlay third-party contents in the following two steps.

First, for each group of third-party elements, we compute the *minimum* portion of a *first-party* element that it overlaps with. Specifically, we scroll the browser window virtually to compute all the possible overlapped regions with each *first-party* element. If the covered portion of a first-party element is always greater than a pre-defined threshold (*e.g.*, 25%), we label this group of third-party elements as overlay elements. Since some third-party scripts may implement components allowing a user to cancel out the overlay elements, we further exclude those that no longer significantly overlap with any first-party element after our automatic clicks, which must include a click on one of such cancel-out buttons if there are any. However, this method may not work well in some cases. For example, the covering elements could first be hidden by a click on a cross button, and later be revealed by another click on another button. We consider it as a limitation and plan to leverage knowledge in computer vision to develop a better automated testing method in our future work.

Next, we detect third-party transparent overlay element groups by comparing the *opacity* value collected in the display properties with a small threshold (*e.g.*, 0.1). A zero opacity value indicates complete transparency. We do not consider elements whose style is *visibility: hidden* or *display: none* because user clicks are not passed to these invisible elements. In addition, we keep only the transparent third-party element groups that are big enough to be easily clickable, *i.e.*, the

container size is greater than 1% of the browser window size.

## 5 Click Interception in the Wild

In this section, we first present our analysis on data collected in our web crawl (§5.1), then characterize click interception by demonstrating *how* different techniques (§5.2) are employed by *which* scripts (§5.3) to intercept user clicks, and finally explain *why* they do it and its consequences (§5.4).

### 5.1 Dataset

We crawled data from the main pages of Alexa top 250K websites in May 2018. Excluding those that timed out or crashed in our data collection process, we were able to gather valid data of 228,614 (91.45%) websites. We identified *third-party* navigation URLs (the first URL the browser would visit upon a user click) collected in a web page using the method described in §4.2. We obtained 2,065,977 unique third-party navigation URLs, which corresponded to 427,659 unique domains. On average, a web page contains 9.04 third-party navigation URLs, pointing to 1.87 domains.

We visited each of the 2M navigation URLs and recorded both the intermediate redirect URLs and the landing URL. We could not visit 39 URLs in our experiment because of various errors (*e.g.*, HTTP 404 status code, too many redirects, *etc.*). We managed to obtain 1,982,613 unique landing URLs.

We collected 413,075 intermediate redirect URLs (excluding the navigation URLs and the landing URLs) in this process. Specifically, we observed no redirection for 1,263,754 (61.17%) navigation URLs. We encountered at most 29 intermediate hops before we reached a final landing URL.

We detected 2,001,081 distinct third-party scripts that were loaded from 1,170,582 different domains. On each page, there are on average 8.75 third-party scripts.

### 5.2 Click Interception Techniques

In this section, we demonstrate how the different techniques that we identify in §4.3 are employed for click interception.

#### 5.2.1 Interception by Hyperlinks

We identify three possible ways that a *third-party* script can intercept user clicks through hyperlinks (§4.3.1). In total, we observe that 4,178 hyperlinks on 221 websites were intercepted, which can lead a user to 2,695 distinct *third-party* URLs. We present in Table 1 the breakdown of the 4,178 links and the total number of daily visits to the affected websites<sup>6</sup>.

**Hyperlink Modifications.** Surprisingly, the *href* attribute of 4,027 first-party `<a>` tags on 100 websites were directly tampered by a third-party script. For instance, the ad URL shortening script <https://cdn.adf.ly/js/link-converter.js> modified the *href*

<sup>6</sup>We get the statistics using the SimilarWeb API.

**Table 1:** Categorization of Click Interception Techniques

Technique	#Cases	#Websites	%Cases	#Visits/day
<b>Hyperlinks</b>	4,178	221	89.52	12,686,591
Modifying 1st-party links	4,027	100	86.29	2,496,620
Modifying 3rd-party links	31	2	0.66	638,247
Inserting huge 3rd-party links	120	119	2.57	9,551,724

attribute of one anchor element to [http://ay.gy/2155800/...](http://ay.gy/2155800/) on the website <http://magazinweb.net/>. Similarly, the third-party script <https://cpm4link.com/js/full-page-script.js> modified hyperlinks on the website <https://www.lnmta.com/> to <https://cpm4link.com/full/?api=...>. They are obviously privilege abuses. In addition, we find that 31 third-party hyperlinks on 2 websites were modified by a different third-party script. For example, the script [https://s7.addthis.com/js/300/addthis\\_widget.js](https://s7.addthis.com/js/300/addthis_widget.js) modified 11 third-party hyperlinks on the website <https://www.crazy-net.com/> to <https://plus.google.com/110631064773293614230>; the script [http://media1.admicro.vn/core/log\\_cafef.js](http://media1.admicro.vn/core/log_cafef.js) modified 20 third-party hyperlinks on the website <http://cafef.vn/> to <http://lg1.logging.admicro.vn/nd?nid=...>. This indicates that those third-party scripts indiscriminately modify anchor elements to intercept user clicks.

**Huge Hyperlinks.** We observe 120 huge *third-party* `<a>` tags on 119 websites. These anchor elements enclose contents whose size is at least 75% of the browser window size. As a result, a visitor has a very high chance to click such an anchor element. For example, on the website <http://torrents73.ru/>, the third-party script <http://gynax.com/js/MjgxMw==.js> created a large anchor, which encloses a huge background image. Users would be directed to another page <https://wheel.grand-casino48.com/> upon a click. We also identify that 135 websites used 148 huge *first-party* `<a>` tags, which we currently consider as legitimate as we discussed in §3.1.

#### 5.2.2 Interception by Event Handlers

We analyze how event handlers are exploited to intercept user clicks. Overall, we find 203 elements across 172 websites were attached with *navigation event handlers*, which would drive a user to a *third-party* URL upon click.

We observe that 189 *first-party* elements of 161 websites were added at least one *third-party* navigation event handler. For example, the third-party script <https://smashseek.com/rq/4949> intercepted user clicks on the website <https://www1.mydownloadtube.com> by adding a navigation event listener to the `<html>` element. The user's browser would open a new URL (the specific URL changes upon each user click) when

a user clicks any element on this page<sup>7</sup>. Another example is detected on the page <http://azasianow.com/>, where the third-party script <http://fullspeeddownload.com/rq/4297> registered an event handler on the <body> element. We also consider such practices as a type of privilege abuse, as they force a user to visit a URL when the user interacts only with first-party contents. What is worse, even an experienced user with some technical background cannot easily find out that the navigation is actually controlled by a third-party script rather than the website she/he directly visits.

Interestingly, we find on 12 websites that 14 *third-party* elements were attached with navigation event handlers by a third-party script of a different organization. For example, the website <https://www.mlbstream.io/> included the third-party script <https://amadagasca.com/rgCQwi5INUm04AxMu/5457>, which registered an event handler on an <img> element. The user would be directed to [https://jackettrain.com/imp/5457/?scontext\\_r=...](https://jackettrain.com/imp/5457/?scontext_r=...) upon clicking on that image and finally land at a random website. One possible reason is that the attaching scripts were loaded after the other third-party scripts had inserted those elements, so that they mistakenly attached event handlers to the other third-party elements.

We do not find any third-party script intercepting user clicks by registering navigation event handlers with huge third-party elements. On the other hand, we discover 2 websites added navigation event handlers to their own huge elements. In particular, the websites <http://www.force-download.net/> and <http://www.force-download.es/> both registered a navigation event handler to the <html> node to intercept user clicks, just as the above-mentioned third-party scripts. Nevertheless, we do not consider them as malicious.

### 5.2.3 Interception by Visual Deception

We analyze how the two visual deception techniques, *mimicry* and *transparent overlay* (§4.3.3) are used in the wild.

**Mimicry.** We discover 140 *mimic* third-party element groups on 87 websites. These *third-party* contents are carefully designed to resemble nearby *first-party* contents. Hence, unwary users are very likely to be fooled and consequently click them.

Figure 1(a) shows an example of such a *mimicry* trick that we detect on the website <https://www.bintang.com>. The contents enclosed within the yellow rectangle were inserted by the third-party script [https://securepubads.g.doubleclick.net/gpt/pubads\\_impl\\_207.js](https://securepubads.g.doubleclick.net/gpt/pubads_impl_207.js), whereas those in the red rectangles were the organic first-party contents. Without scrutiny, they just look like each other. The only visual hint for discriminating them is the text *Sponsored*, which was displayed in a very small font size just as the first-party sub captions in the red rectangles. Even though a user may notice this small text, she/he may still decide to click the third-party elements as they appear to be provided directly by the first-party website which

<sup>7</sup>This is not true for elements with other click event listeners that stop the event propagation.

(a) Mimicry.

(b) Transparent overlay.

Figure 1: Examples of visual deceptive third-party contents.

she/he trusts. However, such trust would be abused in this case because those contents were generated solely by a third-party script the user does not know. In particular, the navigation URL was under the full control of this unknown third-party script and could take the user to any (potentially unsafe) page. We will discuss more about the security implication in §5.4.

**Transparent Overlay.** We detect 146 *transparent overlay* third-party element groups on 144 websites. Specially, they covered a significant portion (at least 25%) of first-party elements regardless of mouse scroll. We could not cancel them out by automatically clicking elements in those websites. Further, they were either completely transparent or translucent with a very low *opacity* style value. What is worse, many of them contained NO user-perceivable content (e.g., texts or images), hence being *transparent*. As a result, they were almost—if not absolutely—invisible and thus difficult to be noticed.

Figure 1(b) demonstrates an example of such a visual trick that we identify on the website <http://jgsdf.ucoz.com>. The yellow rectangle includes the *third-party* contents that overlapped with the underlying *first-party* contents, which are enclosed by the cyan rectangles. The script that created these third-party contents is <http://pl14318198.puserving.com/a2/49/14/a2491467a19ffc3f9fe0dbe66e54bae0.js>. Although the overlay third-party contents were not visible in this case, they constantly covered about 50% of the first-party contents in the cyan rectangles no matter how a user scrolled this page. As a result, this script could intercept any click on the covered first-party elements, because the click would be first passed to the overlay third-party elements. When a user clicked within the area of yellow rectangle, an ad link was opened in a new window.

Although third-party scripts can deceive a user with different tricks, the effectiveness can vary dramatically depending on their implementation and the end user's technical background. In general, we think they are less effective compared with the other two direct techniques we have discussed above. In particular, whether the *mimic* contents are deceptive is really subjective. We leave it for our future work to examine

how effective the visual deceptions are on real users.

## 5.2.4 Evasion of Detection

We also detect a few cases that third-party scripts *selectively* intercepted user clicks. In particular, they would limit the rate at which they intercept the clicks to avoid a user's suspicion. For instance, some scripts would activate the page navigation code in their event handlers only when a user *first* visits a page. This can be easily implemented by dropping a cookie in a user's browser. They might clear this flag after some time (e.g., a day) to reactivate the click interception code. However, we do not have enough data to learn the timeouts they use. We discuss next such a detection evasion example.

The script <https://pndelfast.com/riYfAyTH5nYD/4869>—included by the website <https://torrentcounter.to/>—selectively intercepted the user clicks on the background of the website. We observed the interception only when we visited the page with a clean cookie, which suggests the script used a cookie to log click interception status. Interestingly, we find the script was obfuscated to prevent a normal user from analyzing it. We deobfuscate the script (Listing 1), and search for the keyword *cookie*. As expected, we find several functions that are used to control the rate of click interception. Lines 8, 13, and 16 define the functions "setCookie", "removeCookie", and "getCookie", respectively. Line 6 defines the "timeout" variable that we suspect to control the interception timeout or interval. It sets the cookie in Line 28, if the return value of the function `init` defined in Line 20 is not true. The cookie is deleted in Line 33. This script also defines several variables, e.g., "certain\_click", "every\_x\_click", "delay\_before\_start\_clicks", "click\_num", "interval\_between\_ads\_clicks", which we believe to be used to control click interception. As is limited by the space, we do not discuss in more details how the script works. It would be an interesting research topic to investigate how these scripts cloak their malicious activities to avoid detection.

**Summary.** We confirm that various click interception techniques have been used in the wild. Third-party scripts intentionally intercepted user clicks using event listeners, and manipulate user clicks through visual deceptions. They also leveraged huge anchor elements to deliberately intercept user clicks. Further, many *third-party* scripts even modified *first-party* hyperlinks to intercept user clicks.

## 5.3 Click Interception Scripts

In this section, we characterize click interception based on the third-party scripts that intercept user clicks. Further, we investigate how they were embedded to intercept user clicks.

```
1 var _0x3e0d = ["...", "certain_click", "every_x_click",
2   , "delay_before_start_clicks", "click_num", "
3   interval_between_ads_clicks", "has_adblock", "...
4   "];
5 var build = function() {
6   var target = {
7     "data" : {
8       "key" : "cookie",
9       "value" : "timeout"
10    },
11    "setCookie" : function(value, name, path, headers)
12    {
13      var cookie = name + "=" + path;
14      headers["cookie"] = cookie;
15    },
16    "removeCookie" : function() {
17      return "dev";
18    },
19    "getCookie" : function(match, href) {
20      var v = match(new RegExp("(?:^|; )" + href["
21        replace"])/([. $?*|{}() []\/+^]) /g, "$1") + "
22        =([^;]*)");
23      return v ? decodeURIComponent(v[1]) : undefined;
24    }
25  };
26 var init = function() {
27   var test = new RegExp("\\w+ *\\(\\) *{\\w+
28   *['\\\"].+['\\\"];? *}");
29   return test["test"](target["removeCookie"]()["
30     toString"]());
31 };
32 target["updateCookie"] = init;
33 var array = "";
34 var _0x418128 = target["updateCookie"]();
35 if (!_0x418128) {
36   target["setCookie"]("...", "counter", 1);
37 } else {
38   if (_0x418128) {
39     array = target["getCookie"](null, "counter");
40   } else {
41     target["removeCookie"]();
42   }
43 }
44 }
```

**Listing 1:** A simplified click interception script from <https://pndelfast.com>.

### 5.3.1 Third-party Scripts Characterization

Our results in §5.2 demonstrate that third-party scripts leverage all the three techniques to intercept user clicks. We present the statistics of these scripts—the *unique* number of script URLs, origins, and domains in Table 2.

**Huge Hyperlinks.** We detect 86 unique *third-party* scripts that injected huge `<a>` tags into their embedding pages. We show the top 5 origins of such scripts in Table 3. The noticeable scripts are those loaded from <http://gynax.com>. They were found to create one huge `<a>` element on each of 47 websites they were included. Each `<a>` tag was enclosed within a `<noindex>` element, which further contained a full-page image. All the hyperlinks would finally reach <https://wheel.28grand-casino.com/>, which is an online gambling game website.

**Hyperlink Modifications.** We detect 57 unique *third-party* scripts that directly intercepted user clicks by modifying *first-party* hyperlinks. We show the top 10 origins of such scripts in Table 4. The top script <https://cdn.adf.ly/js/link-converter.js>

**Table 2:** Statistics of unique click interception scripts.

Technique	#URLs	#Origins	#Domains
<b>Hyperlinks</b>	145	76	63
Modifying 1st-party links	57	41	35
Modifying 3rd-party links	2	2	2
Inserting huge 3rd-party links	86	33	26
<b>Event Handlers</b>	106	72	58
On 1st-party nodes	103	69	55
On 3rd-party nodes	7	7	7
On huge 3rd-party nodes	0	0	0
<b>Visual Deceptions</b>	197	173	95
Mimicry	78	60	54
Transparent Overlay	119	114	42

**Table 3:** Top 3rd-party script origins injecting huge anchors.

Script	#Websites	#Elements
http://gynax.com	47	47

https://yastatic.net	7	7
http://bgmndi.com	6	6
http://js883.guangzizai.com	5	5

was found on 18 websites. *Adf.ly* is a short URL service that helps websites monetize their links. As its name suggests, this script converts *every first-party* hyperlinks to a *third-party* hyperlink. If a user clicks any converted hyperlink, the user would be taken to an intermediary page of *adf.ly* hosted on <http://clearload.bid/>. This page displayed an advertisement as shown in [Figure 2](#). The user can click the *SKIP AD* button on the right top corner to continue to visit the original *first-party* hyperlink. Many other top scripts in [Table 4](#), e.g., <https://linkshrink.net/fp.js>, [https://api.getsurl.com/js/get\\_auto.js](https://api.getsurl.com/js/get_auto.js) and <https://adshort.co/js/full-page-script.js>, worked in a very similar way. This is definitely very distracting to users. However, as we will demonstrate next in [§5.4](#), the first-party websites explicitly included these click interception scripts to monetize their websites.

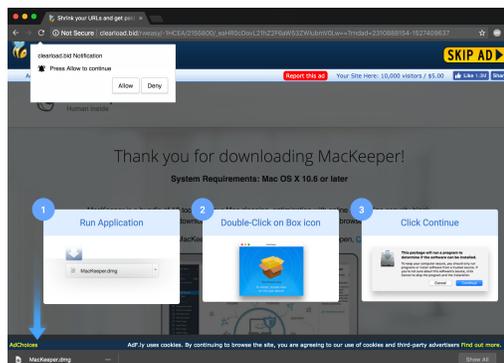

**Event Handlers and Visual Deceptions.** We find 103 unique third-party scripts which listened for clicks on first-party elements to intercept user clicks. We also discover 78 and 119 unique *third-party* scripts that injected mimic and transparent overlay contents, respectively, into the embedding websites. We discuss next that how these click interception third-party scripts were included in those “victim” websites.

### 5.3.2 Click Interception Script Inclusion

While we discover that third-party scripts deliberately intercepted clicks via several tricks, it is not clear if they were intentionally included by the first-party websites. To this end, we analyze the script dependency data to figure out the inclusion relationship between third-party scripts and first-party websites. In particular, we aim to determine if a click interception third-party script was *directly included by the website*

**Table 4:** Top 3rd-party script origins modifying first-party links.

Script	#Websites	#Elements
https://cdn.adf.ly	18	583
https://cdn.shopify.com	11	245

http://shinkme.com	2	38
https://adshort.co	2	28

**Figure 2:** A drive-by download page visited via click interception.

*itself*, or *indirectly included by another third-party script*.

We categorize how a remote third-party script can be included into three classes. First, a third-party script is *statically included by the first-party website*, if the corresponding `<script>` tag is statically defined in the original web page HTML source. Next, a third-party script is *dynamically included by the first-party website*, if it is loaded through a `<script>` tag that is dynamically created by a first-party script, including those first-party scripts hosted on a different domain. Finally, a third-party script is *dynamically included by another third-party script*, if it is loaded through a `<script>` tag that is dynamically created by another third-party script. We summarize the results in [Table 5](#).

**Static Inclusion.** We find that the majority of these third-party scripts, *i.e.*, 280 unique scripts (64.07%) out of 437 third-party click interception scripts, were statically included by 397 websites. This indicates that these websites deliberately included the click interception scripts, even though they may not intercept user clicks by themselves. In particular, the short URL monetization script <https://cdn.adf.ly/js/link-converter.js> was found to be statically included by those 18 websites. The script <https://wchat.freshchat.com/js/widget.js> was statically included by 17 websites. These websites *explicitly allowed such scripts to intercept their users’ clicks in exchange for payments*.

**Dynamic Inclusion.** We discover that 103 unique third-party scripts (23.57%) were dynamically included by first-party

**Table 5:** How third-party click interception scripts are included.

Inclusion Type	#Websites	#Scripts
Statically included by 1st-party website	397	280
Dynamically included by 1st-party website	112	103
Included by another 3rd-party script	104	63

websites. For instance, the scripts `script=http://gynax.com/j/w.php` and `http://bgrndi.com/js/NTQw.js` were dynamically included by 5 and 4 first-party websites, respectively. In other words, these websites used JavaScript to dynamically create `<script>` tags to include those scripts. Such websites would be responsible for the privilege abuses by those click interception scripts even if they do not intercept user clicks. They either *did not scrutinize the scripts before including them*, or *deliberately allowed them to intercept user clicks*.

**Indirect Inclusion.** On the other hand, we discover that only 63 third-party click interception scripts (14.42%) were indirectly included by other third-party scripts. One such a top script is `https://tags.bkrtx.com/js/bk-coretag.js`, which was included by other third-party scripts on 6 websites. For example, it was included by the script `https://s.accesstrade.net/js/atd/bluekai/atd_bluekai.js?id=...` on the website `https://haken-mikata.com`. The latter script was also indirectly included by another script `https://s.accesstrade.net/js/atd/satd.js?pt=824F2E4C4077D97ECC014C7A3DE07136725853`, which was statically included by the first-party website. In such cases, we cannot blame the first-party websites for indulging those suspicious scripts. Click interception caused by these scripts could be prevented if the websites configure a proper Content Security Policy (CSP) [33] that disallows the browser to load scripts from unknown sources. However, in practice it is difficult and even infeasible to use CSP because many websites need to allow dynamic inclusion of advertising scripts that may be loaded from arbitrary sources due to ad syndication. Therefore, a finer-grained security policy that limits the privilege of included scripts would be more desirable in preventing such privilege abuses.

**Summary.** We discover that 437 third-party scripts attempted to intercept user clicks on a total of 613 websites. Several top third-party scripts deliberately intercepted user clicks on all their embedding websites. Surprisingly, many of them were included directly by the first-party websites, to monetize the hyperlinks, or more accurately, the user clicks, of those websites.

## 5.4 Click Interception Reasons and Consequences

We have demonstrated that some third-party scripts intercepted user clicks through various tricks. In this section, we seek to understand the motivations and consequences of such undesired activities.

**Table 6:** Advertising click interception navigation URLs.

Technique	#URLs	#Ad URLs	%Ad URLs
Hyperlinks	2,695	1,088	40.37
Event Handlers	186	21	11.29
Visual Deceptions	380	74	19.47

### 5.4.1 Monetization

As we have demonstrated in §5.3.1, many *third-party* scripts offer monetization services by converting *first-party* hyperlinks into *third-party* ad links. They force a user to view an advertisement before navigating to the original destination page when the user clicks any hijacked link. As a result, both the third-party click interception script and the first-party website can earn some commission from those participating advertisers. Similarly, we find many other cases where a click was intercepted by a third-party script to visit an advertiser’s landing page.

**Identifying Advertising URLs.** To understand if monetization via advertising is really a common reason for click interception, we compare the navigation URLs in the click interception cases with all the other navigation URLs in our dataset. Specifically, we leveraged the Ghostery extension to determine if one navigation URL is *advertising-related* by testing if it matches the URL pattern of any known advertising company. A navigation URL is marked as an advertising URL, if a positive match is found for any of its intermediate redirect URLs (if any) and the landing URL. We also manually labeled the URLs generated by those short URL monetization scripts as ad URLs because they are not known to the extension.

Surprisingly, we find that 1,183 (36.39%) out of the 3,251 unique click interception navigation URLs are advertising URLs (Table 6), which is a *18.7 times higher* rate than that of normal third-party navigation URLs<sup>8</sup>. In total, only 40,278 (1.95%) out of the 2,065,977 third-party navigation URLs are identified as advertising URLs.

**Potential Click Fraud.** These click interception websites and scripts have a “good” reason to trick users into clicking those advertising URLs. In online display advertising, the publishers and the ad networks are paid by an advertiser when a user clicks the advertiser’s ad under the pay-per-click billing mode. Although they can also earn some commission for an ad impression in the pay-per-view billing mode, the money is much less than what they can get paid when the ad is clicked. However, the ad click-through rate is usually very low—around 2% (in a business-to-consumer banner ad case [18]). To boost ad revenue, the straightforward and effective approach is to leverage real user clicks, as modern ad networks can accurately detect bot-based click frauds [2, 6, 9, 38]. On the other hand, the third-party scripts also have the incen-

<sup>8</sup>We exclude all first-party navigation URLs in our analysis.

tive to cheat advertisers for higher income because many of them are also ad networks. This well explains why the short URL monetization scripts, which also operate as ad networks, have been helping websites intercept user clicks.

In our research, we observe that third-party scripts have leveraged various click interception techniques to monetize user clicks. Further, our results demonstrate that click interception has become an emerging way for generating realistic click traffic to commit ad click fraud.

### 5.4.2 Distributing Malicious Content

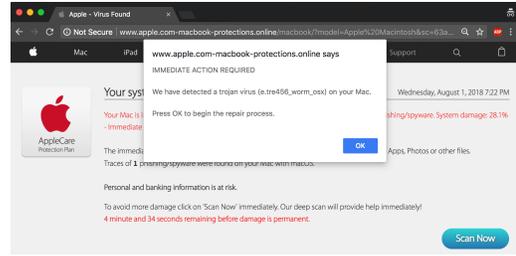

Besides monetization, we find that click interception can lead a user to visit malicious contents. In particular, we were directed to some fake anti-virus (AV) software and drive-by download pages when we manually examined some of the click interception URLs.

For instance, we were forced to visit an ad click URL by the script <https://pndelfast.com/riYfAyTH5nYD/4869> on the website <https://torrentcounter.to/>. Since the navigation URL is an ad click URL, the landing URL is random each time we visit. Nonetheless, one landing URL we visited is a fake AV website, as shown in [Figure 3\(a\)](#). This website showed some fake warnings about virus infection with alarm to fool the user into clicking the *Scan Now* button. After that, it displayed some scanning animation and finally generated a fake scan report to trick the user into installing the fake AV software, as shown in [Figure 3\(b\)](#). The Google search results of the domain *Ibcde.com* also suggest it is a malicious redirect website.

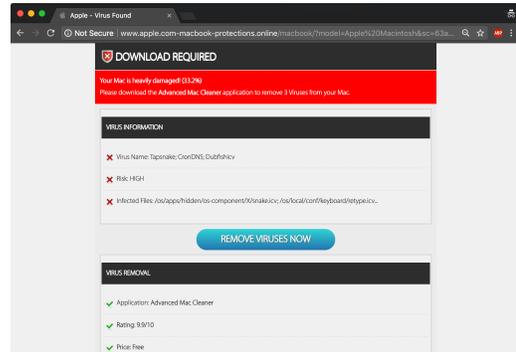

We also find that the script <http://cdn.adf.ly/js/link-converter.js> converted one link of the website <http://magazinweb.net/> into <http://ay.gy/2155800/...>, which is an advertising link. It once took our browser to a drive-by download page, as shown in [Figure 2](#). When we visited the page, our browser automatically started downloading the MacKeeper installer, which is considered as scamware [20]. The page even shows detailed instruction to trick the user into installing this scamware.

These are just two of many malicious examples we have encountered in our manual investigation. We think that there were much more malicious cases that we have yet to discover. Unfortunately, manually verifying all the 2 million URLs in our dataset is infeasible. We plan to leverage automated URL scanning techniques to automatically detect the malicious URLs associated with click interception in the future.

**Summary.** We identify that many third-party scripts intercept user clicks to monetize user clicks. In particular, they intercept real user clicks to fabricate ad clicks as a new form of committing ad click fraud. Further, the landing URLs that they trick the users into visiting can be malicious.

(a)

(b)

**Figure 3:** A fake AV website visited because of click interception.

## 6 Discussion and Future Work

We discuss the limitations of our work, the possible mitigation of the click interception threat, and our future work.

**Third-party Script Detection.** Our methodology for distinguishing first-party scripts from third-party scripts is not 100% accurate. First, the domain substring matching can be problematic if an adversary can create victim-specific subdomains. For example, a third-party can intentionally generate a subdomain [xyz.third-party.org](http://xyz.third-party.org) by adding a new entry in its name server. Our technique would mislabel this subdomain as a first-party URL if it is included by [xyz.com](http://xyz.com). Second, an organization may use distinct email addresses for its subsidiaries. For instance, the SOA email address of <https://www.instagram.com/> is [awsdns-hostmaster@amazon.com](mailto:awsdns-hostmaster@amazon.com), whereas that of <https://www.facebook.net/> is [dns@facebook.com](mailto:dns@facebook.com). We classify scripts loaded directly from Facebook on Instagram as third-party scripts even though Instagram is owned by Facebook. Although our approach to determining the relationship between two hosts is not complete, it is good enough for achieving our goal and provides better results compared with a similar approach using only whois records [4].

**Measurement Scope.** We visited only the main pages of Alexa top 250K websites, so we could miss scripts that are loaded only in their sub pages. However, our goal is to have a preliminary understanding of the click interception problem. We do not intend to and are not able to cover all pages and scripts that can be found on these websites. In the future, we

will consider sub pages of these websites to investigate the differences between the main pages and the sub pages.

**Artificial Interaction with Web Pages.** OBSERVER applies an artificial way to interact with websites, *i.e.*, using a script to click all the elements on a page, in order to automate the analysis. This could be different from the normal behavior of a real human being. Nevertheless, our goal is to collect as much click-related data as possible in each page visit. It would be an interesting research topic to study if developers would write code to distinguish authentic clicks from automatically generated ones<sup>9</sup>.

**Generating Security Warnings.** Click interception can direct a user to an unknown URL by modifying first-party hyperlinks or hijacking user clicks on first-party elements. It exploits the fact that the user cannot determine the provenance of the URL that he or she is about to visit (unintentionally). To protect a user from visiting potentially attacker-controlled URLs, a possible defense is to provide the user the provenance information regarding each hyperlink and click. In particular, the browser can display a message alongside each hyperlink about its provenance, *e.g.*, if the associated URL is provided by the first-party website or a third party. The additional message needs to be unforgeable and tamper-proof from JavaScript code, such that the adversary cannot manipulate such security-related data. One potential implementation is to utilize the browser UI that is usually not accessible to JavaScript. For example, we can display the message in the status bar when the user hovers the mouse over a link. Similarly, to defend against event-listener interception, we can display an unforgeable warning message if the user hovers over an element that is potentially intercepted by a third-party script. However, this may cause a lot of false positives as an event handler may not necessarily initiate a navigation upon user click. Therefore, it might be better to show such warning when the user actually performs the click, as [10] does. According to our experiment, OBSERVER introduces negligible performance overhead on navigation. It is thus suitable to be extended as a real-time detection tool for the end users. We plan to extend OBSERVER by incorporating these defenses, and conduct a user study to evaluate their effectiveness.

**Ensuring Link and Click Integrity.** The above defenses require a user to make security decisions, which might not be very effective in practice. Alternatively, we can let the browser automatically enforce integrity policies for hyperlinks and click event handlers. For example, an integrity policy can specify that all first-party hyperlinks shall not be modifiable by third-party JavaScript code. One may further specify that third-party scripts are not allowed to control frame navigations, although listening for user click is still permitted. Enforcing all such policies would effectively prevent click-interception by hyperlinks and event handlers. However, it might also

<sup>9</sup>The clicks in our experiment were generated through Selenium and are different from those generated using JavaScript, which can be easily detected.

break the functionalities of some third-party components. To give the user and the website administrator better control, the policies can specify the permissions for each script, matched by an absolute URL, a domain name, a wild card, or a secret token, mimicking the Content Security Policy [33]. We plan to develop and evaluate such an integrity protection mechanism as our future work.

## 7 Conclusion

We have investigated the click interception problem on the Web with a custom analysis framework developed based on the Chromium browser. We collected data from the Alexa top 250K websites and identified several techniques that can be employed to intercept user clicks. We detected that 437 third-party scripts intercepted user clicks using hyperlinks, event handlers and visual deceptions on 613 websites. We further revealed that many third-party scripts intercept user clicks for monetization via committing ad click fraud. In addition, we demonstrated that click interception can lead victim users to malicious contents. Our research sheds light on an emerging client side threat, and highlights the need to restrict the privilege of third-party JavaScript code.

# What Are You Searching For?

## A Remote Keylogging Attack on Search Engine Autocomplete

John V. Monaco

Naval Postgraduate School, Monterey, CA

### Abstract

Many search engines have an autocomplete feature that presents a list of suggested queries to the user as they type. Autocomplete induces network traffic from the client upon changes to the query in a web page. We describe a remote keylogging attack on search engine autocomplete. The attack integrates information leaked by three independent sources: the timing of keystrokes manifested in packet inter-arrival times, percent-encoded Space characters in a URL, and the static Huffman code used in HTTP2 header compression. While each source is a relatively weak predictor in its own right, combined, and by leveraging the relatively low entropy of English language, up to 15% of search queries are identified among a list of 50 hypothesis queries generated from a dictionary with over 12k words. The attack succeeds despite network traffic being encrypted. We demonstrate the attack on two popular search engines and discuss some countermeasures to mitigate attack success.

### 1 Introduction

Search queries contain sensitive information about individuals, such as political preferences, medical conditions, and personally identifiable information [7, 25]. They can reveal user demographics, hobbies, and interests, and are routinely used for targeted advertising [4, 24]. To protect user privacy, all major search engines now encrypt search query traffic.

Autocomplete is a feature that provides suggested queries to the user as they type based on the partially completed query, trending topics, and the user's search history [2]. Intended to enable the user to find information faster, autocomplete requires the user's client to communicate with the server as keyboard input events are detected. As a result, the user's keystrokes manifest in network traffic.

We present a remote keylogging attack on websites that implement autocomplete. The attack detects keystrokes in encrypted network traffic and identifies search queries using information from three independent sources: keystroke timings

manifested in packet inter-arrival times, percent-encoding of Space characters in a URL, and the static Huffman code used in HTTP2 header compression.

The attack we developed, called KREEP (Keystroke Recognition and Entropy Elimination Program), consists of five stages: keystroke detection, which separates packets that correspond to keystrokes from background traffic; tokenization to delineate words in the packet sequence; dictionary pruning, which uses an HTTP2 header compression side channel to eliminate words from a large dictionary; word identification, performed by a neural network that predicts word probabilities from packet inter-arrival times; and a beam search, which generates hypothesis queries using a language model. KREEP is a remote passive attack that operates entirely on encrypted network traffic.

Autocomplete has been incorporated into almost every major search engine. We demonstrate our attack on two popular search engines and evaluate its performance using a collected dataset of 16k search queries. Using a dictionary with over 12k words, KREEP identifies 15% of queries and recovers up to 60% of the query text among a list of 50 hypothesis queries. The attack is robust to packet delay variation (PDV). We simulate up to  $\pm 32$ ms of network noise and find relatively little loss in performance with moderate levels of PDV. However, the attack is not robust to padding and we propose a simple padding defense that mitigates both the HTTP2 header compression side channel and ability to delineate words.

To summarize, the main contributions of this work include:

- 1) *A method to detect packets induced by autocomplete and delineate words in a query.* The pattern of autocomplete packet sizes from each search engine is characterized by a deterministic finite automaton (DFA). We generalize the longest increasing subsequence problem, which has an efficient dynamic programming solution, to that of finding the longest subsequence accepted by the DFA. This approach can detect keystrokes in network traffic with near-perfect accuracy and delineate words with greater than 90% accuracy.

- 2) *A side channel attack that leverages the static Huffman code used in HPACK, the HTTP2 header compression for-*

*mat*. Previously, it was shown that HPACK leaked relatively little information through compressed size [50]. However, with autocomplete, a search query is built up incrementally one character at a time and then recompressed. Due to this incremental compression, the information leaked is more than previously thought. We describe a method to leverage this information leakage to prune a dictionary, which increases the accuracy of our remote keylogging attack.

3) *A neural network that identifies words from keystroke timings*. We define a neural network architecture that takes into account the preceding and succeeding context of each observed timing and a method to identify words from a dictionary containing over 12k entries. The network is trained on keystrokes recorded from 83k typists, and words are correctly identified with 19% accuracy.

4) *The integration of a language model and keystroke timing attack to leverage the relatively low entropy of English language*. Previous keystroke timing attacks have noted the relatively low entropy of natural language compared to password input [47]. We introduce a method that combines a keystroke timing attack with a language model to generate hypothesis search queries. The use of a language model significantly improves performance.

In the next section, we provide background information on keylogging side channels and autocomplete. The attack workflow and threat model are described in Section 3, followed by keystroke detection and tokenization in Section 4. Dictionary pruning and the HTTP2 header compression side channel are described in Section 5. Word identification from timings and the language model are described in Section 6. Sections 7 and 8 contain results and discussion, respectively, and Section 9 concludes.

## 2 Background

### 2.1 Keylogging side channels

A keylogging side channel attack aims to recover the keystrokes of a victim through unintended information leakage. Such attacks have been demonstrated for a wide range of modalities such as acoustics [5], seismic activity [31], hand motion [54], and spikes in CPU load [46]. These generally fall into two different categories: spatial attacks, which utilize a channel that leaks spatial information about where a key is located on the keyboard, and temporal attacks, which utilize a channel that leaks only the timing of the keyboard events [34]. Our attack leverages both spatial and temporal information leaked through network traffic generated by a website with autocomplete.

Temporal keylogging attacks attempt to recognize which keys a user typed based only on the key press and release timings. This is possible because different key sequences can result in characteristic time intervals, such as typing the key sequence “th” quicker than “aq”. Consequently, the exposure

of keyboard event timings is a threat to user privacy. Remote keystroke timing attacks may target applications in which a keystroke induces network traffic from the victim’s host, such as SSH [47] or a search engine with autocomplete functionality [51]. Packet inter-arrival times, when observed remotely, reveal the time between successive keystrokes. Keyboard input events can also be detected from within a sandboxed environment on the host [46] or on a multi-user system [59].

Keylogging attacks can be characterized by the type of input that occurs. For password input, an attack may assume that each key has an equal probability of occurrence, i.e., maximum entropy, whereas for natural language it is often assumed that the user typed a word contained in a dictionary [29]. For the purpose of identifying search queries, we assume natural language input which enables KREEP to leverage a language model in generating hypothesis queries.

Two main problems arise when trying to determine keystrokes from timings. The first is keystroke detection: given a sequence of events, such as network packets, spikes in CPU load, or memory accesses, determine which events correspond to keystrokes and which do not. This is a binary classification problem. In our attack, we consider a sequence of network packets emitted by the victim which includes background traffic in addition to the HTTP requests induced by autocomplete. The second problem is key identification: given that a key press has occurred, the attacker must determine which key it was. This is a multi-class classification problem. In our attack, we assume that each key is either an English alphabetic character (A-Z) or the Space key, for a total of 27 keys.

We address the problems of keystroke detection and key identification separately. KREEP detects keystrokes by finding a subsequence of packet sizes that are characteristic of autocomplete requests. For key identification, KREEP leverages both packet size and packet inter-arrival timings, which faithfully preserve key-press latency.

### 2.2 Web search autocomplete

Many websites have autocomplete functionality. With this feature, a list of suggested search queries is presented to the user as they enter text into a search form. The list of suggested queries is determined by an algorithm based on the user’s search history, current trending topics, and geographic location [2]. Because the suggestions are automated, this can sometimes result in unfavorable associations implied between search terms which has made autocomplete the focus of several legal disputes [27].

As changes to the query are detected, the client sends an HTTP GET request to the server and the server responds with a list of suggested search queries [26]. This results in a series of HTTP requests following keyboard events, such as those shown in Figure 1. The request contains the partially completed query in addition to other parameters, such as an

Figure 1: Autocomplete requests for the query “the lazy dog” in Google (left) and Baidu (right). After each key press, the client sends an HTTP GET request that contains the partially completed query in the URL (shown in bold). Packet size is in bytes.

authentication token and page load options, which generally do not change between successive requests. As a result, each request changes by only a single character, and the size of each packet increases by about 1 byte over the previous.

There are primarily two methods to implement autocomplete [35]. The first is a polling model in which a web page periodically checks the contents of the query input field at fixed intervals. When a change is detected, an autocomplete request is sent to the server to retrieve the query suggestions. Depending on the polling rate and the speed of the typist, an autocomplete request may not immediately follow every keystroke. If two keystrokes occur before the polling timer expires, then they will both be included in the next autocomplete request. In this situation when the typing rate exceeds the polling rate, the keyboard input event times are not faithfully preserved in packet inter-arrival times due to multiple keys being merged into a single request.

The second method of implementing autocomplete is a callback model in which the requests are triggered by HTML DOM `keydown` or `keyup` input events. In this approach, each autocomplete request immediately follows each input event such that the packet inter-arrival times faithfully preserve the time between keyboard events. Non-printable characters, such as Shift, Ctrl, and Alt, are ignored since these alone do not result in visible changes to the query.

We focus only on search engines that implement autocomplete requests triggered by `keydown` events. This results in packet inter-arrival times that are highly correlated with key-press latencies, i.e., time between successive `keydown` events. Previously, we determined that Bing implements a polling model with 100 ms timer, DuckDuckGo implements a callback model triggered by `keyup` events, and Baidu, Google, and Yandex implement a callback model triggered by `keydown` events [35]. Because Yandex is not vulnerable to the method of tokenization described in Section 4, we consider only search engines Google and Baidu. As of January,

2019, Google search comprises over 90% of worldwide market share [49], and Baidu comprises over 70% of the market share within China [48].

### 3 Attack overview

In this section, we define the threat model and describe the attack workflow. We then summarize the performance metrics used to evaluate each component of KREEP separately as well as overall attack success.

#### 3.1 Threat model

We assume a remote passive adversary who can capture encrypted network traffic emitted by a victim using a search engine with autocomplete. We do not make any assumptions about background traffic or the ability to detect when a web page loaded; KREEP is able to isolate the subsequence of packets that contain autocomplete requests.

We assume the victim types only alphabetic keys and the Space key (27 keys total) to form a query made of lower-case English words with each word separated by a Space. This excludes queries that were copied and pasted, the use of Backspace and Delete keys, and any other input that might cause the cursor to change position, such as arrow keys. The victim might select an autocomplete suggestion before typing a complete query; KREEP can identify the query up to the point a selection was made.

The query must contain words in a large English dictionary known to the attacker. We use a dictionary of over 12k words comprised of the 10k most common English words [32] together with English words that appear in the Enron email corpus and English gigaword newswire corpus [19] (used to simulate search queries, see Section 7.1 for dataset details). KREEP does not require any labeled data from the victim for the keystroke timing attack; the neural network that performs

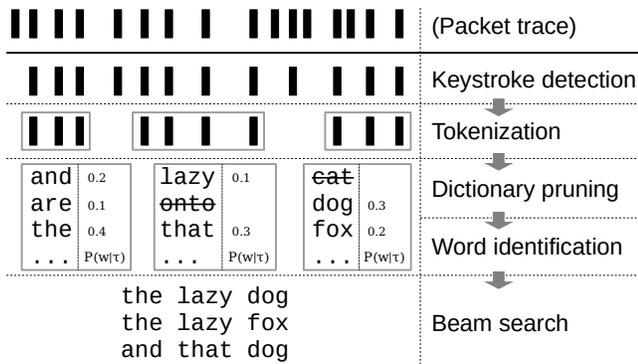

Figure 2: Attack workflow. Input to KREEP is a packet trace containing autocomplete and background traffic; output is a list of hypothesis search queries. Each component provides input to the next. See text for component definitions.

word identification is trained on an independent dataset. We assume that the attacker has access to this dataset.

### 3.2 Workflow

Our attack consists of five stages applied in a pipeline architecture shown in Figure 2 and summarized below.

**Keystroke detection:** packets that correspond to keyboard events are first detected from the full packet trace. This is a binary classification problem where each packet is labeled as either key-press or non-key-press. Each autocomplete request contains the query typed up to that point, so the sequence of autocomplete packet sizes has approximate linear growth over time. This makes it possible to separate keystrokes from background traffic, described in Section 4.2.

**Tokenization:** from the detected subsequence of packets, words are delineated based on packet size differences. Tokenization is also a binary classification problem where each packet is labeled as either Space or non-Space. Space characters in a URL are encoded by a three-byte escape sequence whereas other characters occupy a single byte. This behavior enables tokenization, described in Section 4.3.

**Dictionary pruning:** packet size differences are compared to a dictionary to eliminate words that could not have resulted in the observed sequence. This effectively prunes the hypothesis query search space. Dictionary pruning is possible due to the static Huffman code in HTTP2 header compression. This side channel is described in Section 5.

**Word identification:** the probability of each word remaining in the dictionary is determined from the observed packet inter-arrival times, which faithfully preserve key-press latencies. Word identification is performed by a neural network described in Section 6.1.

**Beam search:** word probabilities are combined with a language model in a beam search that generates hypothesis queries. The number of hypothesis queries is controlled by

the beam width. The beam search is described in Section 6.2.

### 3.3 Performance metrics

We measure the performance of each component of the attack separately as well as overall attack success.

Both keystroke detection and tokenization are binary classification problems. For keystroke detection, a false positive occurs when a packet is incorrectly labeled as an autocomplete request, and a false negative occurs when an autocomplete request packet is missed. Likewise, a tokenization false positive occurs when a letter is incorrectly labeled as a Space, and false negative occurs when a Space is missed. Let  $fp$ ,  $fn$  be the number of false positives and false negatives, and let  $tn$ ,  $tp$  be the number of true negatives and true positives, respectively. We measure the performance of both keystroke detection and tokenization by the F-score,

$$F_1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (1)$$

where

$$\text{Precision} = \frac{tp}{tp+fp}, \quad \text{Recall} = \frac{tp}{tp+fn}. \quad (2)$$

The F-score varies between 0, for missing all positives, and 1, for perfect precision and recall. Both keystroke detection and tokenization provide input to later stages of the attack, the success of which critically depends on performing well at both these tasks. As demonstrated in Section 7.2, making these tasks more difficult significantly reduces overall performance.

The utility of dictionary pruning is measured by the information gain due to incremental HTTP2 header compression. We compare this to the information gain in a classical compression side channel where only the total compressed size of the query is known.

For word identification, we report the word classification accuracy from packet timings, assuming perfect detection and tokenization. This evaluates word identification separately from the other components.

We consider two metrics to measure overall attack success. First is the rate at which a query is correctly identified among the list of hypothesis queries. Using a beam width of 50, this corresponds to a top-50 classification accuracy. Since the hypotheses may contain queries that are close, but do not exactly match, the true query, we also consider the Levenshtein edit distance between the true and hypothesis queries. Edit distance is used instead of character or word classification accuracy since failures in keystroke detection can result in a predicted query that is either shorter or longer than the original query. This metric is thought to better reflect the overall performance of a keylogging attack in such cases [16]. We report the minimum edit distance among the hypotheses to the true query, which roughly corresponds to the maximum proportion of keys that are correctly identified.

## 4 Keystroke detection and tokenization

In this section, we characterize the network traffic emitted by autocomplete in two different search engines. We then describe the first two stages of attack: a method to detect packets that contain autocomplete requests and a method to delineate words in the query. Both stages leverage characteristics of autocomplete packet sizes.

### 4.1 Autocomplete packet sizes

The problem of keystroke detection involves deciding whether each captured packet was induced by a keyboard event or not. As the user types a query into a search engine with autocomplete, the client emits HTTP requests that contain the partially completed query, such as those shown in Figure 1. However, these are mixed together with requests to load page assets, such as HTML and CSS files, AJAX requests supporting dynamic web content, and other background traffic. We found that typing a query with 12 characters on Google search induces 95 outgoing packets with payload greater than 0 bytes (436 packets including those with empty payloads), only 12 of which correspond to autocomplete requests.

Each autocomplete request contains a new character appended to the URL path. As a result, the sequence of packet sizes is monotonically increasing, shown in Figure 1. We perform keystroke detection by isolating a subsequence of packets that exhibit this pattern, taking into account the particular behavior of each search engine described below.

The behavior of each search engine is characterized by the sequence of size differences between successive autocomplete request packets. That is, let  $s_i$  be the size in bytes of the  $i$ th autocomplete request and  $s_0$  the size of the first request. Packet size differences are given by  $d_i = s_i - s_{i-1}$  for  $i > 0$ . This sequence reflects packet size growth as a function of query length, invariant to the size of other parameters contained in the request which vary across hosts due to different sized identifiers, authentication tokens, and page load options. However, these parameters typically remained unchanged in successive autocomplete requests from a single host.

Figure 3 shows the distribution of  $d_i$  as a function of query length for both Google and Baidu. From this figure and a manual inspection of several HTTP request packets, we make several observations about the behavior of each search engine. We then use these observations to build a DFA that accepts a sequence of autocomplete packet size differences.

Google autocomplete emits packets that typically increase by between 0 and 3 bytes. As each new character is appended to the “q=” parameter of the URL, the size increases by about a byte. The 2 and 3 byte increases correspond to the addition of percent-encoded characters in the URL, described in Section 4.3. The 0 byte increases are an artifact of HTTP2 header compression, described in Section 5.1. A larger increase of approximately 20 bytes occurs after about 12 requests. At

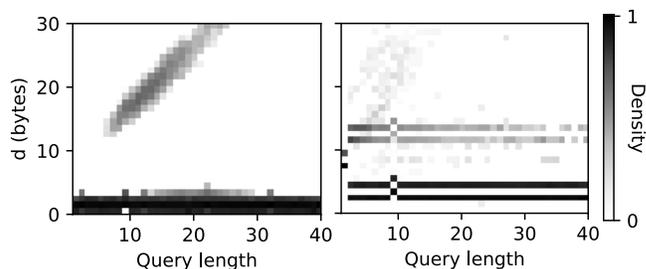

Figure 3: Density of packet size difference between successive autocomplete requests for Google (left) and Baidu (right).

this point, an additional “gs\_mss” parameter with the partially completed query is added to the URL. This results in a sudden increase of about 20 bytes: 8 bytes for “&gs\_mss=” and 12 bytes for the query. The request then continues to increase by about 1 byte per character thereafter.

The autocomplete packet sizes of Baidu typically increase by either 2 or 4 bytes per character, with a larger increase of 7 or 9 bytes at the beginning of the sequence. After the first request, an additional parameter “pwd=” referring to the previous query is appended to the URL. For example, if the user types “th”, the first request will contain “wd=t” followed by “wd=th&pwd=t”, resulting in a 7 byte increase (6 bytes for “&pwd=t” and 1 byte for “h”). A 4 byte increase corresponds to the addition of escaped characters in the URL, which occupy 3 bytes. Baidu requests also occasionally include a new cookie not present in previous requests, resulting in a larger increase of either 11 or 13 bytes.

Both search engines include a parameter that keeps track of the request number. In Google, this parameter is “cp=”, where “cp” increments with each request (see Figure 1), and Baidu uses the “csor=” parameter. On the 10th request, “cp=9” becomes “cp=10”, resulting in an additional 1 byte increase.

### 4.2 Keystroke detection

Since autocomplete request size is monotonically increasing, keystroke detection could be performed by finding the longest increasing subsequence (LIS) of packet sizes which has an efficient solution through dynamic programming [44]. However, the LIS fails to capture the fact that packets typically increase by a fixed amount and that two successive packets may be the same size due to HTTP2 header compression. To that end, we generalize the LIS problem to that of finding the longest subsequence accepted by a sequence detector DFA based on observations in the previous section.

We define a DFA that accepts a sequence of packet size differences generated by the autocomplete of each search engine. The DFA for Google autocomplete packets is shown in Figure 4, where edges denote a constraint on  $d$  that must be met to traverse to the next state. States  $a$  and  $b$  correspond to

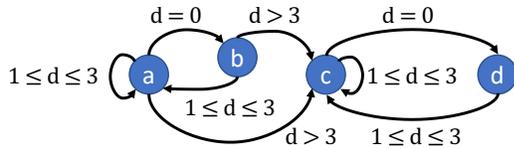

Figure 4: DFA that accepts a sequence of packet size differences generated by autocomplete in Google search.

increases of between 0 and 3 bytes prior to the large increase from the addition of the “gs\_mss” parameter, and states *c* and *d* are reached after the large increase. The absence of a recurrent connection on states *b* and *d* indicate that two consecutive non-increases cannot occur. This DFA takes as input a sequence of packet size differences, and if at any point an unreachable state is met, it rejects the sequence.

Let the longest automaton subsequence (LAS) be the longest subsequence accepted by the DFA. Keystrokes are detected by finding the LAS in the sequence of packet sizes. The LAS is determined efficiently through dynamic programming in a similar manner to that of the LIS problem. Let *F* be an acceptor DFA and *L<sub>i</sub>* the longest subsequence accepted by *F* ending in the *i*th packet. Assume the LAS ending in element *L<sub>i</sub>* must necessarily be part of the solution if it contains *L<sub>i</sub>* (optimal substructure). Then *L<sub>i</sub>* need only be computed once and may be considered as the prefix to any other subsequence *L<sub>j</sub>* where *j* > *i* (overlapping subproblems). We then need only check if the DFA that accepted the sequence ending in packet *i* can transition to packet *j*. Note that in general, these assumptions may not hold and thus the dynamic programming solution might be suboptimal; however, we found this method to work well in practice and leave for future work a formal treatment of the LAS problem.

### 4.3 Tokenization

Tokenization is the process of delineating words in the sequence of autocomplete requests. Since we assume the search query to be made of English words separated by a Space, this enables the following stages of attack (dictionary pruning, word identification, and beam search) to be conducted at the word level. Like detection, tokenization is a binary classification problem since each packet may be labeled as either a delimiter or part of a word. We consider the Space character as the only delimiter between words.

Percent-encoding is an escape sequence used to represent a character in a URL that is outside the set of allowable characters [8]. A percent-encoded sequence consists of three ASCII characters, “%” followed by two hexadecimal digits. The Space character (ASCII=32) in a URL has percent-encoding “%20”. When the user types a Space into the search query field, this escape sequence is appended to the URL causing the uncompressed request packet to increase by 3 bytes.

Google autocomplete packets increase by 2 bytes when the

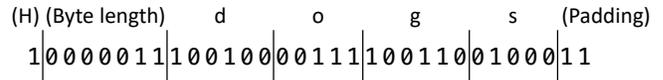

Figure 5: Huffman encoded string literal “dogs” in HPACK.

Space key is pressed as a result of HTTP2 header compression. The Huffman code for characters “%”, “2”, and “0” have bit lengths 6, 5, and 5 respectively, and the sequence “%20” has a total compressed bit length of 16 bits. Tokenization is performed by marking packets that increase by 2 bytes as word boundaries.

Baidu does not use HTTP2, so the escape sequence “%20” occupies 3 bytes. However, since the previous query is included in each request, when a Space is pressed the packet size increases by 4 bytes: 1 for the new character appended to the “pwd” parameter, and 3 for “%20” appended to the “wd” parameter. This also occurs twice in a row since when another letter key is pressed following the Space, “%20” is then appended to the “pwd” parameter. For example, see the URL and sizes of the third and fourth packets in Figure 1 (right), which demonstrate two consecutive 4 byte increases. Tokenization of Baidu queries is achieved by detecting the first of any two consecutive 4 byte increases.

## 5 Dictionary pruning

We describe a side channel that leverages the static Huffman code used in HTTP2 header compression. This enables pruning the dictionary, but is only applicable to Google which supports HTTP2. Baidu does not currently support HTTP2.

### 5.1 Incremental compression side channel

HPACK is the HTTP2 header compression format, which uses a static Huffman code to encode string literals [39]. A Huffman code is a near-optimal lossless compression scheme. Symbols are encoded by bit string with length based on the frequency of the symbol. Huffman codes are prefix-free, such that the code for a symbol is not the prefix to any other. The encoded string becomes the concatenation of all encoded symbols, avoiding the need for symbol delimiters. In HPACK, the encoded string is padded with between 0 and 7 bits to align with the nearest octet boundary.

The static Huffman code in HPACK was determined using a large sample of HTTP headers, and all HPACK implementations must use the same Huffman code defined in the specification [39]. The sizes of lowercase letters range from 5 bits for frequently used characters, such as “e” and “t”, to 7 bits for infrequent characters, such as “j” and “z”. As an example, the compressed string literal “dogs” is shown in Figure 5. The encoded symbols occupy 6+5+6+5=22 bits, which is then padded with 2 bits for a total size of 3 bytes.

It was previously determined that size alone does not leak a considerable amount of information in HPACK [50]. Let  $h_i$  be the bit length of the  $i$ th symbol in a string as specified by the static Huffman code and  $b = \sum h_i$  the total bit length of the compressed string. The size  $b$  reveals only that the string must be some linear combination of encoded symbols to achieve the same compressed size. For example, the string “fish” has compressed length  $6+5+5+6=22$  bits, exactly the same compressed size as “dogs” in Figure 5.

Less than 0.05 bits per character are revealed in this way, making an HTTP2 compression side channel impractical [50]. This estimate is actually an upper bound since compressed string literals in HPACK are padded to the nearest octet. Instead of  $b$ , an adversary observes byte size  $B = \frac{p+\sum h_i}{8}$  where  $0 \leq p \leq 7$  is an unknown amount of padding to align the compressed bit string with the nearest octet.

However, the query in a sequence of autocomplete requests grows incrementally. Each request contains a single new character appended to the URL path, which then passes through header compression before being sent to the server. We refer to this as *incremental compression*. As a result, instead of total size  $B$ , an adversary observes the sequence of cumulative byte sizes  $B_1, \dots, B_n$  of the compressed query after each new character is appended. Due to differences in the size of each symbol, different words grow at different rates and the cumulative byte size sequence can reveal the query.

To leverage the information leaked through incremental compression, we compare the observed sequence of cumulative byte sizes to the cumulative sizes of every word contained in the dictionary. The sizes of words in the dictionary are precomputed for each possible amount of padding, which is unknown to the attacker. Words for which the observed sequence never occurs can be eliminated from the dictionary.

Let  $d_i$  be the observed size increase in bytes of the  $i$ th request packet and let  $B_j = \sum_{i \leq j} d_i$  for  $1 \leq j \leq n$  be the observed cumulative size up to the  $n$ th request. The sequence  $B_1, \dots, B_n$  characterizes the size growth of a word after undergoing incremental compression. The cumulative byte size sequence  $B_1^{w,p_0}, \dots, B_n^{w,p_0}$  is computed for each word  $w$  in the dictionary, given by

$$B_j^{w,p_0} = \left\lfloor \frac{p_0 + \sum_{i \leq j} h_i}{8} \right\rfloor \quad (3)$$

where  $0 \leq p_0 \leq 7$  is an unknown amount of padding applied to the compressed URL *prior* to the request containing the first character of the word. The observed size sequence  $B_1, \dots, B_n$  is compared to every sequence  $B_1^{w,p_0}, \dots, B_n^{w,p_0}$  in the dictionary to discover potential matches and eliminate words that could not have been typed by the user.

An example is shown in Figure 6 where the user typed a 4 letter word with cumulative byte size  $[1, 2, 3, 3]$ . Comparing this sequence to the dictionary, there are two potential matches: the observed sequence  $[1, 2, 3, 3]$  appears for the word “dogs” with padding  $p_0 = 0$  and for the word “guns”

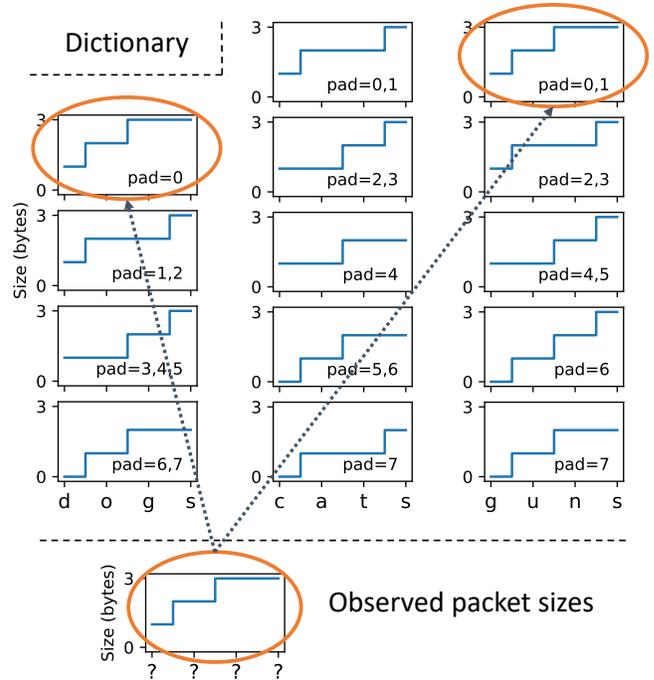

Figure 6: Dictionary pruning. The dictionary contains every possible sequence of cumulative packet size, determined for each word in the dictionary under each unknown prior padding amount (0 to 7 bytes). The cumulative size of an observed query is compared to each sequence in the dictionary. Words that don’t have any matches to the observed sequence are eliminated. The observed sequence  $[1, 2, 3, 3]$  matches “dogs” with no padding and “guns” with 0 or 1 byte padding; “cats” has no matches and can be safely eliminated.

with  $p_0 = 0$  or  $p_0 = 1$ . It’s therefore possible that the query contains either the word “dogs” or “guns”. However, the user definitely did not search for “cats” since the sequence  $[1, 2, 3, 3]$  is not attainable for the word “cats” under any padding  $p_0$ . The total size alone does not reveal this much information since all words in the dictionary could have the same total compressed size as the query (3 bytes) given some unknown amount of padding.

Note that in general, if  $h_i \leq p_{i-1}$ , then  $d_i = 0$ , where  $p_i$  is the padding applied after the  $i$ th character. That is, when the bit length of a new character is equal to or less than the previous amount of padding used, the packet size will remain the same. Since the lengths of lowercase ASCII characters range from 5 to 7 bits, an increase of at least 1 byte is guaranteed when  $p_{i-1} < 5$ . It is also never the case that  $d_i = 0$  and  $d_{i+1} = 0$ , i.e., every two consecutive requests must increase by at least one byte.

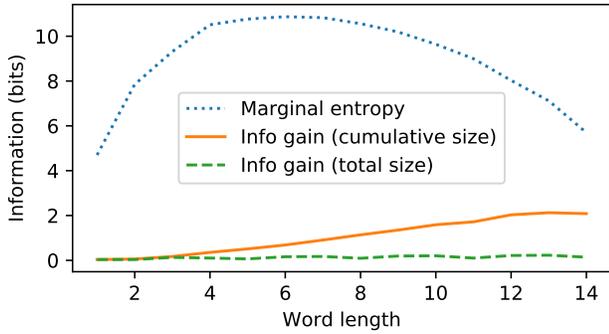

Figure 7: Information gain from an incremental compression side channel, where the cumulative size of a string is exposed, compared to a conventional compression side channel, where only the total size is exposed.

## 5.2 Pruning and information gain

To measure the impact of this side channel, we determined the expected information gain using a dictionary of 12k common English words and compare this to the information gained from total size alone. Given observed cumulative byte size sequence  $\mathbf{B} = B_1, \dots, B_n$ , the probability of each word in the dictionary may be computed by Bayes' formula,

$$P(w|\mathbf{B}) = \frac{P(\mathbf{B}|w)P(w)}{P(\mathbf{B})} \quad (4)$$

where  $P(\mathbf{B}|w)$  is the probability of sequence  $\mathbf{B}$  given word  $w$ ,  $P(w)$  is the marginal probability of word  $w$ , and  $P(\mathbf{B})$  is the marginal probability the sequence  $\mathbf{B}$ . Note that multiple byte size sequences could be observed for a particular word depending on the amount of padding used. For example in Figure 6,  $P([1, 2, 3, 3] | \text{"guns"}) = \frac{2}{8}$  since the sequence  $[1, 2, 3, 3]$  is possible for the word "guns" with paddings of 0 and 1 out of 8 possible padding amounts. In the same example, the marginal  $P([1, 2, 3, 3]) = \frac{3}{24}$  since the sequence  $[1, 2, 3, 3]$  appears 3 times in the dictionary with 24 precomputed sequences (3 words  $\times$  8 padding amounts). Words for which  $P(w|\mathbf{B}) > 0$  are retained in the dictionary in the later stages of the attack and words for which  $P(w|\mathbf{B}) = 0$  are eliminated.

From  $P(w|\mathbf{B})$ , the conditional entropy  $H(w^n|\mathbf{B})$  is determined for words of length  $n$ . Information gain is given by  $I(w^n; \mathbf{B}) = H(w^n) - H(w^n|\mathbf{B})$ , where  $H(w^n)$  is the marginal entropy of words of length  $n$ . We assume each word has an equal probability of occurrence, i.e.,  $H(w^n)$  has maximum entropy. The information gain is shown in Figure 7. Note that information gain from total byte size  $B$  is negligible as previously reported [50]. However, the information gain from cumulative size increases for longer words due to the "uniqueness" of the cumulative byte sizes revealed through incremental compression. These gains lead to more accurate query identification.

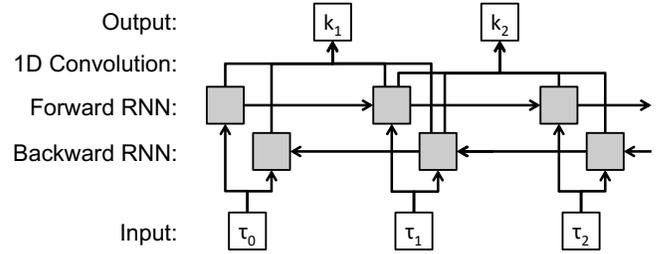

Figure 8: Neural network architecture that predicts  $n$  keys from  $n + 1$  packet inter-arrival times.

## 6 Word identification and beam search

In the last stages of KREEP, packet inter-arrival timings are used to predict which words the user typed. Word probabilities are determined for the remaining words in the dictionary after pruning, and these probabilities are combined with a language model in a beam search to generate hypothesis queries.

### 6.1 Word identification from timings

Since each autocomplete request is triggered by a key-press event, packet inter-arrival times faithfully preserve key-press latencies. These latencies are used to predict which keys the user pressed. Unlike previous work which considered either each latency in isolation [47], or words in a limited dictionary [29], we define a model that predicts key probabilities considering their surrounding context and also able to recognize words not seen during training.

We use a three-layer neural network to predict key probabilities. Generally, each word of length  $n$  has  $n + 1$  packet inter-arrival times since a Space precedes the first character and follows the last character. The model takes as input the sequence of latencies  $\tau_i$  for  $0 \leq i \leq n$  and predicts  $P(k_i)$ , the probability of each key  $k_i$  for  $1 \leq i \leq n$ .

The first layer of the network is a bidirectional recurrent neural network (RNN) with gated recurrent units (GRU) that takes as input the sequence of  $n + 1$  time intervals. The second layer is a 1-dimensional convolutional layer with kernel size 2 and no padding. The convolutional layer reduces the size of the output from  $n + 1$  to  $n$ . The last layer is a dense layer with softmax activation that predicts the probability of each key (26 classes) at each time step. This architecture is shown in Figure 8.

The network architecture was motivated by several factors. The use of a bidirectional RNN ensures that the predictions at key  $i$  are made within the context of latencies preceding and following  $i$ . The convolutional layer with kernel size 2 combines the latency immediately before and after key  $i$ , reducing the size of the sequence from  $n + 1$  (number of latencies) to  $n$  (number of keys). Note that while generally a word of length  $n$  has  $n + 1$  latencies, the first and last words in the query each have  $n$  latencies due to missing the leading Space and trailing

Space, respectively. We augment the missing intervals with the mean latency obtained over the entire training dataset.

Word probabilities are determined from the sequence of key probabilities output by the network. The probability of word  $w$  is the joint probability of all keys in that word,

$$P(w|\tau) = \prod_{k_i \in w} P(k_i) \quad (5)$$

where  $\tau$  is the sequence of observed latencies. Making predictions at the key-level and then calculating word probability by the joint key probability has several advantages. First, the number of output classes in the network remains small (26 keys) compared to the number of possible words (over 12k). Second, the probability of any word can be determined whether or not it was contained in the dataset used to train the model. In this way, the dictionary used to generate hypothesis queries is independent of the key identification model.

Finally, learned features may be shared across words. For example, if a particular pattern of latencies is indicative of the sequence “th”, the model can learn to recognize “th” in different words such as “the”, “there”, “beneath”, and so on. If instead predictions were made at the word level, these features would have to be learned separately for each word.

## 6.2 Language model and beam search

In the last stage, word probabilities are combined with a language model to generate hypothesis queries in a beam search.

We assume the query to be a sequence of  $N$  words  $w_i$  for  $1 \leq i \leq N$  and take advantage of the fact that some words are more likely to follow others in natural language. As an example, consider trying to predict an 8-letter word that follows the sequence “recovering from a \_”. The probability of words such as “sprained” and “fractured” should be relatively higher than other words such as “purchase” and “position”.

The use of a language model enables constraints of English language to be leveraged in conjunction with word probabilities from packet timings. A language model estimates the probability of a word given the words that preceded it, denoted by  $P(w_i|w_1 \dots w_{i-1})$ . We combine the language model with the keystroke timing model to determine the probability of an entire query  $\mathbf{w} = [w_1, \dots, w_N]$ , given by

$$P(\mathbf{w}) = \prod_{w_i \in \mathbf{w}} P(w_i|\tau) P(w_i|w_1 \dots w_{i-1})^\alpha \quad (6)$$

where  $\alpha$  is a parameter that controls the weight of the language model. Smaller  $\alpha$  places more weight in the packet inter-arrival timings, while larger  $\alpha$  places more weight on the language model. In this work, we found  $\alpha$  in the range of 0.2 to 0.5 work well and we use  $\alpha = 0.2$ . The language model is a 5-gram model with Kneser-Ney smoothing [21] trained on the Billion Word corpus [11].

Determining the sequence with maximum *a posteriori* probability (MAP) is NP-hard due to the exponential growth of the

search space. It is also unlikely that the MAP sequence itself exactly matches the true query. Instead, KREEP generates a list of hypothesis queries using a beam search. Beam search is a breadth-first greedy search algorithm that maintains a list of top candidates (the “beam”) as it progresses the search tree.

For each token, all the words in the dictionary are appended to each hypothesis in the beam, which starts with the empty string. This results in a list of  $W \times D$  candidates, where  $W$  is the beam width and  $D$  is the size of the dictionary. The  $W$  sequences with highest likelihood are retained, and the rest discarded. This repeats until the last token is reached, at which point the search returns a list of  $W$  hypothesis queries. We use a beam width of 50. To measure the performance of KREEP, we determine the rate at which the query is correctly identified among the 50 hypotheses as well as the minimum edit distance in the list of 50 hypotheses to the true query.

## 7 Results

In this section, we describe our data collection setup and evaluate attack performance. KREEP is first tested under ideal conditions. We then evaluate performance with increasing levels of simulated network noise and propose a simple padding defense to mitigate attack success.

### 7.1 Data collection

We built a system that captures network traffic while a query is typed into a search engine with autocomplete. The measurement setup consists of a keystroke dataset previously collected from human subjects, browser automation with Selenium WebDriver, and a process to replay keystrokes by writing keyboard events to `/dev/uinput` in real time.

To train the neural network, we used a subset of a publicly available keystroke dataset collected from over 100k users typing excerpts from the Enron email corpus and English gigaword newswire corpus [15]. From this dataset, we retained 83k users with US English locale on either desktop or laptop keyboards and QWERTY keyboard layout.

To simulate search queries, we randomly selected 4k phrases between 1 and 20 words in length containing only letters and the Space key. This selection contains a wide variety of typing speeds, ranging from 1.5 to 22 keys per second. Of the 4k phrases, 3k are unique. They contain a total of 1717 unique words ranging from 1 to 14 characters with an average word size of 6 characters. None of the users in the evaluation data appeared in the dataset used to train the neural network.

Each capture proceeded as follows. The web browser was opened and cookies cleared before starting the capture process (tshark). One second after the capture began, the website was loaded using Selenium. There was then a two second delay before replaying the keystrokes. The keystroke sequence was replayed by writing the sequence of key events to the

	Google		Baidu	
	Chrome	Firefox	Chrome	Firefox
Detect F-score	99.99	99.96	99.62	99.98
Perfect detect rate	99.72	98.70	96.35	99.52
Token F-score	97.26	95.45	96.85	97.33
Perfect token rate	81.12	74.89	86.70	88.30

Table 1: Keystroke detection and tokenization F-scores (%) and rates (%) of achieving perfect accuracy (F-score=100%).

uinput device with delays between each event that correspond to the original keystroke sequence. The data collection was performed on an Ubuntu Linux desktop machine with kernel version 4.15 compiled with the `CONFIG_NO_HZ=y` option, which omits scheduling clock ticks when the CPU is idle [1]. This ensures keyboard event times are replayed with high fidelity and not quantized due to the presence of a global system timer.

We captured 4k unique queries on search engines Google and Baidu, both of which default to an HTTPS connection and generate autocomplete requests upon key-press events. All results were obtained on the encrypted traffic: TLSv1.3 for Google and TLSv1.2 for Baidu. Both sites leak information through the size of the TLS records, which includes the size of the payload plus a fixed amount for the authentication code (GMAC). Thus, TLS preserves differences in payload length, although TLSv1.3 does contain a provision for record padding to hide length [40].

To understand how the browser itself might affect network timings, the data collect was performed in both Chrome (v.71, with QUIC disabled) and Firefox (v.64). The captured dataset contains a total of 16k queries (4k queries  $\times$  2 search engines  $\times$  2 web browsers), obtained over approximately 7 days. During this time, we did not experience any rate limiting. However, a small number of captures did miss some of the outgoing traffic (< 1%). The unsuccessful captures were repeated until success.

## 7.2 Attack performance

The first step of the attack is to detect keystrokes. Keystroke detection accuracy is reported separately for each website in each browser in Table 1. In both websites and browsers, keystrokes are detected with near perfect accuracy with a high rate of achieving perfect detection. Tokenization F-scores are also shown in Table 1. The rates of achieving perfect tokenization are strictly lower than that of detection since tokenization is applied after detection.

We examined the cases in which tokenization failed. We found that false positives in Google were due mainly to rollover of the `String Length` field in the HPACK header, which specifies the size in bytes of a compressed string. In HPACK, the string length starts as a 7-bit integer (see Figure

Google		Google (no prune)		Baidu	
Chrome	Firefox	Chrome	Firefox	Chrome	Firefox
15.83	15.13	14.20	13.55	12.85	12.63

Table 2: Top-50 classification accuracy: % of queries that are correctly identified among the 50 hypothesis queries.

5). When the number of compressed bytes exceeds  $2^7 - 1$ , an additional byte is allocated for the string length, resulting in an overall increase of 2 bytes (+1 from the `String Length` increase and +1 from the new character in the query). Since it is generally not known where this rollover occurs, we cannot distinguish whether the 2 byte increase was due to `String Length` rollover or the addition of a percent-encoded Space.

False negatives in both Google and Baidu were due mainly to larger changes in packet size coinciding with a Space. In Google, this occurs when the “`gs_mss`” parameter is added to the query in the same request as a Space, and in Baidu, from the inclusion of a cookie that was not previously present. These larger changes (> 10 bytes) mask the change in size due to the Space key (2 or 4 bytes).

Following detection and tokenization, the dictionary is pruned, word probabilities from packet inter-arrival timings are determined, and hypothesis phrases are generated in a beam search. Attack success critically depends on accurate keystroke detection and tokenization. This is because the later stages of the attack assume that word lengths have been correctly identified. If the wrong word lengths have been determined, due either to a failure in detection or tokenization, then the correct query cannot be identified.

This behavior is shown qualitatively in Figure 9. In this example, perfect detection and tokenization result in hypothesis queries that have the correct word lengths and low edit distance to the true query. When either a false negative or false positive detection error occurs, the hypothesis queries will have a different length than the true query. In Figure 9 (middle), the 7th packet (containing the 1st “r” in “recovering”) is incorrectly labeled as non-keystroke. As a result, the third word in the hypothesis has 9 letters instead of 10. This results in sequences that have relatively high edit distance to the true query. Tokenization errors have a similar effect in that word lengths in the hypothesis will not match the query. In Figure 9 (right) the 11th packet (containing the 2nd “e” in “recovering”) is incorrectly labeled as a Space. The hypothesis queries have the same total length as the true query but differ in word lengths, resulting in relatively high edit distance.

The proportion of attacks in which the true query is identified among the hypotheses queries, analogous to a top-50 classification accuracy, is shown Table 2. We also determined the minimum edit distance for each search engine as a function of query length and compare this to a baseline attack in which the timing and language model probabilities are ignored. Baseline performance is obtained by generating 50 ran-

Perfect detection/tokenization		Keystroke detection false negative		Tokenization false positive	
he is recovering from a sprained	0	to be president from a position	18	is to learn from such a position	23
he is recovering from a strained	1	to be president from a business	17	is to learn from such a purchase	23
he is recovering from a fracture	7	to be president just a fraction	22	is to learn more from a position	20
he is recovering from a position	7	to be president from a possible	18	is to learn from such a pressing	22
he is recovering from a possible	7	to be president from a southern	18	is to learn from such a practice	21

Figure 9: Query hypotheses in three different scenarios: perfect detection and tokenization (left), false negative keystroke detection (center, the 7th packet is missed), and false positive tokenization (right, the 11th packet is labeled as a Space). The edit distance to the true query “he is recovering from a sprained”, is shown to the right of each hypothesis.

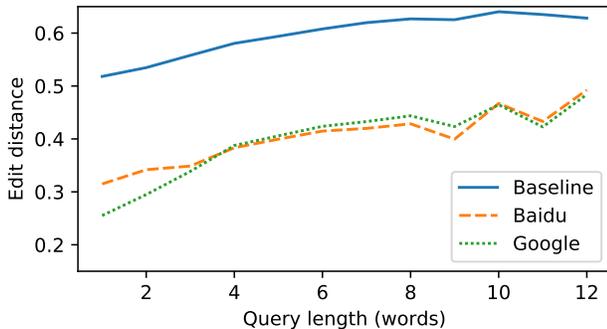

Figure 10: Minimum edit distance (the closest query among 50 hypotheses to the true query) vs query length.

dom hypotheses, choosing dictionary words the same length as the detected tokens. Note that this baseline still uses information gained through keystroke detection and tokenization. These results are shown in Figure 10.

Generally, the difficulty in identifying the query increases with query length. The hypotheses have an average minimum edit distance of 0.37 to the true query. Note that edit distance reduces to Hamming distance for strings of equal length, and perfect detection (F-score of 100%) is achieved in about 98% of queries. Therefore, 0.37 edit distance is roughly a 63% key identification accuracy. We did not find any significant difference in performance across browsers, but did achieve overall higher query identification rates on Google due information leaked through incremental compression.

We found the example in Figure 9 to be representative of attack success which generally had polarized outcomes: the hypotheses were either very similar to or very different from the true query. This behavior is revealed in the distribution of minimum edit distances shown in Figure 11, which has two modes: one occurring near the baseline (0.55, achieved by guessing random words) and the other at 0.

### 7.3 Information sources

To better understand the relative contribution of each component, we evaluate attack performance ignoring the packet timings, language model probabilities, or header compression.

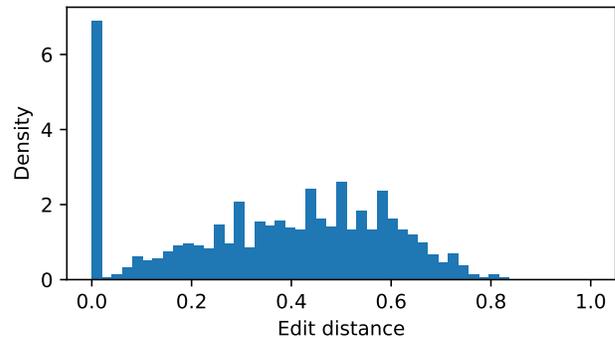

Figure 11: Minimum edit distance distribution. Two modes indicate that KREEP either exactly identifies a query (0 edit distance) or performs near the baseline (0.55 edit distance).

Considering only queries in Google (Baidu does not support HTTP2), performance is evaluated for three scenarios: using only the packet timings (TM only), using timings and the language model (TM+LM), and using both with dictionary pruning applied (TM+LM+Pruning).

These results are shown in Figure 12 with baseline performance as described in the previous section. The largest gains are achieved with the use of packet timings and language model. The neural network alone identifies words with 19.1% accuracy. Incremental gains are then achieved when the dictionary is pruned.

### 7.4 Effects of network noise

We tested the robustness of the attack to network noise. Since key identification uses packet inter-arrival times, packet delay variation (PDV) can potentially reduce attack success. PDV corresponds to changes in network latency, which can obfuscate the key-press timings in packet inter-arrival times. In this regard, variations in routing delay potentially provide a natural defense to remote keystroke timing attack.

The Laplace distribution has previously been proposed as a model for PDV [60]. We simulate PDV by drawing samples from a Laplace distribution parameterized by the mean absolute deviation (MAD). The simulated PDV is added to

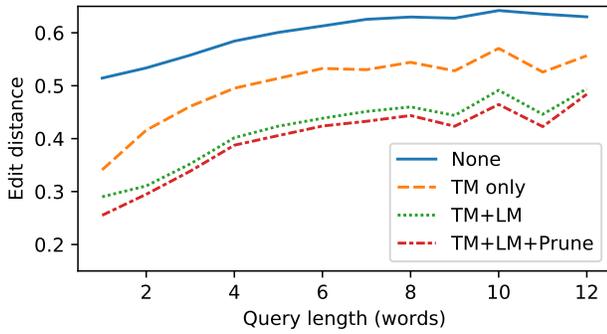

Figure 12: Performance with/without the use of the timing model (TM), language model (LM) and dictionary pruning.

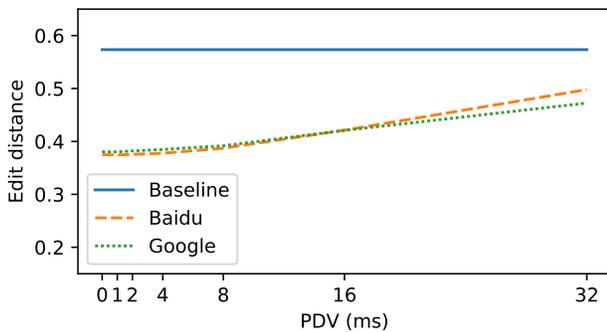

Figure 13: Effects of packet delay variation. Baseline ignores packet timing, uses only packet size to generate hypotheses.

the captured packet times before attempting to identify the query with KREEP. Performance as a function of increasing PDV is shown in Figure 13. The attack is relatively robust to PDV less than 8 ms, but approaches baseline performance with PDV in excess of 32 ms.

## 7.5 Effects of padding

With the attack being robust to low levels of network noise, we explored other means of mitigating attack success. Query identification critically depends on accurate detection and tokenization, and chances of attack success can be greatly reduced with a simple padding scheme.

We simulate random padding by modifying the captured packet sizes. The size of each autocomplete packet is increased by 1 byte with probability 0.5. The sizes of other

Detect F-score		Token F-score		Min edit distance	
Original	Padded	Original	Padded	Original	Padded
99.89	94.46	96.72	51.23	37.76	61.32

Table 3: Effects of randomly padding packets with 0 or 1 byte.

packets in the trace remain unchanged such that the padding defense could be implemented entirely in the client side auto-complete logic.

The effects of this defense nearly double the minimum edit distance, shown in Table 3. While this scheme does not greatly reduce the ability to detect keystrokes, it makes tokenization difficult which poisons later stages of the attack. Note that tokenization could also be made more difficult by encoding the Space key as a single character, such as “+” instead of the 3 byte sequence “%20”. Search engines Yandex and DuckDuckGo both use this strategy. However, this does not exclude the possibility of tokenization through other means such as timings, an item we leave for future work.

## 8 Discussion

Search engines with autocomplete are part of a larger class of applications in which the manifestation of human-computer interactions in network traffic can lead to a remote side channel attack. This includes VoIP: as utterances are compressed and transmitted in real time, spoken phrases can be identified in encrypted network traffic [55, 56]; SSH: single characters are transmitted to and echoed back by the server, exposing the timing of key presses [47]; HTTP: unencrypted network traces contain a user’s web browsing activity [36, 57]; and HTTPS: in dynamic web applications, server response size can reveal interactions with specific elements on a web page [12].

### 8.1 Related work

**Keystroke timing attacks** Keystroke timing attacks were introduced in [47], which considered the identification of key pairs (bigrams) from key-press latencies to aid in password inference. Such an attack is generally possible because of the non-zero mutual information between keys and keystroke timings, e.g., keys far apart are usually pressed in quicker succession than keys that are close together [43]. This behavior generalizes across subjects, similar to other phenomena in human-computer interaction (HCI) such as Fitts’ Law [17]. There has been some debate whether a remote keystroke timing attack poses a credible threat [3, 22]. Evidence suggests that while information gain is generally possible, attack success is user-dependent with some users being more vulnerable than others [33, 34].

In [47], a hidden Markov model and generalization of the Viterbi algorithm were used to generate candidate passwords from timings. The key-press latencies used to train the model were recorded in isolation, wherein subjects pressed a key pair as opposed to typing a full password. In addition, the keystrokes were recorded on the host under the assumption that the key-press latencies would be faithfully preserved in the network traffic. Our work confirms that assumption by using timings obtained from actual network traffic and users typing complete phrases instead of isolated bigrams.

There have been numerous works focused on the *detection* of keyboard events (which enables a timing attack), such as through spikes in CPU load [45], cache and memory usage [41], and the `proc` filesystem [23]. Few works have considered remote keylogging attacks [12,58]. In [51], the authors examine the extent to which autocomplete exposes key-press latencies in network traffic and found that multiple observations were required to recover the true latency. In a recent work, we characterized the autocomplete network traffic of five major search engines and measured the correlation between key-press latencies on the host and packet inter-arrival times observed remotely [35], finding search engines Google and Baidu to leak the most information. The findings in [35] partly motivated the development of KREEP.

Since the work [47], several studies have examined timing attacks on password [6,59] and PIN [29,30] input. We depart from prior work, which has focused on sequences with maximum prior entropy, by targeting natural language input, which is more susceptible to keystroke timing attack due to a relatively lower prior entropy (roughly 1 bit per char, as noted in [47]). We introduced a method to combine language model probabilities with information leaked through keystroke timings, inspired by the use of language models in conjunction with acoustic models in automatic speech recognition [20]. In addition, our attack combines multiple independent sources of information leakage beyond keystroke timings, including URL escape sequences and HTTP2 header compression.

**Compression side channels** A compression side channel leverages information leaked through the compression of a plaintext prior to encryption [28]. Because different strings compress to different sizes, compressed size can reveal information about the plaintext. HTTPS exposes the length of an encrypted payload, making it vulnerable to attack when the payload is compressed. There have been several attacks on HTTPS based on this principle.

The CRIME attack exploits compression in TLS and in the now deprecated SPDY protocol [42]. This attack requires a man-in-the-middle vantage in which an attacker inserts a guess for a secret, e.g., an HTTP cookie or a CSRF token, into a message and observes the compressed size. The DEFLATE compression algorithm in SPDY uses redundancy to compress a string [14] such that the compressed size of a packet containing the correct guess will be smaller than an incorrect guess. The BREACH attack leveraged a similar principle for server responses, targeting compression at the HTTP level (e.g., gzip) [18], and the TIME attack used server response time as a proxy to measure response size [9].

HEIST lowered the bar for attack, enabling CRIME-like attacks to be deployed remotely within a victim's web browser [52]. The size of a compressed server response is determined at the application level by examining whether the response time spans multiple round trips, an indication that the entire response exceeded the TCP congestion window. This general

technique can be used in a variety of side channel attacks beside guessing secrets, such as determining whether a user is logged into a particular site [52].

DEFLATE, the compression algorithm used in gzip, uses a combination of LZ77 and Huffman coding [14]. To date, all compression attacks against HTTPS have exploited the LZ77 component of DEFLATE, which builds a dictionary from the redundant parts of a string. The Huffman code in DEFLATE has been treated as noise, typically dealt with by making guesses in pairs. For example, to find out whether a secret starts with “p”, an attacker guesses “secret=p\_” and “secret=\_p”: if the sizes are the same, then only Huffman coding is used and the guess is wrong; otherwise, if the sizes are different, the LZ77 component was invoked based on redundancy between the first guess and the secret, and only Huffman coding was invoked in the second guess.

HPACK, the header compression format in HTTP2, was designed to be resistant to CRIME-like attacks targeting LZ77 compression, although HTTP2 borrowed many concepts from SPDY [39]. Commonly used header fields are compressed with a dictionary lookup, and string literals are compressed using a static Huffman code, which was previously determined to leak relatively little information [50]. But unlike previous attacks, KREEP leverages the static Huffman code in HPACK rather than an LZ77 dictionary. We found considerably more information is leaked due to several contributing factors:

1. *HTTPS exposes payload size.* HTTPS was previously shown to leak information by exposing the length of an encrypted payload. The HTTPS Bicycle attack uses the size differences between HTTP requests to infer the size of an unknown secret [53]. An attacker simply subtracts the size of all known parts of the request, leaving only the size of the secret. Our attack relies on a similar principle, taking the difference in size between successive autocomplete requests.

2. *Characters are independently compressed.* The size difference between two compressed payloads that differ only by the insertion of a single character reveals the compressed size of that character. However, Huffman encoded strings in HPACK are padded to the nearest octet, mitigating the amount of information that would otherwise be leaked without padding. Since byte, and not bit, size differences are observed, the symbol size is known only to within a margin of error that depends on an unknown amount of padding.

- 3) *The Huffman code is standard.* Every HPACK implementation uses the same Huffman code, which is publicly available [39]. An attacker needs only to map dictionary words to their cumulative compressed sizes, taking into account the unknown amount of padding applied beforehand. Potential matches to a secret are revealed by comparing its cumulative compressed size to every word in the dictionary.

**Search query identification** Previous work on identifying search queries has utilized features obtained primarily through traffic analysis. In [37], keywords in search queries are identi-

fied over Tor using both inbound and outbound autocomplete traffic. Keystrokes were replayed in a data collection setup similar to ours described in Section 7.1. Packet inter-arrival times were not considered since the replayed keystrokes used random, and not human, timings. Instead, each search query is characterized by packet counts and sizes, inbound and outbound Tor cell counts, and other features specific to Tor traffic. The work of [37] did not attempt keystroke detection but instead focused on the identification of queries that contain a particular keyword from a set of target keywords. With this approach, a query containing any one of 300 target keywords could be identified with 85% accuracy, and individual keywords with 48% accuracy.

We instead aim to reconstruct an entire query rather than identify the presence of some target words, and we leverage information leaked through packet size, which is obfuscated by cell size in Tor traffic. While keystroke detection may be possible in traffic over Tor, for example by detecting traffic that has “keystroke-like” packet inter-arrival times, tokenization and dictionary pruning cannot be applied since the autocomplete packet sizes are masked behind Tor cell sizes. An attack that uses *only* packet inter-arrival times might be feasible in Tor, but would require a different approach than our attack.

While previous work has shown HTTP response size to leak a considerable amount of information about a user’s query when autocomplete suggestions are provided [12], we chose to focus only on HTTP requests. In [12], an attacker guesses a victim’s query one letter at a time by trying all combinations and matching the server response size. This assumes the attacker can submit queries that induce the same suggestions as the victim received. In practice, this is difficult because autocomplete suggestions depend on the victim’s search history and location, among other factors [2]. To our knowledge, KREEP is the first attack targeting autocomplete traffic from the client independent of these factors, relying only on packet inter-arrival times and packet size differences.

## 8.2 Countermeasures

Keylogging attacks require successful keystroke detection *and* key identification. Therefore, it is sufficient to prevent keystroke detection *or* key identification to counter the attack. We consider the tradeoffs of several countermeasures and how they affect each source of information leakage.

**Padding** Padding could be applied in two different ways: pad each request by a random amount, or pad to ensure all requests are the same size. To increase keystroke detection false negatives, the pad amounts must be sufficiently large to disguise autocomplete traffic with other background traffic, the size of which is generally not known a priori. Therefore, padding may not be effective to mitigate keystroke detection and does not provide any protection against a timing attack. However, we have confirmed that padding by a small random

amount (1 byte with probability 0.5) does effectively mitigate tokenization and incremental compression. Note that padding in this way should be applied only to alphabetic characters and not to the addition of a Space; otherwise, some packets with a Space will increase by 3 bytes (2 bytes + 1 padding byte), while all other packets increase by no more than 2 bytes. The pad amounts should be chosen such that the *observed* packet size differences closely follow a uniform distribution.

**Dummy traffic** While padding aims to increase detection false negatives, generating dummy traffic aims to increase false positives. A false positive occurs when background traffic is labeled as a keystroke. Generating dummy autocomplete requests with approximately the same size as the actual request would make keystroke detection a difficult task. With each autocomplete request, the client could send a burst of several packets with similar size (within several bytes), randomly ordering the actual request within the dummy request. While an attacker might still be able to perform detection with a low false negative rate, this comes at a cost of an increased false positive rate. This method mitigates tokenization, compression, and timing attacks. The background traffic would overwhelm the actual requests, similar to the generation of dummy keyboard events in KeyDrown [45]. This approach has the cost of increased bandwidth, a tradeoff reminiscent of the anonymity trilemma [13], and requires some cooperation from the server to ignore the dummy requests.

**Merge requests** Most search engines make an autocomplete request immediately following each new character appended to the input field [35]. Instead, combining multiple characters into a single request would mitigate our attack in two different ways. First, with multiple characters merged into a single request, the number of false negative detection errors must increase since a packet contains multiple keystrokes. This conceals the timing information of all but the last character in the merged request, reducing information leakage through a keystroke timing attack.

Additionally, merged requests effectively eliminate the incremental compression side channel since the increase in packet size corresponds not to a single character but to multiple characters. The compressed size of the merged characters must be some linear combination of symbols in the Huffman code, and as string length increases, the number of combinations grows exponentially [50].

Combining requests could be achieved in several ways: 1) update the list of autocomplete suggestions after every other, or every *n*th, key (similar to Nagle’s algorithm, except at the application level); 2) use a polling model with polling rate slower than the user’s typing speed (Bing performs polling with 100ms interval, making this attack impractical for fast typists); or 3) trigger callbacks on *keyup* events instead of *keydown* events (DuckDuckGo does this), which merges requests when consecutive keystrokes overlap [35], a typing

phenomenon referred to as *rollover* [15]. The drawback in all cases is that merging requests could adversely affect usability since the suggested queries are delayed to the user.

### 8.3 Limitations and future work

We point out several limitations of our attack, emphasizing the conditions under which it succeeds, and identify ways in which KREEP could be extended or improved.

**Other websites** In this work, KREEP has only been tested on search engines Google and Baidu. Keystroke detection and tokenization are both application-specific, based on the packet size pattern each search engine emits. Extensions to other search engines or websites would require modification to these components. For websites that aren't vulnerable to tokenization, delimiters might be identified based on packet inter-arrival times (e.g., larger intervals indicate Space, smaller intervals indicate letters).

**Other modalities** Since autocomplete requests are induced by keyboard events, KREEP is applicable only up to the point when a user stops typing or selects a suggested query. We assumed that no deletions or corrections were made and that the user did not press any non-printable keys, e.g., arrow keys, that cause the caret to change position. However, selecting a query from the provided suggestions does not preclude the possibility of other attacks that incorporate the timing of both autocomplete requests and server responses. It may be the case that the way the user interacts with the autocomplete suggestions also leaks course-grained information, such as user identity or the type of query (navigational, informational, or transactional) [10]. One might also consider the timing of mouse clicks that induce network traffic as a source of information leakage by leveraging a general model that governs click behavior, such as Fitts' Law [17].

**Targeted attacks** Finally, while we made an effort to evaluate our attack on phrases that are representative of natural language, the content of actual search queries is quite different and varies between users as evidenced by the AOL search dataset [7, 38]. Some strings that have a low probability of occurrence in natural language, such as "www", tend to occur frequently in search queries. This affects the prior probability of each symbol, which must be properly accounted for in the language model. We verified this difference by comparing the frequency of characters in the AOL search dataset to the keystroke dataset we used to evaluate KREEP (which itself borrowed phrases from the Enron email corpus [15]). These are shown in Figure 14. Notably, the frequencies of "w" and "c" in search queries are about twice that of natural language, likely due to the presence of navigational queries to a specific URL, such as "www.example.com". Likewise, Space characters in search are about half as frequent compared to natural

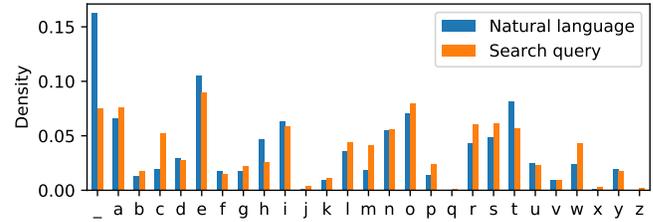

Figure 14: Character frequency in natural language (Enron corpus) compared to search queries (AOL search dataset).

language. In a targeted attack, the language model in KREEP could be tailored towards a particular victim, leveraging information such as the victim's native language, geographic location, and public blog entries.

## 9 Conclusion

KREEP leverages multiple independent sources of leaked information to identify search queries in encrypted network traffic. Autocomplete request packets are detected based on packet size; queries are tokenized by detecting the presence of URL-escaped characters; keys are identified based on packet inter-arrival times; and impossible words are eliminated from a dictionary based on incremental compression. Despite many moving pieces, the attack obtains a reasonable success rate, recovering more than half the characters in a query on average. But more importantly, the pieces that contribute to this attack present some starting points for future research.

The static Huffman code used in HTTP2 header compression leaks more information than previously thought [50] when incremental changes are made to a string in the header. This kind of attack is not limited to search engines with autocomplete but could apply to any website with dynamic content that updates incrementally. It will be beneficial to identify other web applications that exhibit incremental compression. Besides websites that provide search suggestions, this could include mapping services, which modify the geographic coordinates in a URL as the user drags the map center location, or websites that autosave the contents of a text field.

Likewise, websites that generate network traffic in response to user input events may be vulnerable to timing attack. Sites that support remote document editing, such as Google Docs, frequently transmit the document state from the client to the server. When this process is event driven, i.e., triggered by `keydown` events, the network traffic can leak information about the user's actions or document content. Similarly, chat applications that aim to provide real-time updates about a conversation partner's activity, e.g., by displaying a notification that "X is typing", also risk exposing keystroke timings in network traffic if those notifications are directly driven by the conversation partner's keystrokes.

## Availability

KREEP is available at <https://github.com/vmonaco/kreep>. The keystroke dataset is publicly available [15].

## Acknowledgements

We thank the anonymous reviewers and our shepherd for valuable feedback during the review process. The manuscript was much improved based on insightful discussions with colleagues Justin Rohrer and Robert Beverly, who also provided comments on an early draft.

# Iframes/Popups Are Dangerous in Mobile WebView: Studying and Mitigating Differential Context Vulnerabilities

GuangLiang Yang, Jeff Huang, Guofei Gu  
Texas A&M University  
{ygl, jeffhuang, guofei}@tamu.edu

## Abstract

In this paper, we present a novel class of Android WebView vulnerabilities (called *Differential Context Vulnerabilities* or *DCVs*) associated with web iframe/popup behaviors. To demonstrate the security implications of DCVs, we devise several novel concrete attacks. We show an untrusted web iframe/popup inside WebView becomes dangerous that it can launch these attacks to open holes on existing defense solutions, and obtain risky privileges and abilities, such as breaking web messaging integrity, stealthily accessing sensitive mobile functionalities, and performing phishing attacks.

Then, we study and assess the security impacts of DCVs on real-world apps. For this purpose, we develop a novel technique, *DCV-Hunter*, that can automatically vet Android apps against DCVs. By applying DCV-Hunter on a large number of most popular apps, we find DCVs are prevalent. Many high-profile apps are verified to be impacted, such as Facebook, Instagram, Facebook Messenger, Google News, Skype, Uber, Yelp, and U.S. Bank. To mitigate DCVs, we design a multi-level solution that enhances the security of WebView. Our evaluation on real-world apps shows the mitigation solution is effective and scalable, with negligible overhead.

## 1 Introduction

Nowadays, mobile app developers enjoy the benefits of the amalgamation of web and mobile techniques. They can easily and smoothly integrate all sorts of web services in their apps (*hybrid* apps) by embedding the browser-like UI component “WebView”. WebView is as powerful as regular web browsers (e.g., desktop browsers), and well supports web features, including the utilization of *iframes/popups*.

In the web platform, iframes/popups are frequently used, but also often the root cause of several critical security issues (e.g., frame hijacking [11] and clickjacking [23, 43]). In past years, in regular browsers, their behaviors have been well studied, and a variety of mature iframe/popup protection solutions (e.g., Same Origin Policy (SOP) [6], HTML5 iframe sandbox [4], and navigation policies [11]) have been deployed.

**Inconsistencies Between Browsers and WebView.** However, in WebView, a totally different working environment is provided for iframes/popups, due to WebView’s own programming and UI features. Although these features improve app performance and user experience, they extensively impact iframe/popup behaviors and introduce security concerns. In particular, WebView enables several programming APIs (Figure 1) to help developers customize iframe/popup behaviors. For example, the setting APIs allow developers to configure their WebView instances. In the customized web environment (WebView), it is unclear whether existing iframe/popup protection solutions are still effective.

Furthermore, WebView UI is designed in a simple style (Figure 2) that only one UI area for rendering web content is provided. Due to the lack of the address bar, it is difficult for users to learn what web content is being loaded; due to the lack of the tab bar, it is unknown how multiple WebView UI instances (WUIs) are managed. Therefore, if an iframe/popup has abilities to secretly navigate the main frame (the top frame) or put their own WUI to the foremost position for overlaying the original WUI, phishing attacks occur and may cause serious consequences. Consider the scenario shown in Figure 3 and 4. The Huntington banking app (one million+ downloads) uses WebView to help users reset passwords (Figure 3-a,b). Inside WebView, the main frame contains an iframe for isolatedly loading untrusted third-party tracking content (Figure 4). However, if the untrusted web content inside the iframe obtains the ability of stealthily redirecting the main frame to a fake website (Figure 3-c), serious security risks are posed. For example, users’ personal (e.g., SSN info and Tax ID) and bank account information may be stolen, and further financial losses may also be caused.

**Differential Context Vulnerability (DCV).** Motivated by above security concerns, we conduct the first security study of iframe/popup behaviors in the *context* of Android WebView. In this paper, we use the term “context” to refer to a web environment that includes GUI elements (e.g., the address and tab bars), corresponding web management APIs (e.g., the setting APIs in WebView), and security policies (e.g., SOP

Table 1: A Summary of Differential Context Vulnerabilities (DCVs)

Critical Features & Behaviors	Different Contexts		Attacks	Explanations	Consequences
	Browsers	WebView			
Main-Frame Creation	Address Bar	Java APIs	Origin Hiding Attack	Special common origins (e.g., null) Of Main-Frame	Sensitive functionalities behind postMessage and JavaScript Bridges can be leveraged, which may cause the leakage of sensitive information (e.g., location), and risky access on Hardware (e.g., camera and microphone)
Management of new popups	Tab Bar	Android Frameworks	WUI overlap attack WUI closure attack	No protection on the WUI rendering sequence	Phishing attacks
Main-Frame Navigation	Address Bar	Java APIs	Traditional navigation based attack Privileged navigation attack	Permissive navigation policies Harmful conflict between WebView Customizations and web APIs	

and navigation policies).

As a consequence, our study uncovers a novel class of vulnerabilities and design flaws in WebView. These vulnerabilities are rooted in the inconsistencies between different contexts of regular browsers and WebView. As summarized in Table 1, several critical web features and behaviors (i.e., main-frame creation, popup creation, and main-frame navigation) are involved (see more details in Section 3). These features and behaviors are harmless or even safe in the context of regular browsers, but become risky and dangerous in the context of WebView. To demonstrate their security implications, we devise several concrete attacks. We show through these attacks, remote adversaries (e.g., web or network attackers on iframes/popups) can obtain several unexpected and risky privileges and abilities:

- 1) *Origin-Hiding*: hiding the origin when
  - breaking the integrity of web messaging (i.e., postMessage) [8], which allows the communication between mutually distrusted web frames; and
  - secretly accessing web-mobile bridges [21], which link the web layer with the *mobile* or *native* layer (e.g., Java for Android) (Figure 1);

Existing work has shown that postMessage’s message receivers [44, 47] and web-mobile bridges [21, 49, 53] often carry sensitive functionalities. Thus, these functionalities can be further stealthily accessed by the untrusted iframe/popup through the attack. As a result, sensitive information (e.g., GPS location) may be stolen, and important hardware (e.g., microphone) may be unauthorizedly accessed.

- 2) *WebView UI Redressing*: performing phishing attacks by overlapping the foremost benign WUI with an untrusted WUI;
- 3) (*Privileged*) *Main-Frame Navigation*: freely redirecting the main frame to a fake website.

Moreover, we examine the effectiveness of existing protection solutions, which include not only the solutions designed for regular browsers (inherited by WebView), but also the solutions proposed for Android UI and WebView. We find that these solutions are ineffective to defend against the above attacks:

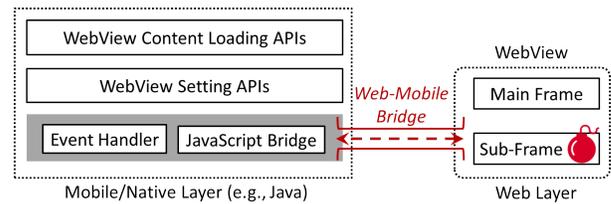

Figure 1: WebView Programming Features

- 1) For origin-hiding attacks, existing defense solutions for postMessage [11, 44, 47, 52] and web-mobile bridges [18, 21, 38, 45, 49] usually provide security enforcement relying on origin validation. However, unfortunately, the key origin information of the untrusted iframe/popup can be hidden during attacks, which leads to the bypass of the security enforcement.
- 2) For WUI redressing attacks, they are similar to Android UI redressing attacks [15, 20, 35]. However, the associated Android UI protection solutions (e.g., [13, 41]) are circumscribed to prevent WUI addressing attacks. This is mainly because that these protections work by monitoring exceptional Android UI state changes between different apps, while the WUI state change occurs within an app during attacks.
- 3) For main-frame navigation attacks, one related solution is the iframe sandbox security mechanism, which can effectively limit the navigation capability of an arbitrary iframe. However, through DCV attacks, an untrusted iframe can still break the above limitation and cause privilege escalation.

More details about the vulnerabilities and the weakness of existing defense solutions are presented in Section 3. For convenience, considering the root reason of this new type of vulnerability (i.e., the inconsistencies between the contexts of regular browsers and WebView), we refer to the vulnerabilities as *Differential Context Vulnerabilities* or *DCVs*, and the associated attacks as DCV attacks.

**DCV-Hunter & Findings.** We next study and assess the security impact of DCVs on real-world hybrid apps. To achieve the goal, we develop a novel static vulnerability detection technique, *DCV-Hunter*, to automatically vet given apps against

Figure 2: UI Comparison

Figure 3: Attacking the Huntington Bank App

DCVs. Then, by applying DCV-Hunter on a number of most popular apps, we show that DCVs are prevalent. More specifically, we find 38.4% of 11,341 hybrid apps are potentially vulnerable, including 13,384 potentially vulnerable WebView instances and 27,754 potential vulnerabilities. Up to now, the potentially impacted apps have been downloaded more than 19.5 Billion times in total. Furthermore, our evaluation shows DCV-Hunter is scalable and effective, and has relatively low false positives (~1.5%).

We also manually verify that many high-profile apps are vulnerable (a list of video demos of our attacks can be found online [2]), including Facebook, Instagram, Facebook Messenger, Google News, Skype, Uber, Yelp, WeChat, Kayak, ESPN, McDonald's, Kakao Talk, and Samsung Mobile Print. Several popular third-party development libraries, such as Facebook Mobile Browser and Facebook React Native, are also vulnerable and they influence hundreds of apps. Several special sensitive categories of apps are affected including leading password management apps (such as dashlane, lastpass, and 1password), and popular banking apps (such as U.S. bank, Huntington bank, and Chime mobile bank).

In our analysis, we also find that some apps implement their own URL address and title bars, which reduce the inconsistencies between regular browsers and WebView. However, these home-brewed URL bars hardly eliminate DCVs due to several limitations. One major limitation is that their implementation is often error-prone. For example, Facebook Messenger (Figure 5, one billion+ downloads) is equipped with the library "Facebook Mobile Browser" to handle URLs contained in messages (e.g., SMS). The browser library implements its own address bar (Figure 5-b) to reflect the change of web content (Figure 5-c) and mitigate DCV attacks (e.g., the WUI overlap attack). However, this address bar contains a design flaw (race condition). By combining a couple of DCV attacks, untrusted iframes/popups can still launch phishing attacks (Figure 5-d). Due to the inclusion of the vulnerable library, many high-profile apps are impacted, such as Facebook and

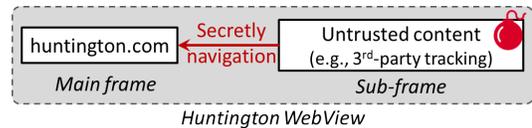

Figure 4: Attack Scenario

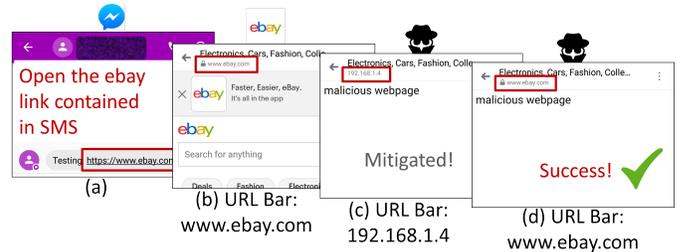

Figure 5: Attacking Facebook Messenger

Instagram. In addition to the vulnerable library, we find this design flaw is shared by many other popular apps that are not equipped with that library, such as Kakao Talk (100 million+ downloads).

We have reported our findings to the Android security team and many app developers. Up to now, a number of them (e.g., the Android and Facebook security teams) have confirmed our findings.

**DCV Mitigation.** DCVs are not caused by programming mistakes. It is extremely difficult for developers to eliminate the DCV security issues, especially considering the existence of the limitations in WebView (Section 3.6). To mitigate the problem, we propose a multi-level protection solution by enhancing the security of WebView programming and UI features. Our defense solution is implemented by instrumenting WebView's independent library, but without touching the source code of Android frameworks. Our solution is easy to use, and can simply work after developers involve our instrumented library, and provide a list of trusted domains. Our evaluation on real-world apps shows that our solution is effective and scalable, and introduces negligible overhead. Furthermore, considering the Android version fragmentation issue, we also test the compatibility of our solution. The result shows our solution is available in many major popular Android versions (5.0+), and covers almost 90% of Android devices in use.

**Contributions.** In sum, we make the following contributions:

- We investigate the security of iframe/popup in Android WebView, and discover several novel and fundamental design flaws and vulnerabilities in WebView (i.e., DCVs).
- We design a novel automatic vulnerability detection tool "DCV-Hunter" to quantify the prevalence of DCVs.
- We apply DCV-Hunter on a set of popular apps, and confirm that DCVs have severe security impacts.
- We further propose a multi-level solution to mitigate DCV attacks.

## 2 Background and Threat Model

Before we dive into our study of iframe/popup security, we first introduce necessary background information and our threat model.

### 2.1 Iframes/Popups and Related Protections

Iframes/popups are frequently used in web apps, for example, to view files in various formats (e.g., images, videos and PDFs), or load third-party untrusted web content (e.g., ads). They are easy to use. To create an iframe, developers can 1) either use the HTML element `<iframe>`; 2) or run JavaScript code to dynamically build an iframe DOM node.

Furthermore, to enable a popup, developers can use the following HTML code to generate a link:

```
<a href="URL" target="_blank|_top|frame_name|...".
```

When users click the link, “URL” will be opened in the frame that is determined by the “*target*” attribute. If *target* is “\_blank”, a new popup window will be opened to show “URL”. Moreover, if *target* is “\_top” or a specific frame name, “URL” will be loaded in the main frame or the specific frame determined by “*frame\_name*”. Developers can also use JavaScript code to open or close a web window:

```
window.open(URL, <target>, ...) or window.close().
```

Similar to the usage of the HTML element `<a>`, “*window.open()*” can also determine where to open popup content.

**Related Protections.** Up to now, several practical protection solutions were designed and deployed in regular browsers:

- *Same origin policy (SOP)*: SOP isolates web frames whose origins are different. Note that SOP causes side effects that different origins are not allowed to communicate with each other. To mitigate the problem, the *postMessage* mechanism is designed in HTML5.
- *Built-in security policies*: Several built-in policies are available. For example, remote web code is not allowed to create a new sub-frame for loading local files, and the main frame is not allowed to load the data scheme URL.
- *HTML5 iframe sandbox*: The iframe sandbox mechanism can limit iframes’ abilities, mainly including the enablement of JavaScript, main-frame navigation (“`<a>`” or “*window.open()*”), and popup-creation. Since the security of the popup behavior is one of our research objectives, we assume the popup-creation ability is allowed in iframe sandbox. Thus, in this paper, we mainly consider the abilities related to JavaScript enablement and main-frame navigation.
- *Navigation policies*: As studied in existing work [11], in regular browsers, the main frame is often exempt from strict navigation policies, which means any sub-frame can directly navigate the main frame by using “`<a>`” or “*window.open()*”. There are several reasons for such a design. First, this type of navigation is frequently used by benign web apps, for example, for preventing framing attacks [43]. Second, even though the main frame is navigated, the consequence is quite limited in consideration of the stealth-

iness: any navigation can be explicitly reflected by URL indicators (e.g., the URL address bar).

### 2.2 WebView and Related Protections

WebView is an embedded, browser-like UI component. Android WebView is equipped with the newest kernel of the regular browser “Chrome/Chromium”, and performs as powerful as regular browsers.

As discussed in Section 1, there are several inconsistencies between regular browsers and WebView. First, WebView UI is like a small and compacted version of a regular browser. It does not contain several common UI elements, including the address, tab, title and status bars.

Second, WebView UI is a case of view group, a collection of multiple Android UI components. More than that, it can also be added to an existing view group. A view group may consist of a set of WUIs with the same size. It manages multiple WUIs with a *rendering queue*, and only rendering the foremost WUI to users.

Third, the manners of initializing web content are different. Compared to regular browsers, which allow users to manually type the address of a website, WebView initializes web content through programming APIs (Figure 1), including

- *loadUrl(URL/file/JS)*: loading content in the main frame;
- *loadData(HTML, ...)*: loading code with the “null” origin;
- *loadDataWithBaseURL(origin,HTML,...)*: loading HTML code with a specified origin.

Last, as shown in Figure 1, developers can customize a WebView instance through several programming features, such as settings, and web-mobile bridges. Settings can manage WebView configurations, while Web-mobile bridges can link the web and mobile layers together. Generally, the bridges include 1) event handlers, which let mobile code handle web events that occur inside WebView; and 2) JavaScript bridges, which can allow JavaScript code to directly access mobile methods.

Furthermore, as shown in Table 2, several programming features can impact iframe/popup behaviors. To enable the creation of a popup, the setting *SupportMultipleWindows* should be set as true, and the event handler *onCreateWindow()* is also required to be implemented and return true. This event handler should create or open a WUI for rendering this popup, and also return the WUI to Android. Otherwise, the popup-creation operation will be ignored. This also means that *different popup windows are rendered by different WUIs at one time*. Besides, to support the closure of a WUI, the event handler *onCloseWindow()* should be also implemented. Note that when any web frame, including the main frame, loads content, the content should be approved by the event handler “*shouldOverrideUrlLoading()*”.

**Summary of Related Protections.** In past years, WebView security, especially the security of web-mobile bridges, has drawn more and more attention [12, 16, 21, 27, 30, 33, 34, 50, 53–55]. Several defense solutions [18, 21, 38, 45, 49, 50]

Table 2: Iframe/Popup-Related Programming Features

Features	Content	Explanation
Settings	<code>OpenWindowsAutomatically</code>	Enable “ <code>window.open()</code> ”
	<code>SupportMultipleWindows</code>	Enable the event handler “ <code>onCreateWindow()</code> ”
Event Handlers	<code>onCreateWindow()</code>	Handle window-creation
	<code>onCloseWindow()</code>	Handle window-closure
	<code>shouldOverrideUrlLoading()</code>	Handle URL-loading

were proposed to enhance the security of WebView by providing the security enforcement and access control mechanisms. However, we find they are ineffective against our new attacks. Section 7 provides a review of these existing work.

### 2.3 Threat Model

In this paper, we mainly focus on the hybrid app whose WebView contains an untrusted sub-frame. In our threat model, we assume the native or mobile code (e.g., Java code), and the main frame loaded in its WebView are secure and trusted. The main frame usually loads web content from the *first-party* benign domains (e.g., `developer.com`). For the embedded untrusted sub-frames, we mainly consider two *possible* attack scenarios:

**Network attacks.** When the sub-frames use HTTP network, attackers may perform man-in-the-middle (MITM) attacks to inject attack code into the sub-frames, and then launch DCV attacks. Although HTTPS have been widely adopted in modern web apps, there is still much legacy code using HTTP.

This scenario is feasible, especially considering many public unsafe WiFi hotspots are available [24]. Consider a possible scenario: attackers may set up a free WiFi hotspot in a crowded place. Nearby smartphone users may use this WiFi. If these users open vulnerable apps (e.g., Facebook and skype) and click web links, apps’ WebView may load these links. If the loaded web content embeds iframes/popups using unsafe network channels (e.g., HTTP), attackers may inject malicious code into the iframes/popups and launch attacks.

**Web attacks.** The inclusion of *third-party* content usually introduces security implications [26, 36]. Hence, we assume web attackers may be the owner of a third-party domain (e.g., `ads.com`) severing an embedded untrusted iframe/popup. Our empirical study on a set of popular hybrid apps and mobile websites shows iframes/popups are frequently used to load third-party content, especially third-party advertising and tracking content. Existing work has demonstrated that third-party advertising [28, 56] and tracking [14, 32, 37, 42, 46] services often causes serious security concerns. More than that, as figured out by existing work [39, 48], a third-party iframe may even directly work as a malicious entry point for malware.

This scenario is also possible in practice. For example, as demonstrated in prior work (e.g., [36]), some domains may expire, which still commonly occurs in recent years. Attackers may register and get the control of these domains. If these domains are embedded by some websites in iframes/popups,

attackers may broadcast these websites to lure users to access them using corresponding vulnerable apps (e.g., Facebook or Facebook Messenger). In the vulnerable apps, WebView may be started, and also access the domains controlled by attackers. Thus, attackers obtain chances to inject malicious code and launch attacks.

Furthermore, as discussed in Section 2.1, considering the security of the popup behavior is one of our research objectives, we assume the popup-creation ability of an iframe/popup is enabled in its sandbox attribute.

## 3 Differential Context Vulnerabilities

In this section, we mainly focus on DCVs, and also explain why existing defense solutions are ineffective to prevent DCV attacks. We first show the overview of our security study, and then present the details of each vulnerability. Last, we discuss the advantages of DCV attacks over existing attacks, also with the analysis of the root causes of DCVs.

### 3.1 Study Overview

Guided by the inconsistencies between regular browsers and WebView (Section 2.2), our security study of iframe/popup behaviors is mainly concerned with the following three dimensions:

**The application of common origins.** As introduced in Section 2.2, WebView content initialization APIs may create the main frame with common origins, such as “`file://`” and “`null`”. For example, the invocation

```
WebView.loadUrl('file:///android_asset/index.html')
```

can load a local file with the origin “`file://`”, while `WebView.loadData()` and `WebView.loadDataWithBaseURL()` may create a main frame to load web data with the “`null`” origin.

However, these common origins are not unique for the main frame, and may be reproduced by untrusted iframes/popups in their inside sub-frames for launching attacks. More specifically, if an untrusted sub-frame can generate a new nested sub-frame “ $F_{nested}$ ” with above common origins, the untrusted sub-frame may place its essential attack code inside  $F_{nested}$  to make risky operations, which are aimed to attack all potential objectives, including the main frame, other sub-frames, or WebView itself. In the attack process, the victims may validate the operations by checking the corresponding origins. However, the origin information they can obtain is  $F_{nested}$ ’s origin, rather than the real origin (i.e., the origin of the untrusted sub-frame). Considering  $F_{nested}$  have the same origin as the main frame, the origin validation process fails. Finally, the victims may treat untrusted operations as benign operations and handled them as usual.

Our study confirms that a sub-frame is not allowed to generate a new sub-frame with the “`file://`” origin, due to built-in security policies (Section 2.1). However, a nested sub-frame with a “`null`” origin can still be generated by using the data scheme URL (e.g., `<iframe src="data://...">`), which is frequently used to load simple HTML code (such as images)

in the web platform. Although SOP can prevent cross-frame scripting between two “null” origins (e.g., the main frame and  $F_{nested}$ ), untrusted sub-frames can still leverage the “null” origin to make several nefarious actions (Section 3.2).

**Concise WebView UI design.** As discussed in Section 1, WebView’s UI design causes security risks that untrusted iframes/popups may perform phishing attacks, if they have the abilities of 1) manipulating the rendering order of multiple WUIs; 2) navigating the main frame. To verify the former potential ability, we first conduct an empirical study on a set of popular hybrid apps. This study is aimed to understand how WUIs are managed in practice. We find Android takes the responsibility of managing multiple WUIs. Our study also shows when a popup is created, Android place its WUI behind current WUI *at default*.

This WUI management strategy seems safe. However, it does not meet app development requirements. Instead, some apps manage WUIs by themselves, which is yet error-prone due to the design flaws of the WebView event handler system (Section 3.6). As a result, the crucial ability of manipulating the WUI rendering order is exposed (Section 3.3.1). Thus, an untrusted iframe/popup can get the ability of overlapping begin WUIs with its own WUI. Our study also shows that even when Android’s default WUI management strategy is adopted, it is still possible for untrusted iframes/popups to change the WUI rendering order by combining WUI creation and closure operations (Section 3.3.2).

Second, to confirm the latter potential navigation ability, we study the navigation policies of WebView. We find WebView inherits permissive navigation policies from Chrome/Chromium. These navigation policies have been well investigated in the context of regular browsers (Section 2.1), but rarely scrutinized in the context of WebView. These navigation policies allow an untrusted sub-frame to navigate the main frame. Due to the lack of the address bar, the navigation based attack is stealthier and more powerful in the context of WebView (Section 3.4.1).

Note that the above navigation can be disabled by iframe sandbox (Section 2.1). But considering iframe sandbox is hardly used in practice, the attack is still prevalent and has negative security impacts in real-world hybrid apps. This is also verified in our evaluation (Section 5.2).

**WebView programming features.** As discussed in Section 1, WebView’s programming features may impact the effectiveness of existing defense solutions. To verify it, we extensively test these protection solutions’ performance, when different programming features are enabled. Consequently, we identify a critical conflict between WebView programming features and web popup-creation manners. By leveraging this conflict, untrusted iframes/popups can perform **privileged** main-frame navigation attacks, even when this sub-frame’s navigation capability is disabled by iframe sandbox (Section 3.4.2).

DCVs and DCV attacks are summarized in Table 1. More

details are discussed below.

## 3.2 Origin Hiding Attacks

As introduced in Section 3.1, in the context of WebView, security risks are introduced that untrusted iframes/popups may leverage the “null” origin (created through the data scheme URL) to hide their own origins while making stealthy risky actions. In this section, we introduce two extended attacks: attacking web messaging integrity (Section 3.2.1) and stealthily accessing web-mobile bridges (Section 3.2.2).

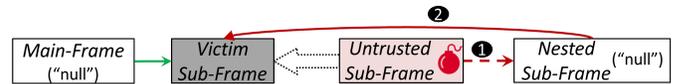

Figure 6: Attacking Web Messaging

### 3.2.1 Attacking Web Messaging

Figure 6 shows an attack scenario for web messaging. Assume the main frame whose origin is “null” sends web messages to a benign victim sub-frame. Meanwhile, the main frame also contains an untrusted sub-frame. If the untrusted sub-frame spawns a new nested sub-frame  $F_{nested}$  with the “null” origin, and let  $F_{nested}$  send a fake message to the victim sub-frame, the victim sub-frame may be fooled.

As shown in Listing 1, the victim sub-frame may validate the origin of the received message to ensure the message is from an authorized frame. However, this may not still recognize the fake message because the fake message has the same origin as the main frame. As a result, the victim sub-frame may handle the message as normal. If the victim sub-frame carries sensitive functionalities, these functionalities may be leveraged, and serious consequences may be caused.

```

1 // Message Handler
2 onmessage = function (e) {
3   // Validating the message source origin
4   if (e.origin == "null") { // From main frame?
5     // Making sensitive actions here
6   }

```

Listing 1: Validating the Message Origin in the Victim Sub-frame

In addition to the above origin validation based protection, the above attack cannot also be prevented by other defense solutions, such as [11, 44, 47, 52], because it is challenging for them to distinguish between the main frame and  $F_{nested}$ .

### 3.2.2 Accessing Web-Mobile Bridges

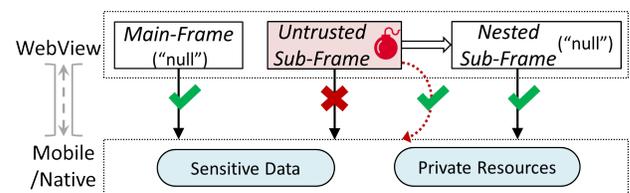

Figure 7: Freely Accessing Web-Mobile Bridges

As shown in Figure 7, the security risks are also posed that untrusted iframes/popups can also secretly access web-mobile bridges by leveraging the “null” origin (Listing 2), but

without being blocked by existing defense solutions. This is because existing defense solutions are coarse-grained, and the origin they can obtain is  $F_{nested}$ 's (i.e., “null”), rather than the origin of the untrusted iframes/popups. Hence, they would approve the untrusted operation.

To verify the attacks, we develop two proof-of-concept (POC) apps that can launch the attacks. Then, we test their performance when the state-of-the-art protection solution “NoFrak” [21] and “Draco” [49] are enforced respectively. NoFrak extends SOP to the mobile layer of a third-party development framework, while Draco implements the access control in WebView. In the first POC app, we integrate the popular third-party hybrid development framework “Apache Cordova” and instrument its plugin manager to implement NoFrak. In the second POC app, we use our instrumented WebView library, which implements Draco’s prototype system [49]. In both POC apps, we find that untrusted accesses by DCV attacks on web-mobile bridges, especially JavaScript bridges, cannot be prevented.

```

1 // Creating a nested sub-frame with the data scheme URL
2 var iframe = document.createElement('iframe');
3 // Triggering onJsAlert()
4 iframe.setAttribute('src', 'data:text/html;charset=UTF-8,<
  html>...<script>alert(\I am the main frame\, \'+\');<
  ' + 'script');
5 document.body.appendChild(iframe);

```

Listing 2: Accessing the Event Handler onJsAlert() in the Untrusted Iframe/Popup

### 3.3 WebView UI Redressing Attacks

The root cause of the attacks is that there is no protection on the WUI rendering order and WebView UI integrity. Hence, the security risks exist that untrusted iframes/popups can freely manipulate it and perform phishing attacks. In this section, we illustrate two extended attacks: the WUI overlap attack (Figure 8-a), and the WUI closure attack (Figure 8-b). We next describe them in detail.

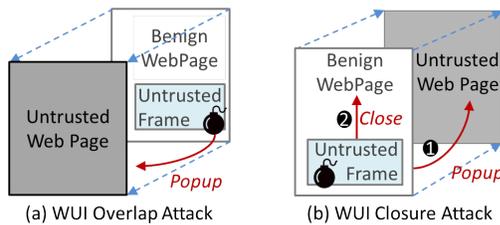

Figure 8: WebView UI Redressing Attacks

#### 3.3.1 WebView UI Overlap Attack

```

1 // Customizing onCreateWindow() to enable popup-creation
2 boolean onCreateWindow(WebView view, ...) {
3     // Creating a new WebView UI
4     WebView myNewWebView = new WebView(getContext());
5     // Initializing the new WebView UI
6
7     // Putting the new WebView UI before current WebView UI
8     view.addView(myNewWebView);
9
10    // Providing the new WebView UI to Android
11    ...

```

Listing 3: Vulnerable onCreateWindow()

Listing 3 shows a representative but vulnerable implementation of the event handler “onCreateWindow()”. When a

popup is created, the event handler is triggered and may select to put the new WUI in the front of current benign WUI by calling “ViewGroup.addView(new WebView)” (Line 8). Thus, the new WUI is presented to users. However, this ability of changing the WUI rendering order can also be obtained by untrusted web code. This is mainly because the event handler onCreateWindow() cannot distinguish between benign and untrusted requests, due to its design flaws (Section 3.6).

As a result, untrusted iframes/popups obtain the ability of performing phishing attacks by simply triggering a popup-creation event, and letting the created WUI load fake web content and overlap the benign WUI. Due to the lack of the address and tab bars, this risky popup-creation operation may be hardly noticed by users. As shown in Listing 4, the overlap attack can be easily set up in practice.

```

1 // Using HTML Code
2 <a href="https://attacker.com" target="_blank" ...
3 // or Calling JavaScript code
4 window.open("https://attacker.com", "_blank" ...)

```

Listing 4: Exploit Code of the WUI overlap attack and the privileged navigation attack

We note that the key API name “addView” also appears in existing work on Android UI redressing attacks such as [35]. However, these APIs are totally different. In existing work, “addView” means “WindowManager.addView()”, which is used to change UI layout between different apps. In this paper, “addView” means “ViewGroup.addView()”, which is used to change a specific UI layout inside an app. To our knowledge, we are the first to discuss the security risk of the latter API.

#### 3.3.2 WebView UI Closure Attack

When apps use the default Android WUI management strategy, it is still possible for an untrusted iframe/popup to change the WUI rendering order (Section 3.1). As shown in Figure 8-b, the untrusted iframe/popup may first create a new popup window, whose corresponding WUI is placed behind current benign WUI. Then, the untrusted code triggers the window-closure event, which is handled by the event handler “onCloseWindow()”. If the event handler is vulnerable and removes the foremost benign WUI (Line 8 in Listing 5) from the WUI rendering order, the former untrusted WUI appears instead and phishing attacks may occur. Similar to the WUI overlap attack, due to the lack of the address and tab bars, such attacks are stealthy, and can be easily launched in practice (e.g., using the code in Listing 6).

```

1 // Customizing onCloseWindow() to enable WebView UI closure
2 public void onCloseWindow(WebView window) {
3     super.onCloseWindow(window);
4     // Destroying the WebView UI being closed
5     ...
6     // Removing the WebView UI being closed from current
7     // view layout
8     myRootWebViewLayout.removeView(window);
9 }

```

Listing 5: Vulnerable onCloseWindow()

```

1 // Creating a new WebView UI
2 window.open("https://attacker.com", "_blank" ...)
3 // Closing current WebView UI
4 window.close()

```

Listing 6: Exploit Code of the WUI Closure Attack

We note that as introduced in Section 1, WebView UI redressing attacks cannot be defended by existing Android UI protection solutions. These two UI redressing attacks are different. Android UI redressing is performed between different apps, while WebView UI redressing occurs within one app.

## 3.4 Main-Frame Navigation Attacks

### 3.4.1 Traditional Navigation Attack

Untrusted iframes/popups can leverage traditional navigation policies (Section 2.1) to launch phishing attacks (e.g., using the code in Listing 7 to perform phishing attacks), when their navigation capabilities are not disabled. Due to the lack of URL indicators (e.g., the address bar), the attack is stealthier and may be hardly noticed by users.

```
1 // Using HTML Code
2 <a href="https://attacker.com" target="_top" ...
3 // Or Calling JavaScript code
4 window.open("https://attacker.com", _top, ...
```

Listing 7: Leveraging Traditional Navigation Policies

### 3.4.2 Privileged Navigation Attack

Even when the navigation capability is disabled by iframe sandbox (which prevents the above traditional navigation-based attack directly), it is still possible for untrusted iframes/popups to launch privilege escalation attacks and obtain the ability of performing navigation attacks. This is mainly caused by the inconsistencies between the WebView programming features and web regular navigation actions. When web popup creation code (e.g., `<a>` and `window.open()`) is executed in a sub-frame, Android always tries to select a WUI to show the popup content. Note that the WUI selection *always* occurs, even when popup-creation is disabled in the mobile layer (e.g., the setting `SupportMultipleWindows` is false). However, when popup-creation is not allowed, there is not a new WUI for rendering. Instead, Android selects current WUI for showing the popup content, which means the main frame is navigated to the popup. Thus, phishing attacks may occur.

In practice, the privileged navigation attack can be easily launched by using the exploit code shown in Listing 4. Note that this code is also used for launching the WUI overlap attack. When popup-creation is disabled (*by default*), the code may launch the navigation attack. Otherwise, the WUI redressing attack may be available.

## 3.5 Advantages of DCV Attacks

Compared to existing Android attacks (such as Trojan attacks [5]), DCV attacks do not require declaring permissions, or carrying payload. Compared to other WebView-based attacks (e.g., [21, 25, 30, 51]), which require JavaScript or JavaScript-bridges to be enabled, DCV attacks do not have these requirements and limitations. More importantly, DCV attacks are more powerful that attackers may obtain abilities to not only access web-mobile bridges, but also directly leverage critical web features.

Furthermore, different from existing MITM attacks on a sub-frame inside WebView, DCV attacks cannot be prevented by existing web protections (e.g., SOP). Unlike existing touch hijacking in WebView [31], DCV attacks do not need to control the mobile code, and craft the placement of multiple WebView components in Activity layout XML.

In addition, DCVs can be leveraged to boost other attacks. For example, event-oriented attacks [53] rely on triggering WebView event handlers, but it is difficult to trigger several critical event handlers (e.g., `onPageStarted()` and `onPageFinished()`). This problem can be well solved through exploiting DCVs, such as the privileged navigation attack (Section 3.4.2).

## 3.6 Root Causes of DCVs

DCVs are rooted in the inconsistencies between WebView and regular browsers in terms of UI and programming features (Section 1 and 3.1). We demonstrate several critical and frequently used web features and behaviors are harmless and safe in the context of regular browsers, but they become risky in the context of WebView.

In addition, we also find the design of the event handler features is also flawed. In theory, through event handlers, developers have chances to reject DCV attacks. However, unfortunately, the design flaws of event handlers make it extremely difficult to achieve the goal. For example, when the WUI overlap attack is performed, the event handler “`onCreateWindow(view, isDialog, isUserGesture, resultMsg)`” is always triggered. If the event handler could deny the creation of an untrusted WUI, attackers would fail to launch the WUI redressing attack. However, this is very difficult because the event handler `onCreateWindow()` does not provide the victim app any origin information about who is creating a popup and what content is being loaded in the popup. Thus, the victim app has to *blindly* allow or deny *all* popup-creation operations, no matter whether the operations are made by benign or untrusted code. In addition to `onCreateWindow()`, other event handlers such as `onCloseWindow()` face similar problems.

Another event handler `shouldOverrideUrlLoading(view, request)` (as introduced in Section 2.2) is always triggered when a URL loading event occurs. This event handler provides the information of the URL that is being accessed, which may be used as a complement of other event handlers to prevent DCV attacks (e.g., allow the victim app to deny untrusted URLs). However, the combination is hardly used in practice. Even when the associated URL is identified and denied, the new WUI is already created and still in the control of untrusted iframes/popups. Untrusted iframes/popups may still use the new WUI to consume the resources (such as CPU and memory) of the victim devices in background. Hence, to avoid this, it is required for the victim app to always explicitly destroy the new WUI.

In addition, `shouldOverrideUrlLoading()` often has its own implementation problems in origin validation. For example, our empirical study shows some hybrid apps do not even per-

form any check, and some of them only check the domain of the URL but ignore the scheme (e.g., “HTTP” or “HTTPS”).

## 4 DCV-Hunter

There are several tools for analyzing hybrid apps [22, 53, 55], however, it is challenging to directly apply these tools to detect DCVs. On the one hand, existing static analysis tools are not designed for the analysis of iframe/popup behavior (e.g., [22, 55]), and they are often coarse-grained (e.g. [33]). More specifically, they can hardly extract and reconstruct the context information of each WebView instance. When there are multiple WebView instances in a hybrid app, which is common in practice, these tools can produce high false positives. On the other hand, existing dynamic analysis tools (e.g., [53]) have high false negatives, as it is very difficult to trigger a WebView instance at runtime. For example, as shown in Figure 5, to trigger WebView inside the Facebook Messenger app, the analysis tools need to automatically log in and open a URL link.

We propose a novel static detection tool, *DCV-Hunter*, that utilizes program analysis to automatically vet apps. As shown in Figure 9, DCV-Hunter’s approach is four-fold. Given an app, DCV-Hunter first generates its complete call graph (CG). Next, DCV-Hunter leverages CG to reconstruct the context of each WebView instance. Then, DCV-Hunter verifies if untrusted sub-frames exists. Finally, DCV-Hunter determines if the given app is potentially vulnerable or not.

### 4.1 Complete Call Graph Construction

We leverage FlowDroid [10] to generate call graphs (CG) of the target app. However, we find FlowDroid faces challenges to analyze WebView related function invocations. This is mainly due to the missing of type information and semantics related to WebView (e.g., the semantics of WebView event handlers). To mitigate this issue, we patch the target app during CG construction by inserting extra instructions, which provide necessary type and semantic information of WebView. Thus, FlowDroid can generate necessary edges and construct complete CG.

### 4.2 WebView Context Reconstruction

In this phase, DCV-Hunter re-constructs the whole context for each WebView instance. First, DCV-Hunter identifies all WebView instances from CG. Then, DCV-Hunter separately reconstructs each WebView instance’s own context, which includes 1) the URL or HTML code to be loaded; 2) settings (e.g., the enablement of popup creation); 3) implementation of event handlers (e.g., “*onCreateWindow()*” and “*onCloseWindow()*”). To reconstruct the WebView context, points-to analysis is applied [33]. For example, when an event handler class that contains the implementation of event handlers is configured through the API “*setWebChromeClient(...)*”, DCV-Hunter can check the points-to information of the API’s parameter, and retrieve the parameter’s actual class name.

However, points-to analysis does not scale well, especially when the target app is complex. To mitigate the problem, we also apply the data flow tracking technique (also provided by FlowDroid) as a complement. For example, when an event handler class is instantiated, the corresponding instance is treated as source. Then, the event handler configuration APIs (e.g., “*setWebChromeClient(...)*”) are treated as sink. Finally, if there is a flow between above source and sink, the event handler class should be a part of the context of the corresponding WebView instance.

In addition to an event handler class, several context-related objects (e.g., URL strings, WebView settings) can also be analyzed using data flow tracking. These objects and their corresponding APIs are treated as source and sink, respectively. More details are shown in Table 3. Note that different from WebView settings and event handlers, which are often class instances, the URL source may have several different formats, such as 1) HTML code or URL string; 2) Intent messages (inter-component communication in Android). Both formats are often used in real-world apps. For example, as shown in Figure 5, in Facebook Messenger, when a link is clicked, an Intent message that includes the link is sent out to an activity (Android UI) to start WebView and show that link.

Table 3: Source and Sink APIs

Source	Sink
URLs	WebView content loading APIs
Settings	WebView Setting APIs
Event Handlers	<i>setWebViewClient()</i>
	<i>setWebChromeClient()</i>
WebView	WebView content loading APIs
	WebView Setting config APIs
	Event handler registration APIs

### 4.3 Untrusted Iframe/Popup Detection

In this phase, given a WebView instance, DCV-Hunter checks whether an untrusted iframe/popup is included in its loaded content. To achieve the goal, DCV-Hunter first extracts the URLs of the untrusted iframe/popup, and then examine the event handler “*shouldOverrideUrlLoading()*” (Section 2.2) through path constraint analysis to determine whether extracted URLs are approved.

#### 4.3.1 Untrusted URL Extraction

Given a WebView instance, the web content loaded in WebView is analyzed based on its formats:

- *HTML code*: This format is usually used by the content loading APIs “*loadData()*” and “*loadDataWithBaseURL()*” (for origin-hiding attacks). Based on the patterns of iframes/popups (Section 2.1), all internal associated links can be extracted and then checked. On the one hand, if a link is unsafe, such as using HTTP, code injection surface should exist, and the link is untrusted. On the other hand, if a link uses HTTPS, it is difficult to determine if the link is third-party, considering the main frame does not have an explicit domain (i.e., the “null”

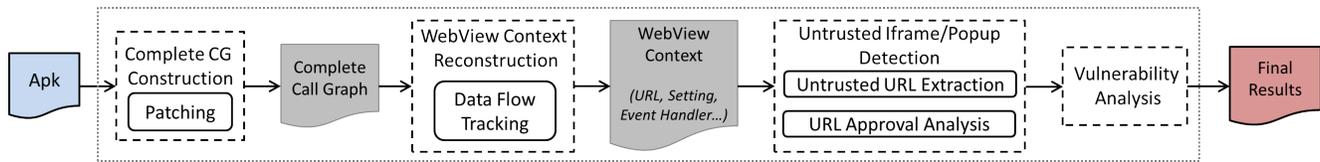

Figure 9: The Overview of DCV-Hunter

origin).

To mitigate the problem (i.e., determine the first-party URLs), we leverage several heuristics: 1) inside the target app, WebView class name and its internal package names are usually related with developers’ website. Hence, we reverse them as first-party URLs. Please also note that the reversed class and package names should not be related to third-party URLs (e.g., [3]). 2) We also check the app information that is provided by developers in Google Play. This information includes the links of developers’ home page, email and “privacy policy”. Finally, these links are also treated as first-party URLs, since they are likely trusted by developers.

- *URL links*: DCV-Hunter handles URL links, based on their formats. If a URL is a network link, we build a crawler based on Selenium [7] to automatically collect the web-pages (the mobile version) that can be navigated to from the URL within three depth levels. For each collected web page, its sub-frame is checked based on our threat model (Section 2.3).

If URL is a local file link (e.g., “file://...”), DCV-Hunter first dumps the corresponding local file from the target app, and then handles it like above regular HTML code. This is mainly because the file scheme link is similar with the null origin and does not provide any first-party domain information.

- *Intent*: Our empirical study on a set of popular hybrid apps shows that the values of the links saved in an intent message may be arbitrary. Hence, to avoid potential false negatives, DCV-Hunter assumes that this format of web content contains untrusted iframes/popups.

### 4.3.2 URL Approval Analysis

To determine whether an extracted untrusted URL is approved by the event handler “shouldOverrideUrlLoading()” or not, we perform a path-sensitive constraint analysis on the event handler code. The key observation behind the idea is that based on the specification of the event handler [9], when untrusted iframes/popups are opened or created, the event handler is triggered, and should return false (Please note returning true is usually used for denying the link or other purposes [53]).

Below is our solution. We construct the conditions (constraints over strings) of the paths to “returning false”, and check whether the extracted URL can satisfy the conditions. More specifically, based on the CG and control-flow graph of the event handler, we first find all the possible paths to the key instruction “returning false”. Then, starting from each key instruction, we perform a fast backward slicing along each path

Table 4: APIs for the Analysis of WUI redressing problems

Attacks	Sensitive APIs
Overlap	<code>ViewGroup.addView()</code>
Closure	<code>ViewGroup.removeView()</code>
	<code>WebView.setVisibility()</code>
	...

to construct the path constraints. The unknown variables in the constraints are all over the string parameters (i.e., URL or request) of “shouldOverrideUrlLoading()”. After that, based on our threat model and the content of extracted URLs, we add more constraints to the collected constraints, including

- 1) `<parameter>.scheme == "HTTP"`
- or 2) `<extracted_URL>.domain == <parameter>.domain`.

The first constraint is aimed to check if attackers can freely inject code into the sub-frame through MITM attacks. The second constraint is used to verify if the domain of the extracted URL is approved. Finally, we use an SMT solver (i.e., z3 [19]) to solve all constraints. If path constraints can be satisfied, it indicates that the extracted URL should be approved.

Our path constraint analysis is implemented by embedding and extending the symbolic execution module of our previous work “EOEDroid” [53]. Please also note we model several frequently used Java classes (e.g., `WebResourceRequest`, `URL`, and `String`) to support the related operations.

### 4.4 Vulnerability Analysis

To determine each vulnerability, DCV-Hunter checks its conditions respectively:

- *Origin-hiding*: DCV-Hunter first verifies whether the origin of the main frame is “null”. This is done by checking the corresponding WebView content loading APIs and their associated parameters. Then, for convenience, the valuable attack targets are also checked, such as web messaging or web-mobile bridges.
- *WUI redressing*: DCV-Hunter first verifies WebView’s settings and event handlers to check whether WUI creation and closure are enabled. Then, DCV-Hunter checks whether the corresponding event handlers `onCreateWindow()` or `onCloseWindow()` are vulnerable or not. This is done by checking the existence of the sensitive APIs listed in Table 4. Based on the analysis of the design flaws of these event handlers (Section 3.6), which have to blindly approve or deny all requests, these simple checks can obtain high accuracy.
- *Main-frame navigation*: For the traditional navigation based problem, iframe sandbox is checked. If iframe sandbox is used, DCV-Hunter then verifies if the navigation capability is disabled. For the privileged navigation attack,

DCV-Hunter checks whether multiple window mode is disabled, which is done by directly checking associated settings.

## 5 Security Impact Assessment

To assess DCVs’s security impacts on real-world popular apps, we collected 17K most popular free apps from Google Play. They are gathered from 32 categories, and each category contains 540 most popular apps. By applying DCV-Hunter on these collected apps, we found 11,341 apps contained at least one path from their entry points to WebView content loading APIs. Among them, 4,358 apps (38.4%) were potentially vulnerable, including 13,384 potentially vulnerable WebView instances and 27,754 potential vulnerabilities (Table 5). This indicates DCVs widely impact real-world apps.

We evaluated the accuracy of DCV-Hunter by measuring its false positives. We randomly selected 400 apps from the apps flagged as “potentially vulnerable” by DCV-Hunter, and manually checked them (see more details in Section 5.1). We find 6 of them (1.5%) are false positives. Our further inspection revealed in four of these apps, during the reconstruction of the URL loaded by WebView (Section 4.2), some unrelated URLs were accounted, due to the imprecise taint analysis (i.e., overtaint). For the remaining two apps, “URL Approval Analysis” (Section 4.3.2) on untrusted iframe/popup links faced difficulty in handling constraints that contained string regular expressions. We leave addressing these weaknesses as our future work.

All experiments were run on a high-performance computer. We ran DCV-Hunter with 100 processes in parallel and each process was assigned with limited resources (two regular computing cores and 8GB memory). Our time cost showed each process needed 144 seconds for each app.

### 5.1 Manual Verification

To manually verify target apps, we firstly modify Android source code (version 6) to let it print necessary WebView related information. Next, we install the modified Android system in a real device (Nexus 5). Then, we test target apps. For each app, when internal WebView instances are started, we inject attack code to target iframes/popups. Last, based on the web content shown in WebView and the logs printed by Android, we determine if the attack code works and the app is vulnerable.

Please note that different from prior work, we do not use proxy for code injection. We find proxy has several shortcomings. For example, it is time consuming and inefficient to locate the target iframes/popups for code injection. Instead, we leverage Chrome’s USB debug interfaces to ease our test. Since we run test in a real device, we connect the device with PC using USB. Then, we open Chrome in PC to inject code to target WebView instances. For example, we select a WebView instance and then open console (in Chrome) to run extra attack code for code injection. But please always keep in mind that before executing any code, we must select a (target)

Table 5: Potential Vulnerability Details

Potential Attacks	Impacted WebView	Impacted Apps	App Downloads
Origin-Hiding	1,737	1,238	3.5 Billion
WUI Overlap	138	89	8 Billion
WUI Closure	5	5	13 Million
Traditional Navigation	13,384	4,358	19.5 Billion
Privileged Navigation	12,490	4,161	17.8 Billion
<b>Total</b>	<b>13,384</b>	<b>4,358</b>	<b>19.5 Billion</b>

sub-frame as the code execution environment in console.

## 5.2 Findings

**Many high-profile apps are impacted by DCVs.** DCVs widely exist in hybrid apps. Up to now, the potentially vulnerable apps have been downloaded more than 19.5 Billion times (the fourth column of Table 5). Furthermore, these also include many manually verified popular apps (some examples are shown in Table 6) such as Facebook, Instagram, Facebook Messenger, Google News, Skype, Uber, Yelp, U.S. Bank.

**Almost all categories of apps are affected.** Figure 10 shows the related distribution data. The light blue line and the bars respectively represent the distribution of potentially vulnerable apps and each potential vulnerability in each category. Almost all categories of apps are impacted, including several sensitive categories (e.g., password management and banking apps). This indicates DCVs are common.

We observe some categories are more subject to DCV attacks than others, such as news, dating, and food-drink. We manually analyze a set of apps in these categories, and find these categories of apps use WebView more often to load third-party untrusted content in iframes/popups. For example, the Google News app (one billion+ downloads) provides the news collections to users. It allows any website to be loaded in its WebView. We manually check several news links and find it is common for these news web pages to embed third-party content, especially ads and tracking services.

We also find in some apps, their loaded web pages are safe, and do not include any untrusted content. However, after the web pages are fully loaded, these apps run extra JavaScript code through the API “*WebView.evaluateJavascript()*” to create and embedded new iframes/popups for loading ads content, which introduces security risks.

Furthermore, we find the events and news apps are more likely to suffer from WUI redressing attacks. This is mainly because these apps tend to manage WUIs by themselves. For example, in some news apps, when a user scrolls down to the bottom of the web page, the apps will directly append and show more content, without letting the user click a “next page” button. When the user clicks a concrete news link, a new WUI is created and placed in the front of current WUI to show that link. When the user finishes that web page, developers can close current WUI and show previous WUI. In this way, the state of previous WUI is not changed, and the dynamically appended content is also kept. This rendering

Table 6: Summary of Example (Manually Verified) Vulnerable Apps/Libraries

(\* can be any domain, while OH, WO, WC, TN, PN, and BA respectively mean Origin-Hiding, WUI Overlap, WUI Closure, Traditional Navigation, Privileged Navigation, and Blended attacks.)

Apps/Libraries	Possible Attack Scenarios		Vulnerabilities						Downloads
	Main-Frame	Untrusted Sub-frame	OH	WO	WC	TN	PN	BA	
Facebook	*	*		✓		✓		✓	1 Billion+
Instagram	*	*		✓		✓		✓	1 Billion+

Chime mobile bank	*	*				✓	✓		1 Million+
Facebook Mobile Browser Library	*	*		✓		✓		✓	
Facebook React Native Library	*	*				✓	✓		

strategy improves user experience. However, as described in Section 3.6, due to the design flaws of the event handler system, such a WUI management strategy is also exposed to untrusted iframes/popups, and cause security issues.

**Traditional and privileged navigation attacks impact more apps than other DCV attacks.** As summarized in the second and third columns of Table 5, navigation based attacks are more popular than the other vulnerabilities. It is mainly because the security assumptions of these two attacks are more easily satisfied. For example, many WebView instances prefer using the default configuration (e.g., disabling popup-creation), and suffer from privileged navigation attacks.

**The traditional navigation based attack causes more serious consequences in the context of WebView.** This type attack almost affects all potentially vulnerable apps. One important reason is that the effective defense solution “iframe sandbox” is hardly used in practice. There are several reasons. First, it may be difficult to add the sandbox attribute to an iframe, especially considering developers have to find the corresponding web code of that frame from a large amount of web files and code. Second, it is difficult to manage the sandbox configurations for each iframe. Each iframe has its own specific security configurations, including disabling JavaScript or navigation. When the iframe number rapidly rises, the configuration management may become quite difficult. Third, iframe sandbox is not flexible. Its configurations are often bound with iframes, rather than origins. If an iframe is navigated to a different origin, it is hard for developers to

update the sandbox restriction policies.

### 5.3 Case Studies

We have successfully manually launched DCV attacks in many popular apps (some examples are shown in Table 6). Readers can find also several video demos at [2] (the website is anonymized). In this section, we present two example apps (Skype and Kayak) in detail, and also briefly discuss other examples listed in Table 6.

#### 5.3.1 Skype

This is a very popular communication app (one billion+ downloads). Our study shows it suffers from traditional and privileged main-frame navigation attacks. A possible attack scenario is shown in Figure 11. An attacker sends the victim user a message containing a benign but vulnerable link (e.g., ebay.com). When the user clicks the link, a WebView instance is started to render that link (Figure 11-b). However, the loaded web page includes third-party untrusted tracking web content (e.g., double-click) in iframes. The embedded untrusted content has the ability to secretly navigate the main frame through traditional or privileged navigation attacks, which may result in stealthy phishing attacks (Figure 11-d).

We also observe when a web page is opened, its URL (e.g., ebay.com) is shown in the top of the app. This is relatively helpful to mitigate DCV attacks. However, after the web content is fully loaded by WebView (Figure 11-c), we find the URL is replaced by the title of the loaded web page. After that, the URL will not be shown again, even when a naviga-

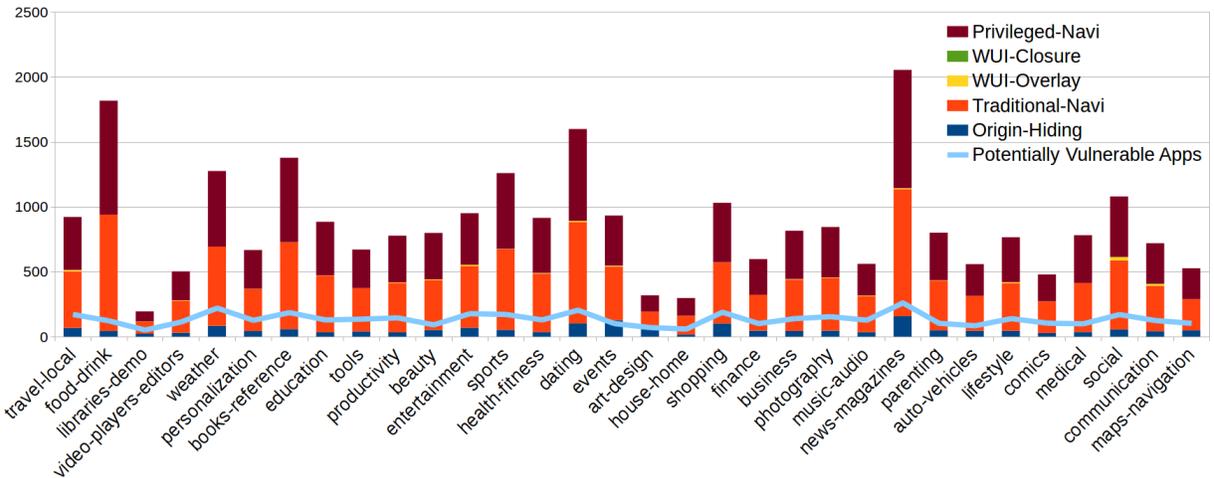

Figure 10: Distribution of Potentially Vulnerable Apps and Potential Vulnerabilities

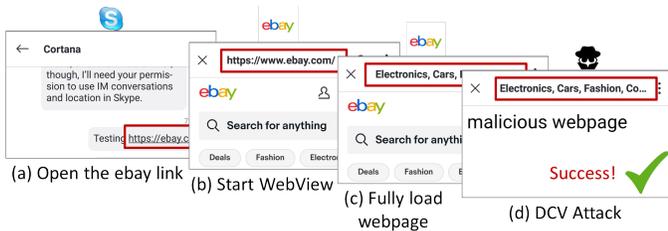

Figure 11: Attacking Skype

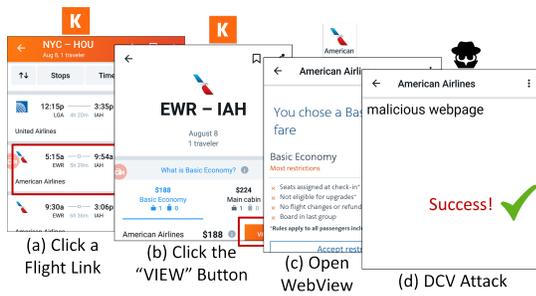

Figure 12: Attacking Kayak

tion event occurs. Hence, when the phishing attack occurs, the victim user may hardly be aware of it.

### 5.3.2 Kayak

It is a leading app (ten million+ downloads) for providing traveling-relevant searching services, which are aimed to help users find better prices of flights, hotels, rental cars, and so on. However, as shown in Figure 12, it suffers from WebView UI redressing attacks, which may cause account information leakage and financial losses. Consider a possible scenario that a user is searching a flight. The user clicks one of the searching results (Figure 12-a), such as the AA flight, and then clicks the "View" button to get more details (Figure 12-b).

Next, a customized WebView instance is triggered to show more flight details from "aa.com" (Figure 12-c). However, in the AA web page, an extra iframe is embedded to load third-party tracking content (tag management). In the Kayak

app, the untrusted iframe obtains the ability of performing phishing attacks by leveraging the WUI overlap issue (Figure 12-d).

In addition, similar with the Skype app, the Kayak app also provides a title bar to reduce the UI inconsistencies. However, this is limited to defend against DCV attacks, since the opened fake web pages often have the same title content.

### 5.3.3 More Examples

In addition to Skype and Kayak, more examples listed in Table 6 are discussed below.

- *Facebook Mobile Browser, Facebook, Instagram, and Facebook Messenger*: The Facebook Mobile Browser library is frequently used in Android apps, such as Facebook, Instagram, and Facebook Messenger. In our study, the traditional navigation and WUI overlap vulnerabilities exist. As shown in Section 1 and Figure 5, an address bar is provided in the library and is helpful to mitigate DCV attacks. However, as discussed in Section 5.4, the address bar may face pixel and race condition flaws. By leveraging these flaws, untrusted sub-frames can still obtain the ability of launching phishing attacks.
- *Kakao Talk*: Kakao Talk is a popular instant messaging app. Although Kakao Talk is not equipped with the Facebook Mobile Browser library, it is also impacted by the above race condition flaw (Section 5.4).
- *Google News*: As introduced in Section 5.2, the Google News app can show any news websites. When there is an untrusted sub-frame in the rendered news web page, which is common in practice, the untrusted sub-frame can perform traditional or privileged navigation attacks.
- *WeChar*: WeChat is another popular instant messaging app. Similar with Skype (Section 5.3.1), WeChat also faces traditional and privileged navigation vulnerabilities.
- *Yelp*: The Yelp app are also impacted by traditional and privileged navigation vulnerabilities. Different with Skype and WeChat, Yelp's WebView is triggered by clicking the

homepage link of a restaurant or a store. When the opened “homepage” web page contains an untrusted sub-frame, the untrusted sub-frame can launch traditional or privileged navigation attacks.

- *Uber*: Uber’s WebView can be started to show “Terms and Conditions” from its own website by sequentially clicking the buttons “menu”, “legal” and “terms&conditions”. Our analysis shows the term and condition webpage contains an untrusted iframe for loading third-party tracking content (market analyst). The untrusted iframe can launch traditional or privileged navigation attacks.
- *ESPN*: The ESPN app shows news from its own website. However, its web pages load third-party tracking content from Google in an iframe. Hence, the untrusted sub-frame can also do phishing attacks by leveraging traditional navigation and WUI overlap vulnerabilities.
- *McDonald’s*: In the app, several events are listed. When an event link (such as “trick n’ treat”) is clicked, WebView is started to show more details from its own website. However, an untrusted sub-frame is also contained that it may exploit traditional or privileged navigation vulnerabilities.
- *Samsung Mobile Print, lastpass, dashlane*: These apps provide an internal web browser to improve user experience. These internal browsers suffer from main-frame navigation attacks. Although they also offer address bars, unfortunately, the length of their address bars is much short than the average length “29 letters” (Section 5.4). For example, in the same environment (Nexus 5), Samsung Mobile Print only shows 23 letters, and lastpass only display 18 letters.
- *Ipassword*: DCV-Hunter finds several paths to WebView content loading APIs. Because we do not have an account to login, this app is not fully tested. However, when we click its discount link, we still find a vulnerable WebView instance is launched. The WebView instance can show any content, and suffers from traditional or privileged navigation attacks.
- *The U.S., Huntington and Chime Mobile Bank apps*: These bank apps provide WebView to load content from their websites. Note that some of their WebView can be navigated to any websites. The loaded content can include third-party (tracking) content, which can launch traditional or privileged navigation attacks.
- *The Facebook React Native library*: This library is designed to help JavaScript developers implement cross-platform mobile apps. In its WebView, the related default configurations are applied. It suffers from traditional and privileged navigation vulnerabilities.

## 5.4 Security Impacts of Home-Brewed URL Address Bars

Our study shows that some hybrid apps implement their own URL address and title bars (such as those in our case studies), which could reduce the UI inconsistencies between WebView

and regular browsers. To better evaluate the security impacts, we conducted an empirical study of 100 apps that contain home-brewed address bars. These apps are collected by filtering the DCV-Hunter analysis results (by checking if there is a path or flow from WebView’s real-time URLs (such as the API “*WebView.getUrl()*”) and the second parameter of the event handler “*onPageFinished(view, url)*”) to UI components’ updating APIs such as “*TextView.setText()*”).

We find that the home-brewed address bars are ineffective to prevent DCV attacks, for two main reasons: limited address bar lengths, and implementation errors.

**Limited Address Bar Lengths.** In our study on a real phone (Nexus 5), which has the representative screen width, we find that typical address bars averagely show 29 letters. When domains, including sub-domains, being accessed exceed that length, security risks could be caused, even when some existing solutions such as showing the rightmost/leftmost of origin/URL are in use (e.g., Chrome/Chromium). This is also partially verified by existing work (e.g., [29]).

**Implementation Errors.** Some apps/libraries, such as “Facebook Mobile Browser”, use very small fonts to show origins (Figure 5). This mitigates the above length limitation problem. As Figure 5-c shows, this address bar can effectively mitigate a DCV attack, such as the WUI overlap attack, since the address bar can show the origin of the fake web page in real time. However, it also has several flaws. First, due to the small font, it faces the pixel problem. Attackers may build a fake and confusing URL by replacing few letters of the benign URL with confusing letters (such as replacing the letter “O” with the number “0”). The fake URL may still spoof users.

Moreover, in these apps, our analysis finds a race condition flaw, which can be utilized to show fake web content in WebView, while still presenting the benign URL (e.g., ebay.com) in the address bar (Figure 5-d). This issue is rooted in the design flaw that several WUIs share only one address bar, while all these WUIs have abilities to update the content of the address bar. Hence, attackers can still perform phishing attacks by combining a couple of DCV attacks. For example, in the Facebook Mobile Browser library, which suffers from the WUI overlap attack, attackers may open a WUI to load fake content, and then immediately update the overlapped benign WUI in background. As a result, the address bar only show attackers’ URL in a very short time and is quickly updated to display the benign URL. In our test, we find sometimes the bad URL may not even appear (see our online demo [2]). This indicates the blended attack is stealthy. In practice, the blended attack can be easily launched by using the code shown in Listing 8.

```
1 // Opening a fake web page (WUI overlap attack)
2 window.open("https://attacker.com", "_blank")
3 // Refreshing the address bar (traditional navigation attack)
4 window.open("https://eaby.com", "_top")
```

Listing 8: Exploit Code of Blended Attacks

## 6 Vulnerability Mitigation

### 6.1 Mitigation Solution

To mitigate DCV attacks, we propose a multi-level solution that enhances the security of WebView. First, we enhance the security of event handlers by addressing their design flaws (Section 3.6). For example, in *onCreateWindow()*, necessary information is provided, including the operator origin who is creating a popup, and the URL the created popup is going to load. Thus, based on the provided information, developers can reject an unauthorized request. To ease the deployment of our solution, we also provide security enforcement. If developers provide the list of trusted URLs in a configuration file inside their apps (located in the app folder “assets”), the untrusted requests can be automatically denied.

Second, we also mitigate the UI inconsistencies by providing floating URL indicators. For example, when the main frame is navigated to a different domain by an *iframe*/popup, the URL indicator can provide users an alert. Furthermore, when users longly press a WebView instance, the origin of the main frame being loaded by the WebView instance is presented.

Note this URL indicator is locally bound with a WUI, which is helpful to avoid the race condition flaw (Section 5.4). When there are multiple WUIs available, only the foremost WUI’s URL indicator is visible.

Third, to mitigate origin-hiding attacks, in critical operations (e.g., accessing web-mobile bridges), we replace the “null” origin with the origin who creates the “null” origin. This makes existing defense solutions effective again, since they can enforce security checks or policies on the new origin.

Fourth, to counter the WebView UI redressing problem, changes of the WUI rendering order are monitored. When a change is performed by an *iframe*/popup, an alert is offered. Last, to limit the navigation based attacks, we introduce same origin restrictions into navigation, and also fix the conflict.

### 6.2 Mitigation Solution Implementation

Our implementation is mainly done by instrumenting the WebView library, without modifying the source code of Android frameworks.

#### 6.2.1 Enhanced Event Handlers

To achieve the goal, event handlers related implementation is instrumented. Take the event handler *onCreateWindow()* as the example. To obtain the origin who is creating a popup, the call site is scanned to locate the last popup-creation operation. Next, the corresponding operator’s web frame information (e.g., origin) is retrieved. However, if the web frame’s origin is “null”, DCV-Hunter checks the web frame tree to get the real frame who create the “null” frame. Then, to learn the URL the created popup is going to load, the parameter of the related API (e.g., *window.open()*) is also extracted. Furthermore, to implement the security enforcement of denying untrusted requests, the default implement of *onCreateWindow()* is also

instrumented. When the configuration file (providing the list of trusted domains) exists, the trusted URLs are extracted and also used to match the URLs that trigger popup-creation requests.

#### 6.2.2 URL Indicators

To present current origin loaded in a WebView instance, the long-click event of the WebView instance is handled. When the event occurs, the origin of the main frame is presented as a notification. However, the long-click event may also be used by developers. To avoid potential conflicts, we create an event handler wrapper, which first shows the origin information, and then calls the essential event handler registered by developers.

To monitor the main-frame navigation, the event handler “*shouldOverrideUrlLoading()*” is leveraged. When the event handler is triggered, the URL is checked. If the main frame is redirected to a different domain by a sub-frame, an alert can be given. Furthermore, considering WebView is also a view group (Section 2.2), we make the indicator *local*: we temporary add a text view to WebView as the indicator.

#### 6.2.3 Replacing the “null” Origin

Since the “null” origin is meaningless, we replace it with the origin who creates the “null” origin. To achieve the goal, we scan the frame tree from bottom to top, and get the root frame, or the last frame whose origin is not “null”. Then, the corresponding origin *O* is extracted for the replacement.

Next, to replace the “null” origin with *O* in *postMessage*, we instrument the associated methods of the class “*WebDOMMessageEvent*” and “*MessageEvent*”. If the source origin is specified as “null”, it will be replaced. Then, the security of web-mobile bridges is enhanced as follows. Take the event handler *onJsAlert(view, url, ...)* as the example. We instrument the event handler’s relevant caller (i.e., “*AwJavaScriptDialogManager::RunJavaScriptDialog*”) inside WebView. In the caller, if *url* is the data scheme URL, it will be replaced by *O*.

#### 6.2.4 Popup Indicator

To mitigate the WebView UI redressing problem, all associated key APIs are monitored, such as *addView()*. When the WUI rendering order is changing by a sub-frame, an alert will be offered (implemented in the associated enhanced event handlers).

#### 6.2.5 Safe Navigation

To avoid traditional navigation problem, we narrow down the navigation policy that navigation occurs only when two frames have the same origins. To achieve the goal, we instrument the key method “*LocalDOMWindow::open()*” to add the origin checks.

Furthermore, to fix privileged navigation problem, the conflict between WebView features and web APIs is handled. More specifically, in the key method “*RenderFrameHostImpl::CreateNewWindow*”, we add more security restrictions. When the setting “*SupportMultipleWindows*” is false,

the popup behavior will be ignored.

### 6.3 Mitigation Evaluation

In our evaluation, we first test the usability of our defense solution, especially about how easy to deploy and apply our solution in practice. To do that, we select 10 real-world vulnerable apps for testing. We find our solution can simply work, if developers involve our own WebView header files, including the declarations of new function prototypes (e.g., *onCreateWindow()*), and also provide the configuration file with the list of third-party domains. Please note that because these real apps lack source code, we repackage them to involve necessary files.

Next, we verify the correctness of our mitigation solution by testing above ten apps. We test them in stock (vulnerable) WebView and the WebView that implements our mitigation solution, respectively. We find that 1) there are no errors introduced by our mitigation solution. Apps work well as usual; 2) DCV attacks are mitigated.

Then, we measure the overhead to check if our mitigation solution impacts user experience. We create a vulnerable app for testing. In the app, we call the WebView API *loadUrl()* to run associate HTML/JavaScript code to trigger all vulnerabilities. Meanwhile, all time costs are recorded. Similarly, we run the app in stock (vulnerable) WebView and the WebView that implements our mitigation solution. By comparing time costs, we find our mitigation solution only introduces tiny overhead: 2ms on average.

Last, considering the Android version fragmentation issue, we also test the compatibility of our mitigation solution by installing our own WebView library and running above the created app in major Android versions. The result shows our solution is available in many major popular Android versions (5.0+), and covers 89.3% of Android devices in use (based on the Android version distribution data of May 2019 [1]).

## 7 Related Work

**Iframe/popup Security.** In web apps, iframes/popup are often the cause of security issues, such as frame hijacking [11], clickjacking [43], and double-click clickjacking [23]. In past years, in the context of regular browsers, iframe/popup behaviors and these security issues were well studied. Many defense solutions were proposed. For example, the HTTP header “X-Frame-Options” and the frame busting [43] solution can prevent being framed. In this work, we mainly focus on the exploration of the abilities of untrusted iframes/popup. The more related security mechanisms, such as SOP, and navigation policies, are discussed in Section 2.1. As shown in Section 1 and 3, existing solutions are circumscribed to prevent DCV attacks.

**WebView security.** WebView security has attracted more and more attention. [17, 30, 33] generically studied WebView security. [21, 25, 27, 40, 49, 53] explored the security of web-mobile bridges, and also discovered several extended attacks.

In Section 3.5, we compare DCV attacks with several related attacks, and show DCV attacks may have a set of advantages.

Several static analysis based approaches [22, 55] were proposed to vet hybrid apps. However, they were limited to analyze iframe/popup behaviors and event handlers (also see our discussion in Section 4). Several defense solutions were designed to provide protection for WebView and web-mobile bridges, such as NoFrak [21], Draco [49], MobileIFC [45], WIREframe [18], and HybridGuard [38]. NoFrak and MobileIFC extended SOP into the mobile layer, while other solutions provided security enforcement on web-mobile bridges. However, as discussed in Section 1 and 3, they were quite limited to prevent DCV attacks.

In addition, many solutions [13, 41] are also designed to mitigate the Android UI deception problems [15, 20, 35]. However, as discussed in Section 1 and 3.3, they cannot monitor the state change of WebView UI, and circumscribed to prevent WUI redressing attacks.

## 8 Discussion

**Research scope.** In this work, we mainly focus on Android, which is currently the most popular mobile OS. However, there are also other WebView formats in other platforms (e.g., WKWebView for iOS). The research on other platforms would be complementary to our work, and we leave this as our future work.

**False negatives.** DCV-Hunter faces false negatives in some situations. For example, in mobile apps, some URLs loaded in WebView are encrypted, some URL related data goes through implicit flows, and some WebView related code is dynamically loaded. Some of these issues can be simply partially mitigated. For example, apps can be dynamically tested for collecting and downloading dynamically loaded code. We leave the improvement of our tool to reduce all false negatives as our future work.

## 9 Conclusion

Iframes/popup are often the root cause of several critical web security issues, and have been well studied in regular browsers. However, their behaviors are rarely understood and scrutinized in WebView, which has a totally new working environment. In this paper, we fill the gap and identify several fundamental design flaws and vulnerabilities, named differential context vulnerabilities (DCVs). We find that by exploiting DCVs, an untrusted iframe/popup becomes very dangerous in Android WebView. We have designed a novel detection technique, DCV-Hunter, to assess the security impacts of DCVs on real-world apps. Our measurement on a large number of popular apps shows that DCVs are prevalent. We have also presented a multi-level protection solution to mitigate DCVs, which is shown to be scalable and effective.

## Acknowledgments

We want to thank our shepherd Yinzhi Cao and the anonymous reviewers for their valuable comments. This material is based upon work supported in part by the National Science Foundation (NSF) under Grant no. 1642129 and 1700544. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of NSF. We also thank Cong Zheng and Yuchen Zhou for the helpful discussions about our threat model and the design of DCV-Hunter.

## Abstract

The popularity of JavaScript has led to a large ecosystem of third-party packages available via the npm software package registry. The open nature of npm has boosted its growth, providing over 800,000 free and reusable software packages. Unfortunately, this open nature also causes security risks, as evidenced by recent incidents of single packages that broke or attacked software running on millions of computers. This paper studies security risks for users of npm by systematically analyzing dependencies between packages, the maintainers responsible for these packages, and publicly reported security issues. Studying the potential for running vulnerable or malicious code due to third-party dependencies, we find that individual packages could impact large parts of the entire ecosystem. Moreover, a very small number of maintainer accounts could be used to inject malicious code into the majority of all packages, a problem that has been increasing over time. Studying the potential for accidentally using vulnerable code, we find that lack of maintenance causes many packages to depend on vulnerable code, even years after a vulnerability has become public. Our results provide evidence that npm suffers from single points of failure and that unmaintained packages threaten large code bases. We discuss several mitigation techniques, such as trusted maintainers and total first-party security, and analyze their potential effectiveness.

## 1 Introduction

JavaScript has become one of the most widely used programming languages. To support JavaScript developers with third-party code, the *node package manager*, or short *npm*, provides hundreds of thousands of free and reusable code packages. The npm platform consists of an online database for searching packages suitable for given tasks and a package manager, which resolves and automatically installs dependencies. Since its inception in 2010, npm has steadily grown into a collection of over 800,000 packages, as of February 2019, and will likely grow beyond this number. As the primary source of third-party

JavaScript packages for the client-side, server-side, and other platforms, npm is the centerpiece of a large and important software ecosystem.

The npm ecosystem is open by design, allowing arbitrary users to freely share and reuse code. Reusing a package is as simple as invoking a single command, which will download and install the package and all its transitive dependencies. Sharing a package with the community is similarly easy, making code available to all others without any restrictions or checks. The openness of npm has enabled its growth, providing packages for any situation imaginable, ranging from small utility packages to complex web server frameworks and user interface libraries.

Perhaps unsurprisingly, npm's openness comes with security risks, as evidenced by several recent incidents that broke or attacked software running on millions of computers. In March 2016, the removal of a small utility package called *left-pad* caused a large percentage of all packages to become unavailable because they directly or indirectly depended on *left-pad*.<sup>1</sup> In July 2018, compromising the credentials of the maintainer of the popular *eslint-scope* package enabled an attacker to release a malicious version of the package, which tried to send local files to a remote server.<sup>2</sup>

Are these incidents unfortunate individual cases or first evidence of a more general problem? Given the popularity of npm, better understanding its weak points is an important step toward securing this software ecosystem. In this paper, we systematically study security risks in the npm ecosystem by analyzing package dependencies, maintainers of packages, and publicly reported security issues. In particular, we study the potential of individual packages and maintainers to impact the security of large parts of the ecosystem, as well as the ability of the ecosystem to handle security issues. Our analysis is based on a set of metrics defined on the package dependency graph and its evolution over time. Overall, our study involves 5,386,239 versions of packages, 199,327 maintainers, and

<sup>1</sup><https://www.infoworld.com/article/3047177/javascript/how-one-yanked-javascript-package-wreaked-havoc.html>

<sup>2</sup><https://github.com/eslint/eslint-scope/issues/39>

609 publicly known security issues.

The overall finding is that the densely connected nature of the npm ecosystem introduces several weak spots. Specifically, our results include:

- Installing an average npm package introduces an implicit trust on 79 third-party packages and 39 maintainers, creating a surprisingly large attack surface.
- Highly popular packages directly or indirectly influence many other packages (often more than 100,000) and are thus potential targets for injecting malware.
- Some maintainers have an impact on hundreds of thousands of packages. As a result, a very small number of compromised maintainer accounts suffices to inject malware into the majority of all packages.
- The influence of individual packages and maintainers has been continuously growing over the past few years, aggravating the risk of malware injection attacks.
- A significant percentage (up to 40%) of all packages depend on code with at least one publicly known vulnerability.

Overall, these findings are a call-to-arms for mitigating security risks on the npm ecosystem. As a first step, we discuss several mitigation strategies and analyze their potential effectiveness. One strategy would be a vetting process that yields trusted maintainers. We show that about 140 of such maintainers (out of a total of more than 150,000) could halve the risk imposed by compromised maintainers. Another strategy we discuss is to vet the code of new releases of certain packages. We show that this strategy reduces the security risk slightly slower than trusting the involved maintainers, but it still scales reasonably well, i.e., trusting the top 300 packages reduces the risk by half. If a given package passes the vetting process for maintainers and code, we say it has “perfect first-party security”. If all its transitive dependencies pass the vetting processes we say that it has “perfect third-party security”. If both conditions are met, we consider it a “fully secured package”. While achieving this property for all the packages in the ecosystem is infeasible, packages that are very often downloaded or that have several dependents should aim to achieve it.

## 2 Security Risks in the npm Ecosystem

To set the stage for our study, we describe some security-relevant particularities of the npm ecosystem and introduce several threat models.

### 2.1 Particularities of npm

**Locked Dependencies** In npm, dependencies are declared in a configuration file called `package.json`, which specifies

the name of the dependent package and a version constraint. The version constraint either gives a specific version, i.e., the dependency is *locked*, or specifies a range of compatible versions, e.g., newer than version X. Each time an npm package is installed, all its dependencies are resolved to a specific version, which is automatically downloaded and installed.

Therefore, the same package installed on two different machines or at two different times may download different versions of a dependency. To solve this problem, npm introduced `package-lock.json`, which developers can use to lock their transitive dependencies to a specific version until a new lock file is generated. That is, each package in the dependency tree is locked to a specific version. In this way, users ensure uniform installation of their packages and coarse grained update of their dependencies. However, a major shortcoming of this approach is that if a vulnerability is fixed for a given dependency, the patched version is not installed until the `package-lock.json` file is regenerated. In other words, developers have a choice between uniform distribution of their code and up-to-date dependencies. Often they choose the later, which leads to a technical lag [12] between the latest available version of a package and the one used by dependents.

**Heavy Reuse** Recent work [11, 18] provides preliminary evidence that code reuse in npm differs significantly from other ecosystems. One of the main characteristic of the npm ecosystem is the high number of transitive dependencies. For example, when using the core of the popular Spring web framework in Java, a developer transitively depends on ten other packages. In contrast, the Express.js web framework transitively depends on 47 other packages.

**Micropackages** Related to the reuse culture, another interesting characteristic of npm is the heavy reliance on packages that consist of only few lines of source code, which we call *micropackages*. Related work documents this trend and warns about its dangers [1, 19]. These packages are an important part of the ecosystem, yet they increase the surface for certain attacks as much as functionality heavy packages. This excessive fragmentation of the npm codebase can thus lead to very high number of dependencies.

**No Privilege Separation** In contrast to, e.g., the Java security model in which a `SecurityManager`<sup>3</sup> can restrict the access to sensitive APIs, JavaScript does not provide any kind of privilege separation between code loaded from different packages. That is, any third-party package has the full privileges of the entire application. This situation is compounded by the fact that many npm packages run outside of a browser, in particular on the Node.js platform, which does not provide any kind of sandbox. Instead, any third-party package can access, e.g., the file system and the network.

<sup>3</sup><https://docs.oracle.com/javase/6/docs/api/java/lang/SecurityManager.html>

**No Systematic Vetting** The process of discovering vulnerabilities in npm packages is still in its infancy. There currently is no systematic vetting process for code published on npm. Instead, known vulnerabilities are mostly reported by individuals, who find them through manual analysis or in recent research work, e.g., injection vulnerabilities [30], regular expression denial of service [9, 29], path traversals [16], binding layer bugs [6].

**Publishing Model** In order to publish a package, a developer needs to first create an account on the npm website. Once this prerequisite is met, adding a new package to the repository is as simple as running the “npm publish” command in a folder containing a package.json file. The user who first published the package is automatically added to the maintainers set and hence she can release future versions of that package. She can also decide to add additional npm users as maintainers. What is interesting to notice about this model is that it does not require a link to a public version control system, e.g., GitHub, hosting the code of the package. Nor does it require that persons who develop the code on such external repositories also have publishing rights on npm. This disconnect between the two platforms has led to confusion<sup>4</sup> in the past and to stealthy attacks that target npm accounts without changes to the versioning system.

## 2.2 Threat Models

The idiosyncratic security properties of npm, as described above, enable several scenarios for attacking users of npm packages. The following discusses threat models that either correspond to attacks that have already occurred or that we consider to be possible in the future.

**Malicious Packages (TM-mal)** Adversaries may publish packages containing malicious code on npm and hence trick other users into installing or depending on such packages. In 2018, the *eslint-scope* incident mentioned earlier has been an example of this threat. The package deployed its payload at installation time through an automatically executed post-installation script. Other, perhaps more stealthy methods for hiding the malicious behavior could be envisioned, such as downloading and executing payloads only at runtime under certain conditions.

Strongly related to malicious packages are packages that violate the user’s privacy by sending usage data to third parties, e.g., *insight*<sup>5</sup> or *analytics-node*<sup>6</sup>. While these libraries are legitimate under specific conditions, some users may not want to be tracked in this way. Even though the creators of these packages clearly document the tracking functionality, transitive dependents may not be aware that one of their dependencies deploys tracking code.

<sup>4</sup><http://www.cs.tufts.edu/comp/116/archive/spring2018/etolhurst.pdf>

<sup>5</sup><https://www.npmjs.com/package/insight>

<sup>6</sup><https://www.npmjs.com/package/analytics-node>

**Exploiting Unmaintained Legacy Code (TM-leg)** As with any larger code base, npm contains vulnerable code, some of which is documented in public vulnerability databases such as npm security advisories<sup>7</sup> or Snyk vulnerability DB<sup>8</sup>. As long as a vulnerable package remains unfixed, an attacker can exploit it in applications that transitively depend on the vulnerable code. Because packages may become abandoned due to developers inactivity [8] and because npm does not offer a forking mechanism, some packages may never be fixed. Even worse, the common practice of locking dependencies may prevent applications from using fixed versions even when they are available.

**Package Takeover (TM-pkg)** An adversary may convince the current maintainers of a package to add her as a maintainer. For example, in the recent *event-stream* incident<sup>9</sup>, the attacker employed social engineering to obtain publishing rights on the target package. The attacker then removed the original maintainer and hence became the sole owner of the package. A variant of this attack is when an attacker injects code into the source base of the target package. For example, such code injection may happen through a pull request, via compromised development tools, or even due to the fact that the attacker has commit rights on the repository of the package, but not npm publishing rights. Once vulnerable or malicious code is injected, the legitimate maintainer would publish the package on npm, unaware of its security problems. Another takeover-like attack is typosquatting, where an adversary publishes malicious code under a package name similar to the name of a legitimate, popular package. Whenever a user accidentally mistypes a package name during installation, or a developer mistypes the name of a package to depend on, the malicious code will be installed. Previous work shows that typosquatting attacks are easy to deploy and effective in practice [31].

**Account Takeover (TM-acc)** The security of a package depends on the security of its maintainer accounts. An attacker may compromise the credentials of a maintainer to deploy insecure code under the maintainer’s name. At least one recent incident (*eslint-scope*) is based on account takeover. While we are not aware of how the account was hijacked in this case, there are various paths toward account takeover, e.g., weak passwords, social engineering, reuse of compromised passwords, and data breaches on npm.

**Collusion Attack (TM-coll)** The above scenarios all assume a single point of failure. In addition, the npm ecosystem may get attacked via multiple instances of the above threats. Such a collusion attack may happen when multiple maintainers decide to conspire and to cause intentional harm, or when multiple packages or maintainers are taken over by an attacker.

<sup>7</sup><https://www.npmjs.com/advisories>

<sup>8</sup><https://snyk.io/vuln/?type=npm>

<sup>9</sup><https://github.com/dominictarr/event-stream/issues/116>

### 3 Methodology

To analyze how realistic the above threats are, we systematically study package dependencies, maintainers, and known security vulnerabilities in npm. The following explains the data and metrics we use for this study.

#### 3.1 Data Used for the Study

**Packages and Their Dependencies** To understand the impact of security problems across the ecosystem, we analyze the dependencies between packages and their evolution.

**Definition 3.1** Let  $t$  be a specific point in time,  $P_t$  be a set of npm package names, and  $E_t = \{(p_i, p_j) | p_i \neq p_j \in P_t\}$  a set of directed edges between packages, where  $p_i$  has a regular dependency on  $p_j$ . We call  $G_t = (P_t, E_t)$  the **npm dependency graph** at a given time  $t$ .

We denote the universe of all packages ever published on npm with  $\mathcal{P}$ . By aggregating the meta information about packages, we can easily construct the dependency graph without the need to download or install every package. Npm offers an API endpoint for downloading this metadata for all the releases of all packages ever published. In total we consider 676,539 nodes and 4,543,473 edges.

To analyze the evolution of packages we gather data about all their releases. As a convention, for any time interval  $t$ , such as years or months, we denote with  $t$  the snapshot at the beginning of that time interval. For example,  $G_{2015}$  refers to the dependency graph at the beginning of the year 2015. In total we analyze 5,386,239 releases, therefore an average of almost eight versions per package. Our observation period ends in April 2018.

**Maintainers** Every package has one or more developers responsible for publishing updates to the package.

**Definition 3.2** For every  $p \in P_t$ , the set of **maintainers**  $M(p)$  contains all users that have publishing rights for  $p$ .

Note that a specific user may appear as the maintainer of multiple packages and that the union of all maintainers in the ecosystem is denoted with  $\mathcal{M}$ .

**Vulnerabilities** The npm community issues advisories or public reports about vulnerabilities in specific npm packages. These advisories specify if there is a patch available and which releases of the package are affected by the vulnerability.

**Definition 3.3** We say that a given package  $p \in \mathcal{P}$  is **vulnerable at a moment  $t$**  if there exists a public advisory for that package and if no patch was released for the described vulnerability at an earlier moment  $t' < t$ .

We denote the set of vulnerable packages with  $\mathcal{V} \subset \mathcal{P}$ . In total, we consider 609 advisories affecting 600 packages. We extract the data from the publicly available npm advisories<sup>10</sup>.

<sup>10</sup><https://www.npmjs.com/advisories>

#### 3.2 Metrics

We introduce a set of metrics for studying the risk of attacks on the npm ecosystem.

**Packages and Their Dependencies** The following measures the influence of a given package on other packages in the ecosystem.

**Definition 3.4** For every  $p \in P_t$ , the **package reach**  $PR(p)$  represents the set of all the packages that have a transitive dependency on  $p$  in  $G_t$ .

Note that the package itself is not included in this set. The reach  $PR(p)$  contains names of packages in the ecosystem. Therefore, the size of the set is bounded by the following values  $0 \leq |PR(p)| < |P_t|$ .

Since  $|PR(p)|$  does not account for the ecosystem changes, the metric may grow simply because the ecosystem grows. To address this, we also consider the average package reach:

$$\overline{PR}_t = \frac{\sum_{p \in P_t} |PR(p)|}{|P_t|} \quad (1)$$

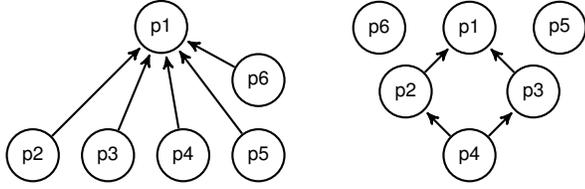

Using the bounds discussed before for  $PR(p)$ , we can calculate the ones for its average  $0 \leq \overline{PR}_t < |P_t|$ . The upper limit is obtained for a fully connected graph in which all packages can reach all the other packages and hence  $|PR(p)| = |P_t| - 1, \forall p$ . If  $\overline{PR}_t$  grows monotonously, we say that the ecosystem is getting more dense, and hence the average package influences an increasingly large number of packages.

The inverse of package reach is a metric to quantify how many packages are implicitly trusted when installing a particular package.

**Definition 3.5** For every  $p \in P_t$ , the set of **implicitly trusted packages**  $ITP(p)$  contains all the packages  $p_i$  for which  $p \in PR(p_i)$ .

Similarly to the previous case, we also consider the size of the set  $|ITP(p)|$  and the average number of implicitly trusted package  $\overline{ITP}_t$ , having the same bounds as their package reach counterpart.

Even though the average metrics  $\overline{ITP}_t$  and  $\overline{PR}_t$  are equivalent for a given graph, the distinction between their non-averaged counterparts is very important from a security point of view. To see why, consider the example in Figure 1. The average  $\overline{PR} = \overline{ITP} = 5/6 = 0.83$  both on the right and on the left. However, on the left, a popular package  $p1$  is dependent upon by many others. Hence, the package reach of  $p1$  is five, and the number of implicitly trusted packages is one for each of the other packages. On the right, though, the number of implicitly trusted packages for  $p4$  is three, as users of  $p4$  implicitly trust packages  $p1, p2$ , and  $p3$ .

(a) Wide distribution of trust:  $\max(\text{PR}) = 5, \max(\text{ITP}) = 1$  (b) Narrow distribution of trust:  $\max(\text{PR}) = 3, \max(\text{ITP}) = 3$   
 Figure 1: Dependency graphs with different maximum package reaches (PR) and different maximum numbers of trusted packages (ITP).

**Maintainers** The number of implicitly trusted packages or the package reach are important metrics for reasoning about TM-pkg, but not about TM-acc. That is because users may decide to split their functionality across multiple micropackages for which they are the sole maintainers. To put it differently, a large attack surface for TM-pkg does not imply one for TM-acc.

Therefore, we define maintainer reach  $\text{MR}_t(m)$  and implicitly trusted maintainers  $\text{ITM}_t(p)$  for showing the influence of maintainers.

**Definition 3.6** Let  $m$  be an npm maintainer. The **maintainer reach**  $\text{MR}(m)$  is the combined reach of all the maintainer’s packages,  $\text{MR}(m) = \cup_{m \in M(p)} \text{PR}(p)$

**Definition 3.7** For every  $p \in P_t$ , the set of **implicitly trusted maintainers**  $\text{ITM}(p)$  contains all the maintainers that have publishing rights on at least one implicitly trusted package,  $\text{ITM}(p) = \cup_{p_i \in \text{ITP}(p)} M(p_i)$ .

The above metrics have the same bounds as their packages counterparts. Once again, the distinction between the package and the maintainer-level metrics is for shedding light on the security relevance of human actors in the ecosystem.

Furthermore, to approximate the maximum damage that colluding maintainers can incur on the ecosystem (TM-coll), we define an order in which the colluding maintainers are selected:

**Definition 3.8** We call an ordered set of maintainers  $L \subset \mathcal{M}$  a **desirable collusion strategy** iff  $\forall m_i \in L$  there is no  $m_k \neq m_i$  for which  $\cup_{j < i} \text{MR}(m_j) \cup \text{MR}(m_i) < \cup_{j < i} \text{MR}(m_j) \cup \text{MR}(m_k)$ .

Therefore, the desirable collusion strategy is a hill climbing algorithm in which at each step we choose the maintainer that provides the highest local increase in package reach at that point. We note that the problem of finding the set of  $n$  maintainers that cover the most packages is an NP-hard problem called *maximum coverage problem*. Hence, we believe that the proposed solution is a good enough approximation that shows how vulnerable the ecosystem is to a collusion attack, but that does not necessary yield the optimal solution.

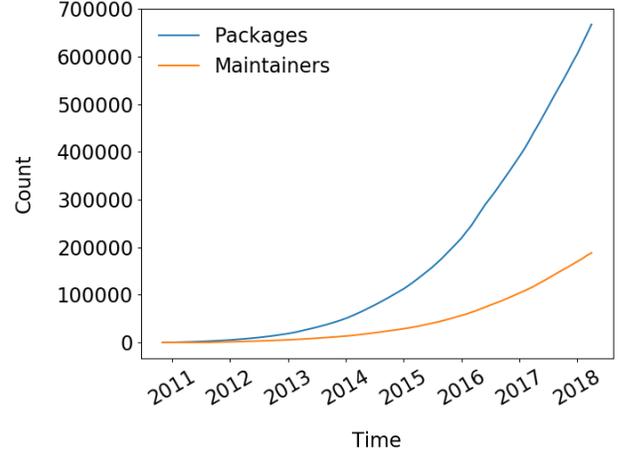

Figure 2: Evolution of number of packages and maintainers.

**Vulnerabilities** For reasoning about TM-leg, we need to estimate how much of the ecosystem depends on vulnerable code:

**Definition 3.9** Given all vulnerable packages  $p_i \in \mathcal{V}_t$  at time  $t$ , we define the **reach of vulnerable code** at time  $t$  as  $\text{VR}_t = \cup_{p_i \in \mathcal{V}_t} \text{PR}(p_i)$ .

Of course the actual reach of vulnerable code can not be fully calculated since it would rely on *all* vulnerabilities present in npm modules, not only on the published ones. However, since in TM-leg we are interested in publicly known vulnerabilities, we define our metric according to this scenario. In these conditions, the speed at which vulnerabilities are reported is an important factor to consider:

**Definition 3.10** Given all vulnerable packages  $p_i \in \mathcal{V}_t$  at time  $t$ , we define the **vulnerability reporting rate**  $\text{VRR}_t$  at time  $t$  as  $\text{VRR}_t = \frac{|\mathcal{V}_t|}{|P_t|}$ .

## 4 Results

We start by reporting the results on the nature of package level dependencies and their evolution over time (corresponding to TM-mal and TM-pkg). We then discuss the influence that maintainers have in the ecosystem (related to TM-acc and TM-coll). Finally, we explore the dangers of depending on unpatched security vulnerabilities (addressing TM-leg).

### 4.1 Dependencies in the Ecosystem

To set the stage for a thorough analysis of security risks entailed by the structure of the npm ecosystem, we start with a general analysis of npm and its evolution. Since its inception in 2010, the npm ecosystem has grown from a small collection of packages maintained by a few people to the world’s largest software ecosystem. Figure 2 shows the evolution of the number of packages available on npm and the

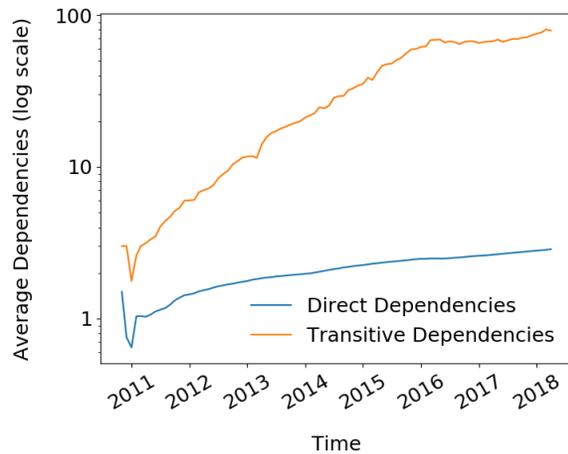

Figure 3: Evolution of direct package dependencies and its impact on transitive dependencies. Note the logarithmic scale on the y-axis.

number of maintainers responsible for these packages. Both numbers have been increasing super-linearly over the past eight years. At the end of our measurement range, there is a total of 676,539 packages, a number likely to exceed one million in the near future. These packages are taken care of by a total of 199,327 maintainers. The ratio of packages to maintainers is stable across our observation period (ranging between 2.81 and 3.51).

In many ways, this growth is good news for the JavaScript community, as it increases the code available for reuse. However, the availability of many packages may also cause developers to depend on more and more third-party code, which increases the attack surface for TM-pkg by giving individual packages the ability to impact the security of many other packages. The following analyzes how the direct and transitive dependencies of packages are evolving over time (Section 4.1.1) and how many other packages individual packages reach via dependencies (Section 4.1.2).

#### 4.1.1 Direct and Transitive Dependencies

Figure 3 shows how many other packages an average npm package depends on directly and transitively. The number of direct dependencies has been increasing slightly from 1.3 in 2011 to 2.8 in 2018, which is perhaps unsurprising given the availability of an increasing code base to reuse. The less obvious observation is that a small, linear increase in direct dependencies leads to a significant, super-linear increase in transitive dependencies. As shown by the upper line in Figure 3, the number of transitive dependencies of an average package has increased to a staggering 80 in 2018 (note the logarithmic scale).

From a security perspective, it is important to note that each directly or transitively depended on package becomes part of the implicitly trusted code base. When installing a package,

each depended upon package runs its post-installation scripts on the user’s machine – code executed with the user’s operating system-level permissions. When using the package, calls into third-party modules may execute any of the code shipped with the depended upon packages.

When installing an average npm package, a user implicitly trusts around 80 other packages due to transitive dependencies.

One can observe in Figure 3 a chilling effect on the number of dependencies around the year 2016 which will become more apparent in the following graphs. Decan et al. [14] hypothesize that this effect is due to the left-pad incident. In order to confirm that this is not simply due to removal of more than a hundred packages belonging to the left-pad’s owner, we remove all the packages owned by this maintainer. We see no significant difference for the trend in Figure 3 when removing these packages, hence we conclude that indeed there is a significant change in the structure of transitive dependencies in the ecosystem around 2016.

#### 4.1.2 Package Reach

The above analysis focuses on depended upon packages. We now study the inverse phenomenon: packages impacted by individual packages, i.e., package reach as defined in Section 3. Figure 4 shows how many other packages a single package reaches via direct or indirect dependencies. The graph at the top is for an average package, showing that it impacts about 230 other packages in 2018, a number that has been growing since the creation of npm. The graph at the bottom shows the package reach of the top-5 packages (top in terms of their package reach, as of 2018). In 2018, these packages each reach between 134,774 and 166,086 other packages, making them an extremely attractive target for attackers.

To better understand how the reach of packages evolves over time, Figure 5 shows the distribution of reached packages for multiple years. For example, the red line shows that in 2018, about 24,500 packages have reached at least 10 other packages, whereas only about 9,500 packages were so influential in 2015. Overall, the figure shows that more and more packages are reaching a significant number of other packages, increasing the attractiveness of attacks that rely on dependencies.

Some highly popular packages reach more than 100,000 other packages, making them a prime target for attacks. This problem has been aggravating over the past few years.

The high reach of a package amplifies the effect of both vulnerabilities (TM-leg) and of malicious code (TM-mal). As an example for the latter, consider the event-stream incident discussed when introducing TM-acc in Section 2.2. By

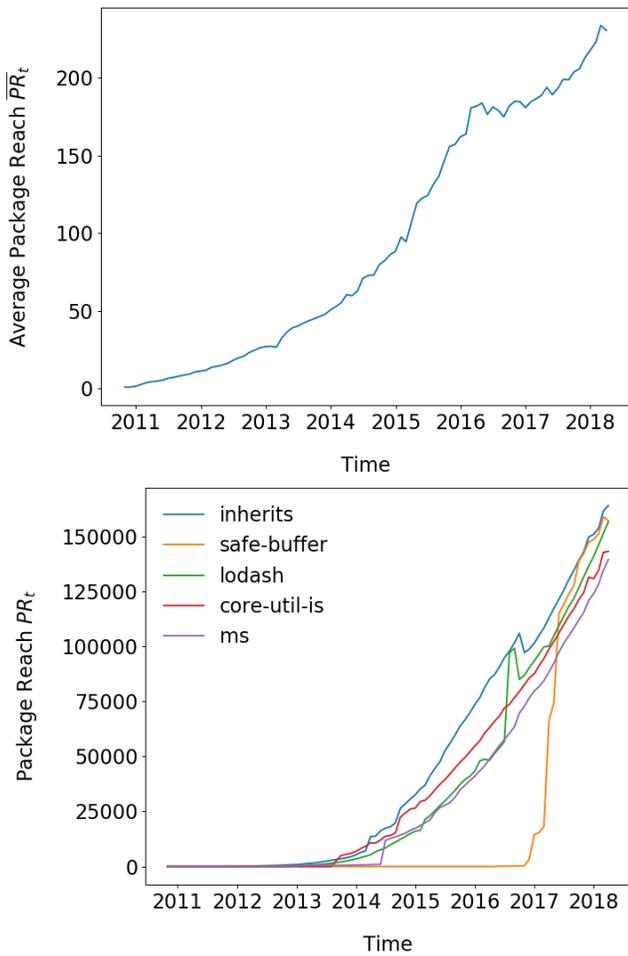

Figure 4: Evolution of package reach for an average package (top) and the top-5 packages (bottom).

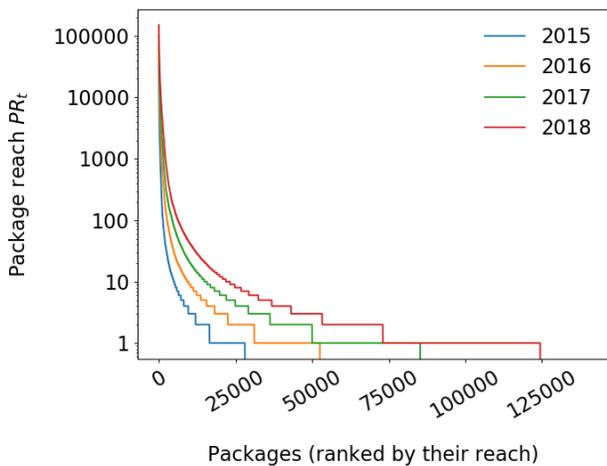

Figure 5: Distribution of package reach by individual packages, and how it changes over time. Note the log scale on the vertical axis.

computing event-stream’s reach and comparing it with other packages, we see that this package is just one of many possible targets. As of April 1, 2018 (the end of our measurement period), event-stream has a reach of 5,466. That is, the targeted package is relatively popular, but still far from being the top-most attractive package to compromise. In fact, 1,165 other packages have a greater or equal reach than event-stream.

Variants of the event-stream attack could easily be repeated with other packages.

In order to perform a similar analysis for the eslint-scope security incident, we need to use a slightly modified version of package reach. This attack targeted a development tool, namely eslint, hence, to fully estimate the attack surface we need to consider dev dependencies in our definition of reach. We do not normally consider this type of dependencies in our measurements because they are not automatically installed with a package, unlike regular dependencies. They are instead used only by the developers of the packages. Therefore the modified version of package reach considers both transitive regular dependencies and direct dev dependencies.

We observe that eslint-scope has a modified reach of more than 100,000 packages at the last observation point in the data set. However, there are 347 other packages that have a higher reach, showing that even more serious attacks may occur in the future.

The attack on eslint-scope has targeted a package with an influence not larger than that of hundreds of other packages. It is likely that similar, or perhaps even worse, attacks will happen and succeed in the future.

## 4.2 Analysis of Maintainers

We remind the reader that there is a significant difference between npm maintainers and repository contributors, as discussed in Section 2.1. Even though contributors also have a lot of control over the code that will eventually end up in an npm package, they can not release a new version on npm, only the maintainers have this capability. Hence, the discussion that follows, about the security risks associated with maintainers, should be considered a lower bound for the overall attack surface.

Attacks corresponding to TM-acc in which maintainers are targeted are not purely hypothetical as the infamous eslint-scope incident discussed earlier shows. In this attack, a malicious actor hijacked the account of an influential maintainer and then published a version of eslint-scope containing malicious code. This incident is a warning for how vulnerable the ecosystem is to targeted attacks and how maintainers influence can be used to deploy malware at scale. We further discuss the relation between packages and maintainers.

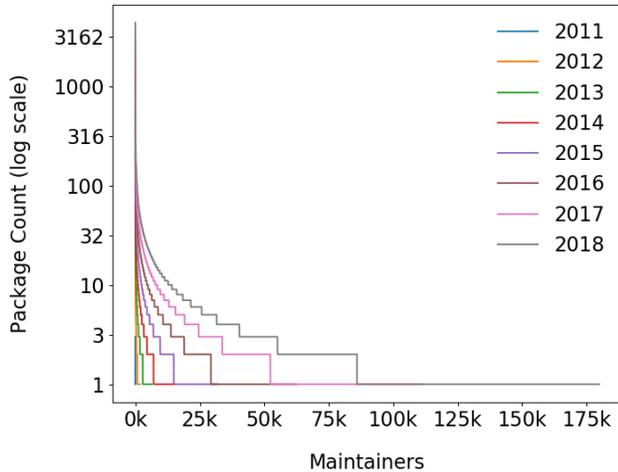

Figure 6: Evolution of maintainers sorted by package count per year.

#### 4.2.1 Packages per Maintainer

Even though the ecosystem grows super-linearly as discussed in Section 4.1, one would expect that this is caused mainly by new developers joining the ecosystem. However, we observe that the number of packages per maintainer also grows suggesting that the current members of the platform are actively publishing new packages. The average number of packages controlled by a maintainer raises from 2.5 in 2012 to 3.5 in 2013 and almost 4.5 in 2018. Conversely, there are on average 1.35 maintainers in the lifetime of a package. The top 5,000 most popular packages have an average number of 2.83 maintainers. This is not unexpected, since multiple people are involved in developing the most popular packages, while for the majority of new packages there is only one developer.

Next, we study in more detail the evolution of the number of packages a maintainer controls. Figure 6 shows the maintainer package count plotted versus the number of maintainers having such a package count. Every line represents a year. The scale is logarithmic to base 10. It shows that the majority of maintainers maintain few packages, yet some maintainers maintain over 100 packages. Over the years, the package count for the maintainers increased consistently. In 2015, only slightly more than 25,000 maintainers maintained more than one package, whereas this number has more than tripled by 2018.

We further analyze five different maintainers in top 20 according to number of packages and plot the evolution of their package count over the years in Figure 7. *types* is the largest maintainer of type definitions for TypeScript, most likely a username shared by multiple developers at Microsoft, *ehsalazar* maintains many security placeholder packages, *jonschlinkert* and *sindresorhus* are maintaining many micropackages and *isaacs* is the npm founder. From Figure 7 we can see that for two of these maintainers the increase is super-linear or even near exponential: *types* and *kylemathews* have

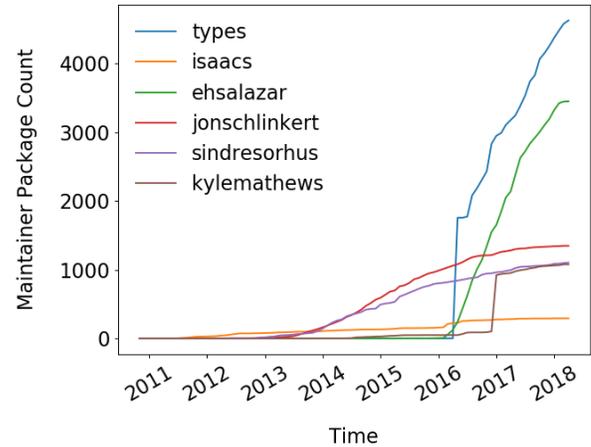

Figure 7: Evolution of package count for six popular maintainers.

sudden spikes where they added many packages in a short time. We explain this by the tremendous increase in popularity for TypeScript in the recent years and by the community effort to prevent typosquatting attacks by reserving multiple placeholder. The graph of the other maintainers is more linear, but surprisingly it shows a continuous growth for all the six maintainers.

The number of packages that both the influential and the average maintainers control increased continuously over the years.

#### 4.2.2 Implicitly Trusted Maintainers

One may argue that the fact that maintainers publish new packages is a sign of a healthy ecosystem and that it only mimics its overall growth. However, we show that while that may be true, we also see an increase in the general influence of maintainers. That is, on average every package tends to transitively rely on more and more maintainers over time.

In Figure 8 we show the evolution of  $\overline{ITM}_t$ , the average number of implicitly trusted maintainers. As can be seen,  $\overline{ITM}_t$  almost doubled in the last three years for the average npm package, despite the plateau of the curve reached in 2016 which we again speculate it is caused by the left-pad incident. This is a worrisome development since compromising any of the maintainer accounts a package trusts may seriously impact the security of that package, as discussed in TM-acc. The positive aspect of the data in Figure 8 is that the growth in the number of implicitly trusted maintainers seems to be less steep for the top 10,000 packages compared to the whole ecosystem. We hypothesize that the developers of popular packages are aware of this problem and actively try to limit the  $\overline{ITM}_t$ . However, a value over 20 for the average popular package is still high enough to be problematic.

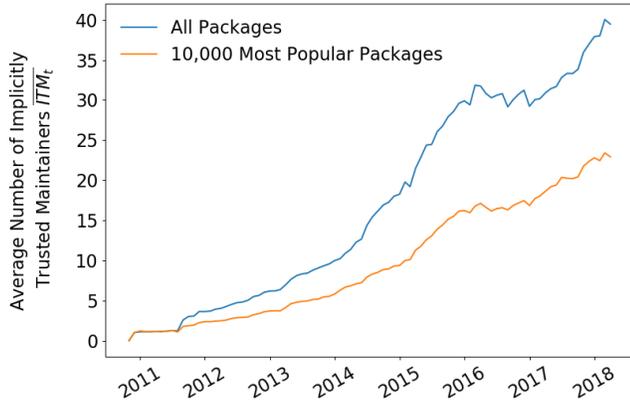

Figure 8: Evolution of average number of implicitly trusted maintainers over years in all packages and in the most popular ones.

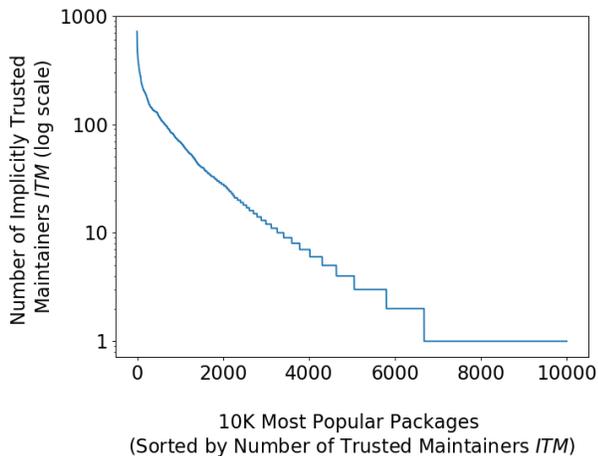

Figure 9: Number of implicitly trusted maintainers for top 10,000 most popular packages.

The average npm package transitively relies on code published by 40 maintainers. Popular packages rely on only 20.

When breaking the average  $\overline{ITM}_t$  discussed earlier into individual points in Figure 9, one can observe that the majority of these packages can be influenced by more than one maintainer. This is surprising since most of the popular packages are micropackages such as "inherits" or "left-pad" or libraries with no dependencies like "moment" or "lodash". However, only around 30% of these top packages have a maintainer cost higher than 10. Out of these, though, there are 643 packages influenced by more than a hundred maintainers.

More than 600 highly popular npm packages rely on code published by at least 100 maintainers.

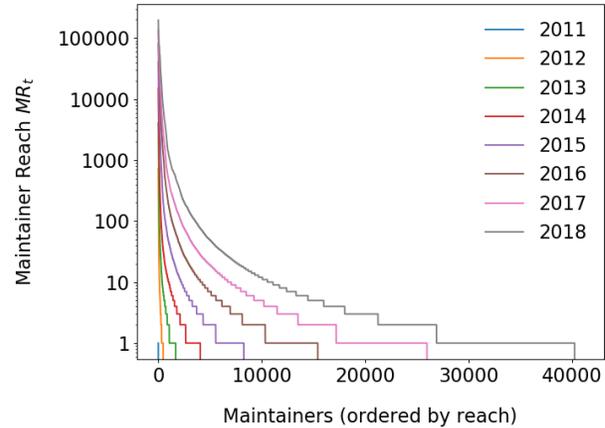

Figure 10: Distribution of maintainers reach in different years.

### 4.2.3 Maintainers Reach

In Figure 10, we plot the reach  $MR_t$  of the maintainers in the npm ecosystem. The reach has increased over the years at all levels. For example, in 2015 there were 2,152 maintainers that could affect more than 10 packages, and this number increased to 4,041 in 2016, 6,680 in 2017 and finally reaching an astonishingly high 10,534 in 2018. At the other end of the distribution, there were 59 maintainers that could affect more than 10,000 packages in 2015, 163 in 2016, 249 in 2017 and finally 391 in 2018. The speed of growth for  $MR_t$  is worrisome, showing that more and more developers have control over thousands of packages. If an attacker manages to compromise the account of any of the 391 most influential maintainers, the community will experience a serious security incident, reaching twice as many packages as in the event-stream attack.

391 highly influential maintainers affect more than 10,000 packages, making them prime targets for attacks. The problem has been aggravating over the past years.

Finally, we look at the scenario in which multiple popular maintainers collude, according to the desirable collusion strategy introduced in Section 3.2, to perform a large-scale attack on the ecosystem, i.e., TM-col. In Figure 11 we show that 20 maintainers can reach more than half of the ecosystem. Past that point every new maintainer joining does not increase significantly the attack's performance.

## 4.3 Security Advisories Evolution

Next, we study how often vulnerabilities are reported and fixed in the npm ecosystem (TM-leg). Figure 13 shows the number of reported vulnerabilities in the lifetime of the ecosystem. The curve seems to resemble the evolution of number of packages presented in Figure 2, with a steep increase in the last two years. To explore this relation further we plot in Figure 14 the evolution of the number of advisories

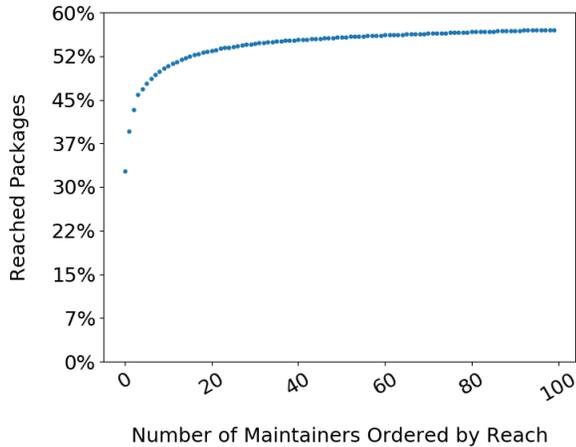

Figure 11: Combined reach of 100 influential maintainers.

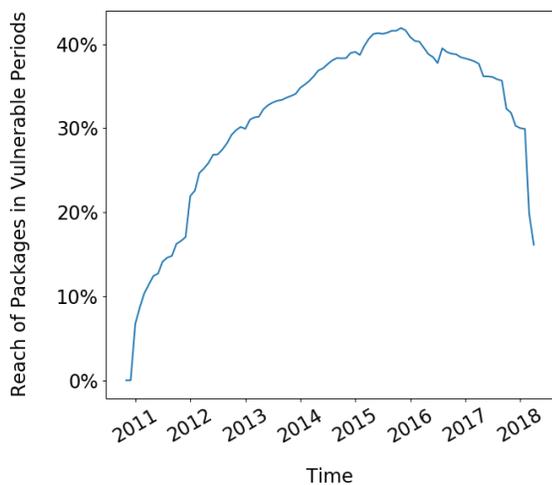

Figure 12: Total reach of packages for which there is at least one unpatched advisory (vulnerability reach  $VR_t$ ).

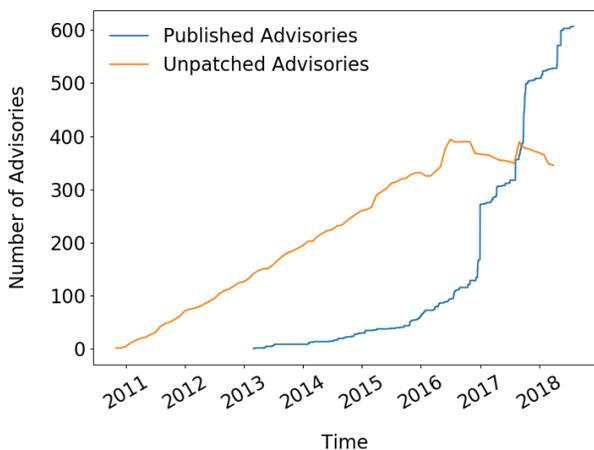

Figure 13: Evolution of the total and unpatched number of advisories.

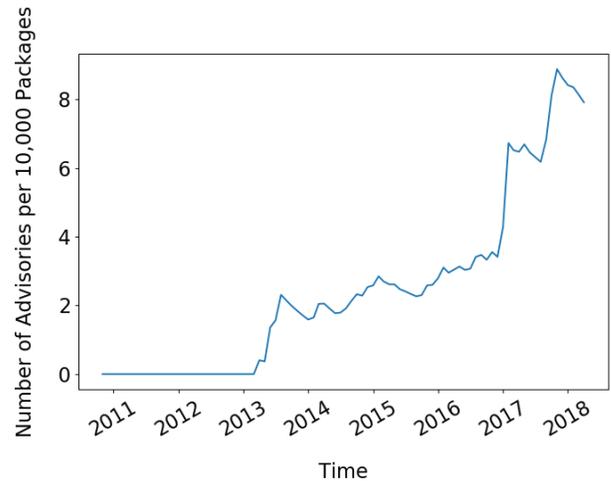

Figure 14: Evolution of  $VRR_t$ , the rate of published vulnerabilities per 10,000 packages.

reported per 10,000 packages and we observe that it grows from two in 2013 to almost eight in 2018. This is a sign of a healthy security community that reports vulnerabilities at a very good pace, keeping up with the growth of the ecosystem.

When analyzing the type of reported vulnerabilities in details, we observe that almost half of the advisories come from two large-scale campaigns and not a broader community effort: First, there are 141 advisories published in January 2017 involving npm packages that download resources over HTTP, instead of HTTPS. Second, there are 120 directory traversal vulnerabilities reported as part of the research efforts of Liang Gong [16]. Nevertheless, this shows the feasibility of large-scale vulnerability detection and reporting on npm.

Publishing an advisory helps raise awareness of a security problem in an npm package, but in order to keep the users secure, there needs to be a patch available for a given advisory. In Figure 13 we show the evolution of the number of unpatched security vulnerabilities in npm, as defined in Section 3. This trend is alarming, suggesting that two out of three advisories are still unpatched, leaving the users at risk. When manually inspecting some of the unpatched advisories we notice that a large percentage of unpatched vulnerabilities are actually advisories against malicious typosquatting packages for which no fix can be available.

To better understand the real impact of the unpatched vulnerabilities we analyze how much of the ecosystem they impact, i.e., vulnerability reach as introduced in Section 3.2. To that end, we compute the reach of unpatched packages at every point in time in Figure 12. At a first sight, this data shows a much less grim picture than expected, suggesting that the reach of vulnerable packages is dropping over time. However, we notice that the effect of vulnerabilities tends to be retroactive. That is, a vulnerability published in 2015 affects multiple versions of a package released prior to that date, hence influencing the data points corresponding to the years 2011-2014 in Figure 12. Therefore, the vulnerabilities

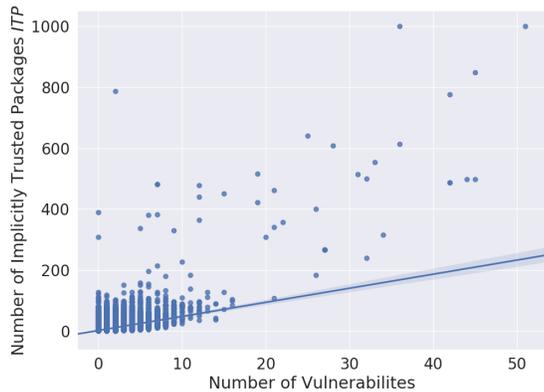

Figure 15: Correlation between number of vulnerabilities and number of dependencies.

that will be reported in the next couple of years may correct for the downwards trend we see on the graph. Independent of the downwards trend, the fact that for the majority of the time the reach of vulnerable unpatched code is between 30% and 40% is alarming.

Up to 40% of all packages rely on code known to be vulnerable.

## 5 Potential Mitigations

The following section discusses ideas for mitigating some of the security threats in the npm ecosystem. We here do not provide fully developed solutions, but instead outline ideas for future research, along with an initial assessment of their potential and challenges involved in implementing them.

### 5.1 Raising Developer Awareness

One line of defense against the attacks described in this paper is to make developers who use third-party packages more aware of the risks entailed by depending on a particular package. Currently, npm shows for each package the number of downloads, dependencies, dependents, and open issues in the associated repository. However, the site does not show any information about the transitive dependencies or about the number of maintainers that may influence a package, i.e., our ITP and ITM metrics. As initial evidence that including such metrics indeed predicts the risk of security issues, Figure 15 shows the number of implicitly trusted packages versus the number of vulnerabilities a package is affected by. We find that the two values are correlated (Pearson correlation coefficient of 0.495), which is not totally unexpected since adding more dependencies increases the chance of depending on vulnerable code. Showing such information, e.g., the ITP metric, could help developers make more informed decisions about which third-party packages to rely on.

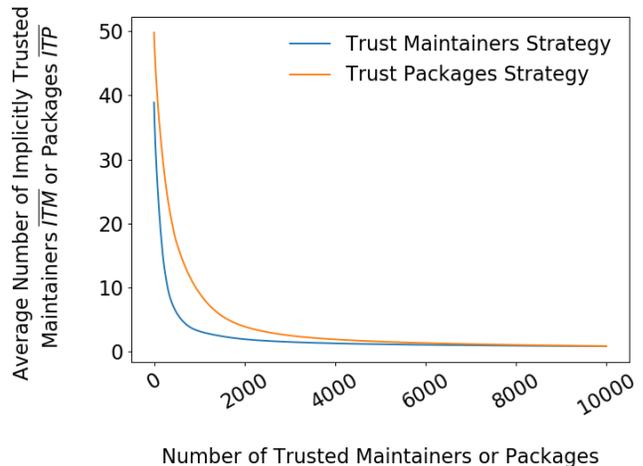

Figure 16: Decrease in average number of implicitly trusted maintainers and packages as the set of trusted maintainers or packages increases.

### 5.2 Warning about Vulnerable Packages

To warn developers about unpatched vulnerabilities in their dependencies, the `npm audit` tool has been introduced. It compares all directly depended upon packages against a database of known vulnerabilities, and warns a developer when depending upon a vulnerable version of a package. While being a valuable step forward, the tool currently suffers from at least three limitations. First, it only considers direct dependencies but ignores any vulnerabilities in transitive dependencies. Second, the tool is limited to known vulnerabilities, and hence its effectiveness depends on how fast advisories are published. Finally, this defense is insufficient against malware attacks.

### 5.3 Code Vetting

A proactive way of defending against both vulnerable and malicious code is code vetting. Similar to other ecosystems, such as mobile app stores, whenever a new release of a vetted package is published, npm could analyze its code. If and only if the analysis validates the new release, it is made available to users. Since the vetting process may involve semi-automatic or even manual steps, we believe that it is realistic to assume that it will be deployed step by step in the ecosystem, starting with the most popular packages. Figure 16 (orange curve) illustrates the effect that such code vetting could have on the ecosystem. The figure shows how the average number of implicitly trusted packages,  $\overline{ITP}$ , reduces with an increasing number of vetted and therefore trusted packages. For example, vetting the most dependent upon 1,500 packages would reduce the  $\overline{ITP}$  ten fold, and vetting 4,000 packages would reduce it by a factor of 25.

An obvious question is how to implement such large-scale code vetting, in particular, given that new versions of packages are released regularly. To estimate the cost of vetting new releases, Figure 17 shows the average number of lines of code

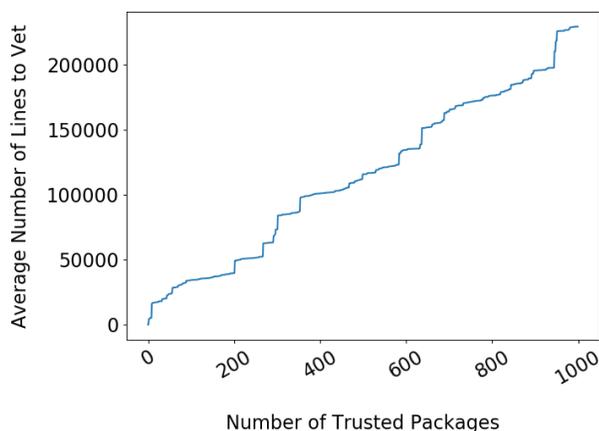

Figure 17: Number of lines of code that need to be vetted for achieving a certain number of trusted packages.

that are changed per release of a package, and would need to be vetted to maintain a specific number of trusted packages. For example, vetting the changes made in a single new release of the top 400 most popular packages requires to analyze over 100,000 changed lines of code. One way to scale code vetting to this amount of code could be automated code analysis tools. Recently, there have been several efforts for improving the state of the art of security auditing for npm, both from academia, e.g., Synode [30], BreakApp [32], NodeSec [16], NoRegrets [25], Node.cure [10], and from industry practitioners, e.g., Semmle<sup>11</sup>, r2c<sup>12</sup>, and DeepScan<sup>13</sup>. Orthogonal to automated code analysis tools, the npm community could establish crowd-sourced package vetting, e.g., in a hierarchically organized code distribution model similar to the Debian ecosystem.

Another challenge for code vetting is that npm packages, in contrast to apps in mobile app stores, are used across different platforms with different security models. For example, XSS vulnerabilities are relevant only when a package is used on the client-side, whereas command injection via the `exec` API [30] is a concern only on the server-side. A code vetting process could address this challenge by assigned platform-specific labels, e.g., “vetted for client-side” and “vetted for server-side”, depending on which potential problems the vetting reveals.

## 5.4 Training and Vetting Maintainers

Another line of proactive defense could be to systematically train and vet highly influential maintainers. For example, this process could validate the identity of maintainers, support maintainers in understanding basic security principles, and ensure that their accounts are protected by state-of-the-art techniques, such as two-factor authentication. To assess the

<sup>11</sup><https://semmlle.com/>

<sup>12</sup><https://r2c.dev/>

<sup>13</sup><https://deepscan.io/>

effect that such a process would have, we simulate how training and vetting a particular number of *trusted maintainers* influences the average number of implicitly trusted maintainers,  $\overline{ITM}$ . The simulation assumes that the most influential maintainers are vetted first, and that once a maintainer is vetted she is ignored in the computation of the  $\overline{ITM}$ . The results of this simulation (Figure 16) show a similar effect as for vetting packages: Because some maintainers are highly influential, vetting a relatively small number of maintainers can significantly reduce security risks. For example, vetting around 140 maintainers cuts down the  $\overline{ITM}$  in half, and vetting around 600 could even reduce  $\overline{ITM}$  to less than five. These results show that this mechanism scales reasonably well, but that hundreds of maintainers need to be vetted to bring the average number of implicitly trusted maintainers to a reasonable level. Moreover, two-factor authentication has its own risks, e.g., when developers handle authentication tokens in an insecure way<sup>14</sup> or when attackers attempt to steal such tokens, as in the `eslint-scope` incident.

## 6 Related Work

In this section we discuss the closest related work contained mainly in two distinct research areas: JavaScript security and software ecosystem studies. While some of this work studies the npm ecosystem, to the best of our knowledge, we are the first to analyze in depth the role maintainers play in the ecosystem and the impact of different types of attacks, as well as the potential impact of vetting code.

**Server-side JavaScript Security** There are many studies that investigate problems with dependency management for the JavaScript or other ecosystems. Abdalkareem et al. [2] investigate reasons why developers would use trivial packages. They find that developers think that these packages are well implemented and tested and that they increase productivity as the developer does not need to implement such small features herself. Another empirical study on micropackages by Kula et al. [19] has similar results. They show that micropackages have long dependency chains, something we also discovered in some case studies of package reach. We also show that these packages have a high potential of being a target of an attack as they are dependent on by a lot of packages. Another previously studied topic is breaking changes introduced by dependencies. Bogart et al. [5] perform a case study interviewing developers about breaking changes in three different ecosystems. They find that npm’s community values a fast approach to new releases compared to the other ecosystems. Developers of npm are more willing to adopt breaking changes to fight technical debt. Furthermore, they find that the semantic versioning rules are enforced more overtime than in the beginning. Similarly, Decan et al. [11] analyze three package

<sup>14</sup><https://blog.npmjs.org/post/182015409750/automated-token-revocation-for-when-you>

ecosystems, including npm, and evaluate whether dependency constraints and semantic versioning are effective measures for avoiding breaking changes. They find that both these measures are not perfect and that there is a need for better tooling. One such tool can be the testing technique by Mezzetti et al. [25] which automatically detects whether an update of a package contains a breaking change in the API. With this method, they can identify type-related breaking changes between two versions. They identify 26 breaking changes in 167 updates of important npm packages. Pfretzschner et al. [27] describe four possible dependency-based attacks that exploit weaknesses such as global variables or monkeypatching in Node.js. They implement a detection of such attacks, but they do not find any real-world exploits. One way to mitigate these attacks is implemented by Vasilakis et al. [32] in *BreakApp*, a tool that creates automatic compartments for each dependency to enforce security policies. This increases security when using untrusted third-party packages. Furthermore, third-party packages can have security vulnerabilities that can impact all the dependents. Davis et al. [9] and Staicu et al. [29] find denial of service vulnerabilities in regular expressions in the npm ecosystem. In another study, Staicu et al. [30] find several injection vulnerabilities due to the *child\_process* module or the *eval* function. Brown et al. [6] discuss bugs in the binding layers of both server-side and client-side JavaScript platforms, while Wang et al. [33] analyze concurrency bugs in Node.js. Finally, Gong [16] presents a dynamic analysis system for identifying vulnerable and malicious code in npm. He reports more than 300 previously unknown vulnerabilities, some of which are clearly visible on the figures in Section 4.3. Furthermore, there are studies that look at how frequent security vulnerabilities are in the npm ecosystem, how fast packages fix these and how fast dependent packages upgrade to a non-vulnerable version. Chatzidimitriou et al. [7] build an infrastructure to measure the quality of the npm ecosystem and to detect publicly disclosed vulnerabilities in package dependencies. Decan et al. [13] perform a similar study but they investigate the evolution of vulnerabilities over time. They find that more than half of the dependent packages are still affected by a vulnerability after the fix is released. However, we show that the problem is even more serious because for more than half of the npm packages there is no available patch.

**Client-Side (JavaScript) Security** Client-side security is a vast and mature research area and it is out of scope to extensively survey it here. Instead, we focus on those studies that analyze dependencies in client-side code. Nikiforakis et al. [26] present a study of remote inclusion of JavaScript libraries in the most popular 10,000 websites. They show that an average website in their data set adds between 1.5 and 2 new dependencies per year. Similar to our work, they then discuss several threat models and attacks that can occur in this tightly connected ecosystem. Lauinger et al. [20] study the inclusion of libraries with known vulnerabilities in both popular and average websites. They show that 37% of the websites in their

data set include at least one vulnerable library. This number is surprisingly close to the reach we observe in npm for the vulnerable code. However, one should take both these results with a grain of salt since inclusion of vulnerable libraries does not necessarily lead to a security problem if the library is used in a safe way. Libert et al. [22] perform a HTTP-level analysis of third-party resource inclusions, i.e., dependencies. They conclude that nine in ten websites leak data to third-parties and that six in ten spawn third-party cookies.

**Studies of Software Ecosystems** Software ecosystem research has been rapidly growing in the last year. Manikas [23] surveys the related work and observes a maturing field at the intersection of multiple other research areas. Nevertheless, he identifies a set of challenges, for example, the problem of generalizing specific ecosystem research to other ecosystems or the lack of theories specific to software ecosystems. Serebrenik et al. [28] perform a meta-analysis of the difficult tasks in software ecosystem research and identify six types of challenges. For example, how to scale the analysis to the massive amount of data, how to research the quality and evolution of the ecosystem and how to dedicate more attention to comparative studies. Mens [24] further looks at the socio-technical view on software maintenance and evolution. He argues that future research needs to study both the technical and the social dimension of the ecosystem. Our study follows this recommendation as it not only looks at the influence of a package on the npm ecosystem, but also at the influence of the maintainers. Several related works advocate metrics borrowed from other fields. For example, Lertwitayatrai et al. [21] use network analysis techniques to study the topology of the JavaScript package ecosystem and to extract insights about dependencies and their relations. Another study by Kabbedijk et al. [17] looks at the social aspect of the Ruby software ecosystem by identifying different roles maintainers have in the ecosystem, depending on the number of developers they cooperate with and on the popularity of their packages. Overall, the research field is rising with a lot of studied software ecosystems in addition to the very popular ones such as JavaScript which is the focus of our study.

**Ecosystem Evolution** Studying the evolution of an ecosystem shows how fast it grows and whether developers still contribute to it. Wittern et al. [34] study the whole JavaScript ecosystem, including GitHub and npm until September 2015. They focus on dependencies, the popularity of packages and version numbering. They find that the ecosystem is steadily growing and exhibiting a similar effect to a power law distribution as only a quarter of packages is dependent upon. Comparing these numbers with our results, we see a continuous near-exponential growth in the number of released packages and that only 20% of all packages are dependent upon. A similar study that includes the JavaScript ecosystem by Kikas et al. [18] collects data until May 2016 and focuses on the evolution of dependencies and the vulnerability of the

dependency network. They confirm the same general growth as the previous study. Furthermore, they find packages that have a high impact with up to 30% of other packages and applications affected. Our study gives an update on these studies and additionally looks at the evolution of maintainers as they are a possible vulnerability in the ecosystem. The dependency network evolution was also studied for other ecosystems. Decan et al. [14] compare the evolution of seven different package managers focusing on the dependency network. Npm is the largest ecosystem in their comparison and they discover that dependencies are frequently used in all these ecosystems with similar connectedness between packages. Bloemen et al. [4] look at software package dependencies of the Linux distribution *Gentoo* where they use cluster analysis to explore different categories of software. German et al. [15] study the dependency network of the *R* language and the community around its user-contributed packages. Bavota et al. [3] analyze the large Apache ecosystem of Java libraries where they find that while the number of projects grows linearly, the number of dependencies between them grows exponentially. Comparing this to the npm ecosystem, we find the number of packages to grow super-linearly while the average number of dependencies between them grows linearly.

## 7 Conclusions

We present a large-scale study of security threats resulting from the densely connected structure of npm packages and maintainers. The overall conclusion is that npm is a small world with high risks. It is “small” in the sense that packages are densely connected via dependencies. The security risk are “high” in the sense that vulnerable or malicious code in a single package may affect thousands of others, and that a single misbehaving maintainer, e.g., due to a compromised account, may have a huge negative impact. These findings show that recent security incidents in the npm ecosystem are likely to be the first signs of a larger problem, and not only unfortunate individual cases. To mitigate the risks imposed by the current situation, we analyze the potential effectiveness of several mitigation strategies. We find that trusted maintainers and a code vetting process for selected packages could significantly reduce current risks.

## Acknowledgments

This work was supported by the German Federal Ministry of Education and Research and by the Hessian Ministry of Science and the Arts within CRISP, by the German Research Foundation within the ConcSys and Perf4JS projects. The authors would also like to thank the team at r2c for their engineering support in obtaining the data for this work.

<sup>2</sup>Münster University of Applied Sciences

## Abstract

OpenPGP and S/MIME are the two major standards to encrypt and digitally sign emails. Digital signatures are supposed to guarantee authenticity and integrity of messages. In this work we show practical forgery attacks against various implementations of OpenPGP and S/MIME email signature verification in five attack classes: (1) We analyze edge cases in S/MIME’s container format. (2) We exploit in-band signaling in the GnuPG API, the most widely used OpenPGP implementation. (3) We apply MIME wrapping attacks that abuse the email clients’ handling of partially signed messages. (4) We analyze weaknesses in the binding of signed messages to the sender identity. (5) We systematically test email clients for UI redressing attacks.

Our attacks allow the spoofing of digital signatures for arbitrary messages in 14 out of 20 tested OpenPGP-capable email clients and 15 out of 22 email clients supporting S/MIME signatures. While the attacks do not target the underlying cryptographic primitives of digital signatures, they raise concerns about the actual security of OpenPGP and S/MIME email applications. Finally, we propose mitigation strategies to counter these attacks.

## 1 Introduction

Email is still the most important communication medium on the Internet and predates the World Wide Web by roughly one decade. At that time, message authenticity was not a major concern, so the early SMTP and email [1, 2] standards did not address confidentiality or the authenticity of messages.

**Email Authenticity** As the ARPANET evolved into the Internet, email usage changed. Email is now used for sensitive communication in business environments, by the military, politicians and journalists. While technologies such as SPF, DKIM, and DMARC can be used to authenticate the domain of the sending SMTP server, these are merely helpful in mitigating spam and phishing attacks [3]. These technologies,

however, do not extend to authenticating the sending *person*, which is necessary to provide message authenticity.

Two competing email security standards, OpenPGP [4] and S/MIME [5], offer end-to-end authenticity of messages by digital signatures and are supported by many email clients since the late 1990s. Digital signatures provide assurance that a message was written by a specific person (i.e., authentication and non-repudiation) and that it was not changed since then (i.e., integrity of messages). Adoption is still low<sup>1</sup> due to severe usability issues, but both technologies have a large footprint either in the industry (S/MIME) or with high-risk roles such as journalists, lawyers, and freedom activists (OpenPGP). One example: Debian (a volunteer group with over 1000 members) relies on the authenticity of signed emails for voting on project leaders and proposals. We thus ask: *Is it possible to spoof a signed email such that it is indistinguishable from a valid one even by an attentive user?*

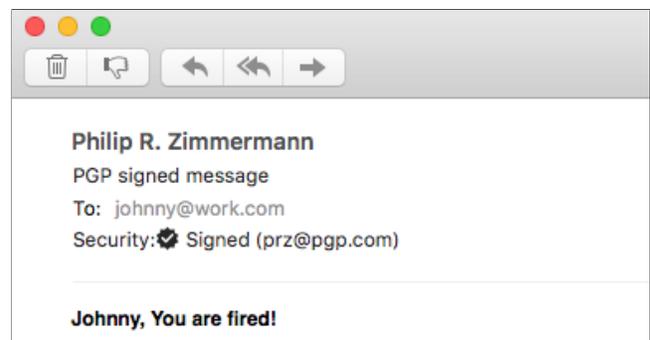

Figure 1: Screenshot of a spoofed PGP signature in Apple Mail, based on wrapping a signed email published by Phil Zimmermann.

**Spoofing Valid Signatures** Signature verification in the context of email is complex. For example, emails can be signed by an entity other than the sender or signed emails may be forwarded (resulting in partly signed messages).

<sup>1</sup>We examined OpenPGP keyservers and measured over 20k key uploads per month consistently over the last 4 years. We also found that Thunderbird reports 150k daily users (on work days) for the PGP-plugin Enigmail.

Also, signatures are an optional feature of email and therefore generally not enforced. Most importantly, the result of the verification must be presented to the user such that there is no room for misinterpretation. Any failure to do so may lead to a signature spoofing attack as shown in Figure 1. This paper describes the results of our analysis of the most widely used email clients supporting PGP or S/MIME signatures.

**Attack Classes** Our attacks do not break the cryptography in digital signatures, but rather exploit weaknesses in the way PGP and S/MIME signatures are verified by email clients, and how the verification outcome is presented to the user.

We define the following five attack classes:

1. **CMS attacks.** Cryptographic Message Syntax (CMS) is a versatile standard for signed and encrypted messages within the X.509 public-key infrastructure. We found flaws in the handling of emails with contradicting or unusual data structures (such as multiple signers) and in the presentation of issues in the X.509 trust chain.
2. **GPG API attacks.** GnuPG is the most widely used OpenPGP implementation, but it only offers a very restricted command line interface for validating signatures. This interface is vulnerable to injection attacks.
3. **MIME attacks.** The body of an email is conceptually a MIME *tree*, but typically the tree has only one leaf which is signed. We construct non-standard MIME trees that trick clients into showing an unsigned text while verifying an unrelated signature in another part.
4. **ID attacks.** The goal of this attack class is to display a valid signature from the identity (ID) of a trusted communication partner located in the mail header, although the crafted email is actually signed by the attacker.
5. **UI attacks.** Email clients indicate a valid signature by showing some security indicators in the user interface (UI), for example, a letter with a seal. However, several clients allow the mimicking of important UI elements by using HTML, CSS, and other embedded content.

**Contributions** We make the following contributions:

- We present the results of our structured analysis of OpenPGP and S/MIME signature verification in 25 widely used email clients.
- We present three new attack classes: attacks based on CMS evaluation, on the syntax of the GnuPG machine interface, and on wrapping signed content within invisible subtrees of the MIME tree.
- We adapt two attack classes of web security to the email context, namely UI redressing and ID spoofing.

- We show that our attacks bypass signature validation in about 70% of the tested email clients, including Outlook, Thunderbird, Apple Mail, and iOS Mail.

**Coordinated Disclosure** We reported all our attacks and additional findings to the affected vendors and gave advice on appropriate countermeasures.

## 2 Background

### 2.1 End-to-End Email Authenticity

The digital signature parts of the OpenPGP and S/MIME standards provide end-to-end authenticity for email messages. First and foremost, both technologies are configured on the endpoints and technically-versed users can therefore choose to use them independently of the email server configuration. In both standards, the keys are bound to users and thus authenticate users independently of the transport.

**OpenPGP Email Signing** Phil Zimmerman invented PGP (Pretty Good Privacy) in 1991 and due to its popularity, PGP was standardized as *OpenPGP* by the IETF [6]. The most popular implementation is GnuPG.<sup>2</sup> There are two common ways to use OpenPGP in emails. With *Inline PGP*, the email body directly contains the OpenPGP data. The MIME multipart standard is not used and the MIME type is `text/plain`. With *PGP/MIME*, the email has a `multipart/signed` MIME structure, where the signed message is the first part and the detached signature is the second part. Some email clients support PGP natively, but most (in particular Thunderbird, Apple Mail, and Outlook) need a plugin, which provides an intermediate layer between the mail client and a PGP implementation like GnuPG.

**S/MIME Email Signing** In 1999, the IETF published S/MIME (Secure/Multipurpose Internet Mail Extension) version 3 as an extension to the MIME standard with certificate-based cryptography [5]. S/MIME is the result of a long history of secure email protocols and can be seen as the first Internet standards-based framework to digitally sign, authenticate, or encrypt emails. S/MIME uses the *Cryptographic Message Syntax (CMS)* as its underlying container format. The signatures themselves are always CMS encoded, but the signed message can either be included in the CMS (*opaque* signature) or be transmitted as the first part of a `multipart/signed` message (*detached* signature).

### 2.2 Trust and Validity

Verifying the cryptographic integrity of a signature is often not sufficient. In addition to this verification, the public key

<sup>2</sup>W. Koch, *GNU Privacy Guard*, <https://gnupg.org/>.

that generated the signature must be connected to some actual person or entity, such as an email address, by a certificate. S/MIME certificates are issued by certificate authorities which are trusted by the email clients. It is easy for users to order S/MIME certificates and sign messages which are accepted by all clients. PGP as a product of the cypherpunk movement distrusts central authorities, so user IDs in PGP are only self-signed by default. This does not provide any protection against spoofing and puts responsibility for trust management into the hands of users and applications. In fact, no version of the OpenPGP standard defines a trust model for user ID binding signatures. Historically, users of PGP were encouraged to participate in the Web of Trust, a decentralized network of peers signing each other’s user IDs, paired with a scoring system to establish *trust paths* between two peers that want to communicate. Signatures and keys are exchanged through a network of public key servers. This approach has been found difficult to use, privacy invasive, and hard to scale, so some email clients implement their own trust model (e.g., OpenKeychain, R2Mail2, and Horde/IMP).

### 3 Attacker Model and Methodology

In our scenario we assume two trustworthy communication partners, Alice and Bob, who have securely exchanged their public PGP keys or S/MIME certificates. The goal of our attacker Eve is to create and send an email with arbitrary content to Bob whose email client falsely indicates that the email has been digitally signed by Alice.

**Attacker Model** We assume that Eve is able to create and send arbitrary emails to Bob. The email’s sender is spoofed to Alice’s address, for example, by spoofing the FROM header, a known impersonation technique which should be prevented by digital signatures. This is our default attacker model with the weakest prerequisites. It is sufficient for the UI attack class, and some CMS and GPG API attacks.

For the MIME attack class and some CMS attacks, we also assume that the attacker has a single valid S/MIME or OpenPGP signature from Alice which may have been obtained from previous email correspondence, public mailing lists, signed software packages, signed GitHub commits, or other sources. This is a weak requirement as well, because digital signatures are usually not kept secret. In fact, in many cases digital signatures are used explicitly to give public proof that some content was created by the signer.

For the ID attack class and one attack in the GPG API class, we assume that Bob trusts Eve’s signatures. For S/MIME this condition always holds because Eve can easily obtain a valid certificate from a trusted CA for her own email address. For OpenPGP, Bob must import Eve’s public key and mark it as valid. This is a stronger condition, but holds if Eve is a legitimate communication partner of Bob.

An overview of the attack classes and attacker models is given in Table 1. Each attack class is described in section 4 and the subscript identifies the specific attack, i.e.,  $M_1$  identifies attack 1 in the MIME attack class.

Attack class	Attacker Model		
	Mail only	Need signature	Key trusted
<b>CMS (4.1)</b>	$C_3, C_4$	$C_1, C_2$	–
<b>GPG (4.2)</b>	$G_1$	–	$G_2$
<b>MIME (4.3)</b>	–	$M_1, M_2, M_3, M_4$	–
<b>ID (4.4)</b>	–	–	$I_1, I_2, I_3$
<b>UI (4.5)</b>	$U_1$	–	–

Table 1: Attacker’s capabilities for all test cases in each attack class.

Our attacker model does not include any form of social engineering. The user opens and reads received emails as always, so awareness training does not help to mitigate the attacks.

**Methodology** We define that the *authenticity of a signed email is broken in the context of an email client UA* if the presentation of a crafted email in *UA* is indistinguishable from the presentation of a “valid” signed email (either as *perfect* or *partial* forgery). Furthermore, we document cases where we could forge *some, but not all* GUI elements required for indistinguishability (i.e., a *weak* forgery).

- **Perfect forgery (●)** If a presentation is identical at any number of user interactions, regardless of any additional actions the user takes within the application, we call the forgery “perfect” (e.g., Figure 1).
- **Partial forgery (◐)** If a presentation is only identical at the first user interaction (i.e., when an email is opened and the standard GUI features are visible), we call the forgery “partial” (e.g., Figure 14).
- **Weak forgery (○)** If a presentation contains contradicting GUI elements at the first user interaction, with some *but not all* elements indicating a valid signature, we call this forgery “weak” (e.g., Figure 15).

We suspect that partial forgeries already go unnoticed by unwitting users, so we classify perfect and partial forgeries as successful attacks. Weak forgeries show signs of spoofing at the first glance. As part of our evaluation, we provide screenshots of interesting cases to illustrate the differences.

**Selection of the Clients** We evaluate our attacks against 25 widely-used email clients given in Table 2 and Table 3. Of these, 20 support PGP and 22 are capable of S/MIME signature verification. They were selected from a comprehensive list of over 50 email clients assembled from public software directories for all major platforms (i.e., Windows, Linux, macOS, Android, iOS, and web). Email clients were

excluded when they did not support PGP or S/MIME signatures, were not updated for several years, or the cost to obtain them would be prohibitive (e.g., appliances). All clients were tested in the default settings with an additional PGP or S/MIME plugin installed, where required.

## 4 Attacks

### 4.1 CMS Attack Class

The Cryptographic Message Syntax (CMS, the container format used by S/MIME) is a versatile standard for signed and encrypted emails. It not only supports a broad range of use cases (e.g., multiple signers), but also copes with legacy problems like lack of software support and misbehaving gateways. This made the standard more complex; several values in a CMS object are optional, or may contain zero or more values.<sup>3</sup> Furthermore, two different signature formats are defined. This makes it difficult for developers to test all possible combinations (either plausible or implausible).

**Opaque and Detached Signatures** The CMS and S/MIME standards define two forms of signed messages: *opaque* and *detached* signatures [7] (also called *embedded* and *external* signatures). The signature is always a CMS object, but the corresponding message can either be embedded into this object or transmitted by other means.

When signing in opaque mode, the to-be-signed content (i.e., “the message text”) is embedded into the binary CMS signature object via a so called *eContent* (or “embedded content”) field (see Figure 2a).

In detached signatures, the *eContent* must be absent in order to signal that the content will be provided by other means. This is what the multipart/signed structure does; the email is split into two MIME parts, the first one is the content and the second one is the CMS signature without the *eContent* field (see Figure 2b).

**eContent Confusion (C<sub>1</sub>)** A confusing situation arises when the *eContent* field is present *even though* the multipart/signed mechanism is used. In this case, the client can choose which of the two contents (i.e., either the opaque or detached contents) to verify *and* which of the two contents to display. Clearly, it is a security issue when the verified content is not equal to the content which is displayed.

The “eContent Confusion” allows perfect forgeries of arbitrary signed emails for a person from which we already have a signed email. Because opaque signatures can be transformed into detached signatures and vice versa, any signed email will work for the attack.

<sup>3</sup>Here *optional* means potentially absent, which is different from present but empty.

```

1 From: Alice
2 To: Bob
3 Subject: Opaque signature
4 Content-Type: application/pkcs7-mime; smime-type=signed-data
5 Content-Transfer-Encoding: base64
6
7 <base64-encoded CMS object with eContent>

```

(a) A message with an opaque signature. The message is embedded in the CMS object and is not directly readable by a human.

```

1 From: Alice
2 To: Bob
3 Subject: Detached signature
4 Content-Type: multipart/signed; protocol="application/pkcs7-
5 signature"; boundary="XXX"
6
7 --XXX
8 Content-Type: text/plain
9
10 Hello, World! This text is signed.
11 --XXX
12 Content-Type: application/pkcs7-signature;
13 Content-Transfer-Encoding: base64
14
15 <base64-encoded CMS object without eContent>
16 --XXX--

```

(b) A message with a detached signature. The message is in the first MIME part and directly readable by a human. Legacy software tended to damage line endings or encoding in such emails, which broke the signature verification.

Figure 2: Opaque and detached signatures as used in S/MIME.

**Attack Refinement.** Although the *eContent* is not shown in the email client, it is easily revealed under forensic analysis that an old email was reused for this attack. Interestingly, the attack can be refined to remove the original content entirely without affecting the outcome of the signature verification.

Similarly to opaque and detached signatures, where an absent *eContent* signals that the content is provided somewhere else, CMS supports so called “signed attributes”, whose absence or presence signals what was signed. If a *signedAttrs* field is present, the signature covers the exact byte sequence of the *signedAttrs* field and not the content per se. If naively implemented, this would of course leave the content unauthenticated. Therefore, the *signedAttrs* field *must* contain a hash of the content [7]. If the *signedAttrs* field is absent, the signature covers the *eContent* directly.

This indirect signing allows the replacement of the original content with the exact byte sequence of the *signedAttrs* field without affecting the signature verification outcome. An email modified in this way will appear “empty” or contain seemingly “garbage” (because the *signedAttrs* is interpreted as ASCII). In either case, this can be used to hide where the old signature originated from. We consider this a noteworthy curiosity.

**Multiple Signers (C<sub>2</sub>)** S/MIME and CMS allow multiple signers in parallel to sign the same content [7]. Obviously, the outcome of the verification may differ for each signer

and the user interface should make that clear. However, it is reasonable to show a simplified version. We consider it a forgery if an *invalid* signature is marked as “valid” due to the presence of an unrelated valid signature.

**No Signers (C<sub>3</sub>)** A CMS signature object may contain zero or more signers. Although RFC 5652 gives limited advice regarding zero signers, it does not state explicitly what to do with “signed messages” without a signer.

**Trust Issues (C<sub>4</sub>)** In contrast to OpenPGP, S/MIME is built upon trust hierarchies. Certificates are authentic as long as they can be traced back to a valid root certificate. In practice, this means that most S/MIME certificates (in the Internet PKI) are indirectly trusted. However, clients must check the validity of the certificate chain. We consider it a forgery if a client accepts invalid certificates, such as self-signed certificates or otherwise untrusted or non-conforming certificates.

## 4.2 GPG API Attack Class

GnuPG, a stand-alone OpenPGP implementation, provides a stateful text-based command-line interface with approximately 380 options and commands. The complexity of the API and the need for consumers to parse GnuPG’s string messages provides a rich attack surface.

**GnuPG Status Lines** GnuPG provides a machine-readable interface by emitting *status lines* in a simple text-based format (see Figure 3), via the `--status-fd` option. Each status line starts with `[GNUPG:]` and one of approximately 100 possible keywords (such as `GOODSIG`), followed by additional text specific to the keyword.

Although some documentation exists, it does not cover all possible sequences of status lines and their significance for any given operation. In fact, due to streaming processing, the complexity of the API reflects the overall complexity of the OpenPGP message format. In particular, we note the following risk factors:

- The API contains text under the attacker’s control (e.g., the `<user-id>` in `GOODSIG`), which must be escaped to prevent injection attacks.
- The number and order of status lines depend on the OpenPGP packet sequence, which is under the attacker’s control. Applications must handle all combinations correctly that are allowed by GnuPG.
- The API is stateful, i.e., the semantics of a status line can depend on its position in the sequence. For example, the validity indicated by a `TRUST_*` line applies only to the signature started by the previous `NEWSIG`.

```

1 $ gpg --status-fd 2 --verify
2 [GNUPG:] NEWSIG
3 [GNUPG:] GOODSIG 88B08D5A57B62140 <alice@good.com>
4 [GNUPG:] VALIDSIG 3CB0E84416AD52F7E186541888B08D5A57B62140

5 [GNUPG:] TRUST_FULLY 0 classic

```

(a) Example output for a single trusted signature (excerpt).

```

1 NEWSIG [<signers-user-id>]
2 GOODSIG <key-id> <user-id>
3 BADSIG <key-id> <user-id>
4 VALIDSIG <fingerprint> <date> <create-timestamp> <expire-
   timestamp> <version> <reserved> <public-key-algorithm> <
   hash-algorithm> <signature-class> [<primary-key-
   fingerprint>]
5 TRUST_NEVER <error-token>
6 TRUST_FULLY [0 [<validation-model>]]
7 PLAINTEXT <format> <timestamp> <filename>
8 PLAINTEXT_LENGTH <length>

```

(b) Important status lines for signature verification from GnuPG.

Figure 3: Status lines output by GnuPG as a side-effect of streaming message processing.

- The use of the API requires a good understanding of OpenPGP and trust models as implemented in GnuPG. The `GOODSIG`, `VALIDSIG` and `TRUST_*` lines have very specific technical meaning that is not always apparent from the inconsistent terminology in the interface.
- By default, GnuPG runs in the context of the user’s home directory, using their configuration files and keyrings, which can influence the output of GnuPG within, and outside of, the status line API.

We focus our work on injection attacks and applications parsing the interface. First, we review the source code of GnuPG to identify places where an attacker could inject untrusted data at trusted positions in the API. Then we review all open source mail clients to identify exploitable mistakes in the API parser.

**In-band Injection Attacks (G<sub>1</sub>)** There are various places in the GnuPG status line API that contain untrusted data under the attacker’s control. For example, the `<user-id>` in a `GOODSIG` status line is an arbitrary string from the public key that can be crafted by an attacker. A naive idea is to append a newline character followed by a spoofed status line into the user ID of a public key. Normally, GnuPG protects against this naive attack by properly escaping special characters.

In addition to the status line API, we also review the logging messages for injection attacks. This is due to a common pattern, where applications using GnuPG conflate the status API and the logging messages by specifying the same data channel `stdout` for both (using the command line option `--status-fd 2`). Best practice requires separate channels to be used, but technical limitations can make this difficult for some plugins and cross-platform applications.

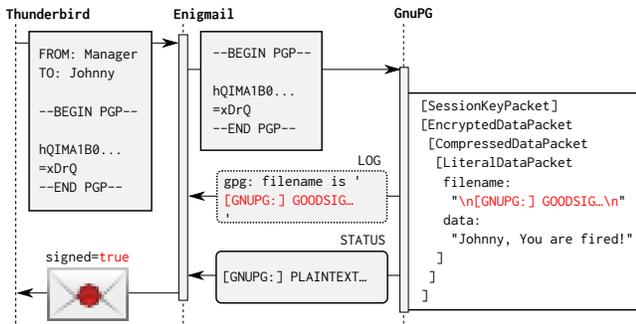

Figure 4: In-band injection of GnuPG status lines via log messages.

If an injection attack is successful, it can be very powerful, as the attacker can spoof the status lines entirely and provide arbitrary data to the application. Such spoofed status lines can include forged indications of a successful signature validation for arbitrary public keys. A valid PGP message containing the injection payload is showed in Figure 4.

**Attacks on Email Clients Using GPG ( $G_2$ )** The GnuPG interface provides only limited functionality; for example, it is not possible to validate a signature against a single public key in the keyring, but only against *all* public keys contained therein. Since this is insufficient for validating the sender of an email, GnuPG returns a string containing the user ID and the result of the validation. By manipulating this string, mail clients can be tricked into giving false validation results.

Applications using the GnuPG status line API have to parse the status lines and direct a state machine, keeping track of verification and decryption results under a wide range of different inputs, user configurations and GnuPG versions. Thus, application developers often use a common design pattern to deal with the complexity, such as: Iterating over all status line messages, parsing the details of those status lines that have information relevant to the task the application is interested in, and ignoring all other unknown or unsupported messages. This can lead to a number of serious vulnerabilities. For example, if an application is unprepared to handle multiple signatures, it might not reset the signature verification state at the NEWSIG status line, conflating the verification result of multiple signatures into a single result state. This might allow an attacker to add more signatures to an existing message to influence the result. Another example is the use of regular expressions that are not properly anchored to the status line API data format, thereby allowing an attacker to inject data that, although it is properly escaped by GnuPG, is then misinterpreted by the application.

### 4.3 MIME Attack Class

In this section we discuss attacks on how email clients handle partially signed messages in the case that the signed part is

wrapped within the MIME tree of a multipart message. For this class of attacks, the attacker is already in possession of at least one message and a corresponding valid signature from the entity to be impersonated. The obtained message can be in *Inline PGP*, *PGP/MIME*, or *S/MIME* as all formats can be embedded as sub-parts within a multipart message.

**Prepending Attacker’s Text ( $M_1$ )** Email clients may display a valid signature verification status even if only a single MIME part is correctly signed. In such a scenario of partially signed emails, the attacker can obfuscate the existence of the correctly signed original message within a multipart email. For example, this can be achieved by prepending the attacker’s message to the originally signed part, separated by a lot of newlines, resulting in a weak forgery.

**Hiding Signed Part with HTML ( $M_2$ )** Another option is to completely hide the original part with HTML and/or CSS, resulting in a perfect forgery. There are several ways to do this. One way occurs if the email client renders the output of multiple MIME-parts within a single HTML document presented to the user, then the signed part can simply be commented out, for example, using HTML comments. Furthermore, it can be embedded in (and therefore hidden within) HTML tags, or wrapped into CSS properties like `display:none`. An example for such a MIME-wrapping attack based on a hidden signed part is shown in Figure 5.

```

1 From: manager@work.com
2 To: johnny@work.com
3 Subject: Signed part hidden with CSS/HTML
4 Content-Type: multipart/mixed; boundary="XXX"
5
6 --XXX
7 Content-Type: text/html
8
9 Johnny, you are fired!
10 <div style="display:none"><plaintext>
11
12 --XXX
13 ---BEGIN PGP SIGNED MESSAGE---
14 Hash: SHA512
15
16 Congratulations, you have been promoted!
17 ---BEGIN PGP SIGNATURE---
18 iQE/BAEBAgApBQJbWltqIhxCcnVjZSBXYXluZSA8YnJ1Y2V3YXluZTQ1...
19 ---END PGP SIGNATURE---
20
21 --XXX--

```

Figure 5: Signature spoofing attack based on MIME wrapping. The signed part is hidden by HTML/CSS, while the message “Johnny, You are fired!” is displayed by the email client.

**Hiding Signed Part in Related Content ( $M_3$ )** Even if there is a strict isolation between multiple MIME parts, it can be broken using `cid:` references (see RFC 2392). This can be achieved by constructing a `multipart/related` message consisting of two parts. The first MIME part contains

```

19 ---END PGP SIGNATURE---
20
21 --XXX--

```

Figure 6: Multipart email with a `cid:` reference to the signed part.

an attacker-controlled text and a `cid:` reference to the original signed part, which is placed into the second MIME part. An example email to demonstrate such an attack is given in Figure 6. It contains an HTML message part and a signed text which was written and published by Phil Zimmermann back in 2001.<sup>4</sup> The `cid:` reference enforces the signed (but invisible) part to be parsed by the mail client, which indicates a valid signature for the shown message (from the first part). This allows us to impersonate Phil Zimmermann<sup>5</sup> for arbitrary messages. A corresponding screenshot of Apple Mail (GPG Suite) is given in Figure 1 on the first page.

**Hiding Signed Part in an Attachment ( $M_4$ )** Even without using HTML, the originally signed part can be hidden by defining it as an attachment. This can be done by placing it into a sub-part with the additional header line shown below:

```
Content-Disposition: attachment; filename=signature.asc
```

## 4.4 ID Attack Class

In this section we discuss attacks on how email clients match a signed message to a sender’s identity. These attacks are less powerful than those previously discussed, because indistinguishability is rarely given at all levels of user interaction, i.e., many clients allow the user to check the signature details, which may reveal signs of manipulation.

**Not Checking If Sender=Signer ( $I_1$ )** When dealing with digital signatures, the question *Signed by whom?* is important. If Bob’s email client simply displayed “valid signature” for any PGP or S/MIME signed message, Eve could sign her

<sup>4</sup>P. Zimmermann, A (Inline PGP signed) note to PGP users, [https://philzimmermann.com/text/PRZ\\_leaves\\_NAI.txt](https://philzimmermann.com/text/PRZ_leaves_NAI.txt)

```

(d) SENDER and FROM headers.

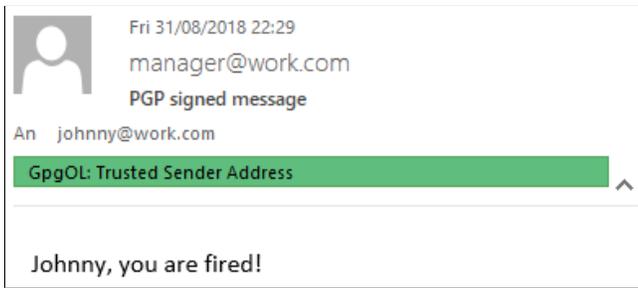

Figure 7: Examples how to fool signature verification logic if the PGP user ID or the Internet mail address in the signer’s S/MIME certificate is compared to sender address in the email header.

message and send it to Bob with Alice set as the sender. This is due to a lack of binding between the user ID from the signature and the address given in the FROM header.

**Display Name Shown as Signer ( $I_2$ )** There are two options to handle this problem. First, a mail client can explicitly display the signer’s identity somewhere in the UI and let the user compare it to the sender address. Second, the email client can check whether the signer’s identity (i.e., email address) equals the sender’s address, and show a warning if this is not the case. The second option gives a lot of room for attacks; RFC 2632 for S/MIME signed messages states that “receiving agents *must* check that the address in the From or Sender header of a mail message matches an Internet mail address in the signer’s certificate”. However, in practice email clients can only check if the FROM header *contains* the signer’s email address because RFC 5322 allows additional display names to be associated with a mailbox (e.g., Name <foo@bar>). If an email client only shows the display name to the user, Eve can simply set *Alice* as display name for her own sender address (see Figure 7a). Also, in such a scenario the display name itself could be set to an email address such as *alice@good.com* that is presented to the user, see Figure 7b.

An example screenshot for Outlook, which required additional effort, is given in Figure 8a. The source code of this mail can be found in Figure 8b. While Outlook always shows the full sender address (*eve@evil.com*), it can simply be “pushed out of the display” by appending a lot of whitespaces to the display name (*manager@work.com*).

**From/Sender Header Confusion ( $I_3$ )** Another problem is how email clients deal with multiple FROM fields in the mail header—especially if PGP or S/MIME support is not implemented directly by the email client, but offered through a

(a) Screenshot of a spoofed PGP signed message in Outlook which was actually signed by the attacker (*eve@evil.com*).

Figure 8: PGP signature spoofing attack against Outlook/GpgOL, based on the RFC 5322 display name shown as the signer’s identity.

third-party plugin—as there may be different implementations on how to obtain the sender address of an email. For example, the email client could display the email address given in the first FROM header while the plugin would perform its checks against any occurrence of this header field (see Figure 7c). Also, the plugin could respect the SENDER header in its checks which “specifies the mailbox of the agent responsible for the actual transmission of the message” [8] while the mail client would display the email address taken from the FROM email header (see Figure 7d). Note that if Eve sets an additional Reply-to: *alice@good.com* header, which instructs the email client to reply to Alice, such attacks go unnoticed by Bob when replying to the email. They can, however, be detected in most clients by reviewing the signature details and spotting Eve as the real signer.

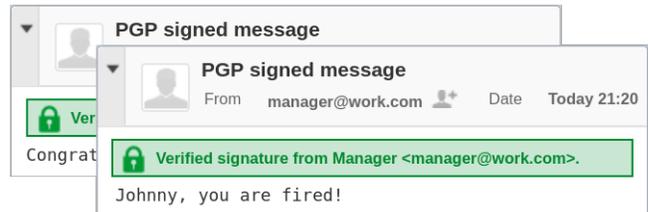

#### 4.5 UI Attack Class ( $U_1$ )

In this section, we discuss UI redressing attacks that exploit the presentation of signature verification results to the user. The attacks are successful if the spoofed message is indistinguishable from a message with a real valid signature.

This attack class exploits that various email clients display the status of the signature within the email content itself. This part of the UI is under the control of the attacker.

With HTML, CSS, or inline images it is easy to reproduce security-critical UI elements displaying a “valid signature”.

Figure 9a shows a signed and a spoofed email in Roundcube. The spoofed email is based on displaying a valid signature indicator with HTML and CSS (an example of UI redressing). The HTML code is provided in Figure 9b.

(a) Two emails with visually indistinguishable signature indicators. One is PGP-signed, the other is a specially crafted HTML email.

## 5 Evaluation

Of the tested 20 clients with PGP support, 15 use *GnuPG* to verify signatures and call it either directly, or through some kind of plugin such as *Enigmail*<sup>6</sup> or *GPG Suite*,<sup>7</sup> or by using the *GPGME*<sup>8</sup> wrapper library. The remaining clients use *OpenPGP.js*,<sup>9</sup> *OpenKeychain*,<sup>10</sup> or a proprietary solution. Of the tested 22 clients with S/MIME support, only five require third party plugins. The results of signature spoofing attacks tested on the various email clients are shown in Table 2 for OpenPGP and in Table 3 for S/MIME.

The results of our evaluation show a poor performance of the overall PGP and S/MIME ecosystems when it comes to trustworthiness of digital signatures; for ten OpenPGP capable clients and seven clients supporting S/MIME we could spoof visually indistinguishable signatures on all UI levels (resulting in perfect forgeries). On four additional OpenPGP

<sup>6</sup>P. Brunswick, *Enigmail*, <https://enigmail.net/>

<sup>7</sup>L. Pitschl *GPG Suite*, <https://gpptools.org/>

<sup>8</sup>W. Koch, *GPGME*, <https://github.com/gpg/gpgme>

<sup>9</sup>ProtonMail, *OpenPGP.js* <https://openpgpjs.org/>

<sup>10</sup>Cotech, *OpenKeychain*, <https://openkeychain.org/>

capable clients and eight clients supporting S/MIME, we could spoof visually indistinguishable signatures on the first UI level (resulting in partial forgeries). While none of the attacks directly target the underlying cryptographic primitives, the high success rate raises concerns about the practical security of email applications. We discuss the results for each class of attack in this section. We also published proof-of-concept attack emails and screenshots of partial and weak forgeries in a public repository.<sup>11</sup>

## 5.1 CMS Attack Class

**eContent Confusion (C<sub>1</sub>)** We found that Thunderbird, Postbox, MailMate, and iOS Mail are vulnerable to eContent confusion. Given a valid S/MIME signature for a specific user, this allows a perfect forgery for any message of this user. Note that opaque signed emails can be transformed into detached signed emails and vice versa. Thus, having *any* signed email from a target is enough to forge an arbitrary number of new messages. Mozilla assigned CVE-2018-18509 to this issue.

**Multiple Signers (C<sub>2</sub>)** Evolution coerces multiple signers into one “valid signature” UI element (see Figure 10). However, the UI reveals the erroneous signature upon further inspection of the UI. By definition, this is a partial forgery.

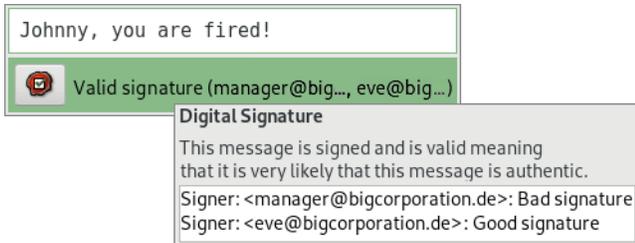

Figure 10: This email has two signers. The first signer did not sign this email. Evolution coerced both signers into one security indicator showing “valid signature”. (Minor details were removed from the screenshot to make it smaller.)

**No Signers (C<sub>3</sub>)** In the case of no signers, three email clients, namely Outlook, Mutt, and MailDroid, show some UI elements suggesting a valid signature and some UI elements doing the opposite. We consider this a weak forgery, because there is no clear indication that signature validation has succeeded/failed. In Outlook an otherwise very prominent red error bar is not shown and a seal indicates a valid signature (although it should show a warning sign), see Figure 11. Interestingly, clicking through the UI in Outlook may *strengthen* the illusion of a validly signed message because of the wording in the subdialogs.

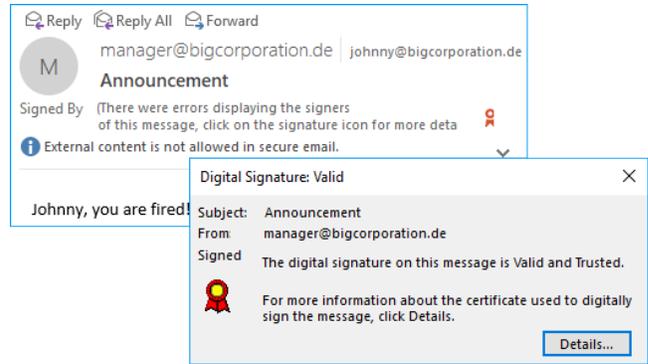

Figure 11: “Signed email” in Outlook with no signers at all.

**Trust Issues (C<sub>4</sub>)** Although none of the clients accepted “extended certificates”, i.e., certificates re-signed by a leaf certificate with no `CA=true` flag, we observed that Trojitá and Claws display conflicting UI elements on untrusted certificates (i.e., “success: bad signature”). Nine and MailDroid do not display information about the origin of a certificate on the first level of the UI. This means that, although there are security indicators suggesting a signed email, the origin may be completely untrustworthy, resulting in partial forgery.

## 5.2 GPG API Attack Class

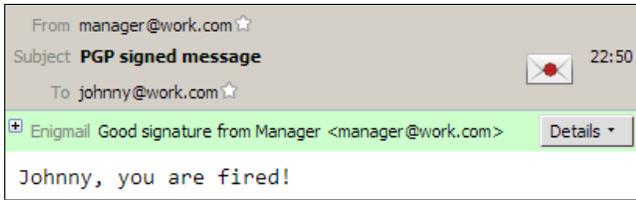

We found an injection attack for the “embedded filename” log message in GnuPG, as well as several issues in Enigmail’s status line parser and state machine.

**Status Line Injection through Embedded Filename (G1).** OpenPGP Literal Data Packets, which contain the actual plaintext of a message, contain some metadata, in particular an *embedded filename* that is usually set by the sender to the original filename of a signed or encrypted file. We found that GnuPG’s logging message for the embedded filename does not escape newline and other special characters. If an application combines the logging messages with the status line API in a single data channel, an attacker can use the embedded filename to inject arbitrary status lines (up to 255 bytes, which can be sufficient to spoof the GOODSIG, VALIDSIG and TRUST\_FULLY lines for a single signature). Figure 12b shows the injected text highlighted. The successful attack is shown in Figure 12a.

Using this attack, we were able to spoof arbitrary signature verification results in Enigmail, GPG Suite, and Mailpile.<sup>12</sup> The attack only assumes our weakest attacker model, as all relevant status lines can be injected into the embedded filename. In fact, the message does not even need to be signed at all; the attack, however, has the additional requirement

<sup>12</sup>Manual signature verification using GnuPG on the command line is also affected; the embedded filename can contain arbitrary terminal escape sequences, allowing the attacker to overwrite any part of the terminal.

Figure 12: Status line injection attack on GnuPG.

that the user has enabled the verbose configuration option. This option is not enabled by default, but it is often used by experts and part of several recommended GnuPG settings.

The vulnerability is present in all versions of GnuPG until 2.2.8. Our finding is documented as CVE-2018-12020. Due to the severity of the attack, we also reviewed non-email applications for similar vulnerabilities, see subsection 7.5.

### State Confusion and Regular Expressions in Enigmail (G2).

We found two flaws in the way Enigmail handles status messages for multiple signatures:

- If the status of the *last* signature is GOODSIG, EXPKEYSIG, or REVKEYSIG, Enigmail will overwrite the signature details (e.g., fingerprint, creation time, algorithms) with those from the *first* VALIDSIG, confusing the metadata of two signatures. The attacker can change the state of a signature to good, expired, or revoked by adding a corresponding second signature.
- If *any* of the signatures is TRUST\_FULLY or TRUST\_ULTIMATE, and the last signature is good, expired, or revoked, then Enigmail will display the information from the first VALIDSIG as trusted.

We also found regular expressions that were not anchored to the beginning of status lines. This allows for injection of fake VALIDSIG and other status lines in malicious user ID strings. Combining this with the above, this allows an attacker to control the signature details completely. The attack involves two signatures on a single message, which Enigmail combines in a complex way to a single signature that is shown to the user. We assume that the attacker is trusted, and further assume that the attacker can poison the user’s keyring with arbitrary untrusted keys. This is not a strong assumption

because in PGP the local keyring is just an insecure cache of public keys. For example, the attacker might rely on automatic key retrieval from public key servers or include the key as extra payload when sending her regular public key to Bob.

The *first signature* in the attack is by a key with a malicious user ID, crafted by the attacker, that injects a spoofed VALIDSIG status line. Because Enigmail processes this line twice using different parsers, some information needs to be duplicated to make the attack work. The *second signature* is a regular valid signature over the same message by the trusted attacker’s key. This signature sets the global flag in Enigmail indicating that a signature is made by a trusted key, but otherwise it is completely ignored. Figure 13 shows which data in the attack is used by Enigmail. The fingerprint will be used to resolve further details such as the user ID of the (spoofed) signing key. The vulnerability is present in all versions of Enigmail until 2.0.7, affecting Thunderbird and Postbox. Our finding is documented as CVE-2018-12019.

## 5.3 MIME Attack Class

On five PGP email clients, including popular products such as Thunderbird and Apple Mail, we could completely hide the original signed part (resulting in perfect forgeries) using multiple techniques, such as wrapping it into attacker-controlled HTML/CSS ( $M_1$ ), referencing it as an “image” ( $M_2$ ), or hiding it as an “attachment” ( $M_3$ ). On another three clients we could only obfuscate the original signed message part (resulting in weak forgeries) by appending it and using a multitude of newlines to cover its existence ( $M_4$ ). Our findings are documented as CVE-2017-17848, CVE-2018-15586, CVE-2018-15587, and CVE-2018-15588.

Our evaluation shows that S/MIME is less vulnerable to signature wrapping attacks by design; all but one tested email clients only show a valid signature verification if the whole email including all sub-parts is correctly signed (i.e., Content-Type: multipart/signed is the root element in the MIME tree). Unfortunately, it seems hard to get rid of partially signed emails or mark them as suspicious, as can be done for partially encrypted messages – a countermeasure Enigmail applied to the EFAIL attacks [9] – because in the PGP world, partially signed is quite common (e.g., mailing lists, forwards, etc.). There seems to be a different philosophy in the S/MIME world; for example, S/MIME forwarding

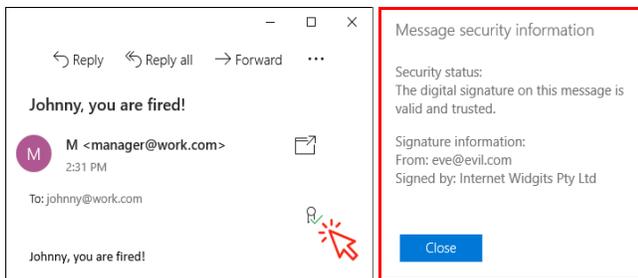

Figure 14: Partial forgery in the Windows 10 mail app. The email is actually signed by Eve which is only visible in the signature details.

intentionally breaks the signature because the forwarding entity should re-sign the message.

## 5.4 ID Class

Eleven PGP email clients and twelve S/MIME clients explicitly show the signer’s identity (i.e., PGP user ID or Internet mail address in the signer’s S/MIME certificate) when receiving a signed email. This can be considered safe because a user gets direct feedback regarding the *signed by whom?* question. The other clients do not show the signer’s identity on the first level of the UI. Of those, two PGP email and three S/MIME mail clients, such as the Windows 10 mail app (see Figure 14), do not perform any correlation between the sender address and the signer’s identity at all. They only show “signed” with no further information, making them easy targets for ID attacks (resulting in partial forgeries). The other seven PGP email clients and eight S/MIME clients compare the sender’s address to the email address found in the public key or certificate matching the signature. This process is error-prone. For four PGP email clients, including GpgOL for Outlook, and eight S/MIME email clients, the correlation could be fully bypassed using the various techniques described in subsection 4.4. If Bob does not manually view the signature details, there is no indicator that the email was signed by Eve instead of Alice (resulting in partial forgery). For two of these clients (GpgOL for Outlook and Airmail) no signature details were available, resulting in perfect forgery.

## 5.5 UI Attack Class

Five tested PGP email clients and four S/MIME clients display the status of signatures within the email body, which is a UI component controlled by the attacker. This allowed us to create fake text or graphics implying a valid signature using HTML, CSS and inline images visually indistinguishable from a real signed message. Only further investigation of the email, such as viewing signature details, could reveal the attack (resulting in partial forgery). Three of these clients do not even have an option for further signature details, re-

sulting in perfect forgery. Spoofing signatures was especially easy for clients where the PGP or S/MIME plugin simply injects HTML code into the email body. We could just copy the original HTML snippet of a valid signature and re-send it within the body of our spoofed email.

Another seven PGP clients and nine S/MIME clients show the results of signature verification in, or very close to, the email body and could be attacked with limitations (causing weak forgeries). Some of these clients have additional indicators in other parts of the UI pointing out that the email is actually signed, but those indicators are missing in the case of spoofed signatures based on UI redressing (see Figure 15). Furthermore, in some of these clients the spoofed signature was not 100% visually indistinguishable.

## 6 Countermeasures

Similarly to other RFC documents, S/MIME [10] and OpenPGP [6] contain a section on *security considerations*. While these sections discuss cryptographic best practices (e.g., key sizes and cryptographic algorithms), they do not discuss how to design secure validation routines and interfaces. In this section, we discuss several possible countermeasures against the presented attacks in order to give guidance for implementing secure email clients.

### 6.1 CMS Attack Class

**eContent Confusion (C<sub>1</sub>)** Both S/MIME signing variants are commonly used<sup>13</sup> and standard compliant clients are expected to support them. Thus, special care must be taken to only display the content which was subject to verification.

The relevant standards, RFC 5652 (CMS) and RFC 5751 (S/MIME), do not give any advice on how to handle the case where both variants are present. We recommend to display neither of them and show an error instead. In fact, Claws reports a “conflicting use”.

<sup>13</sup>Outlook 2016 sends opaque signed messages by default and Thunderbird sends detached messages by default.

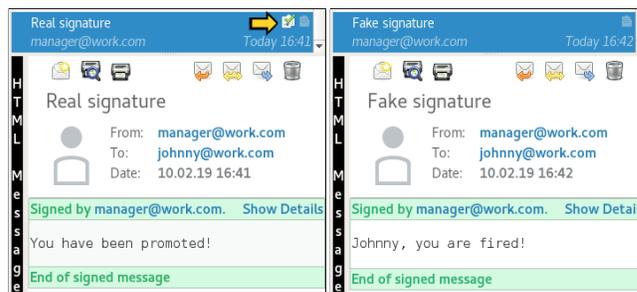

Figure 15: “Weak” forgery in KMail. The check mark UI indicator in the upper right cannot be spoofed using simple UI redressing.

●	Indistinguishable signature on first UI level (partial forgery)			–	No vulnerabilities found		

Table 2: Out of 20 tested email clients 14 were vulnerable to our OpenPGP signature spoofing attacks (perfect or partial forgery).

**Disallow Multiple Signers ( $C_2$ )** It is difficult to give good advice on the presentation of multiple signers, as different clients may implement different UI concepts. Furthermore, introducing UI elements might worsen the usability or introduce security problems on its own (e.g., UI redressing).

However, a simple solution is to not implement multiple signer support at all. Many up-to-date clients do not support multiple signers, e.g., Thunderbird and Outlook 2016. Additionally, we know of no client which is able to *produce* a message with multiple signers. Thus, it seems reasonable to us to not support this feature.

**Error Out If No Signers ( $C_3$ )** Messages with no signer should be treated as erroneous or as not signed. In either case there should be no UI element indicating a signed message. We recommend to not show the message and show an error instead. This is due to the possible application of signature stripping attacks as demonstrated by [11] and [9].

**Redesign Trust Management and Workflow ( $C_4$ )** Clients must validate the complete certification path and fail the signature verification on trust issues. Furthermore, certificates should be checked automatically. Clients must not accept self-signed certificates. If needed, a separate trust chain should be configured on the device or in the application.

## 6.2 GPG API Attack Class

GnuPG developers can improve the documentation and the API, but they have to consider backwards compatibility and extensibility. GnuPG must track attacker controlled data and always escape newlines and other special characters in all outputs. GnuPG should also validate the structure of OpenPGP messages and provide clear guidelines on how to achieve common tasks such as certificate pinning.

Frontend developers can harden the invocation of the backend (e.g. by using dedicated channels for log and status lines or adding `--no-verbose` to disable logging), their status line parsers (e.g., by anchoring all regular expressions), and the state machine aggregating the results (e.g., by keeping track of multiple signatures, as indicated by NEWSIG). However, applications that are too strict risk incompatibilities with future backend upgrades or unconventional user configurations.

The OpenPGP standard should be updated to provide a strict grammar for valid message composition, as the present flexibility (such as arbitrary nesting of encrypted, signed, and compressed messages) is unjustified in practice and puts the burden on implementations to define reasonable limits. Specifically, the OpenPGP standard should only allow one optional encryption layer, one optional compression layer, and one possibly signed literal data packet. More complex message composition (e.g., sign+encrypt+sign to allow for

early spam mitigation) may be desirable for certain applications in the future. These should then be covered in future standard revisions to ensure that they can be supported without introducing new risk factors. Until then, they can be supported either by nesting several distinct messages explicitly or as non-standard extensions that are disabled by default in compliant implementations.

### 6.3 MIME Attack Class

There are two approaches to counter signature spoofing attacks on partially signed messages which are hidden in the MIME tree. Either email clients should show exactly which part of the message was signed, for example, by using a green frame. However, note that this is hard to implement in a secure way because all edge cases and potential bypasses, such as internal `cid:` references, need to be considered, and it must be made sure that the frame cannot be drawn by the attacker using HTML/CSS. Or email clients should be conservative and only show a message as correctly signed if the whole message (i.e., the MIME root) was correctly signed. While this will break digital signatures in some mailing lists and in forwarded emails, such an *all-or-nothing* approach

can be considered as more secure and is preferred by the authors of this paper. Furthermore, if the signature contains a timestamp, it should be shown to the user to draw suspicion on re-used and wrapped old signatures. For incoming new messages the timestamp could be compared to the current system time and an alert could be given if the signature contains a timestamp older than a certain threshold. This can also protect from attacks such as non-realtime surreptitious forwarding.

### 6.4 ID Attack Class

Approaches to encrypted and digitally signed email headers like Memory Hole [12] (a non-standard OpenPGP extension) or RFC 7508 (Securing Header Fields with S/MIME) aim to guarantee a cryptographic binding between the signature and the sender address. However, few email clients support these standards. Furthermore, clients supporting Memory Hole (Thunderbird/Enigmail, R2Mail2) still accept signed emails without header protection for backwards compatibility.

Even worse, Enigmail did not guarantee consistency between unprotected email headers and headers protected by Memory Hole in our tests. Clients remain vulnerable to ID

attacks unless further mitigations are applied. Hence, it can be considered a good practice to explicitly show the signer user IDs when displaying a PGP signed message. A comparison to the FROM or SENDER header fields may not be sufficient because—as our evaluation shows—that approach is error prone and hard to implement in a secure way.

## 6.5 UI Attack Class

The results of signature verification should not be shown in attacker-controlled parts of the UI, such as the message content itself, which may contain arbitrary graphics. In the context of webmail and native email clients using HTML5 for their UI, such as Electron<sup>14</sup> or XUL,<sup>15</sup> it must be ensured that there is a strict isolation (e.g., separate DOM) between the message content and the rest of the UI. Otherwise, it may be possible to influence the appearance of the UI, for example by injecting CSS properties into the message content. Following the example of browsers with regard to HTTPS, the trend is to avoid positive UI indicators and only show indicators if something is wrong. These systems aim to be secure by default. However, this is obviously infeasible for email signatures as long as most emails are unsigned.

## 7 Additional Findings

### 7.1 Crashes

We discovered multiple crashes during testing. For example, we found a nullpointer dereference in Mozilla’s NSS library, which is also used in Evolution and Postbox. Although the security impact is rather low, sending a specifically crafted email does lead to a permanent denial of service, as email clients will cache this email and crash upon startup. We experienced a similar issue with iOS Mail, but did not evaluate the origin of the crash. Additionally, we observed crashes in MailMate, R2Mail2, Maildroid (Exception), Roundcube, and Windows 10 Mail.

### 7.2 Airmail Accepts Invalid PGP Signatures

We found that the Airmail GPG-PGP plugin does not properly validate OpenPGP signatures, accepting even invalid ones, irregardless of their status. This makes signature spoofing attacks trivial.

Also, Airmail does not correctly verify the validity of the signing key even for good signatures, allowing impersonation attacks by injecting public keys into the user’s keyring with the email address that should be spoofed.

The vulnerability is present in all versions of Airmail GPG-PGP until "1.0 (9)". Our finding is documented as CVE-2019-8338.

<sup>14</sup>GitHub Inc., *Electron*, <https://electronjs.org/>

<sup>15</sup>Mozilla Foundation, *XUL*, <https://developer.mozilla.org/XUL>

## 7.3 OpenPGP Message Composition Attacks

OpenPGP messages and keys are sequences of (possibly nested) packets (see Fig. 16). This structure is under control of the attacker, so it must be validated by the implementation. According to the OpenPGP standard, any arbitrary nesting of encryption, compression, and signatures is allowed without restrictions. This flexibility is unjustified, and seems to be an oversight in the specification, as only a small number of combinations are actually meaningful in practice. It also opens PGP up to vulnerabilities such as decompression attacks [13]. In practice, implementations must enforce additional limits; for example, GnuPG allows up to 32 levels of nesting.

```
[SessionKeyPacket]
[EncryptedDataPacket
 [CompressedDataPacket
  [OnePassSignaturePacket]
  [LiteralDataPacket]
  [SignaturePacket]
 ]
]
```

(a) Example structure of an OpenPGP message that is signed with one signing key, compressed, and encrypted to one recipient key.

```
message :- encrypted | signed | compressed | literal.
encrypted :- SessionKeyPacket*, EncryptedDataPacket(message).
signed :- OnePassSignaturePacket, message, SignaturePacket.
compressed :- CompressedDataPacket(message).
literal :- LiteralDataPacket.
```

(b) Grammar for OpenPGP message composition from RFC 4880 (simplified excerpt). This grammar does not include rules for compatibility with older PGP versions.

Figure 16: Valid OpenPGP message and its grammar specification.

Status lines are emitted by GnuPG as packets are processed recursively. However, the status lines do not represent packet boundaries nor the depth of nesting. As a consequence, the status interface is a flat projection of the nested structure, and some information is lost in the process.

**Message Composition Attacks** GnuPG outputs status lines as a side-effect of recursive processing of packets in OpenPGP messages. This has led to signature spoofing attacks in the past, where an attacker can prepend or append additional unsigned plaintext to a message [14]. We verified that current versions of GnuPG handle this correctly, and could not find any similar issues for signature verification.

**Encryption Spoofing** Some attacks to spoof signature verification can also be used to spoof decryption results, causing the email client to indicate an encrypted message where in fact the plaintext was transmitted in the clear. Although by itself this is not a security violation, it is concerning and might be a precursor or building stone for other attacks.

Besides the obvious adaptation of our UI redressing and status line injection attacks, we found a flaw in the message composition verification of GnuPG. Since 2006 [14], GnuPG only allows at most one plaintext (i.e., one Literal Data Packet) in a message. However, GnuPG does not verify that the plaintext of an encrypted (non-conforming) message is actually contained within the encrypted part of the message. By replacing the plaintext in an Encrypted Data Packet with a dummy packet ignored by GnuPG (the OpenPGP standard makes a provision for private/experimental packet types), and prepending or appending the (unencrypted) Literal Data Packet, we can cause GnuPG to output the same status lines as for a properly encrypted message, excluding the order. The following output shows the result for a properly encrypted message (differences in red and bold):

```

1 [GNUPG:] BEGIN_DECRYPTION
2 [GNUPG:] PLAINTEXT 62 0
3 [GNUPG:] DECRYPTION_OKAY
4 [GNUPG:] END_DECRYPTION

```

The next output shows the result for an empty Encrypted Data Packet, followed by a Literal Data Packet in the clear:

```

1 [GNUPG:] BEGIN_DECRYPTION
2 [GNUPG:] DECRYPTION_OKAY
3 [GNUPG:] END_DECRYPTION
4 [GNUPG:] PLAINTEXT 62 0

```

Both messages are displayed identically (resulting in a perfect forgery) in Thunderbird, Evolution, Mutt, and Outlook, revealing the flexibility of the PGP message format, GnuPG's parser, and the GnuPG status line parsers in email client applications.

## 7.4 Short Key PGP IDs

Short key IDs of 32 bit (the least significant 4 bytes of the fingerprint) were used in the PGP user interface, on business cards, by key servers, and other PGP-related utilities in the past until pre-image collisions were demonstrated to be efficient in practice [15]. Unfortunately, the Horde/IMP email client still uses short key IDs internally to identify public keys and automatically downloads them from key servers to cache them in internal data structures. Our attempts to exploit these collisions for ID attacks were inconsistent due to caching effects, which is why we did not include these attacks in the evaluation. Horde/IMP should mitigate these attacks by using full-length fingerprints to identify PGP keys.

## 7.5 GPG API Attacks Beyond Email

Based on source code searches on GitHub<sup>16</sup> and Debian,<sup>17</sup> we looked for software applications or libraries other than email clients which might be susceptible to API signature spoofing attacks. Candidates were programs that invoke

<sup>16</sup>GitHub Code Search, <https://github.com/search>

<sup>17</sup>Debian Code Search, <https://codesearch.debian.net/>

GnuPG with `--status-fd 2`, thereby conflating the logging messages with the status line API, and programs that do not correctly anchor regular expressions for status lines (involving `[GNUPG:]`). We identified three broad classes of programs using the GnuPG status line API: (1) Wrapper libraries that provide an abstraction layer to GnuPG, usually for particular programming languages. (2) Applications using certificate pinning to verify the integrity of files when stored under external control (cloud storage), including version control systems like Git. (3) Package managers that use GnuPG for integrity protection of software packages.

We found vulnerable software in all three categories, but due to the large number of libraries and applications using GnuPG, we could not yet perform an extensive review. Also, we found that the available code search engines are not a good match for the task of identifying applications calling an external application through a shell interface. We therefore fear that there may still be a significant number of vulnerable applications using GnuPG out there.

**Python-GnuPG** Python-gnupg<sup>18</sup> is a library interface to GnuPG for the Python language. It uses the status line interface and conflates it with the logging messages, making 717 applications using it<sup>19</sup> potentially susceptible to the embedded filename injection attack described above, depending on how and in which context they use the Python library.

**Bitcoin Source Code Repository Integrity** The Bitcoin project uses the Git version control system, which supports signatures on individual software patches to verify the integrity of the whole repository as it changes over time. A shell script using GnuPG to verify the integrity of all commits is included in the distribution.<sup>20</sup> This script uses the status line API and does not anchor the regular expressions, making it susceptible to the malicious user ID injection attack described above. An attacker who can inject arbitrary keys into the keyring of the user can simply re-sign modified source code commits and thus bypass the verification script.

The Bitcoin source code is frequently used as the basis for other crypto-currencies,<sup>21</sup> and thus this error may propagate to many other similar projects such as Litecoin.

**Signature Bypass in Simple Password Store** Pass<sup>22</sup>, a popular password manager for UNIX, uses the GnuPG status line API to encrypt password files and digitally sign configuration files and extension plugins. It does not anchor the regular expressions, making it susceptible to the malicious

<sup>19</sup>According to *libraries.io*, <https://libraries.io/pypi/python-gnupg/usage>

<sup>20</sup>Bitcoin Source Code, <https://github.com/bitcoin/bitcoin/blob/master/contrib/verify-commits/gpg.sh>

<sup>21</sup>According to *GitHub* the Bitcoin code has 21379 forks as of Nov. 2018

<sup>22</sup>J. A. Donenfeld, *pass*, <https://www.passwordstore.org/>

user ID injection attack described above. If `pass` is used to synchronize passwords over untrusted cloud storage, an attacker with control over that storage can add their public key to the configuration, which causes `pass` to transparently re-encrypt the passwords to the attacker's key (in addition to the user's key) over time. Also, if extension plugins are enabled, the attacker can get remote code execution. This finding is documented as CVE-2018-12356.

**Yarn Package Manager** Yarn is a package manager by Facebook for the JavaScript runtime Node.js. The Yarn installer script<sup>23</sup> primarily relies on TLS to secure the integrity of the installation package itself. However, it also attempts to use GnuPG signature verification, presumably to secure the integrity of the installer from the build server to the download server, which can be different from the server that hosts the installer script (e.g., for nightly builds).

Unfortunately, Yarn fails to do any form of certificate pinning or trust management, and will accept any valid signature by any key in the local keyring, even by untrusted keys. If the attacker can inject a public key into the user's keyring, and perform a MiTM attack against one of Yarn's download servers, the attacker can replace the installation package with one containing a backdoor, thereby gaining remote code execution on the user's machine. This finding is documented as CVE-2018-12556.

## 7.6 Unsuccessful Cryptographic Attacks

We analyzed 19 of 20 OpenPGP email clients from Table 2 (all but Airmail, which we could not test, see subsection 7.2) and all 22 email clients supporting S/MIME signatures from Table 3 if they are vulnerable to well-known attacks on the PKCS#1v1.5 signature scheme for RSA with exponent  $e = 3$ . Specifically, we checked for mistakes in the handling of the padding [16] and ASN.1 structures [17]. All tested clients resisted our attempts.

## 8 Related Work

The OpenPGP standard [6] only defines how to sign the email body. Critical headers such as SUBJECT and FROM are not signed if no further extensions, such as Memory Hole [12], Secure Header Fields [18] or XML-based techniques as described in [19], are applied. Levi et al. [20] developed a GUI for users to better understand the limitations of S/MIME digital signatures for emails, i.e., showing which parts of the email are actually signed by whom. Usability papers such as [21] discuss the difficulties that inexperienced users have to manually verify the validity of a signature and understand the different PGP trust levels.

<sup>23</sup>Yarn installer script, <https://yarnpkg.com/install.sh>

It is well known that messages signed by a certain entity can be reused in another context. For example, a malicious former employer in possession of a signed “I quit my job” message by Alice can simply re-send this message to Alice's new employer. Such attacks have been referred to as “surreptitious forwarding” in 2001 by Davis [22] who also showed how to strip signatures in various encryption schemes. Gillmor [23] touches upon the problems of partially-signed Inline PGP messages as well as non-signed attachments and the UI challenge such constructs present for MUAs. Furthermore, he demonstrates a message tampering attack through header substitution: by changing the encoding, a signed message with the content *€13/week* can be presented as *£13/week*, while the signature remains valid.

Recently, Poddebniak et al. [9] described two attacks to directly exfiltrate the plaintext of OpenPGP encrypted messages. One works by wrapping the ciphertexts into attacker-controlled MIME parts. This is related to our MIME wrapping attacks on signatures, as both techniques exploit missing isolation between multiple MIME parts. However, we present attacks which do not require mail clients to put trusted and untrusted input into the same DOM, using advanced approaches such as `cid: URI` scheme references.

GnuPG had signature spoofing bugs in the past. In 2006, it was shown that arbitrary unsigned data can be injected into signed messages [14]. Until 2007, GnuPG returned a valid signature status for a message with arbitrary text prepended or appended to an Inline PGP signature, allowing an attacker to forge the contents of a message without detection [24].

In 2014, Klafter et al. [15] showed practical collisions in 32-bit PGP key IDs, named the “Evil 32” attack, which can be dangerous in case a client requests a PGP key from a key-server using the 32-bit ID. Collisions with 64-bit IDs are also feasible but require more computing power, therefore only full 160-bit fingerprints should be used.

“Mailsploit” [25] enables attackers to send spoofed emails, even if additional protection mechanism like DKIM are applied, by abusing techniques to encode non-ASCII chars inside email headers as described in RFC 1342. In 2017, Ribeiro [26] demonstrated that CSS rules included in HTML emails can be loaded from a remote source, leading to changes in the appearance of—potentially signed—emails after delivery.

Our partial (●) and weak (○) forgery attacks can potentially be detected by carefully inspecting the GUI or manually clicking to receive more signature details. A user study analyzing user behavior would be necessary to reveal the real impact of such inconsistencies. Lausch et al. [27] reviewed existing cryptographic indicators used in email clients and performed a usability study. With their 164 “privacy-aware” participants they were able to select the most important indicators. They argue that further research with participants with general skills should be performed in the future work. It would be interesting to extend this user study with specific

corner cases from our paper. Similar studies were performed to analyze the usage of TLS indicators in web browsers. Schechter et al. performed laboratory experiments where they analyzed user behavior in respect to different browser warnings [28]. For example, they found out that all 63 tested users used their banking credentials on banking websites delivered over pure HTTP. Sunshine et al. [29] performed a study on SSL warning effectiveness. Their conclusion is that blocking unsafe connections and minimizing TLS warnings would improve the warning effectiveness and user security. Felt et al. studied TLS indicators in different browsers, including Chrome, Firefox, Edge, and Safari [30]. They performed a user study with 1329 participants to select the most appropriate indicators reporting positive as well as negative TLS status. The selected indicators have then been adopted by Google Chrome. Other researchers concentrated on special cases like the evaluation of Extended Validation certificates [31] or TLS indicators in mobile browsers [32].

## 9 Future Work

**User Study** On most clients the evaluation results were obvious. In the case of perfect or partial forgery, little to no discussion is needed because it should be clear that a user can not distinguish between a valid and a spoofed signature. However, some clients displayed conflicting information, for example, an erroneous seal *and* a success dialog. Other clients expect a more elaborate workflow from the user, such as clicking through the UI.

We currently classify a weak forgery as "not vulnerable" because the user has at least a chance to detect it and we did not measure if users actually detected it. A user study could clarify whether our weak forgery findings (e.g., conflicting security indicators) would convince email users, and answer the following research questions: Do users pay attention to email security indicators in general? Do users examine digital signature details (in particular for partial forgeries)? How do users react once they detect broken signatures?

We believe that such a study would help to understand the current email security ecosystem and our paper lays the foundations for such a study.

**S/MIME Signatures in AS2** *Applicability Statement 2* (AS2) as described in RFC 4130 is an industry standard for secure Electronic Data Interchange (EDI) over the Internet. It relies on HTTP(S) for data transport and S/MIME to guarantee the authenticity and integrity of exchanged messages. As critical sectors such as the energy industry heavily rely on AS2 for their business processes, it would be interesting to evaluate if our attacks (e.g., in the CMS class) can be applied to AS2. Unfortunately, we did not have the opportunity to test commercial AS2 gateways yet.

**Email Security Fuzzing** As described in subsection 7.1, our tests with different attack vectors led to unintentional crashes in several email applications. More rigorous testing and systematic fuzzing with MIME, S/MIME and PGP structures could uncover further vulnerabilities.

## 10 Conclusion

We demonstrated practical email signature spoofing attacks against many OpenPGP and S/MIME capable email clients and libraries. Our results show that email signature checking and correctly communicating the result to the user is surprisingly hard and currently most clients do not withstand a rigorous security analysis. While none of the attacks directly target the OpenPGP or S/MIME standards, or the underlying cryptographic primitives, they raise concerns about the practical security of email applications and show that when dealing with applied cryptography, even if the cryptosystem itself is considered secure, the overall system needs to be looked at and carefully analyzed for vulnerabilities. Implementing countermeasures against these vulnerabilities is very challenging and, thus, we recommend that OpenPGP, MIME, and S/MIME offer more concrete implementation advices and security best practices for developing secure applications in the future.

## Abstract

The TLS protocol provides encryption, data integrity, and authentication on the modern Internet. Despite the protocol's importance, currently-deployed TLS versions use obsolete cryptographic algorithms which have been broken using various attacks. One prominent class of such attacks is CBC padding oracle attacks. These attacks allow an adversary to decrypt TLS traffic by observing different server behaviors which depend on the validity of CBC padding.

We present the first large-scale scan for CBC padding oracle vulnerabilities in TLS implementations on the modern Internet. Our scan revealed vulnerabilities in 1.83% of the Alexa Top Million websites, detecting nearly 100 different vulnerabilities. Our scanner observes subtle differences in server behavior, such as responding with different TLS alerts, or with different TCP header flags.

We used a novel scanning methodology consisting of three steps. First, we created a large set of probes that detect vulnerabilities at a considerable scanning cost. We then reduced the number of probes using a preliminary scan, such that a smaller set of probes has the same detection rate but is small enough to be used in large-scale scans. Finally, we used the reduced set to scan at scale, and clustered our findings with a novel approach using graph drawing algorithms.

Contrary to common wisdom, exploiting CBC padding oracles does not necessarily require performing precise timing measurements. We detected vulnerabilities that can be exploited simply by observing the content of different server responses. These vulnerabilities pose a significantly larger threat in practice than previously assumed.

## 1 Introduction

In 2002, Vaudenay presented an attack which targets messages encrypted with the Cipher Block Chaining (CBC) mode of operation [39]. The attack exploits the malleability of the CBC mode, which allows altering the ciphertext such that specific cleartext bits are flipped, without knowledge of

the encryption key. The attack requires a server that decrypts a message and responds with 1 or 0 based on the message validity. This behavior essentially provides the attacker with a cryptographic oracle which can be used to mount an adaptive chosen-ciphertext attack. The attacker exploits this behavior to decrypt messages by executing adaptive queries. Vaudenay exploited a specific form of vulnerable behavior, where implementations validate the CBC padding structure and respond with 1 or 0 accordingly.

This class of attacks has been termed *padding oracle attacks*. Different forms of padding oracle attacks were demonstrated to break cryptographic hardware [6], XML Encryption [23], or web technologies like Java Server Faces [33] and ASP.NET web applications [15]. Rizzo and Duong used a padding oracle attack to steal secrets and forge authentication tokens, gaining access to sensitive data [15]. In all of these works, the attacker was able to use a direct side channel – different error messages – to instantiate a padding oracle and decrypt confidential data.

Transport Layer Security (TLS) employs CBC mode in a MAC-then-Pad-then-Encrypt scheme which makes it potentially vulnerable to these attacks. Indeed, different types of CBC padding oracles have been used to break confidentiality TLS connections [39, 4, 3, 20]. All these attacks require the attacker to perform precise timing measurements. This requirement stems from the properties of the TLS protocol; after establishing a TLS connection, all TLS error messages are sent encrypted and are of the same length. Therefore, even if an attacker is able to cause the server to send different error messages, the attacker is generally unable to distinguish between the different encrypted responses.

Since most previous analyses have only analyzed padding oracle attacks based on timing side channels, they required testing an implementation in a local environment. These evaluations uncovered many new vulnerabilities [4, 3, 20]. However, implementing a proper countermeasure to these vulnerabilities is very challenging and requires complex constant-time implementations. It is not surprising that the implementation of such countermeasures could introduce

new attacks. For example, in an attempt to fix the Lucky 13 padding oracle, the OpenSSL cryptographic library introduced a different vulnerability where OpenSSL responded with different TLS alert messages [37]. Analysis of implementations in lab settings therefore requires laborious testing for each new version of different implementations. This is obviously unrealistic, and therefore this type of analysis is performed sporadically.

Given the complexity of constant-time TLS padding verification, we expect that vulnerabilities similar to the one introduced by OpenSSL [37] could have been introduced in other implementations as well. Therefore, this work moves away from the above method of lab analyses and evaluates CBC padding oracles using large-scale Internet scans. We attempt to answer the two following questions: *How prevalent are padding oracle vulnerabilities? Are these attacks only exploitable by using timing side-channels?*

**Contributions.** In our work, we employ a novel scanning methodology that is capable of scanning for TLS CBC padding oracles at scale. We use this methodology to find new padding oracle vulnerabilities and perform responsible disclosures. We identify nearly 100 different padding oracles. We show that some of them can be exploitable without subtle timing side channels and thus pose a significantly larger threat in practice compared to most recently-discovered padding oracles.

**New large-scale scanning methodology.** Scanning at scale for padding oracles is challenging. Such scans detect vulnerabilities by sending different malformed inputs and observing server behavior. As shown by Böck et al. [9], in some cases these inputs only trigger vulnerabilities when using specific TLS versions or cipher suites. Scanning with all possible combinations of protocol versions, cipher suites and malformed inputs is not feasible since it would require an enormous number of connections to each scanned host.

We overcome this limitation by carefully selecting a set of probes, which allows for effective scans at scale. We systematically analyzed padding oracles previously described in the literature [39, 4, 3, 20, 37, 27, 25, 10, 29, 28]. We then carefully selected 25 inputs exhibiting padding oracle malformities, which we refer to as *malformed records*. These TLS records exhibit different combinations of valid and invalid padding and MAC, and are generated using the TLS-Attacker framework [37].

Even with only 25 malformed records, scanning with every combination of malformed record, TLS version and cipher suite would be impractical. We refer to these combinations as *test vectors*. We performed a preliminary scan on 50,000 random TLS hosts with all test vectors. We then reduced our test vector set, such that all vulnerabilities detected in the preliminary scan are still triggered by the reduced set. We were able to scan the Alexa Top 1 Million

websites with this reduced test vector set within three days. Our scanner observes different server responses, not only in the TLS layer, but also in the TCP layer, similar to [9]. Our results indicate that about 1.83% of TLS servers are vulnerable to CBC padding oracle attacks.

**Minimizing false positives.** When a host first displays vulnerable behavior, we rescan it to make sure the behavior is not a scanning artifact. We only consider a host to be vulnerable if it responds identically in three separate scans to each of our test vectors. It is unlikely that hosts will be mislabeled as vulnerable under this criterion. We therefore believe our statistics for vulnerability are a conservative lower estimate.

**Nearly 100 different padding oracle vulnerabilities.** The detected vulnerabilities have to be clustered in order to notify different vendors. Until now, this was done manually [9]. To achieve this automatically, we re-scan vulnerable hosts against a larger set of test vectors. We refer to the set of the host responses to all test vectors as the host's *response map*. This response map is essentially a fingerprint of the host's vulnerability. We then cluster the scanned hosts according to their response maps. This process identified 93 different response maps, i.e., 93 different vulnerabilities. These vulnerabilities include different behaviors, ranging from typical padding oracles with different TLS alert messages [39], to TCP connection timeouts triggered by specific invalid MAC bytes, or closed connections observed when using invalid padding values.

We treat distinct response maps as distinct vulnerabilities. We argue that this is the natural way to count vulnerabilities since it captures the case of the same vulnerability occurring in similar, yet different implementations. Consider two hosts that respond identically to all test vectors. These hosts likely share an identical or very similar part of the implementation that causes the vulnerability to manifest with identical response maps. However, they do not necessarily share the exact same code. They may use different versions of the same TLS library, or two different libraries with a shared component.

**Effective clustering of vulnerable hosts.** Before we responsibly disclosed our findings to the affected parties, we grouped the vulnerable hosts by their response maps. To further refine our grouped servers, we used a novel approach based on a two-dimensional force-directed graph drawing ForceAtlas2 algorithm [21]. This algorithm allowed us to create a graph of vulnerable server hosts and thus, efficiently handle our responsible disclosure process.

**New vulnerabilities that are realistic to exploit.** For padding vulnerabilities to be exploitable, the attacker needs

to distinguish between different responses to correct and incorrect padding. This is usually not the case in TLS: Even if a server sends two different alert messages, the messages are encrypted, and the attacker cannot observe the difference. For this reason, most previous padding oracle attacks against TLS relied on timing measurements to distinguish between different error cases [4, 3, 20].

However, we show that many TLS implementations exhibit *observable* differences between correct and incorrect padding. For example, a server may gracefully close the TCP connection in one error case and ungracefully close it in a different case. Similarly, some servers send a different number of alert messages depending on specific padding errors. Both behaviors are easily observable.

**Responsible disclosure and ethical considerations.** In collaboration with affected website owners, we responsibly disclosed our findings to several vulnerable vendors. As a result of a successful attack, the attacker is able to decrypt secret values repeatedly transmitted in the TLS connection. By performing our scans, we were not able to reconstruct server private keys or other confidential data. We performed our scans with dummy data and never attempted to decrypt real user traffic.

We responsibly disclosed our findings among others to the following vendors and affected parties: IBM, Amazon, Slack, Cisco, Citrix, Oracle, Heroku, Netflix, Sonicwall, Venmo and Vine.

## 2 Background

The TLS protocol provides confidentiality, integrity, and authentication on the modern Internet. The latest version of the protocol is TLS 1.3 [31]. This version is gradually being deployed as of this writing. Until TLS 1.3 is fully deployed, the latest version in widespread use is TLS 1.2 [14]. Modern clients and servers typically also support two previous versions, TLS 1.0 and 1.1 [12, 13]. In the rest of the paper, we discuss only versions 1.0 to 1.2, which are commonly used today and share a similar structure.

The TLS protocol consists of two phases. In the first phase, called the *handshake*, the client and server choose the cryptographic algorithms that will be used for the session and establish session keys. In the second phase, the peers can securely send and receive application data, which is encrypted and authenticated using the keys and algorithms established in the previous phase.

The aforementioned choice of cryptographic algorithms is called a TLS *cipher suite* [14]. More precisely, a cipher suite is a concrete selection of algorithms for all of the required cryptographic tasks. Cipher suites are named by concatenating their choices for these algorithms. For example, the cipher suite `TLS_RSA_WITH_AES_128_CBC_SHA` uses RSA public-key encryption in order to establish a shared session

key in the first phase, and also uses symmetric AES-CBC encryption with a 128-bit key and SHA-1-based HMACs in order to encrypt and authenticate data in the second phase.

### 2.1 The TLS Handshake

The client initiates the TLS handshake with a `ClientHello` message. This message advertises the TLS versions and cipher suites supported by the client. The server then responds with a `ServerHello` message specifying the selected cipher suite. It also sends its certificate in the `Certificate` message and indicates the end of transmission with the `ServerHelloDone` message. The client then generates a secret value called the `premaster secret`, encrypts it under the server's RSA key, and sends the encrypted ciphertext in a `ClientKeyExchange` message. Having shared knowledge of the `premaster secret`, both parties now derive symmetric encryption and MAC keys to be used in the session, based on the `premaster secret`. Finally, both parties send the `ChangeCipherSpec` and `Finished` messages. The `ChangeCipherSpec` message notifies the receiving peer that subsequent messages will be encrypted and authenticated under the session keys, and using the symmetric encryption and HMAC algorithms specified in the cipher suite. The `Finished` message contains an HMAC computed over all the previous handshake messages based on a key derived from the `premaster secret`. As this message is sent after the `ChangeCipherSpec` message, it is the first message in the session which is encrypted and authenticated using symmetric encryption and MAC. If the `Finished` message correctly decrypts and verifies on both sides, both parties can now securely exchange application data.

### 2.2 CBC Mode

There are many possible encryption algorithms in TLS, but we focus on the CBC encryption mode in this work. In CBC mode, each plaintext block is XOR'ed to the previous ciphertext block before being encrypted by the block cipher. Formally, if we denote plaintext blocks by  $p_i, i = 0, \dots$ , ciphertext blocks by  $c_i$  and the encryption with a block cipher under key  $k$  as  $Enc_k(\cdot)$ , then  $c_i = Enc_k(p_i \oplus c_{i-1}), i = 1, \dots$ . The above holds for all blocks except the first one, where there is no previous ciphertext block – instead, that block is XOR'ed with an initialization vector (IV) before encryption:  $c_0 = Enc_k(p_0 \oplus IV)$ .

**CBC mode malleability.** The CBC mode allows an attacker to perform meaningful plaintext modifications without knowing the symmetric key. Concretely, assume the attacker knows some block of the original plaintext  $p_i$ , and wants to alter the ciphertext such that block  $i$  instead decrypts to  $p'_i$ . The attacker can change the previous ciphertext block  $c_{i-1}$  to  $c'_{i-1} = c_{i-1} \oplus p_i \oplus p'_i$ . This comes at the cost of

corrupting the previous block, which now decrypts to some value that the attacker, in general, cannot predict.

Furthermore, the attacker can change the order of blocks while using this technique. If the attacker knows the plaintext block  $p_i$  and replaces ciphertext block  $c_j$  with  $c_i$ , then block  $j$  will now decrypt to  $p'_j = p_i \oplus c_{i-1} \oplus c_{j-1}$ .

This “malleability” property of CBC mode has been used in many cryptographic attacks, and is also a cornerstone of the attacks presented here.

### 2.3 TLS Record Layer

The TLS record layer encapsulates protocol messages. In essence, the record layer wraps the protocol message with a header containing the message length, message type, and protocol version. Once `ChangeCipherSpec` messages are exchanged, subsequent TLS records will encapsulate messages which are encrypted.

In our work, we focus on cipher suites using the CBC mode of operation. These cipher suites use a Message Authentication Code (MAC) to protect the authenticity of TLS records and encrypt application data using a block cipher in CBC mode (e.g., AES or 3DES). The TLS specification prescribes the *MAC-then-Pad-then-Encrypt* mechanism [14]. The encryptor first computes a MAC over the plaintext, concatenates the MAC to the plaintext, pads the message such that its length is a multiple of the block length, and finally encrypts the MAC’ed and padded plaintext using a block cipher in CBC mode.

TLS specifies the exact value of the padding bytes. The last byte of the padded plaintext specifies how many padding bytes are used, excluding that last byte. The value of the rest of the padding bytes is identical to the value of the last byte. For example, if 4 padding bytes are used including the last byte, then the value of all four bytes will be `0x03`.

To demonstrate the full process, if the encryptor encrypts five bytes of data with the `TLS_RSA_WITH_AES_128_CBC_SHA` cipher suite, he uses HMAC-SHA (whose output is 20 bytes long) and AES-CBC. After applying HMAC-SHA to the original plaintext, the concatenation is 25 bytes in length, which fits into two AES 16-byte blocks. The encryptor will typically select the minimum viable amount of padding, which would be 7 bytes in this case. The first block contains the data and the first 11 HMAC bytes. The second block contains the remaining 9 HMAC bytes and 7 bytes of padding `0x06`, see Figure 1. Note that the encryptor can also choose longer padding and append 23, 39, ...or 247 padding bytes (while setting the value of the padding bytes accordingly).

## 3 A Brief History of Padding Oracle Attacks

One of the main design failures in SSLv3 and TLS is the specification of the *MAC-then-Pad-then-Encrypt* scheme in

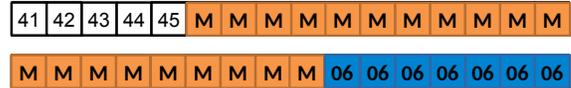

Figure 1: When processing five plaintext bytes with AES-CBC and HMAC-SHA, the encryptor needs to append 20 bytes of the HMAC-SHA output and seven bytes of padding.

CBC cipher suites. This scheme was responsible for a series of attacks on TLS implementations named padding oracle attacks. Even though the countermeasures are explicitly summarized in the TLS specification [14, Section 6.2.3.2], their correct implementation is challenging.<sup>1</sup>

### 3.1 Vaudenay’s Padding Oracles

In 2002, Vaudenay showed that the MAC-then-Pad-then-Encrypt scheme introduces potential vulnerabilities in security protocols, in the form of so-called padding oracles [39]. The attacks leveraging these vulnerabilities are based on the malleability of the CBC mode of operation. We focus on the case of TLS.

Consider the TLS record layer when using CBC mode. After decryption, the decrypting party needs to verify the padding bytes and the MAC bytes. The natural way to implement these two checks is first to verify the padding bytes and, if they verify correctly, then verify the MAC bytes. If the padding bytes are invalid, it is natural for an implementation to emit an error message, without checking the MAC bytes. On the other hand, if the padding bytes are valid but the MAC is invalid, it is then natural to emit a (potentially different) error message.

Assume a decryptor that indeed emits two different error messages in these cases. The attacker can decrypt the last byte of any message block  $p_i$  as follows. He sets the last ciphertext block to  $c_i$  and replaces the last byte of the previous block  $c_{i-1}$  with a value between 0 and 255. If the last cleartext byte is `0x00`, then the padding will be valid (other forms of valid padding are much less likely). When the padding byte correctly verifies, the attacker detects this by observing that the decryptor emitted an “invalid MAC” error, rather than an “invalid padding” error. The attacker learns the value of the last byte of  $p_i$  after sending at most 255 ciphertexts to the decryptor.

Using his knowledge of the last plaintext byte, the attacker can proceed to decrypt the second-to-last byte of  $p_i$ . By doing so, he aims to create valid padding of length 2. More generally, using this technique, the attacker can iteratively decrypt every byte in  $p_i$ . We omit the formal description of the rest of the attack and refer the reader to [39].

<sup>1</sup>We note that the countermeasures summarized in [14] do not protect from timing-based attacks [4].

Note that the above attack relies on the ability to distinguish between ciphertexts decrypting to valid and invalid padding. It would therefore appear trivial for TLS implementations to prevent this attack by making sure they always emit the same error message. Indeed, Vaudenay was unaware of a way for an attacker to directly distinguish between these two cases in the context of TLS. The reason is that even if the TLS error messages differ, their distinction is impossible since they are encrypted with TLS session keys. This is one of the challenges we address in our work.

### 3.2 BEAST Attack Model

One question left open in Vaudenay’s paper is how to exploit what he terms an “exploding oracle” – an oracle that is usable only until it first returns a negative answer. This models the problem where a TLS implementation will abort the session as soon as a message doesn’t decrypt correctly. Hence, an attacker that relies on changing messages in a TLS session would not be able to continue the attack as soon as the first decryption error arises.

Canvel et al. used a model where the client repeatedly connects to the server [11], observing that this occurs due to polling behavior of email clients at the time, and exfiltrating an authentication password. The BEAST attack [34] essentially used the same model, but rather relied on the behavior of modern web browsers. In the simplest form of the BEAST model, a victim is tricked into visiting a malicious website controlled by the attacker. That website contains javascript which causes the victim browser to repeatedly connect to the victim website. Every website request then contains the user authentication cookie, which is automatically sent by the browser. This behavior allows the attacker to force the victim to repeatedly send encrypted values to the server.

Our attacks work in this model. We assume that the attacker can cause the victim client to repeatedly connect to a victim server while retransmitting the same sensitive information. We also assume the attacker is a man in the middle (MitM) and can change messages in transit. This model has now become standard in literature for modern attacks.

### 3.3 POODLE

The predecessor to TLS, SSLv3, uses a similar *MAC-then-Pad-then-Encrypt* scheme. However, unlike TLS, the value of the padding bytes in SSLv3 is under-specified. The last byte of the plaintext denotes how many padding bytes are present, but the rest of the padding bytes can take any value.

Consider a message with one full block of 16 padding bytes. The last block of plaintext will have a last byte of 0x0F, and the first 15 bytes can take any value. Therefore, an attacker can use the techniques described in Section 3.1 to replace the last block with any block whose last byte decrypts to 0x0F, and obtain a validly padded message. This

property of SSLv3 led to a devastating attack called “POODLE”. See [27] for a full description of the attack.

Although POODLE relies on the under-specification of the padding bytes in SSLv3, it surprisingly also affects TLS implementations. In essence, there is nothing forcing a careless TLS developer to verify the (specified) padding bytes after decryption; a TLS implementation will interoperate just fine even if it does not check the padding bytes at all. In fact, it is *easier* for the developer to reuse the same code that handles SSLv3 padding in a TLS implementation. This has led to a variant of the POODLE attack that affects TLS implementations [25]. Even after these two high-profile discoveries, variants of POODLE continued emerging [10, 29, 28]. These works detected different TLS record processing vulnerabilities; some TLS implementations only verified the first MAC byte, the others skipped validation of specific padding bytes.

### 3.4 Lucky 13 and Other Timing Attacks

In 2013, AlFardan and Paterson [4] used a similar technique to break TLS confidentiality and dubbed their attack “Lucky 13”. The attack relies on an important observation: Common HMAC functions require different processing times when processing inputs of different lengths. By performing clever padding byte manipulations, the attacker can force the server to execute HMAC computations on plaintexts of different lengths. This is because the padding length determines the amount of data used as input into the HMAC function. The attacker can then measure the different processing times and learn information about the padding byte. We refer the reader to [4] for the full attack description.

The fix to Lucky 13 was to change the MAC verification code in TLS implementations to be constant-time, regardless of the number of processed cleartext blocks. This is possible, but writing and maintaining such code is hard, even for experts. In 2016, Somorovsky identified a bug in the patched code of OpenSSL [37]. The bug introduced a similar and even more severe vulnerability which allowed an attacker to distinguish between two alert messages. A different message could be triggered if the decrypted message only contained two or more valid padding blocks.

Amazon’s s2n TLS library was released in 2015 [24], after the Lucky 13 attack was published. s2n’s developers were aware of Lucky 13 and introduced specific countermeasures that seemed to render the code constant-time, thereby preventing the attack. They also introduced randomized timing delays to make the attack more difficult, in the unexpected case that the code turned out to be vulnerable. Despite all these efforts, s2n was still vulnerable to variants of Lucky 13 [3, 35]. All vulnerabilities were found despite the code having been formally verified.

### 3.5 Bleichenbacher's Attack and its Variants

Bleichenbacher's attack [8] is also a form of a padding oracle attack. Rather than targeting symmetric encryption, it targets a padding scheme used in RSA encryption, called PKCS#1 v1.5. It also similarly exploits a malleability property of RSA encryption and relies on a decryptor (i.e., a server) emitting error messages in case of invalidly-padded cleartexts. The standard countermeasure is similar to that of CBC padding oracles; the server must not behave differently when encountering error states in RSA decryption. This countermeasure has become part of the TLS standard.

However, implementing the countermeasure correctly is challenging. Böck et al. scanned for vulnerable TLS servers vulnerable to Bleichenbacher's attack [9]. They found vulnerabilities in servers used by high-profile websites such as Facebook and Paypal. Interestingly, their vulnerabilities could be triggered by using different TLS protocol flows or exploiting TCP connection states (TCP resets or timeouts). As with CBC padding oracles, Bleichenbacher's attack shows a similar sequence of an attack variant being discovered every few years in different contexts [26, 22, 6].

## 4 Scanning and Evaluation Methodology

The ultimate goal of our research is to estimate the number and the impact of padding oracle vulnerabilities and report our findings to the responsible vendors. To accomplish this, we proceed in three steps. We first define a list of test vectors potentially triggering observable differences which result in padding oracles. We then reduce this test vector list and perform a large-scale scan. Finally, we analyze the identified vulnerabilities and responsible vendors.

### 4.1 Test Vector Generation

In order to detect padding oracles in implementations, we connect and send various malformed records. These records contain different malformities in regards to the padding, MAC, and application data. We then observe if there are any differences in responses, in the TLS layer, or in lower layers. An implementation that responds differently to two malformed records may be vulnerable.

It is infeasible to test with all possible malformed records. For example, a vulnerable implementation could correctly check all padding bytes unless the padding bytes are exactly 16 bytes long, in which case the implementation does not check a specific bit in the padding.<sup>2</sup> Since there could be up to 256 padding bytes, testing the correct validation of each bit for all possible padding lengths would require testing with  $\sum_{i=1}^{256} 8i = 263,168$  different records. These records

<sup>2</sup>The above behavior may sound contrived, but similar behaviors have been found in the wild, see e.g. [29, 28, 37].

need to be tested with different cipher suites or protocol versions which makes such a comprehensive test infeasible. We therefore carefully selected a set of malformed records which are motivated by previous research.

We concede this way of selecting the set of malformed records means we can only detect vulnerabilities that are similar to known ones. However, this approach is cost-effective and well-suited to large-scale scans. Since only a limited number of messages can be sent to individual servers during large-scale scans, automatic approaches for the test vector generation, like fuzzing, are usually infeasible.

#### 4.1.1 Malformed Records

Our malformed records are all 80 bytes in length. Equal lengths ensure that differences in responses are likely caused by a padding oracle vulnerability and are not false positives triggered by different record lengths. Unusual record lengths may lead to errors that are unrelated to decryption; for example, recent OpenSSL versions respond with a different error message if the encrypted TLS record is shorter than the MAC length. We decided to use 80 bytes to have enough room for an HMAC output combined with two full padding blocks. This allows us to construct records protected by SHA-384, whose output is 48 bytes in length. We summarize our 25 malformed records in the following paragraphs. See also Table 1 for a summary of these malformed records for the case of TLS\_RSA\_WITH\_AES\_128\_CBC\_SHA.

**Flipped MAC bits.** We start with a valid record containing application data, a MAC, and four padding bytes. We then create three malformed records based on this record: One by flipping the most significant bit in the first MAC byte, one by flipping a middle bit in the middle of the MAC bytes, and one by flipping the least significant bit of the last MAC byte. We chose these malformed records to detect implementations where the MAC is not completely checked. The specific bit flipping positions are motivated by the recent OpenSSL vulnerability [1], where OpenSSL only checked the least significant bit of each byte on some platforms, and by further vulnerabilities caused by incomplete MAC validations [29, 28].

**Missing One MAC byte.** We start with a valid record containing empty application data, but with valid MAC and padding. We then modify it to create two malformed records: One where we delete the first MAC byte, and one where we delete the last MAC byte. We then add another padding byte in both messages. These malformed records could also trigger vulnerabilities caused by incomplete MAC validations and are indirectly motivated by [28].

**Missing MAC.** Motivated by [37], we created two malformed records which only contain padding and do not con-

Nr.	MAC			Padding		
	Len	Pos	Modification	Len	Pos	Modification
1	20	20	⊕ 0x01	56	–	–
2	20	11	⊕ 0x08	56	–	–
3	20	1	⊕ 0x80	56	–	–
4	19	1	DEL	56	–	–
5	19	20	DEL	56	–	–
6	0	–	–	80	ALL	0x4F
7	0	–	–	80	ALL	0xFF
8	20	–	–	60	1	⊕ 0x80
9	20	–	–	60	31	⊕ 0x08
10	20	–	–	60	60	⊕ 0x01
11	20	1	⊕ 0x80	60	–	–
12	20	9	⊕ 0x08	60	–	–
13	20	16	⊕ 0x01	60	–	–
14	20	1	⊕ 0x01	60	1	⊕ 0x80
15	20	1	⊕ 0x01	60	31	⊕ 0x08
16	20	1	⊕ 0x01	60	60	⊕ 0x01
17	20	–	–	6	1	⊕ 0x80
18	20	–	–	6	3	⊕ 0x08
19	20	–	–	6	6	⊕ 0x01
20	20	1	⊕ 0x80	6	–	–
21	20	9	⊕ 0x08	6	–	–
22	20	16	⊕ 0x01	6	–	–
23	20	1	⊕ 0x01	6	1	⊕ 0x80
24	20	1	⊕ 0x01	6	3	⊕ 0x08
25	20	1	⊕ 0x01	6	6	⊕ 0x01

Table 1: A summary of our malformed records, as constructed for `TLS_RSA_WITH_AES_128_CBC_SHA`. The columns indicate length, position, and modification for MAC and padding bytes, respectively.  $\oplus$  denotes XOR'ing the listed value in the listed position. DEL denotes deleting one byte in the listed position.

tain a MAC at all: One where we supply exactly 80 bytes of valid padding (0x4F), and one where we supply 80 bytes of incomplete padding of value 0xFF. The latter is not only missing the MAC but also contains invalid padding since if the value of the last byte is 0xFF, there should be 256 padding bytes.

**Combining valid and invalid MAC and padding.** The last group of malformed records contains messages with combinations of valid and invalid MAC and padding of three types: valid MAC and invalid padding, invalid MAC and invalid padding, and invalid MAC and valid padding. For each of these three types, we create three sub-types, depending on which bit positions we flip; we flip either the most significant, middle, or least significant bit in the first, middle, or 16th byte, respectively. For each of these nine sub-types, we create one version which contains application data, and one without. The length of the application data is chosen such that the padding bytes are contained within one plaintext block, while the malformed records without application data contain more than one block of padding. This aims to detect implementations which check only the last block of padding bytes.

#### 4.1.2 Combining Malformed Records with Protocol Versions and Cipher Suites

We use each malformed record with several TLS protocol versions and cipher suites. As previously stated, we use the term *test vector* to refer to the combination of a malformed record, protocol version, and cipher suite. As we later show, testing each malformed record with different protocol versions and cipher suites is necessary; some vulnerabilities are only triggered with such specific combinations. At first glance this is surprising, but this actually follows the findings of [9]. We conjecture that implementations may use completely different code stacks depending on the negotiated version and cipher suite, and some vulnerabilities are only present in a subset of those code stacks.

### 4.2 Empirical Test Vector Reduction

Depending on the configuration of the server, the above set of test vectors is quite large. Assuming a server supporting TLS 1.0 and TLS 1.1 with 10 CBC cipher suites, there would be  $10 \cdot 2 \cdot 25 = 500$  test vectors. Note that every test vector requires establishing a new TLS connection and performing an expensive handshake. This large number of test vectors would not allow us to perform large-scale scans. On the other hand, removing test vectors could lead to false negatives and missing vulnerabilities. To reduce the number of test vectors without lowering the detection rate, we propose an empirical test vector reduction approach. We sample 50,000 random hosts which respond on port 443. We then perform a full scan on these hosts with the aforementioned 25 malformed records and all supported cipher suites and TLS version combinations. We can then analyze our test vector combinations and create the smallest set of test vectors detecting all padding oracle vulnerabilities. These empirical steps ensure that 1) with high probability we do not miss vulnerabilities, and 2) we can use the reduced set for large-scale analyses.

### 4.3 Clustering Vulnerabilities

Once we reduce the number of test vectors we can perform our full scan. For this purpose, we use one of the *Internet top lists* which typically contain a good mixture of up-to-date server implementations. Among Internet top lists, the Alexa Top 1 Million dataset contains the most significant number of hosts responding to TLS connections (about 75%) and is recommended for TLS scans [36].

After performing the TLS scan with a reduced vector set, we create a list of vulnerable hosts. We re-scan these hosts with our full test vector list. For every host, we store its *response map*. The response map describes the complete host behavior when responding to our test vectors. The response map consists of *cipher suite fingerprints*. A cipher suite fingerprint describes the server response behavior for a specific cipher suite and TLS version.

One of our major goals is to notify vulnerable vendors. For this purpose, it is necessary to group vulnerable hosts using the resulting response maps and contact their administrators to find out the vulnerable implementation version. Böck et al. performed this step manually and were able to approach the most important vendors [9]. However, such an approach is laborious and error-prone. We aim to group vulnerable implementations automatically.

Although grouping vulnerable hosts appears to be easy given all response maps, response maps differ even if they use the same vulnerable implementation version. TLS servers running identical implementations can use different configurations, enabling different cipher suites and TLS versions. For example, server A may be vulnerable to a padding oracle attack and has only one TLS cipher suite enabled: `TLS_RSA_WITH_AES_128_CBC_SHA256`. Server B is vulnerable using the same cipher suite fingerprint. However, server B is configured to use additional cipher suites as well which are not vulnerable to the attack. Are these two servers using the same implementation or just a similar one? To estimate this, we devised a novel approach based on a two-dimensional force-directed graph drawing algorithm [21]. These algorithms embed a network of nodes on a plane that allows for spatially interpreting the network. They do so by creating a two-dimensional graph which contains as few crossing edges as possible. In our approach we use the ForceAtlas2 algorithm [21]: *ForceAtlas2 simulates a physical system in order to spatialize a network. Nodes repulse each other like charged particles, while edges attract their nodes, like springs. These forces create a movement that converges to a balanced state. This final configuration is expected to help the interpretation of the data [21].*

We represent the scanning results as a graph as follows: Each node in the graph represents a host. Each pair of hosts is connected by an edge if their response maps do not include different cipher suite fingerprints for the same cipher suite.

This approach works well on our dataset, and servers exhibiting similar vulnerabilities are grouped closely. We augmented the graph by coloring nodes according to their degree (i.e., their number of edges). The resulting visualization indeed allows identifying similar implementations. We show the concrete results in Section 8.

## 5 Large Scale TLS Scanning

We developed our padding oracle test vectors with TLS-Attacker [37], a framework for systematic analyses of TLS implementations. TLS-Attacker supports creating malicious TLS workflows and message malformities. TLS-Attacker has already been used for detecting padding oracle attacks, but only against specific implementations in lab conditions, not at scale. Our approach of creating an optimized set of test vectors was not previously included in this framework.

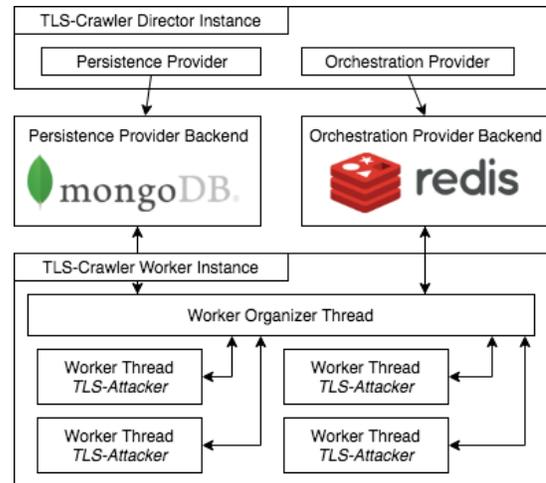

Figure 2: Our TLS scanning infrastructure is based on well-established components for data persistence and on TLS-Attacker for performing TLS evaluations.

### 5.1 TLS-Crawler

In order to scan a large number of hosts, we developed a framework which scans multiple servers in parallel and writes the results to a database. This allows us to parallelize the scan by using multiple machines. The database provides a querying interface for the scan data, which allows for easier analysis of the large result datasets. We call our framework TLS-Crawler.

TLS-Crawler is split into a director instance and potentially multiple worker instances. The worker instances perform the actual TLS host scans. Each worker instance implements a thread pool which distributes scanning work across available threads. The instance then bundles the results and coordinates parallelized database access. A director instance coordinates the worker instances. The director instance contains an orchestration provider responsible for the coordination and distribution of scanning tasks across workers. The results are persisted in a database using a persistence provider. We use MongoDB<sup>3</sup> as the persistence provider, and orchestrate instances via a Redis queue.<sup>4</sup> Figure 2 visualizes the TLS-Crawler architecture.

### 5.2 Performing the TLS Scans

Before scanning each host with test vectors, we perform a brief scan in order to learn the CBC cipher suites and TLS protocol versions supported by the host. We excluded export and anonymous cipher suites from these tests since they are already trivially broken by a MitM attacker. We then perform our scan using our set of test vectors for each CBC cipher

<sup>3</sup><https://www.mongodb.com>

<sup>4</sup><https://redis.io>

suite and its supported protocol version.

Previous large-scale TLS scans have mostly focused on vulnerabilities in the TLS handshake [9, 2], certificates [19], or vulnerabilities which could be triggered before the TLS handshake succeeds [17]. These previous scans only require performing a successful handshake once, usually with a commonly supported cipher suite. In contrast, in order to test for padding oracle vulnerabilities, it is necessary to perform a full TLS handshake for each tested cipher suite. This is complicated by TLS implementations exhibiting intolerances [7] which might prevent a server from completing the TLS handshake, or even responding to the initial `ClientHello` message. We tried to minimize the effect of these intolerances on our scans, but 20% of servers exhibited enough intolerances that we could not effectively scan them.

Even completing a TLS handshake does not guarantee we can effectively scan a host. For example, in some tests, the target hosts temporarily stopped responding for a few seconds. This is likely because the servers crashed or blocked our requests as part of a Denial-of-Service defense. In order to avoid false negatives from such scans, we scan multiple hosts in parallel (up to 2000) such that no host is overloaded by our requests. Additionally, we wait at least 10 seconds between scanning a host with two cipher suite/version pairs, further limiting the load on scanned hosts.

When performing these scans it is critical to select an appropriate timeout. If the timeout is too low, we might miss responses due to high server load. Conversely, a high timeout value would decrease the scanning performance. Setting a high timeout value also means we no longer distinguish between a server immediately closing the connection, and requiring a noticeable time to recover and close the connection. Additionally, the server's answers may span multiple TCP packets, so there is no simple way to ascertain the scanner has received the server's answer in full at any point in time. (Some responses do not include a TCP RST or FIN packet.) We empirically determined that a timeout of one second works well in practice, and mostly guarantees that the server did have enough time to process our record and respond. However, even when using this timeout value, we found servers that responded non-deterministically due to high load or various bugs.

To work around non-deterministic responses, we re-scanned each suspected vulnerability in order to avoid false positives. We only consider a server as vulnerable if it responds identically in three separate scans to each of our test vectors.

## 6 Evaluation

For the scans, we used a machine with 2 Xeon E5-2683v5 CPUs (with a total of 64 cores) and 48 GB of RAM. The scan used an average of 5Mbit/s of upstream data and 15Mbit/s of downstream data.

### 6.1 Pre-Scanning with All Malformed Records

We performed a preliminary scan of 50,000 random TLS hosts, aimed at reducing the set of malformed records. The scan took place in October 2018 and required three days. The results confirmed that the choice of key exchange algorithm and protocol version indeed affects whether a given host exhibits CBC padding oracle vulnerabilities. We then reduced the set of malformed records. To do this, we first identified all vulnerable hosts, i.e. hosts that would be identified when scanning with the full set of malformed records. We then examined subsets of malformed records of increasing sizes, and for each subset, examined the number of hosts that would be identified when scanning only with this subset of malformed records. This process was stopped when a subset of four malformed records identified all vulnerable hosts. That is, all hosts that would be identified when scanning with the full set of malformed records, would also be identified when scanning with the reduced set of malformed records. This reduced set includes the following malformed records (all of these records are 80 bytes in length):

1. A record with missing MAC and correct padding (of value `0x4F`).
2. A record with missing MAC and incorrect padding (of value `0xFF`).
3. An empty record with no application data, with invalid padding and valid MAC. The highest bit in the first padding byte is flipped.
4. An empty record with no application data, with valid padding and invalid MAC. The lowest bit in the first MAC byte is flipped.

Please note that we still test every TLS host with all of its supported cipher suites and TLS protocol versions.

**Is the malformed record set reduction lossy?** The reduced malformed record set detects all vulnerabilities detected by the larger, original malformed record set, *on the sample data of the preliminary scan*. It is natural to ask whether there are hosts that are vulnerable to a malformed record from the original set, but not to a malformed record from the reduced set. There are obviously no such hosts in the sample data, but there could be such hosts outside of the sample. If there is a large number of such hosts on the Internet, then the malformed record reduction process would be lossy, i.e. by using fewer malformed records, we detect fewer vulnerabilities in the full scan. As we now explain, this source of scanning inaccuracy is likely small enough to not materially affect our results. Put another way, the reduced set of malformed records likely detects most vulnerabilities

triggered by the full set of malformed records, not just on the sample data.

Indeed, let  $p$  denote the percentage of hosts, out of all TLS-speaking hosts, that are vulnerable to one malformed record from the full set of malformed records, but not to any malformed records from the reduced set. I.e.,  $p$  describes the percentage of hosts that the reduction misses; we will now show it is rather small. In the random sample of  $N = 50000$  hosts used for the preliminary scan, we did not encounter any such hosts. In order to compute the 99% confidence interval, we require  $(1 - p)^N = 0.01$ . Solving for  $p$ , we obtain  $p = 0.0092\%$ . We therefore determine with 99% confidence that there are at most 0.0092% additional vulnerable hosts that our scans miss due to the malformed record reduction.

We provide an intuitive explanation of the above, for the reader's convenience. As per the above calculation, we estimate the percentage of vulnerable hosts on the Internet that would be missed because we scan with the reduced set of malformed records is 0.0092%. Censys [16] estimates there are about 42.4 million hosts which serve TLS on port 443 as of February 2019. Therefore, our estimate is that the reduction misses at most  $42400000 \cdot 0.0092\% = 3900$  hosts. Intuitively, the term "99% confidence interval" means there is roughly a 1% chance that this estimate is wrong, i.e. that there are more than 3900 such hosts on the Internet.

## 6.2 Alexa Top Million Scan

We used the reduced set of malformed records to scan the Alexa Top Million websites. Among the top lists, Alexa Top 1 Million provides the highest percentage of hosts supporting TLS [36] and is thus suitable for large-scale TLS scans. The list likely includes most high-profile TLS implementations.

The scan required approximately 72 hours. Of the initial one million hosts, 785,295 responded on port 443. We were able to perform TLS handshakes with CBC cipher suites with 627,493 hosts. We excluded all other hosts from the evaluation. We discovered a total of 18,257 Alexa Top Million hosts (1.83%) which are vulnerable to padding oracle attacks.

The data supports our conjecture that implementations may be vulnerable on a cipher suite with one protocol version, but not vulnerable on the same cipher suite with a different protocol version. A total of 649 servers were only vulnerable in either TLS 1.0 or TLS 1.1/1.2 although the vulnerable cipher suite was supported in the other version. Similarly, in some cases, the negotiated key exchange algorithm affects whether implementations exhibit a CBC vulnerability. 601 hosts were vulnerable on one cipher suite, but not on another cipher suite with a different key exchange algorithm but the same symmetric cipher and HMAC function. A total of 3,247 hosts were vulnerable on all CBC cipher suites they supported.

After identifying vulnerable hosts, we rescanned them

with the full set of test vectors to get their full response maps. As noted above, to label a host as vulnerable we require the response maps to be consistent across three different scans.

## 6.3 Results of Our Clustering Approach

Analyzing each vulnerable host manually is infeasible. We therefore clustered the vulnerable hosts, such that hosts exhibiting the same cipher suite fingerprints are clustered together. This minimizes the manual work required to identify the vendor (or vendors) responsible for each vulnerable behavior. We reiterate that this clustering is not trivial, as explained in Section 4.3.

We identified 93 different cipher suite fingerprints. Table 2 summarizes the 40 most common cipher suite fingerprints. Using the first row as an example, 7297 hosts responded with BAD\_RECORD\_MAC and CLOSE\_NOTIFY TLS alerts and timed out the connection for malformed records 11 and 12 (☹). For all other malformed records these hosts closed the TCP connection (☹) after sending the same TLS alerts.

We also identified four groups exhibiting behavior similar to the CVE-2016-2107 vulnerability in OpenSSL [37] (cipher suite fingerprints #41, #75, #14, and #54 in Table 2). They respond to malformed records 6 and 7 (see Table 1) with a RECORD\_OVERFLOW TLS alert. To all other malformed records they respond with BAD\_RECORD\_MAC. These are likely unpatched OpenSSL implementations, or security appliances running older OpenSSL versions.

For vulnerable cipher suites on the same host, cipher suite fingerprints are largely consistent. Of hosts exhibiting at least one vulnerable cipher suite, 99.6% have an identical cipher suite fingerprint on all vulnerable cipher suites. We removed the remaining 0.4% of hosts to make clustering easier. However, hosts sharing the same cipher suite fingerprint on vulnerable cipher suites don't necessarily share the same implementation. As an example, consider two hosts, A and B, with two cipher suites supported by both hosts, 1 and 2. A is vulnerable on cipher suite 1 with cipher suite fingerprint X, but is not vulnerable on cipher suite 2. B is not vulnerable on cipher suite 1, but is vulnerable on cipher suite 2 with the same cipher suite fingerprint X. This difference indicates the hosts don't share the same implementation, as we would expect the shared implementation to have a consistent set of vulnerable cipher suites. (We concede that it is possible the hosts exhibit different behavior because of different configuration flags despite sharing the same implementation, but we consider this unlikely).

We denote the above situation (in its general form) as "contradictory response maps"; two hosts exhibiting the same cipher suite fingerprint on vulnerable cipher suites, but where there exists a cipher suite supported by both hosts such that one host is vulnerable on that cipher suite and the other host is not. We refer to the complement situation as "compatible response maps".

Nr.	Cipher suite fingerprint									Strength		Count

Table 2: Analysis of the 40 most common cipher suite fingerprints, each consisting of responses to 25 malformed records. For ease of reading, we group together malformed records for which responses are identical within each cipher suite fingerprints. We use the following notation: Application message (A), Fatal Alert with error code  $k$  ( $F_k$ ), Warning Alert (W), connection closed ( $\textcircled{\circ}$ ), TCP reset ( $\textcircled{\text{f}}$ ), timeout ( $\textcircled{\ominus}$ ). We use the following TLS Alert codes: UNEXPECTED\_MESSAGE (10), BAD\_RECORD\_MAC (20), DECRYPTION\_FAILED\_RESERVED (21), RECORD\_OVERFLOW (22), DECOMPRESSION\_FAILURE (30), HANDSHAKE\_FAILURE (40), ILLEGAL\_PARAMETER (47), DECODE\_ERROR (50), DECRYPT\_ERROR (51), INTERNAL\_ERROR (80). Alerts with code CLOSE\_NOTIFY always used the warning level.  $\textcircled{\text{m}}$  denotes an encrypted response. The oracle *strength* definition is provided in Section 7; observable differences are depicted with  $\textcircled{\text{e}}$ , unobservable differences with  $\textcircled{\text{v}}$ . We use *W* and *S* for weak and strong padding oracles, respectively (a strong and observable oracle is exploitable). *P* represents behavior similar to POODLE (which is also exploitable if it is observable).

We then use a graph algorithm in order to further split host groups. For each group of hosts with an identical cipher suite fingerprint, we construct a graph where each node represents a host. We draw an edge between two hosts if and only if their response maps are compatible. We then embed the graph in a two-dimensional plane using the ForceAtlas2 algorithm, as implemented in the Gephi software.<sup>5</sup> The ForceAtlas2 algorithm clusters together nodes connected by an edge, so nodes with compatible response maps are clustered together. Identically configured servers which behave identically will be connected to the same nodes and will therefore have the same degree. Since these servers are connected to the same nodes, ForceAtlas2 will draw them close to one another. By coloring the nodes by their degree it becomes easy to manually spot similarly configured and identically behaving implementations in the graph. These sub-groups can then be examined for candidates for manual analysis and responsible disclosure.<sup>6</sup>

**Example for one vulnerability group.** An example of this visualization is provided in Figure 3. The figure clearly shows two distinct sub-groups which do not share edges (meaning their response maps are contradictory and they likely do not share the same implementation). Hosts shown in green are vulnerable on `TLS_RSA_WITH_AES_128_CBC_SHA` and `TLS_DHE_RSA_WITH_3DES_EDE_CBC_SHA`, while servers shown in pink are only vulnerable to `TLS_DHE_RSA_WITH_3DES_EDE_CBC_SHA` and not on `TLS_RSA_WITH_AES_128_CBC_SHA`. Interestingly the hosts in the middle of the graph (mostly in teal) do not support `TLS_RSA_WITH_AES_128_CBC_SHA` (they are vulnerable on `TLS_DHE_RSA_WITH_3DES_EDE_CBC_SHA`). They may share their implementation with either the green or pink group and therefore share edges with the members of both groups. Hosts in red are very similar to the pink group but do not share edges with the teal group. This means that either a third group exists, or the teal group actually belongs to the green group and the red group belongs to the pink group. Individual nodes are likely rare configurations of one of the implementations of the bigger groups. We performed a DNS lookup and determined both groups are operated by a Czech hosting company.

This approach allowed us to also contact other prominent websites in each group and ask what TLS implementation they use.

<sup>5</sup><https://github.com/gephi/gephi>

<sup>6</sup>We note that further grouping by the server agent string could provide more insights into the different groups. However, it is also very likely that it would also falsify our results. In many cases, TLS is terminated in reverse proxies or firewalls, and the server agent string is generated on a different machine handling HTTP traffic.

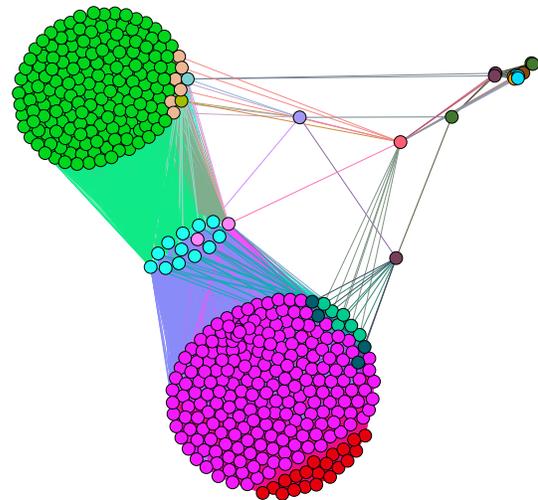

Figure 3: Visualisation of group #23 from Table 2.

**Breakdown of response maps.** Figure 4 visualizes the prevalence of the various cipher suite fingerprints. A few very common vulnerabilities account for the majority of vulnerable hosts. The newly-discovered vulnerabilities in Amazon/OpenSSL and Citrix account for slightly more than half of all vulnerable hosts. These are listed as #15 and #84 and described in more detail in Section 8.2. In addition, response maps #41 and #75, which likely stem from implementations based on unpatched OpenSSL versions, account for roughly a third of vulnerable hosts. Response map #23 is found in the above-mentioned Czech hosting company.

## 7 Realistically Exploitable Padding Oracles

Not all of the oracles we identified enable effective decryption attacks. The rest of this section explains exploitation in more detail.

The padding oracles we discovered are based on direct message side channels, i.e. on TLS implementations where two error states trigger different error responses from the TLS server. They may be exploitable in the BEAST attacker model, which relies on two assumptions: (a) the victim client visits a website under the attacker’s control, which triggers HTTPS requests to the victim server, and (b) the attacker is a MitM and can observe the session and modify transmitted ciphertexts. In addition to those standard assumptions, an oracle is exploitable if it satisfies two additional requirements: (R1) *Observability* and (R2) *Perfect padding distinguishability*.

### 7.1 (R1) Observability

Unlike timing side channels, little attention has been paid to direct message side channels in the case of TLS, and common wisdom seems to assume they are *unobservable* to the

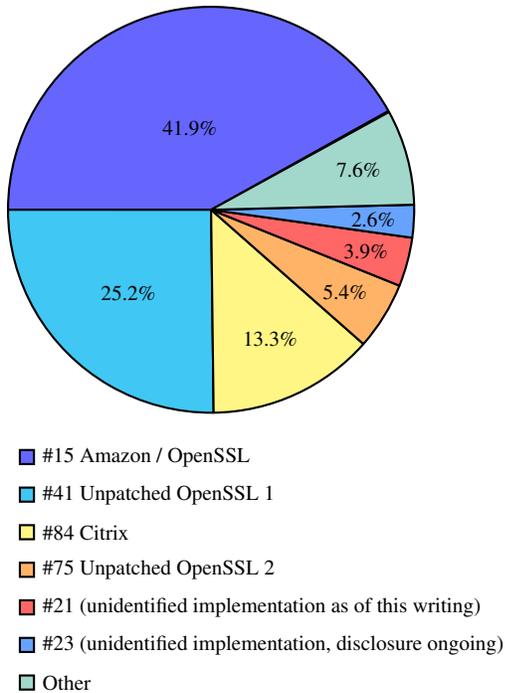

Figure 4: A visualization of the prevalence of cipher suite fingerprints. A few widely-prevalent vulnerabilities account for the majority of vulnerable hosts. Out of the above cipher suite fingerprints, #84 and #15 are exploitable. They are described in more detail in Section 8.2.

attacker. Indeed, this is true for implementations which send a single alert in all error cases and the behavior is identical except perhaps for the content of the alert message. Such behavior cannot be exploited by the attacker to create a side channel because the alert message is encrypted. However, we identified many cases where implementations do exhibit an observable difference in behavior. These observable differences can roughly be divided into two classes:

- **TCP layer.** We found implementations which leak information about the padding validity in the TCP layer. For example, in the case of Amazon, most test vectors with invalid padding caused the server to immediately close the TCP connection. However, specific, carefully crafted test vectors caused the server to abort the TLS session while keeping the TCP connection open.
- **Number of TLS records.** We observed TLS servers that responded with a different number of records based on the padding validity. While the attacker cannot decrypt these records, he is able to observe the total ciphertext length. For example, the servers from group 23 (see Table 2) responded with *one* TLS alert in the case of valid padding, while for invalid padding they responded with *two* TLS alerts.

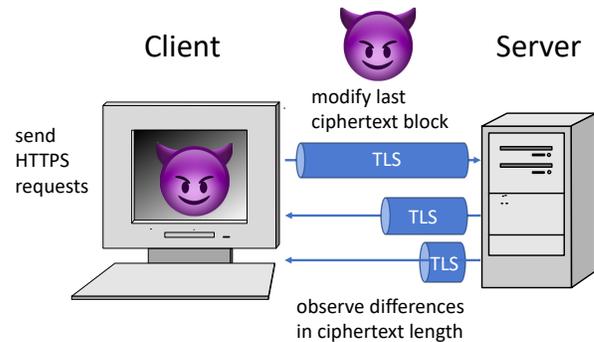

Figure 5: Exploiting observable error-based padding oracles in a BEAST scenario. Differences in total ciphertext length result from different numbers of TLS alerts being sent.

Consider an attacker  $\mathcal{A}$  who can distinguish between the two cases of `valid_padding` and `invalid_padding` based on the validity of the last padding byte (see Figure 6). The attacker decrypts an HTTPS session cookie as follows:<sup>7</sup>

1.  $\mathcal{A}$  lures the victim client to load a web page he controls. This web page contains JavaScript code which sends HTTPS requests to the victim server, with a URL of  $\mathcal{A}$ 's choice.
2.  $\mathcal{A}$  observes the first TLS handshake and determines if the negotiated cipher suite is vulnerable to padding oracle attacks. If not, he aborts.
3. If a vulnerable cipher suite is used,  $\mathcal{A}$  instructs the client to send another HTTPS request, modifying the URL such that the first character of the session cookie is the last byte in cipher block  $c_i$ .
4. As a MitM,  $\mathcal{A}$  intercepts the ciphertext  $(c_1, \dots, c_i, \dots, c_n)$  and modifies it such that  $c_i$  becomes the last ciphertext block, for example by replacing  $c_n$  with  $c_i$ .
5. Decryption of this last block  $c_i$  is a pseudorandom transform, so the padding will likely be invalid, triggering an observable `invalid_padding` error event.
6. In about 1 out of 256 requests, the padding will randomly be valid. When the padding is valid, it is most likely to be one byte in length, as depicted in Figure 6. The preceding bytes will be parsed by the TLS server as MAC data, and will be invalid with overwhelming probability. In this case,  $\mathcal{A}$  observes a `valid_padding` error event, and computes the first character of the HTTPS

<sup>7</sup>We present here a more general form of the attack, which is also applicable to POODLE-style oracles. This form requires 256 sessions on average in order to decrypt one plaintext byte [27]. For oracles which completely disregard the MAC, there is a faster form which requires 128 sessions on average to decrypt one plaintext byte.

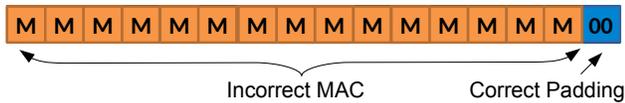

Figure 6: Our attacks rely on a vulnerable server that delivers different responses based on the validity of the last padding byte.

session cookie as  $c_{n-1}[-1] \oplus c_{i-1}[-1]$ , where the  $[-1]$  operator denotes taking the last byte of a block.

7.  $\mathcal{A}$  then prepares another HTTPS URL where the second character of the session cookie is shifted to the last byte of  $c_i$ , and starts again with step 3.

## 7.2 (R2) Perfect Padding Distinguishability

In the above example, we considered a simple oracle that allows for distinguishing between `valid_padding` and `invalid_padding` based on the validity of the last padding byte. However, even when providing different responses, implementations do not necessarily expose such simple oracles. For example, an older OpenSSL version responds with a different alert message only in the specific case of an empty record containing at least two full valid padding blocks [37]. We identified vulnerable implementations that only respond differently to ciphertexts containing several valid padding or MAC bytes. Such vulnerabilities are less likely to be exploitable since using the algorithm above, the attacker would need to perform far more than 256 oracle queries to decrypt each byte. The attacker may be able to overcome this limitation by inserting bytes of his choice directly after the cookie value. Due to the malleability property of CBC, it is only possible to insert one block of successive chosen data. Therefore, CBC allows for the creation of practical exploits if the number of chosen padding bytes is smaller than the block size.<sup>8</sup>

Therefore, in our impact estimation, we take a conservative approach. To consider a vulnerable implementation as exploitable, we require that it responds with `valid_padding` to ciphertexts with at most one block of valid padding. We call such oracles *strong* and refer to other oracles as *weak*. In addition to these two oracles, we consider oracles which do not correctly validate the complete CBC padding and only validate the MAC. We refer to such oracles as *POODLE oracles*. These oracles could also be exploited by applying attacks similar to POODLE.

Column *R2* in Table 2 identifies the oracle strength. For example, servers with the second most prevalent cipher suite

<sup>8</sup>Decrypting parts of the cookies with weak oracles or exploiting weak oracles could also be possible with extended techniques. We do not analyze the exploitability of these more complex oracles. Such an analysis would likely need to be done manually for each oracle and would need to consider specific browser behaviors.

fingerprint (#41) respond to malformed records #6 and #7 from Table 1 with a `RECORD_OVERFLOW`. In all other cases, the servers send the `BAD_RECORD_MAC` alerts. We consider this group to be weak since the attacker needs to send more than one block of valid padding to trigger the `RECORD_OVERFLOW` alert with a malformed record #6 or #7.

We consider servers with cipher suite fingerprint #2 to be strong oracles. The servers from this group respond with a TCP connection reset (⚡) if they receive a malformed record with a valid padding (see malformed records #20 and #21). There are also several groups with behavior similar to POODLE. These groups ignore modifications in the MAC bytes and respond differently to malformed records #8, #9, #17, and #18.

## 7.3 Exploitability

We consider observable POODLE and observable strong oracles as exploitable. We consider all other oracles as non-exploitable. However, note that weak oracles may be exploitable using more advanced techniques. Our estimate of the number of exploitable hosts is, therefore, a conservative lower estimate.

**Estimation of exploitable hosts.** Our scan identified 18,257 hosts vulnerable to padding oracle attacks. Of those, 11,225 (61.4%) exhibit observable vulnerabilities that allow an attacker to distinguish between two malformed records. See also column *R1* in Table 2. At least 10,688 hosts provided strong or POODLE-styled oracles, which is 58% of vulnerable hosts. See also column *R2* in Table 2. In total, 10,501 hosts are practically exploitable, i.e. they meet both requirements.

**Are CBC cipher suites negotiated?** Most modern browsers support AEAD cipher suites. If a vulnerable server prefers AEAD cipher suites, they would likely be negotiated, and this precludes CBC attacks. 31,651 hosts or 4.03% only support RC4 or CBC cipher suites. Most modern browsers have disabled support for RC4 cipher suites due to [30], so modern browsers would likely negotiate CBC cipher suites with these hosts. Of those hosts, 1,400 were vulnerable to padding oracle attacks.

## 8 Findings

In this section we review our assumptions and present notable vulnerabilities we found in different implementations.

### 8.1 Do our Initial Assumptions Hold?

We performed our scans under the assumption that scanning with different cipher suites and protocol version is necessary

in order to detect vulnerable hosts. As explained below, our findings confirm this assumption.

### Is scanning with different protocol versions necessary?

Böck et al. found that some servers exhibit RSA padding oracle vulnerabilities only on some of the protocol versions they support [9]. As noted in Section 3.5, we suspected the same holds for CBC padding vulnerabilities. Our findings confirm this assumption: We identified at least 744 hosts that support the same cipher suite in both TLS 1.0 and 1.2, but are vulnerable when using that cipher suite only in one of those versions. In some cases the vulnerable protocol version is the newer version, and in other cases, the older one. As an example of the former case, vine.co was vulnerable using TLS 1.2 with the TLS\_RSA\_WITH\_3DES\_EDE\_CBC\_SHA cipher suite, but was not vulnerable when using the same cipher suite in TLS 1.0.

Surprisingly, when only one protocol version is vulnerable with the same cipher suite, there are more cases where the newer version is vulnerable. Out of those 744 hosts, 120 hosts are vulnerable in TLS 1.0 but not in TLS 1.2, and 624 are vulnerable in TLS 1.2 but not in TLS 1.0.

### Is scanning with different cipher suites necessary?

Böck et al. also found that scanning with different cipher suites is necessary to detect as many vulnerabilities as possible [9]. In the above work, this finding held even when scanning with cipher suites using different symmetric ciphers, while the vulnerability was in the (theoretically unrelated) RSA implementation.

We find similar behavior in our results. We identified at least 601 hosts with two cipher suites, one vulnerable and one secure, where the only difference between the two cipher suites is the *key exchange algorithm*. This finding is unintuitive, as one would expect an implementation to be uniformly vulnerable or secure on all cipher suites with the same symmetric cipher. To give one example, one website is secure when using TLS\_RSA\_WITH\_AES\_256\_CBC\_SHA256 with TLS 1.2, but is vulnerable when using TLS\_DHE\_RSA\_WITH\_AES\_256\_CBC\_SHA256, also with TLS 1.2.

**Rationale behind the server behaviors.** Both behaviors may seem unintuitive but are actually expected. Many implementations take completely different code paths depending on the negotiated cipher suite or protocol version. These code paths may, for example, rely on hardware acceleration or use an optimized assembly implementation when possible. It is therefore likely (and, as we see, common) to find implementations that exhibit vulnerabilities only in some of the supported cipher suites and protocol versions, even when the same symmetric cipher is used.

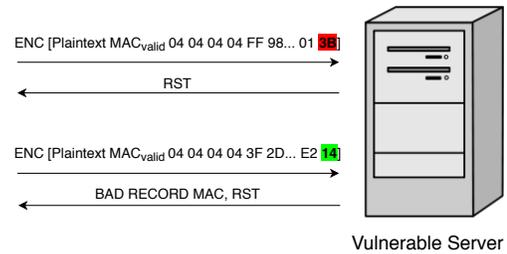

Figure 7: Behavior of Citrix implementations with cipher suite fingerprint #84.

## 8.2 Notable Vulnerabilities

In our scans we identified multiple devices from Cisco, two different IBM servers, and multiple devices from Sonicwall and Oracle. In the following, we describe specific vulnerabilities we identified and responsibly disclosed in Citrix, OpenSSL, and IBM servers.

Our disclosure is still an ongoing process. Our recent findings and the current state of countermeasures implemented by affected vendors are summarized on <https://github.com/RUB-NDS/TLS-Padding-Oracles>.

**Amazon/OpenSSL.** With the help of the Amazon security team, we identified a vulnerability (cipher suite fingerprint #15) which was mostly found on Amazon servers and Amazon Web Services (AWS). Hosts affected by this vulnerability immediately respond to most records with BAD\_RECORD\_MAC and CLOSE\_NOTIFY alerts, and then close the connection. However, if the hosts encounter a zero-length record with valid padding and a MAC present, they do not immediately close the TCP connection, regardless of the validity of the MAC. Instead, they keep the connection alive for more than 4 seconds after sending the CLOSE\_NOTIFY alert. This difference in behavior is easily observable over the network. Note that the MAC value does not need to be correct for triggering this timeout, it is sufficient to create valid padding which causes the decrypted data to be of zero length. Therefore, we classify this as a strong oracle which is also exploitable.

Further investigations revealed that the Amazon servers were running an implementation which uses the OpenSSL 1.0.2 API. In some cases, the function calls to the API return different error codes depending on whether a MAC or padding error occurred. The Amazon application then takes different code paths based on these error codes, and the different paths result in an observable difference in the TCP layer. The vulnerable behavior only occurs when AES-NI is not used.

We had in fact previously tested the vulnerable OpenSSL code manually, in lab settings, but had not identified this vulnerability. This is because the vulnerability only manifests

under a combination of specific conditions: subtle interactions between OpenSSL and external code, and only when AES-NI is not used, which is rare nowadays. We view this as an illustrative example of the usefulness of large-scale scans in detecting vulnerabilities that lab tests may sometimes miss.

We suspect this OpenSSL behavior underlies a number of similar vulnerabilities we identified, not only vulnerability #15. Therefore, we hope that once OpenSSL releases a patch, other vulnerabilities will be fixed as a result. The issue was assigned CVE-2019-1559.

**The IBM vulnerabilities.** We found multiple vulnerabilities in servers hosted by IBM. One of the vulnerabilities is described by cipher suite fingerprint #77 in Table 2. Affected servers respond with a BAD\_RECORD\_MAC alert if either the MAC or the padding is incorrect. If the padding is correct and the MAC is incomplete or not present, the server responds with a DECODE\_ERROR alert. The latter behavior occurs even if the records are too short to contain a MAC, as long as the record contains at least two blocks of ciphertext, independently of the used MAC algorithm. An attacker can send only two blocks with an IV, which guarantees there is not enough room for a MAC. This provides the attacker with a classic CBC padding oracle. We therefore consider this a strong oracle. Since the alerts are encrypted, we classify this vulnerability as unobservable, and the oracle is therefore not exploitable.

The IBM security team decided to disable CBC cipher suites on the affected servers and to only support AES-GCM.

**Citrix.** The described vulnerability is identified by cipher suite fingerprint #84 in Table 2. The vulnerable implementation first checks the last padding byte and then verifies the MAC. If the MAC is invalid, the server closes the connection. This is done with either a connection timeout or an RST, depending on the validity of the remaining padding bytes. However, if the MAC is valid, the server checks if all other remaining padding bytes are correct. If they are not, the server responds with a BAD\_RECORD\_MAC and an RST (if they are valid, the record is well-formed and is accepted). We visualize this behavior in Figure 7. This behavior can be exploited with an attack similar to POODLE. Since the oracle is also observable, we consider this group as exploitable. We first detected this vulnerability in Amazon Web Services. In cooperation with the Amazon security team, we determined that Citrix Application Delivery Controller (ADC) and NetScaler Gateway are responsible for this behavior. The vulnerability was assigned CVE-2019-6485.

## 9 Related Work

We now highlight past work that focused on large-scale scans for vulnerabilities on the modern Internet. For a survey of re-

lated work on padding oracle attacks, we refer the reader to Section 3. ZMap [18] is a network scanner capable of reaching high scanning speeds. Durumeric et al. [17] used ZMap to scan the IPv4 address space to quantify the impact of the Heartbleed vulnerability [32]. Heninger et al. [19] scanned TLS and SSH for weak keys generated using insufficient entropy. Adrian et al. [2] introduced the Logjam vulnerability and used Internet-wide scanning to quantify its effects, depending on attacker computational resources. Aviram et al. [5] introduced the DROWN vulnerability and similarly used Internet-wide scanning to quantify its effects. Böck et al. [9] performed large-scale scans for Bleichenbacher’s vulnerability, while also observing side channels such as changes in the TCP connection state, as we do here. Valenta et al. [38] scanned for known vulnerabilities in elliptic curve implementations, searching for a combination that could enable a powerful attack named CurveSwap.

## 10 Conclusions and Future Work

This work demonstrates that padding oracle vulnerabilities still exist on the modern Internet and will likely continue to threaten users’ security. These vulnerabilities are often hard to detect: they may rely on subtle side channels or require specifically-crafted inputs in order to trigger.

In the past, major new TLS attacks had positive effects on the ecosystem. For example, the work by Adrian et al. [2] resulted in an “enforcement” effort, where major browsers changed their behavior and refused to connect to servers with weak DH parameters. It is an interesting open question how the security community can better help server operators detect and remediate more subtle kind of vulnerabilities (CBC oracles in particular, and other classes of vulnerabilities in general).

One solution in the context of CBC oracles would be to disallow CBC cipher suites altogether. Recently, major browser vendors have declared their intention to remove support for the old 1.0 and 1.1 TLS versions. This forces many server operators to upgrade their implementations or change configuration. Indeed, a case could be made that browser vendors can also remove support for CBC cipher suites, forcing again server operators to upgrade. These changes are not without their costs; they usually require notice of months in advance, may require coordination between browser vendors, and obviously, create additional work for server operators.

Our results again confirm that large-scale scans make it feasible to uncover a large variety of security vulnerabilities, previously not detected by lab testing. We believe that our approach is of general interest when performing large-scale scans, not only in the context of TLS. One open question is how to identify vulnerable implementation versions and their vendors. In the SSH and IPsec protocols, these data are typically transmitted as message fields in the protocol.

Transmitting such data in TLS would make disclosure easier, but on the other hand would lead to privacy issues and easier fingerprinting.

## Acknowledgments

We would like to thank Dennis Felsch who assisted us with our hardware and network infrastructure, and our anonymous reviewers for many insightful comments. Additionally, we would like to thank the Amazon, Citrix and OpenSSL teams for their professional responses and help with disclosure.

## Abstract

We present an attack on the encryption key negotiation protocol of Bluetooth BR/EDR. The attack allows a third party, without knowledge of any secret material (such as link and encryption keys), to make two (or more) victims agree on an encryption key with only 1 byte (8 bits) of entropy. Such low entropy enables the attacker to easily brute force the negotiated encryption keys, decrypt the eavesdropped ciphertext, and inject valid encrypted messages (in real-time). The attack is stealthy because the encryption key negotiation is transparent to the Bluetooth users. The attack is standard-compliant because all Bluetooth BR/EDR versions require to support encryption keys with entropy between 1 and 16 bytes and do not secure the key negotiation protocol. As a result, *the attacker completely breaks Bluetooth BR/EDR security without being detected*. We call our attack **Key Negotiation Of Bluetooth (KNOB)** attack.

The attack targets the firmware of the Bluetooth chip because the firmware (Bluetooth controller) implements all the security features of Bluetooth BR/EDR. As a standard-compliant attack, it is expected to be effective on any firmware that follows the specification and on any device using a vulnerable firmware. We describe how to perform the KNOB attack, and we implement it. We evaluate our implementation on more than 14 Bluetooth chips from popular manufacturers such as Intel, Broadcom, Apple, and Qualcomm. Our results demonstrate that all tested devices are vulnerable to the KNOB attack. We discuss countermeasures to fix the Bluetooth specification and its implementation.

## 1 Introduction

Bluetooth BR/EDR (referred for the rest of this paper as Bluetooth), is a short-range wireless technology widely used by many products such as mobile devices, laptops, IoT and industrial devices. Bluetooth provides security mechanisms to achieve authentication, confidentiality and data integrity at the link layer [6, p. 1646].

The security and privacy of Bluetooth has been attacked and fixed several times, going all the way back to Bluetooth v1.0. [15, 32]. Several successful attacks on the (secure simple) pairing phase [28, 13, 4] have resulted in substantial revisions of the standard. Attacks on Android, iOS, Windows and Linux implementations of Bluetooth were also discussed in [2]. However, little attention has been given to the security of the *encryption key negotiation protocol*, e.g., the Bluetooth security overview in the latest Bluetooth core specification (v5.0) does not mention it [6, p. 240].

The encryption key negotiation protocol is used by two Bluetooth devices to agree on the entropy of the link layer encryption key. Entropy negotiation was introduced in the specification of Bluetooth to cope with international encryption regulations and to facilitate security upgrades [6, p. 1650]. To the best of our knowledge, all versions of the Bluetooth standard (including the latest v5.0 [6]) *require* to use entropy values between 1 and 16 bytes. The specification of Bluetooth states this requirement as follows: “For the encryption algorithm, the key size may vary between 1 and 16 octets (8 - 128 bits)” [6, p. 1650]. Our interpretation of this requirement is that any device to be standard-compliant has to support encryption keys with entropy varying from one to sixteen bytes. The attack that we present in this work confirms our interpretation.

The encryption key negotiation protocol is conducted between two parties as follows: the initiator proposes an entropy value  $N$  that is an integer between 1 and 16, the other party either accepts it or proposes a lower value or aborts the protocol. If the other party proposes a lower value, e.g.,  $N - 1$ , then the initiator either accepts it or proposes a lower value or it aborts the protocol. At the end of a successful negotiation the two parties have agreed on the entropy value of the Bluetooth encryption key. The entropy negotiation is performed over the Link Manager Protocol (LMP), it is not encrypted and not authenticated, and it is transparent to the Bluetooth users because LMP packets are managed by the firmware of the Bluetooth chips and they are not propagated to higher layers [6, p. 508].

In this paper we describe, implement and evaluate an attack capable of making two (or more) victims using a Bluetooth encryption key with 1 byte of entropy without noticing it. The attacker then can easily brute force the encryption key, eavesdrop and decrypt the ciphertext and inject valid ciphertext without affecting the status of the target Bluetooth piconet. In other words, *the attacker completely breaks Bluetooth BR/EDR security without being detected*. We call this attack the **Key Negotiation Of Bluetooth (KNOB)** attack.

The KNOB attack can be conducted remotely or by maliciously modifying few bytes in one of the victim's Bluetooth firmware. Being a standard-compliant attack it is expected to be effective on any firmware implementing the Bluetooth specification, regardless of the Bluetooth version. The attacker is not required to possess any (pre-shared) secret material and he does not have to observe the pairing process of the victims. The attack is effective even when the victims use the strongest security mode of Bluetooth (Secure Connections). The attack is stealthy because the application using Bluetooth and even the operating systems of the victims cannot access or control the encryption key negotiation protocol (see Section 3.2 for the details).

After explaining the attack in detail, we implement it leveraging our development of several Bluetooth security procedures to generate valid link and encryption keys, and the InternalBlue toolkit [21]. Our implementation allows a man-in-the-middle attacker to intercept, manipulate, and drop LMP packets in real-time and to brute force low-entropy encryption keys, without knowing any (pre-shared) secret. We have disclosed our findings about the KNOB attack with CERT and the Bluetooth SIG, and following that, we plan to release our tools as open-source at <https://github.com/francozappa/knob>. This will enable other Bluetooth researchers to take advantage of our work.

We summarize our main contributions as follows:

- We develop an attack on the encryption key negotiation protocol of Bluetooth BR/EDR that allows to let two unaware victims negotiate a link-layer encryption key with 1 byte of entropy. The attacker then is able to brute force the low entropy key, decrypt all traffic and inject arbitrary ciphertext. The attacker does not have to know any secret material and he can target multiple nodes and piconets at the same time.
- We demonstrate the practical feasibility of the attack by implementing it. Our implementation involves a man-in-the-middle attacker capable of manipulating the encryption key negotiation protocol, brute forcing the key and decrypting the traffic exchanged by two (or more) unaware victims.
- All standard-compliant devices should be vulnerable to our attack, including the ones using the strongest Bluetooth security mode. In order to demonstrate that

this problem has not somehow been fixed in practice, we test more than 14 different Bluetooth chips and find all of them to be vulnerable.

- We discuss what changes should be made, both to the Bluetooth standard and its implementation, in order to counter this attack.

Our work is organized as follows: in Section 2 we introduce the Bluetooth BR/EDR stack. In Section 3 we present the Key Negotiation Of Bluetooth (KNOB) attack. An implementation of the attack is discussed in Section 4. We evaluate the impact of our attack in Section 5 and we discuss the attack and our proposed countermeasures in Section 6. We present the related work in Section 7. We conclude the paper in Section 8.

## 2 Background

### 2.1 Bluetooth Basic Rate/Extended Data Rate

Bluetooth Basic Rate/Extended Data Rate (BR/EDR), also known as Bluetooth Classic, is a widely used wireless technology for low-power short-range communications maintained by the Bluetooth Special Interest Group (SIG) [6]. Its physical layer uses the same 2.4 GHz frequency spectrum of WiFi and (adaptive) frequency hopping to mitigate RF interference. A Bluetooth network is called a piconet and it uses a master-slave medium access protocol. There is always one master device per piconet at a time. The devices are synchronized by maintaining a reference clock signal, defined as CLK. Each device has a Bluetooth address (BTADD) consisting of a sequence of six bytes. From left to right, the first two bytes are defined as non-significant address part (NAP), the third byte as upper address part (UAP) and the last three bytes as lower address part (LAP).

To establish a secure Bluetooth connection two devices first have to pair. This procedure results in the establishment of a long-term shared secret defined as *link key*, indicated with  $K_L$ . There are four types of link key: initialization, unit, combination and master. An initialization key is always generated for each new pairing procedure. A unit key is generated from a device and utilized to pair with every other device, and its usage is not recommended because it is insecure. A combination key is generated using Elliptic Curve Diffie-Hellman (ECDH) on the P-256 elliptic curve. This procedure is defined as Secure Simple Pairing (SSP) and it provides optional authentication of the link key. Combination keys are the most secure and widely used. A master key is generated only for broadcast encryption and it has limited usage. The master key is temporary, while the others are semi-permanent. A semi-permanent key can persist until a new link key is requested (link key is bonded) or it can change within the same session (link key is not bonded). In this paper we deal with combination link keys generated using authenticated SSP.

The specification of Bluetooth defines custom security procedures to achieve confidentiality, integrity and authentication. In the specification their names are prefixed with the letter E. In particular, a combination link key  $K_L$  is mutually authenticated by the  $E_1$  procedure. This procedure uses a public nonce (AU\_RAND) and the slave's Bluetooth address (BTADD<sub>S</sub>) to generate two values: the Signed Response (SRES) and the Authenticated Ciphering Offset (ACO). SRES is used over the air to verify that two devices actually own the same  $K_L$ .

The symmetric encryption key  $K_C$  is generated using the  $E_3$  procedure. When the link key is a combination key  $E_3$  uses ACO (computed by  $E_1$ ) as its Ciphering Offset Number (COF) parameter, together with  $K_L$  and a public nonce (EN\_RAND).  $E_1$  and  $E_3$  use a custom hash function defined in the specification of Bluetooth with H. The hash function is based on SAFER+, a block cipher that was submitted as an AES candidate in 1998 [22].

Once the encryption key  $K_C$  is generated there are two possible ways to encrypt the link-layer traffic. If both devices support Secure Connections, then encryption is performed using a modified version of AES CCM. AES CCM is an authenticate-then encrypt cipher that combines Counter mode with CBC-MAC and it is defined in the IETF RFC 3610 [14]. As a side note, the specification of Bluetooth defines a message authentication codes (MAC) with the term message integrity check (MIC). If Secure Connections is not supported then the devices use the  $E_0$  stream cipher for encryption. The cipher is derived from the Massey-Rueppel algorithm and it is described in the specification of Bluetooth [6, p. 1662].  $E_0$  requires synchronization between the master and the slaves of the piconet, this is achieved using the Bluetooth's clock value (CLK).

Modern implementations of Bluetooth provides the Host Controller Interface (HCI). This interface allows to separate the Bluetooth stack into two components: the host and the controller. Each component has specific responsibilities, i.e., the controller manages low-level radio and baseband operations and the host manages high-level application layer profiles. Typically, the host is implemented in the operating system and the controller in the firmware of the Bluetooth chip. For example BlueZ and Bluedroid implement the HCI host on Linux and Android, and the firmware of a Qualcomm or Broadcom Bluetooth chip implements the HCI controller. The host and the controller communicate using the Host Controller Interface (HCI) protocol. This protocol is based on commands and events, i.e., the host sends (acknowledged) commands to the controller, and the controller uses events to notify the host.

The Link Manager Protocol (LMP) is used over the air by two controllers to perform link set-up and control for Bluetooth BR/EDR. LMP is neither encrypted nor authenticated. The LMP packets do not propagate to higher protocol layers, hence, the hosts (OSes) are not aware about the LMP packets exchanged between the Bluetooth controllers.

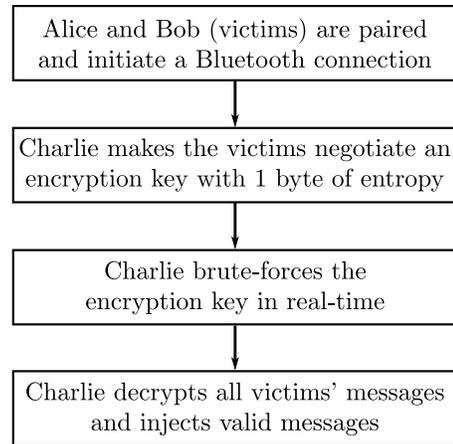

Figure 1: High level stages of a KNOB attack.

### 3 Exploiting Low Entropy in the Encryption Key Negotiation Of Bluetooth BR/EDR

In this section we describe the Key Negotiation Of Bluetooth (KNOB) attack. The attack allows Charlie (the attacker) to reduce the entropy of the encryption key of any Bluetooth BR/EDR (referred as Bluetooth) connection to 1 byte, without being detected by the victims (Alice and Bob). The attacker can brute force the encryption key without having to know any (pre-shared) secret material and without having to observe the Secure Simple Pairing protocol. As a result, the attacker can eavesdrop and decrypt all the traffic and inject arbitrary packets in the target Bluetooth network (piconet). The attack works regardless the usage of Secure Connections (the strongest security mode of Bluetooth). The KNOB attack high level stages are shown in Figure 1 and they are described in detail in the rest of this section.

#### 3.1 System and Attacker Model

We assume a system composed of two or more legitimate devices that communicate using Bluetooth (as described in Section 2). One device is the master and the others are slaves. Without loss of generality, we focus on a piconet with one master and one slave (Alice and Bob). We indicate their Bluetooth addresses with BTADD<sub>M</sub> and BTADD<sub>S</sub>, and the Bluetooth clock with CLK. The clock is used for synchronization and it does not provide any security guarantee. The victims are capable of using Secure Simple Pairing and Secure Connections. This combination enables the highest security level of Bluetooth and should protect against eavesdropping and active man in the middle attacks. For example, if both devices have a display their users have to confirm that they see the same numeric sequence to mutually authenticate.

The attacker (Charlie) wants to decrypt all messages exchanged between Alice and Bob and inject valid encrypted messages, without being detected. The attacker has no access

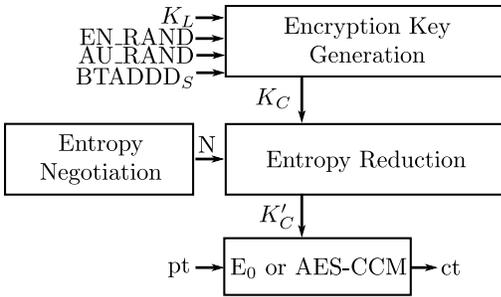

Figure 2: Generation and usage of the Bluetooth link layer encryption key ( $K'_C$ ). Firstly,  $K_C$  is generated from  $K_L$  and other public parameters.  $K_C$  has 16 bytes of entropy, and it is not directly used as the encryption key.  $K'_C$ , the actual encryption key, is computed by reducing the entropy of  $K_C$  to  $N$  bytes.  $N$  is an integer between 1 and 16 and it is the result of the encryption key negotiation protocol. The  $N$  byte entropy  $K'_C$  is then used for link layer encryption by either the  $E_0$  or the AES-CCM cipher.

to any (pre-shared) secret material. i.e., the link key  $K_L$  and the encryption key  $K_C$ . Charlie can observe the public nonces (EN.RAND and AU.RAND), the Bluetooth clock and the packets exchanged between Alice and Bob.

We define two attacker models: a *remote* attacker and a *firmware* attacker. A remote attacker controls a device that is in Bluetooth range with Alice and Bob. He is able to passively capture encrypted messages, actively manipulate unencrypted communication, and to drop packets using techniques such as network man-in-the-middle and manipulation of physical-layer signals [31, 26]. The firmware attacker is able to compromise the firmware of the Bluetooth chip of a single victim using techniques such as backdoors [7], supply-chain implants [12], and rogue chip manufacturers [27]. The firmware attacker requires no access to the Bluetooth host (OS) and applications used by the victims.

### 3.2 Negotiate a Low Entropy Encryption Key

Every time a Bluetooth connection requires link-layer encryption, Alice and Bob compute an encryption key  $K_C$  based on  $K_L$ , BTADDD<sub>S</sub>, AU.RAND, and EN.RAND (see top part of Figure 2).  $K_L$  is the link key established during secure simple pairing and the others parameters are public. Assuming ideal random number generation, the entropy of  $K_C$  is always 16 bytes.

$K_C$  is not directly used as the encryption key for the current session. The actual encryption key, indicated with  $K'_C$ , is computed by reducing the entropy of  $K_C$  to  $N$  bytes.  $N$  is the outcome of the Bluetooth *encryption key negotiation protocol* (Entropy Negotiation in Figure 2). The protocol is part of the Bluetooth specification since version v1.0, and it was introduced to cope with international encryption regulations and

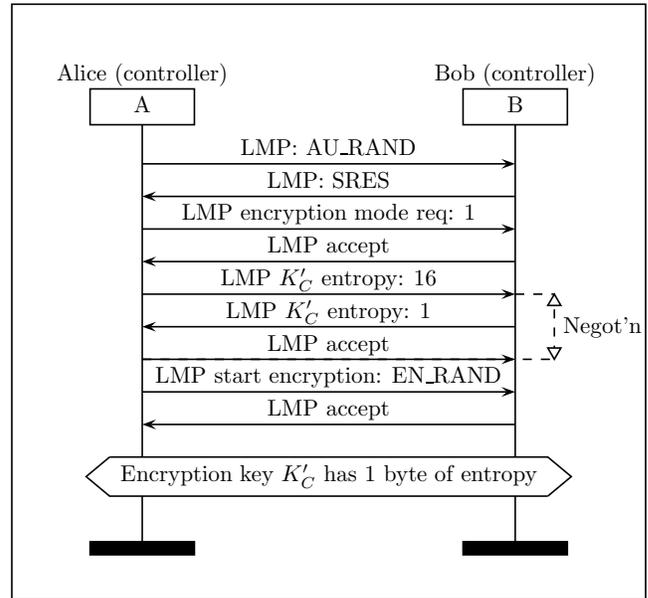

Figure 3: Alice and Bob negotiate 1 byte of entropy for the encryption key ( $K'_C$ ). The protocol is run by Alice and Bob controllers (implemented in their Bluetooth chip) over the air using LMP.

to facilitate security upgrades [6, p. 1650]. The specification of the Bluetooth encryption key negotiation protocol contains three significant problems:

1. It allows to negotiate entropy values as low as 1 byte, regardless the Bluetooth security level.
2. It is neither encrypted nor authenticated.
3. It is implemented in the Bluetooth controller (firmware) and it is transparent to the Bluetooth host (OS) and to the user of a Bluetooth application.

Hence, an attacker (Charlie) can convince any two victims (Alice and Bob) to negotiate  $N$  equal to 1, the lowest possible, yet standard-compliant, entropy value. As a result the victims compute and use a Bluetooth encryption key ( $K'_C$ ) with one byte of entropy. The victims (and their OSes) are not aware about the entropy reduction of  $K'_C$  because the negotiation happens between the victims' Bluetooth controller (firmware) and the packets do not propagate to the victims' Bluetooth host (OS).

To understand how an attacker can set  $N$  equal to 1 (or to any other standard-compliant value), we have to look at the details of the encryption key negotiation protocol. The protocol is run between the Bluetooth chip of Alice and Bob. In the following, we provide an example where Alice (the master) proposes 16 bytes of entropy, and Bob (the slave) is only able to support 1 byte of entropy (see Figure 3). The standard enables to set the minimum and maximum entropy

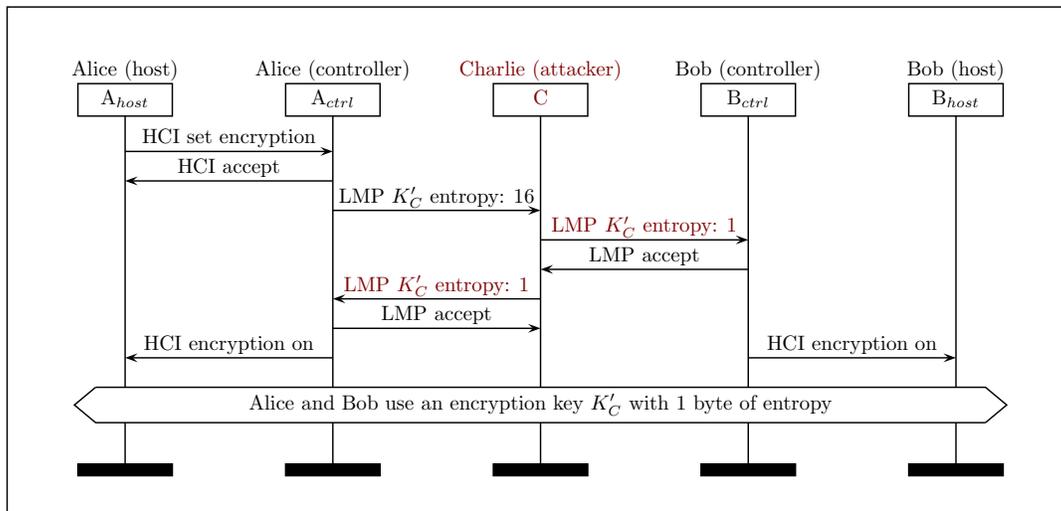

Figure 4: The KNOB attack sets the entropy of the encryption key ( $K'_C$ ) to 1 byte. Alice requests Bob to activate encryption and starts the encryption key negotiation protocol. The attacker (Charlie) changes the entropy suggested by Alice from 16 to 1 byte. Bob accepts Alice’s proposal and Charlie changes Bob’s acceptance to a proposal of 1 byte. Alice, who originally proposed 16 bytes of entropy and she is asked to use 1 byte accepts the (standard-compliant) proposal. Charlie drops Alice’s acceptance message because Bob already accepted Alice’s proposal (modified by Charlie). Charlie does not know any pre-shared secret and does not observe SSP.

values by setting two parameters defined as  $L_{min}$  and  $L_{max}$ . These values can be set and read only by the Bluetooth chip (firmware). Indeed, our scenario describes a situation where Alice’s Bluetooth firmware declares  $L_{max} = 16$  and  $L_{min} = 1$ , and Bob’s Bluetooth firmware declares  $L_{max} = L_{min} = 1$ .

The encryption key negotiation protocol is carried over the Link Manager Protocol (LMP). The first two messages in Figure 3 allow Alice to authenticate that Bob possesses the correct  $K_L$ . Then, with the next two messages, Alice requests to initiate Bluetooth link layer encryption and Bob accepts. Now, the negotiation of  $N$  takes place (Negot'n in Figure 3). Alice proposes 16 bytes of entropy. Bob can either propose a smaller value or accept the proposed one or abort the negotiation. In our example, Bob proposes 1 byte of entropy because it is the only value that he supports and Alice accepts it. Then, Alice requests to activate link-layer encryption and Bob accepts. Finally, Alice and Bob compute the same encryption key ( $K'_C$ ) that has 1 byte of entropy. Note that, the Bluetooth hosts of Alice and Bob do not have access to  $K_C$  and  $K'_C$ , they are only informed about the outcome of the negotiation. The key negotiation procedure can also be initiated by the Bob (the slave), resulting in the same outcome.

Figure 4 describes how the attacker (Charlie) manages to let Alice and Bob agree on a  $K'_C$  with 1 byte of entropy when both Alice and Bob declare  $L_{max} = 16$  and  $L_{min} = 1$ . In this Figure we also show the local interactions between hosts and controllers to emphasize that at the end of the negotiation the hosts are not informed about  $N$  and  $K'_C$ .

The attack is performed as follows: Alice’s Bluetooth host

requests to activate (set) encryption. Alice’s Bluetooth controller accepts the local requests and starts the encryption key negotiation procedure with Bob’s Bluetooth controller over the air. The attacker intercepts Alice’s proposed key entropy and substitutes 16 with 1. This simple substitution works because LMP is neither encrypted nor integrity protected. Bob’s controller accepts 1 byte. The attacker intercepts Bob’s acceptance message and change it to an entropy proposal of 1 byte. Alice thinks that Bob does not support 16 bytes of entropy and accepts 1 byte. The attacker intercepts Alice’s acceptance message and drops it. Finally, the controllers of Alice and Bob compute the same  $K'_C$  with one byte of entropy and notify their respective hosts that link-layer encryption is on.

It is reasonable to think that the victim could prevent or detect this attack using a proper value for  $L_{min}$ . However, the standard does not state how to explicitly take advantage of it, e.g., deprecate  $L_{min}$  values that are too low. The standard states the following: “The possibility of a failure in setting up a secure link is an unavoidable consequence of letting the application decide whether to accept or reject a suggested key size.” [6, p. 1663]. This statement is ambiguous because it is not clear what the definition of “application” is in that sentence. As we show in Section 5, this ambiguity results in no-one being responsible for terminating connections with low entropy keys in practice. In particular, the entity who decides whether to accept or reject the entropy proposal is the firmware of the Bluetooth chip by setting  $L_{min}$  and  $L_{max}$  and participating in the entropy negotiation protocol. The

“application” (intended as the Bluetooth application running on the OS using the firmware as a service) cannot check and set  $L_{min}$  and  $L_{max}$ , and it is not directly involved in the entropy acceptance/rejection choice (that is performed by the firmware). The application can interact with the firmware using the HCI protocol. In particular, it can use the HCI Read Encryption Key Size request, to check the amount of negotiated entropy *after* the Bluetooth connection is established and theoretically abort the connection. This check is neither required nor recommended by the standard as part of the key negotiation protocol.

The low entropy negotiation presented in Figure 4 can be performed by both attacker models presented in Section 3.1. The remote attacker has the capabilities of dropping and injecting valid plaintext (the encryption key negotiation protocol is neither encrypted nor authenticated). The firmware attacker can modify few bytes in the Bluetooth firmware of a victim to always negotiate 1 byte of entropy. Furthermore, the negotiation is effective regardless of who initiates the protocol and the roles (master or slave) of the victims in the piconet.

### 3.3 Brute forcing the Encryption Key

Bluetooth has two link layer encryption schemes one is based on the  $E_0$  cipher (legacy) and the other on the AES-CCM cipher (Secure Connections). Our KNOB attack works in both cases. If the negotiated entropy for the encryption key ( $K'_C$ ) is 1 byte, then the attacker can trivially brute force it trying (in parallel) the 256  $K'_C$ 's candidates against one or more cipher texts. The attacker does not have to know what type of application layer traffic is exchanged, because a valid plaintext contains well known Bluetooth fields, such as L2CAP and RFCOMM headers, that the attacker can use as oracles.

We now describe how to compute all 1 byte entropy keys when  $E_0$  and AES-CCM are in use. Each encryption mode involves a specific entropy reduction procedure that takes  $N$  and  $K_C$  as inputs and produces  $K'_C$  as output (Entropy Reduction in Figure 2). The specification of Bluetooth calls this procedure Encryption Key Size Reduction [6].

$$K'_C = g_2^{(N)} \otimes (K_C \bmod g_1^{(N)}) \quad (E_s)$$

In case of  $E_0$ ,  $K'_C$  is computed using Equation ( $E_s$ ), where  $N$  is an integer between 1 and 16 resulted from the encryption key negotiation protocol (see Section 3.2).  $g_1^{(N)}$  is a polynomial of degree  $8N$  used to reduce the entropy of  $K_C$  to  $N$  bytes. The result of the reduction is encoded with a block code  $g_2^{(N)}$ , a polynomial of degree less or equal to  $128 - 8N$ . The values of these polynomials depend on  $N$  and they are tabulated in [6, p. 1668]. If  $N = 1$ , then we can compute the 256 candidate  $K'_C$  by multiplying all the possible 1 byte reductions  $K_C \bmod g_1^{(1)}$  (the set  $0x00\dots0xff$ ) with  $g_2^{(1)}$  (that equals to  $0x00e275a0abd218d4cf928b9bbf6cb08f$ ).

In case of AES-CCM the entropy reduction procedure is simpler than the one of  $E_0$ . In particular, the 16 –  $N$  least significant bytes of  $K_C$  are set to zero. For example, when  $N = 1$  the 256  $K'_C$  candidates for AES-CCM are the set  $0x00\dots0xff$ .

In the implementation of our KNOB attack brute force logic, we pre-compute the 512 keys with 1 byte of entropy and we store them in a look-up table to speed-up comparisons. Table 4 in Appendix A shows the first twenty  $K'_C$  with 1 byte of entropy for  $E_0$  and AES-CCM. More details about the brute force implementation are discussed in Section 4.

### 3.4 KNOB Attack Implications

*The Key Negotiation Of Bluetooth (KNOB) attack exploits a vulnerability at the architectural level of Bluetooth. The vulnerable encryption key negotiation protocol endangers potentially all standard compliant Bluetooth devices, regardless their Bluetooth version number and implementation details. We believe that the encryption key negotiation protocol has to be fixed as soon as possible.*

In particular the KNOB attack has serious implications related to its *effectiveness, stealthiness, and cost*. The attack is effective because it exploits a weakness in the specification of Bluetooth. The Bluetooth security mode does not matter, i.e., the attack works even with Secure Connections. The implementation details do not matter, e.g., whether Bluetooth is implemented in hardware or in software. The time constraints imposed by the Bluetooth protocols do not matter because the attacker can eavesdrop the traffic and brute force the low-entropy key offline. The type of connection does not matter, e.g., the attack works with long-lived and short-lived connections. In a long-lived connection, e.g., victims are a laptop and a Bluetooth keyboard, the attacker has to negotiate and brute force a single low-entropy  $K'_C$ . In a short-lived connection, e.g., victims are two devices transferring files over Bluetooth, the attacker has to negotiate and brute force multiple low-entropy  $K'_C$  over time re-using the same attack technique without incurring in significant runtime and computational overheads.

The attack is stealthy because only the Bluetooth controllers (implemented in the victims’ Bluetooth chip) are aware of  $N$  and  $K'_C$ . By design, the controllers are not notifying the Bluetooth hosts (implemented in the OSes) about  $N$ , but only about the outcome of the entropy negotiation. The users and the Bluetooth application developers are unaware of this problem because they use Bluetooth link-layer encryption as a trusted service.

The attack is cheap because it does not require a strong attacker model and expensive resources to be conducted. We expect that a remote attacker with commercial-off-the-shelf devices such as a software defined radio, GNU Radio and a laptop can conduct the attack.

### 3.5 KNOB Attack Root Causes

The root causes of the KNOB attack are shared between the specification and the implementation of Bluetooth BR/EDR confidentially mechanisms. On one side the specification is defining a vulnerable encryption key negotiation protocol that allows devices to negotiate low entropy values. On the implementation side (see Section 5), the Bluetooth applications that we tested are failing to check the negotiated entropy in practice. This is understandable because they are implementing a specification that is not mandating or explicitly recommending an entropy check.

We do not see any reason to include the encryption key negotiation protocol in the specification of Bluetooth. From our experiments (presented in Section 5) we observe that if two devices are not attacked they always use it in the same way (a device proposes 16 bytes of entropy and the other accepts). Furthermore, the entropy reduction does not improve runtime performances because the size of the encryption key is fixed to 16 bytes even when its entropy is reduced.

## 4 Implementation

We now discuss how we implemented the KNOB attack using a reference attack scenario. In particular, we explain how we manipulate the key negotiation protocol, brute force the encryption key ( $K'_C$ ) using eavesdropped traffic, and validate  $K'_C$  by computing it from  $K_L$  as a legitimate device (as in Figure 2). In our attack scenario, the attacker is able to decrypt the content of a link-layer encrypted file sent from a Nexus 5 to a Motorola G3 using the Bluetooth OBject EXchange (OBEX) profile. A Bluetooth profile is the equivalent of an application layer protocol in the TCP/IP stack.

Our implementation required significant efforts mainly due to the lack of low-cost Bluetooth protocol analyzers and software libraries implementing the custom Bluetooth security primitives (such as the modified SAFER+ block cipher). Using our implementation we conducted successful KNOB attacks on more than 14 different Bluetooth chips, the attacks are evaluated in Section 5.

### 4.1 Attack Scenario

To describe our implementation we use an attack scenario with two victims a Nexus 5 and a Motorola G3, Table 1 lists their relevant specifications. The Nexus 5 is used also as a man-in-the-middle attacker by adding extra code to its Bluetooth firmware. This setup allows us to *simulate* a remote man-in-the-middle attacker (more details in Section 4.2). To perform eavesdropping, we use an Ubertooth One [24] with firmware version 2017-03-R2 (API:1.02). To the best of our knowledge, Ubertooth One does not capture all Bluetooth BR/EDR packets, but it is the only open-source, low-cost, and practical eavesdropping solution for Bluetooth that we

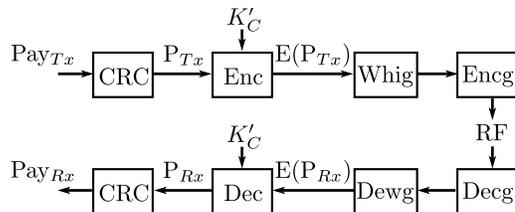

Figure 5: Transmission and reception of an  $E_0$  encrypted payload. The concatenation of the payload and its CRC ( $P_{Tx}$ ) is encrypted, whitened, encoded and then transmitted. On the receiver side the steps are applied in the opposite order. RF is the radio frequency wireless channel.

know about. To brute force  $K'_C$  and decrypt the ciphertext we use a ThinkPad X1 laptop running a Linux based OS.

The victims use the following security procedures: Secure Simple Pairing to generate  $K_L$  (the link key) and authenticate the users, the entropy reduction function from Equation ( $E_s$ ), and  $E_0$  legacy encryption. The victims use legacy encryption because the Nexus 5 does not support Secure Connections. Nevertheless, the KNOB attack works also with Secure Connections.

Every  $E_0$ -encrypted packet that contains data is transmitted and received as in Figure 5. A cyclic redundancy checksum (CRC) is computed and appended to the payload ( $Pay_{Tx}$ ). The resulting bytes ( $P_{Tx}$ ) are encrypted with  $E_0$  using  $K'_C$ . The ciphertext is whitened, encoded, and transmitted over the air. On the receiver side the following steps are applied in sequence: decoding, de-whitening, decryption, and CRC check. The encryption and decryption procedures are the same because  $E_0$  is a stream cipher, i.e., the same keystream is XORed with the plaintext and the ciphertext. Whitening and encoding procedures do not add any security guarantee and the Ubertooth One is capable of performing both procedures.

### 4.2 Manipulation of the Entropy Negotiation

We implement the manipulation of the encryption key negotiation protocol (presented in Section 3.2) by extending the functionalities of InternalBlue [21] and using it to patch the Bluetooth chip firmware of the Nexus 5. Our InternalBlue modifications allow to manipulate all incoming LMP messages *before* they are processed by the entropy negotiation logic, and all outgoing LMP messages *after* they've been processed by the entropy negotiation logic. The entropy negotiation logic is the code in the Nexus 5 Bluetooth firmware that manages the encryption key negotiation protocol, and we do not modify it. As a result, we can use a Nexus 5 (or any other device supported by InternalBlue) as a victim and a remote KNOB attacker without having to deal with the practical issues related with wireless attacks over-the-air.

InternalBlue is an open-source toolkit capable of interfacing with the firmware of the BCM4339 Bluetooth chip in

Phone	OS	Bluetooth			
		Version	MAC	SC	Chip
Nexus 5	Android 6.0.1	4.1	48:59:29:01:AD:6F	No	Broadcom BCM4339
Motorola G3	Android 6.0.1	4.1	24:DA:9B:66:9F:83	Yes	Qualcomm Snapdragon 410

Table 1: Relevant technical specifications of Nexus 5 and Motorola G3 devices used to describe our attack implementation. The SC column indicates if a device supports Secure Connections.

Nexus 5 phones. To use it, one has to root the target Nexus 5 and compile and install the Android Bluetooth stack with debugging features enabled. InternalBlue allows to patch the firmware in real-time (e.g., start LMP monitoring) and read the ROM and the RAM of firmware at runtime. InternalBlue provides a way to hook and execute arbitrary code in the Bluetooth firmware. At the time of writing, InternalBlue is not capable of hooking directly the key negotiation logic. However, we managed to extend it to enable two victims (one is always the Nexus 5) to negotiate one (or more) byte of entropy.

Our manipulation of the entropy negotiation works regardless the role of the Nexus 5 in the piconet and it does not require to capture any information about the Secure Simple Pairing process. Assuming that the victims are already paired, we test if two victims are vulnerable to the KNOB attack as follows:

1. We connect over USB the Nexus 5 with the X1 laptop, we run our version of InternalBlue, and we activate LMP and HCI monitoring.
2. We connect and start the Ubertooth One capture over the air focusing only on the Nexus 5 piconet (using UAP and LAP flags).
3. We request a connection from the Nexus 5 to the victim (or vice versa) to trigger the encryption key negotiation protocol over LMP.
4. Our InternalBlue patch changes the LMP packets as Charlie does in Figure 4.
5. If the victims successfully complete the protocol, then they are vulnerable to the KNOB attack and we can decrypt the ciphertext captured with the Ubertooth One.

We now describe how we extended InternalBlue to perform the fourth step of the list. In this context, the most important file of InternalBlue is `internalblue/fw_5.py`. This file contains all the information about the BCM4339 firmware, and it provides two hooks into the firmware, defined by Mantz (the main author of InternalBlue) as `LMP_send_packet` and `LMP_dispatcher`. The former hook allows to execute code every time an LMP packet is about to be sent and the latter

whenever an LMP packet is received. The hooks are intended for LMP monitoring, and we upgraded them to be used also for LMP manipulation.

Listing 1 shows three ARM assembly code blocks that we added to `fw_5.py` to let the Nexus 5 and the Motorola G3 negotiate 1 byte of entropy. In this case the Nexus 5 is the master and it initiates the encryption key negotiation protocol. The first block translates to: if the Nexus 5 is sending an LMP  $K'_C$  entropy proposal then change it to 1 byte. This block is executed when the Nexus 5 starts an encryption key negotiation protocol. The code allows to propose any entropy value by moving a different constant into `r2` in line 5.

The second block from Listing 1 translates to: if the Nexus 5 is receiving an LMP accept (entropy proposal), then change it to an LMP  $K'_C$  entropy proposal of 1 byte. This code is used to let the Nexus 5 firmware believe that the other victim proposed 1 byte, while she already accepted 1 byte (assuming that she is vulnerable). The third block translates to: if the Nexus 5 is sending an LMP accept (entropy proposal), then change it to an LMP preferred rate. This allows to obtain the same result of dropping an LMP accept packet because the LMP preferred rate packet does not affect the state of the encryption key negotiation protocols. We developed and used similar patches to cover the other attack cases: Nexus 5 is the master and does not initiate the connection, Nexus 5 is the slave and initiates the connection and Nexus 5 is the slave and does not initiate the connection.

### 4.3 Brute Forcing the Encryption Key

Once the attacker is able to reduce the entropy of the encryption key ( $K'_C$ ) to 1 byte, he has to brute force the key value (key space is 256). In this section we explain how we brute forced and validated a  $E_0$  encryption key with 1 byte of entropy. The key was used in one of our KNOB attacks to decrypt the content of a file transferred over a link layer encrypted Bluetooth connection.

The details about the  $E_0$  encryption scheme are presented in Figure 6, we describe them backwards starting from the  $E_0$  cipher.  $E_0$  takes three inputs:  $BTADD_M$ ,  $CLK_{26-1}$  and  $K'_C$ .  $CLK_{26-1}$  are the 26 bits of  $CLK$  in the interval  $CLK[25:1]$  (assuming that  $CLK$  stores its least significant bit at  $CLK[0]$ ). The  $BTADD_M$  is the Bluetooth address of the master and it

**Listing 1** We add three ARM assembly code blocks to `internalblue/fw_5.py` to negotiate  $K'_C$  with 1 byte of entropy. In this case the Nexus 5 is the master and it initiates the encryption key negotiation protocol.

is a public parameter. We did not have to implement the  $E_0$  cipher because we found an open-source implementation [8] which we verified against the specification of Bluetooth. To provide valid  $K'_C$  candidates to  $E_0$  we had to implement the  $E_s$  entropy reduction procedure. This procedure takes an input with 16 bytes of entropy ( $K_C$ ) and computes an output with  $N$  bytes of entropy ( $K'_C$ ).  $E_s$  involves modular arithmetic over polynomials in Galois fields and we use the BitVector [16] Python module to perform such computations.

Our Python brute force script takes a ciphertext (captured over the air using Ubertooth One) and tries to decrypt it by using the  $E_0$  cipher with all possible values of  $K'_C$ . We validate our script by decrypting the content of a file sent from the Nexus 5 to the Motorola G3 using the OBEX Bluetooth profile after the negotiation of 1 byte of entropy. The content of the file (in ASCII) is `aaaabbbbccccdddd`. We discuss several brute forcing practical issues in Section 6.3.

Once we found the matching plaintext we wanted to verify that the brute forced key was effectively the one in use by the victims. To do that we had to implement  $E_1$  and  $E_3$ , the former

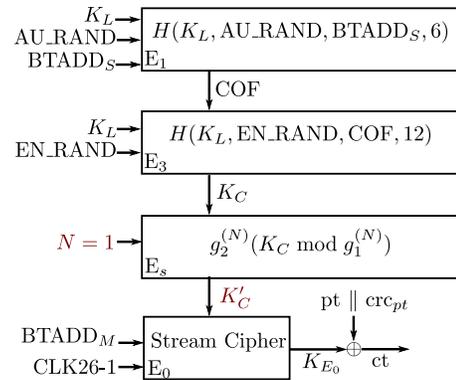

Figure 6: Implementation of the KNOB attack on the  $E_0$  cipher. The attacker makes the victims agree on a  $K'_C$  with one byte of entropy ( $N = 1$ ) and then brute force  $K'_C$ , without knowing  $K_L$  and  $K_C$ .

is used to compute the Ciphering Offset Number (COF), the latter to compute  $K_C$  (see Figure 6). Both procedures use a custom hash function defined in the specification of Bluetooth with  $H$ . We write  $E_1$  and  $E_3$  equations and label them with their respective names as follows:

$$SRES||ACO = H(K_L, AU\_RAND, BTADD_S, 6) \quad (E_1)$$

$$K_C = H(K_L, EN\_RAND, COF, 12) \quad (E_3)$$

Figure 7 shows how  $E_3$  uses the  $H$  hash function,  $H$  internally uses SAFER+, a block cipher that was submitted as an AES candidate in 1998 [22]. SAFER+ is used with 128 bit block size (8 rounds), in ECB mode, and only for encryption. SAFER+' (SAFER+ prime) is a modified version of SAFER+ such that the input of the first round is added to the input of the third round. This modification was introduced in the specification of Bluetooth to avoid SAFER+' being used for encryption [6, p. 1677].

We implemented in Python both SAFER+ and SAFER+' including the round computations and the key scheduling algorithm. We tested the two against the specification of Bluetooth (where they are indicated with  $A_r$  and  $A_r'$  [6, p. 1676]). We also implemented the E and O blocks from Figure 7. The E block is an extension block that transforms the 12 byte COF into a 16 byte sequence using modular arithmetic. The same block is applied to the 6 byte  $BTADD_S$  in  $E_1$ . The O block is offsetting  $K_L$  using algebraic (modular) operations and the largest primes below 257 for which 10 is a primitive root. We implement the E and O blocks in Python and we tested them against the specification of Bluetooth. Then, we were able to implement  $H$  and to use it to implement and test  $E_3$  and  $E_1$ .

We validate the brute forced  $K'_C$  by using the necessary parameters from Figure 6 to compute  $K'_C$  from  $K_L$ . We captured the parameters using the Bluetooth logging capabilities offered by Android. Table 2 shows an example of actual public and private values used during one of our KNOB attacks. We

plan to release our code implementing  $E_s$ ,  $E_1$  and  $E_3$  as open-source to help researchers interested in Bluetooth’s security, after we complete the responsible disclosure of our findings<sup>1</sup>.

#### 4.4 Implementation for Secure Connections

The specification of Bluetooth allows to perform the KNOB attack even when the victims are using Secure Connections. We already implemented the entropy reduction function of the brute force script over AES-CCM. However, at the time of writing, InternalBlue is not capable of patching the firmware of a Bluetooth chip that supports Secure Connections, indeed we are not able to implement the low entropy negotiation part of the attack using InternalBlue.

<sup>1</sup>See <https://github.com/francozappa/knob>

## 5 Evaluation

Our implementation of the KNOB attack (presented in Section 4) allows to test if any device accepts an encryption key with 1 byte of entropy ( $N = L_{min} = 1$ ). We focus our discussion on the attack best case (1 byte of entropy) while arguably any entropy value lower than 14 bytes could be considered not secure for symmetric encryption [3].

After successfully conducting the KNOB attack on a Nexus 5 and a Motorola G3 we conducted other KNOB attacks on more than 14 unique Bluetooth chips (by attacking 21 different devices). Each attack is easy to reproduce and testing if a device is vulnerable is a matter of seconds.

Based on our experiments, we concluded that there are no differences between the specification and the implementation of both the Bluetooth controller (implemented in the firmware) and the Bluetooth host (implemented in the OS and usable as an interface by a Bluetooth application). In the former case the specification is not enforcing any minimum  $L_{min}$  and it is not protecting the entropy negotiation protocol. The firmware’s implementers (to provide standard-compliant products) are allowing the negotiation of 1 byte of entropy with an insecure protocol. The only exception is the Apple W1 chip where an attacker can only reduce the entropy to 7 bytes. In the latter case, the Bluetooth specification is providing an HCI Read Encryption size API but it is not mandating or recommending its usage, e.g., a mandatory check at the end of the LMP entropy negotiation. The host’s implementers are providing this API and the applications that we tested are not using it.

### 5.1 Evaluation Setup

To perform our evaluation we collected as many devices as possible containing different Bluetooth chips. At the time of writing, we were able to test chips from Broadcom, Qualcomm, Apple, Intel, and Chicony manufacturers. For each chip we conducted the KNOB attack following the same five steps presented in Section 4.2. As explained earlier, the Nexus 5 is used as a (remote) attacker and a victim. For each test we recorded the manipulated encryption key negotiation protocol over LMP in a pcapng file and we manually verified the protocol’s outcome with Wireshark.

Our evaluation setup is not hard to reproduce and easy to extend because it does not require expensive hardware and uses open-source software. We would like to see other researchers evaluating more Bluetooth chips and devices that currently we do not possess, e.g., Apple Watches.

### 5.2 Evaluation Results

Table 3 shows our evaluation results. Overall, we tested more than 14 Bluetooth chips and 21 devices. The first column contains the Bluetooth chip names. We fill the entries of this

Bluetooth chip	Device(s)	Vuln?
<i>Bluetooth Version 5.0</i>		
Snapdragon 845	Galaxy S9	✓
Snapdragon 835	Pixel 2, OnePlus 5	✓
Apple/USI 339S00428	MacBookPro 2018	✓
Apple A1865	iPhone X	✓
<i>Bluetooth Version 4.2</i>		
Intel 8265	ThinkPad X1 6th	✓
Intel 7265	ThinkPad X1 3rd	✓
Unknown	Sennheiser PXC 550	✓
Apple/USI 339S00045	iPad Pro 2	✓
BCM43438	RPi 3B, RPi 3B+	✓
BCM43602	iMac MMQA2LL/A	✓
<i>Bluetooth Version 4.1</i>		
BCM4339 (CYW4339)	Nexus 5, iPhone 6	✓
Snapdragon 410	Motorola G3	✓
<i>Bluetooth Version <math>\leq 4.0</math></i>		
Snapdragon 800	LG G2	✓
Intel Centrino 6205	ThinkPad X230	✓
Chicony Unknown	ThinkPad KT-1255	✓
Broadcom Unknown	ThinkPad 41U5008	✓
Broadcom Unknown	Anker A7721	✓
Apple W1	AirPods	*

Table 3: List of Bluetooth chips and devices tested against the KNOB attack. ✓ indicates that a chip accepts one byte of entropy. \* indicates that a chip accepts at least seven bytes of entropy. We note that, all chips and devices implementing any specification of Bluetooth are expected to be vulnerable to the KNOB attack because the entropy reduction feature is standard-compliant.

column with Unknown when we are not able to find information about the chip manufacturer and/or model number. The second column lists the devices that we tested grouped by chip, e.g., the Snapdragon 835 is used both by the Pixel 2 and the OnePlus 5. The third column contains a ✓ if the Bluetooth chip accepts 1 byte of entropy and a \* if it accepts at least 7 bytes. The table’s rows are grouped by Bluetooth version in four blocks: version 5.0, version 4.2, version 4.1 and version lower or equal than 4.0.

From the third column of Table 3 we see that all the chips accept 1 byte of entropy (✓) except the Apple W1 chip (\*) that requires at least 7 bytes of entropy. Apple W1 and its successors are used in devices such as AirPods, and Apple Watches. Seven bytes of entropy are better than one, but not enough to prevent brute force attacks. For example, the Data Encryption Standard (DES) uses the same amount of entropy and DES keys were brute forced multiple times with increasing efficacy [19].

Table 3 also demonstrates that the vulnerability spans

across different Bluetooth versions including the latest ones such as 5.0 and 4.2. This fact confirms that the KNOB attack is a significant threat for all Bluetooth users and we believe that the specification of Bluetooth has to be fixed as soon as possible.

## 6 Discussion

### 6.1 Attacking Other Bluetooth Profiles

Cable replacement wireless technologies such as Bluetooth are widely used for all sorts of applications including desktop, mobile, IoT, industrial and medical devices. Bluetooth defines its set of application layer services as profiles. In Section 4 we describe an attack on the OBject EXchange (OBEX) Bluetooth profile, where the attacker breaks Bluetooth security by decrypting the content of an encrypted file without having access to any (pre-shared) secret. Here we describe three KNOB attacks targeting other popular Bluetooth profiles. As in the OBEX case, the attacks have serious implications in terms of security and privacy of the victims. To the best of our knowledge, all the profiles that we discuss in this section rely only on the link-layer for their security guarantees and they are widely used across different vendors. Our list of attacks is not exhaustive and an attacker might exploit the vulnerable encryption key negotiation protocol of Bluetooth in other creative ways.

**HID profile** The attacker could perform a remote keylogging attack on any device that uses the Human Interface Device (HID) profile. This profile is used by input-output devices such as keyboards, mice and joysticks. As a result, the attacker can sniff sensitive information including passwords, credit card numbers, and emails regardless if these information are then encrypted on the (wired or wireless) Ethernet link.

**Bluetooth tethering** The attacker could mount a remote man-in-the-middle attack when the victim uses Bluetooth for tethering. Tethering is used by a device, acting as an hotspot, to share Internet connectivity with other devices in range. Bluetooth transports Ethernet over the Bluetooth Network Encapsulation Protocol (BNEP) [5]. This protocol encapsulates Ethernet frames and transports them over (link-layer encrypted) L2CAP. As a result, the attacker can sniff all Internet traffic of the victims using a Bluetooth hotspot.

**A2DP profile** The attacker could record and inject audio signals when the victim uses the Advanced Audio Distribution Profile (A2DP) profile. As a result, the attacker is able to record phone and Voice over IP (VoIP) calls even if the call is encrypted (e.g., 4G and Skype). The attacker can also tamper with voice commands sent to a personal assistant, e.g.,

Siri and Google Assistant. Recent mobile devices, such as smartphone and tablets, are particularly vulnerable to this threat because Bluetooth is a convenient solution to the lack of an analog audio connector (audio jack).

## 6.2 Attacking Multiple Nodes and Piconets

In our paper we describe the implementation of KNOB attacks targeting two victims. If a Bluetooth piconet contains more than two devices, then (in the worst case for the attacker) each master-slave pair uses a dedicated set of keys. In this scenario the KNOB attack still works because it can be parallelized with minimal effort. For example, the attacker may run the same attack script on different computing units, such as processes or machines, and let each computing unit target a master-slave pair. Each parallel instance of the attack negotiates an encryption key with one byte of entropy, captures the exchanged ciphertext, and brute forces the encryption key. For example, an attacker is able to decrypt all the traffic from a victim using multiple Bluetooth I/O devices to interact with his device e.g., a laptop connected with a keyboard, a mouse and an headset.

The KNOB attack is effective even if the attacker wants to target multiple piconets (Bluetooth networks) at the same time. In this case the attacker has to follow and use a different Bluetooth clock (CLK) value for each piconet to compute the correct encryption key. This is not a problem because the attacker can use parallel KNOB attack instances, where each instance follows a pair of devices in a target piconet.

## 6.3 Practical Implementation Issues

We spent considerable time to fine tune our brute force script. One main reason is that Ubertooth One, used to sniff Bluetooth BR/EDR packets over the air, does not reliably capture all packets and clock values (CLK). This is true even if we limit our capture to a specific piconet by setting the UAP and LAP parameters. As a result, we had to include extra logic in our brute force script to iterate over different CLK values and  $E_0$  keystream offsets. Our basic brute force logic only iterates over the encryption key space (256 iterations). The extra logic can be removed if we get access to a commercial-grade Bluetooth protocol analyzer such as Ellisys [10] or similar. Unfortunately, these devices are very expensive.

We implemented our attack by simulating a remote attacker using InternalBlue. Alternatively, we could have conducted the attacks over the air using signal manipulation [26] and (reactive) jamming [31]. However, the InternalBlue setup is simpler, more reliable, cheaper, and easier to reproduce than the over-the-air setup and it affects the victims in the same way as a remote attacker.

## 6.4 Countermeasures

In this section we propose several countermeasures to the KNOB attack. We divide them into two classes: legacy compliant and non legacy compliant. The former type of countermeasure does not require a change to the specification of Bluetooth while the latter does. We already proposed these countermeasures to the Bluetooth SIG and CERT during our responsible disclosure.

**Legacy compliant.** Our first proposed legacy compliant countermeasure is to require a minimum and maximum amount of negotiable entropy that cannot be easily brute forced, e.g., require 16 bytes of entropy. This means fixing  $L_{min}$  and  $L_{max}$  in the Bluetooth controller (firmware) and results in the negotiation of proper encryption keys. Another possible countermeasure is to automatically have the Bluetooth host (OS) check the amount of negotiated entropy each time link layer encryption is activated and abort the connection if the entropy does not meet a minimum requirement. The entropy value can be obtained by the host using the HCI Read Encryption Key Size Command. This solution requires to modify the Bluetooth host and it might be suboptimal because it acts on a connection that is already established (and possibly in use), not as part of the entropy negotiation protocol. A third solution is to distrust the link layer and provide the security guarantees at the application layer. Some vendors have done so by adding a custom application layer security mechanism on top of Bluetooth (which, in case of Google Nearby Connections, was also found to be vulnerable [1]).

**Non legacy compliant.** A non legacy compliant countermeasure is to modify the encryption key negotiation protocol by securing it using the link key. The link key is a shared (and possibly authenticated) secret that should be always available before starting the entropy negotiation protocol. The new protocol should provide message integrity and might also provide confidentiality. Preferably, the specification should get rid of the entropy negotiation protocol and always use encryption keys with a fixed amount of entropy, e.g., 16 bytes. The implementation of these solutions only requires the modification of the Bluetooth controller (firmware).

## 7 Related Work

The security and privacy guarantees of Bluetooth were studied since Bluetooth v1.0 [15, 32]. Particular attention was given to Secure Simple Pairing (SSP), a mechanisms that Bluetooth uses to generate and share a long term secret (defined as the link key). Several attacks on the SSP protocol were proposed [28, 13, 4]. The Key Negotiation Of Bluetooth (KNOB) attack works regardless of security guarantees provided by SSP (such as mutual user authentication).

The most up to date survey about Bluetooth security was provided by NIST in 2017 [25]. This survey recommends to use 128 bit keys (16 bytes of entropy). It also describes the key negotiation protocol, and considers it as a security issue when one of the connected devices is malicious (and not a third party). Prior surveys do not consider the problem of encryption key negotiation at all [9] or superficially discuss it [29].

The various implementation of Bluetooth were also analyzed and several attacks were presented on Android, iOS, Windows and Linux implementations [2]. Our attack works regardless of the implementation details of the target platform, because if any implementation is standard-compliant then it is vulnerable to the KNOB attack.

The security of the ciphers used by Bluetooth has been extensively discussed by cryptographers. The SAFER+ cipher used by Bluetooth for authentication purposes was analyzed [17]. The  $E_0$  cipher used by Bluetooth for encryption was also analyzed [11]. Our attack works even with perfectly secure ciphers. For our implementation of the custom Bluetooth security procedures (presented in Section 4) we used as main references the specification of Bluetooth [6] and third-party hardware [18] and software [20] implementations.

Third-party manipulations of key negotiation protocols were also discussed in the context of WiFi, for example key reuse in [30]. Compared to those attacks, our attack exploits not only implementation issues, but a standard-compliant vulnerability of the specification of Bluetooth.

Protocol downgrade attacks were discussed in the context of TLS[23], where the two parties are negotiating the cipher suite to use. We note that in contrast to our scenario, for TLS the application developers have commonly direct control over the cipher suites that will be offered by their applications. Therefore, avoiding a fallback to legacy encryption standards can be prevented by the developers. To the best of our knowledge, this is not the case for Bluetooth, as the protocols does not enforce any mandatory checks on the encryption key's entropy.

## 8 Conclusion

In this paper we present the Key Negotiation Of Bluetooth (KNOB) attack. Our attack is capable of reducing the entropy of the encryption key of any Bluetooth BR/EDR connection to 1 byte (8 bits). The attack is standard-compliant because the specification of Bluetooth includes an insecure encryption key negotiation protocol that supports entropy values between 1 and 16 bytes. As a main consequence, an attacker can easily negotiate an encryption key with low entropy and then brute force it. The attacker is effectively breaking the security guarantees of Bluetooth without having to possess any (pre-shared) secret material. The attack is stealthy because the vulnerable entropy negotiation protocol is run by the victims' Bluetooth controller and this protocol is transparent to the

Bluetooth host (OS) and the Bluetooth application used by the victims. We expect that the attack could be run in parallel to target multiple devices and piconets at the same time.

We demonstrate that the KNOB attack can be performed in practice by implementing it to attack a Nexus 5 and a Motorola G3. In our attack we decrypt a file transmitted over an authenticated and link-layer encrypted Bluetooth connection. Brute-forcing a key with 1 byte of entropy introduces a negligible overhead enabling an attacker to decrypt all the ciphertext and to introduce valid ciphertext even in real-time.

We evaluate the KNOB attack on more than 14 Bluetooth chips from different vendors such as Broadcom, Qualcomm and Intel. All the chips accept 1 byte of entropy except the Apple W1 chip that accepts (at least) 7 bytes of entropy. Frankly, we were expecting to find more non standard-compliant chips like the Apple W1. Before submitting the paper, we reported our findings to the Computer Emergency Response Team (CERT) and the Bluetooth Special Interest Group (SIG). Both organizations acknowledged the problem and we are collaborating with them to solve it. After our responsible disclosure, we plan to release the tools that we developed to implement the attacks as open-source.

The KNOB attack is a serious threat to the security and privacy of all Bluetooth users. We were surprised to discover such fundamental issues in a widely used and 20 years old standard. We attribute the identified issues in part to ambiguous phrasing in the standard, as it is not clear who is responsible for enforcing the entropy of the encryption keys, and as a result no-one seems to be responsible in practice. We urge the Bluetooth SIG to update the specification of Bluetooth according to our findings. Until the specification is not fixed, we do not recommend to trust any link-layer encrypted Bluetooth BR/EDR link. In Section 6.4 we propose legacy and non legacy compliant countermeasures that would make the KNOB attack impractical. We also recommend the Bluetooth SIG to create a dedicated procedure enabling researchers to securely submit new potential vulnerabilities, similarly to what other companies, such as Google, Microsoft and Facebook, are offering.

## Abstract

IP headers include a 16-bit ID field. Our work examines the generation of this field in Windows (versions 8 and higher), Linux and Android, and shows that the IP ID field enables remote servers to assign a unique ID to each device and thus be able to identify subsequent transmissions sent from that device. This identification works across all browsers and over network changes. In modern Linux and Android versions, this field leaks a kernel address, thus we also break KASLR.

Our work includes reverse-engineering of the Windows IP ID generation code, and a cryptanalysis of this code and of the Linux kernel IP ID generation code. It provides practical techniques to partially extract the key used by each of these algorithms, overcoming different implementation issues, and observing that this key can identify individual devices. We deployed a demo (for Windows) showing that key extraction and machine fingerprinting works in the wild, and tested it from networks around the world.

## 1 Introduction

Online browser-based user tracking is prevalent. Tracking is used to identify users and track them across many sessions and websites on the Internet. Tracking is often performed in order to personalize advertisements or for surveillance purposes. It can either be done by sites that are visited by users, or by third-party companies which track users across multiple web sites and applications. [2] specifically lists motivations for web-based fingerprinting as “fraud detection, protection against account hijacking, anti-bot and anti-scraping services, enterprise security management, protection against DDOS attacks, real-time targeted marketing, campaign measurement, reaching customers across devices, and limiting number of access to services”.

**Tracking methods** Existing tracking mechanisms are usually based on either *tagging* or *fingerprinting*. With tagging, the tracking party stores at the user’s device some information, such as a cookie, which can later be tracked. Modern web standards and norms, however, enable users to opt-out from tagging. Furthermore, tagging is often specific for one application or browser, and therefore a tag that was stored in one browser cannot be identified when the user is using a different browser on the same machine, or when the user uses

the private browsing feature of the browser. Fingerprinting is implemented by having the tracking party measure features of the user’s machine (for example the set of installed fonts). Corporates, however, often install a single “golden image” (standard set of software packages) on many *identical* (hardware-wise) machines, and therefore it is hard to obtain fingerprints that distinguish among such machines.

In this work we present a new tracking mechanism which is based on extracting data used by the IP ID generator (see Section 1.1). It is the first tracking technique that is able to simultaneously (a) cross the private browsing boundary (i.e. compute the same tracking ID for a private mode tab/window of a browser as for a regular tab/window of the browser); (b) work across different browsers; (c) address the “golden image” problem; and (d) work across multiple networks; all this while maintaining a very good coverage of the platforms involved. To our knowledge, no other tracking method (or a combination of several tracking techniques) achieves all these goals simultaneously. Moreover, the Windows variant of this technique also survives Windows shutdown+startup (but not restart).

Our techniques are realistic: for Windows we only need to have control over 8-30 IP addresses (in 3-13 class B networks), and for Linux/Android, we only need to control 300-400 IP addresses (can be in a single class B network). The Windows technique was successfully tested in the wild.

### 1.1 Introduction to IP ID

The IP ID field is a 16 bit IP header field, defined in RFC 791 [11]. It is used to facilitate de-fragmentation, by marking IP fragments that belong to the same IP datagram. The IP protocol assembles fragments into a datagram based on the fragment source IP, destination IP, protocol (e.g. TCP or UDP) and IP ID. Thus, it is desirable to ensure that given the same source address, destination address and protocol, the IP ID does not repeat itself in short time intervals. Simultaneously, the IP ID should not be predictable (across different destination IP addresses) since “[IP ID] predictability allows traffic analysis, idle scanning, and even packet injection in specific cases” [30].

Designing an IP ID generation algorithm that meets both requirements is not straightforward. Since IPv4 was standardized, several schemes have emerged:

- Global counter – This approach was used in the early IPv4 days due to its simplicity and its non-repetition

\*An extended version of this paper can be found at <http://www.securitygalore.com/site3/usenix2019>.

period of 65536 global packets. However it is extremely predictable and thus insecure, hence abandoned.

- Counter/bucket based algorithms – This family of algorithms, suggested by RFC 7739 [7, Section 5.3], is the focus of our work. It uses a table of counters, and a hash function that maps a combination of a source IP address, destination IP address, key and sometimes other elements into an index of an entry in the table. IP ID is generated by choosing the counter pointed to by the hash function, possibly adding to it an offset (which may depend on the IP endpoints, key, etc.), and finally incrementing the counter. The non-repetition period in this family is 65536 global packets, and at the same time knowing IP ID values for one pair of source and destination IP addresses does not reveal anything about the IP IDs of pairs in other buckets.
- Searchable queue-based algorithm – This algorithm maintains a queue of the last several thousand IP IDs that were used. The algorithm draws random IDs until one is found that is not in the queue. Then this ID is used as the next IP ID, pushed to the queue, and the least-recently used value is popped from the queue. This algorithm ensures high unpredictability, and guarantees a non-repetition period as long as the queue.

Windows (version 8 and later) and Linux/Android implement variants of the counter-based algorithm. MacOS and iOS implement a searchable queue algorithm.

## 1.2 Introduction to KASLR

KASLR (Kernel Address Space Layout Randomization) is a security mechanism designed to defeat attack techniques such as ROP (Return-Oriented Programming [27]) that rely on the predictability of kernel code addresses. KASLR-enabled kernels randomize the kernel image load address during boot, so that kernel code addresses become unpredictable. While, e.g. in the Linux x64 kernel, the entropy of the load address is 9 bits, a brute force attack is deemed irrelevant since each failure usually ends in a system freeze (“kernel panic”). A typical KASLR bypass enables the attacker to obtain a kernel address (from which, addresses to useful kernel code gadgets can be calculated as offsets) without de-stabilizing the system.

## 1.3 Our Approach

The IP ID generation mechanisms in Windows and in Linux (UDP only) both compute the IP ID as a function of the source IP address, the destination IP address, and a key  $K$  which is generated when the source machine is restarted and is never changed afterwards. We run a cryptanalysis attack which analyzes the IP ID values that are sent by a device and extracts the key  $K$ . This key can then be used to identify

the source device, because subsequent attacks will yield the same key value (until the device is restarted).

In more detail, IP ID generation in both systems maintains a table of counters and uses a hash function to choose which counter is used for each connection. It seems hard to deploy an attack based on the *value* of the counter, since each IP ID might depend on a different counter. Instead, our attack techniques rely on identifying and exploiting *collisions* which map two destination IP addresses to the same counter. This enables us to extract information about the key that caused the hash values to collide (Linux), or (in Windows) extract information about the offset of the IP ID from the counter. These values depend on  $K$  and therefore enable us to learn  $K$  and identify the machine.

Our approach does not rely on an a-priori knowledge of the counter values. Moreover, after we reconstruct  $K$ , we can reconstruct the current counter values (in full or in part) by sending traffic to specially chosen IP addresses, obtaining their IP ID values and with the knowledge of  $K$ , work back the counter values that were used to generate them.

**Linux/Android KASLR bypass** Support for network namespaces (part of container technology) was introduced in Linux kernel 4.1. With this change, the key  $K$  was extended to include 32 bits of a kernel address (the address of the `net` structure for the current namespace). Thus, reconstructing  $K$  also reveals 32 bits of a kernel address, which suffices to reconstruct the full address and be able to bypass KASLR.<sup>1</sup>

**Conclusion** In general, our work demonstrates that the usage of a non-cryptographic algorithm for the generation of attacker observable values such as IP ID, may be a security vulnerability even if the values themselves are not security-sensitive. This is due to an attacker’s ability to extract the key used by the algorithm generating the values, and use this key to track or attack the system.

## 1.4 Advantages of our Technique

Tracking machines based on the key that is used for generating the IP ID has multiple advantages:

**Browser Privacy Mode:** Since our technique exploits the behavior of the IP packet generator, it is not affected if the browser runs in privacy mode.

**Cross-Browser:** Since our technique exploits the behavior of the IP packet generator, it yields the same device ID regardless of the browser used. It should be noted that browsers (like Tor browser) that relay transport protocols through other servers are not affected by our technique.

**Network change:** Tracking works across different networks since our technique uses bits of  $K$  as a device ID, and  $K$  does not depend on the device’s IP address or network.

<sup>1</sup>Through our IP ID attack we were also able to achieve partial KASLR bypass, and a partial list of loaded drivers, with regards to Windows 10 RedStone 4. This attack was based on an additional initialization bug in Windows. However, that bug was repaired in the October 2018 security update and the corresponding KASLR bypass is not effective anymore.

**The “Golden Image” Challenge:** Since each device generates its own key  $K$  in a random fashion at O/S restart, even devices with identical software and hardware will most likely have different  $K$  values and thus different device IDs.

**Not easily turned off:** IP ID generation is built into the kernel, and cannot be modified or switched off by the user. Furthermore, the Windows attack can use simple HTTP traffic. The Linux/Android attack requires WebRTC which cannot be turned off for mobile Chrome and Firefox.

**VPN resistant:** The device ID remains the same when the device uses an IP-layer VPN.

**Windows shutdown+startup vs. restart:** The Fast Startup feature of Windows 8 and later,<sup>2</sup> which is enabled by default, saves the kernel to disk on shutdown, and reloads it from disk on system startup. Therefore,  $K$  is not re-initialized on startup, and keeps its pre-shutdown value. This means that the tracking technique for Windows survives system shutdown+startup. On restart, in contrast, the kernel is initialized from scratch, and a new value for  $K$  is generated, i.e. the old device ID is no longer in effect.

**Scalability:** Our technique can support billions of devices (Windows, Linux, newer Androids), as the device ID is random, and thus ID collisions are only expected due to the birthday paradox. Thus the probability of a single device not to have a unique ID is very low.

It should be noted that in the Linux/Android case, due to the use of 300-400 IP addresses, the need to “dwell” on the page for 8-9 seconds, and (in newer Android devices) the excessive attack time, there are use cases in which the technique may be considered invasive and/or inapplicable.

**Additional Contributions:** In addition to the cross-browser tracking technique for Windows and Linux, and the KASLR bypass with respect to Linux, we also provide the first full public documentation of the IP ID generation algorithm in Windows 8 and later versions, obtained via reverse-engineering of the relevant parts of Windows kernel `tcpip.sys` driver, and a cryptanalysis of said algorithm. We also show a demo implementation of the Windows tracking technique and provide results from an extensive in-the-wild experiment spanning 75 networks in 18 countries, demonstrating the applicability of the attack.

We disclosed the vulnerabilities to Microsoft and Linux. Microsoft fixed the issue in Windows April 2019 Security Update (CVE-2019-0688).<sup>3</sup> Linux fixed the kernel address disclosure (CVE-2019-10639) together with partially addressing the key-based tracking technique (by extending the key to 64 bits) in a patch<sup>4</sup> applied to Linux kernel ver-

<sup>2</sup><https://blogs.msdn.microsoft.com/olivnie/2012/12/14/windows-8-fast-boot>

<sup>3</sup><https://portal.msrc.microsoft.com/en-US/security-guidance/advisory/CVE-2019-0688>

<sup>4</sup>“nets: provide pure entropy for net\_hash\_mix()” (<https://github.com/torvalds/linux/commit/>)

sions 5.1-rc4, 5.0.8, 4.19.35, 4.14.112, 4.9.169 and 4.4.179. For 3.18.139 and 3.16.67, Linux applied a patch<sup>5</sup> we developed, that extends the key to 64 bits. The key-based tracking technique (CVE-2019-10638) is fully addressed in a patch,<sup>6</sup> part of kernel version 5.2-rc1, and will be back-ported to kernel versions 5.1.7, 5.0.21, 4.19.48 and 4.14.124.

**Note:** many non-essential details of the attack, as well as proofs for false positive bounds for Windows, are deferred to the extended version of the paper.

## 2 The Setting

We assume that device tracking is carried out over the web, using an HTML snippet (which can be embedded by a 3<sup>rd</sup> party site/page). The snippet forces the browser to send TCP or UDP traffic (one packet per destination IP suffices) to multiple IP addresses under the tracker’s control (8-30 addresses for Windows, 300-400 for Linux/Android). Ideally, such transmission would be rapid. In our experiments, this can be done in few seconds or less.

For the Windows attack, the tracker needs to choose the IP addresses according to some trivial constraints (the Linux IP addresses are not subject to any constraints). A discussion of the exact constraints and their trade-offs can be found in the extended paper. At the server side, the tracker collects the IP ID values sent by the client to each of the IPs, and computes a device ID consisting of bits of the key in the device’s kernel data that is used to calculate the IP ID.

Additional scenarios (KASLR bypass and internal IP disclosure) for Linux/Android attacks are described in the extended paper.

## 3 Related Work

Many tracking techniques were suggested in prior research. At large, proposals can be categorized by their passive/active nature. We use the terminology defined in [31]:

- A *fingerprinting* technique measures properties already existing in the browser or operating system, collecting a combination of data that ideally uniquely identifies the browser/device without altering its state.
- A *tagging* technique, in contrast, stores data in the browser/device, which uniquely identifies it. Further access to the browser can “read” the data and identify the device.

355b98553789b646ed97ad801a619ff898471b92)

<sup>5</sup>“inet: update the IP ID generation algorithm to higher standards” (<https://git.kernel.org/pub/scm/linux/kernel/git/stable/linux.git/commit/?id=55f0fc7a02de8f12757f4937143d8d5091b2e40b>)

<sup>6</sup>“inet: switch IP ID generator to siphash” (<https://git.kernel.org/pub/scm/linux/kernel/git/torvalds/linux.git/commit/?id=df453700e8d81b1bdafdf684365ee2b9431fb702>)

As described in Section 1, fingerprinting techniques typically cannot guarantee the uniqueness of the device ID, in particular with respect to corporate machines cloned from “golden images”. Tagging techniques store data on the device, and as such they are more easily monitored and evaded. A comprehensive discussion of tracking methods can be found in Google Chromium’s web page “Technical analysis of client identification mechanisms” [12].

### 3.1 IP ID Research

**Device tracking via IP ID:** Using IP ID is proposed in [5] (2002) to detect multiple devices behind a NAT, assuming an IP ID implementation using a *global* counter. But nowadays none of the modern operating systems implements IP ID as a global counter. A similar concept is presented by [25] for a single destination IP (the DNS resolver) which theoretically works for devices that have per-IP counter (Windows, to some extent). However, this technique does not scale beyond a few dozen devices, due to IP ID collisions (the IP ID field provides at most  $2^{16}$  values), and requires ongoing access to the traffic arriving at the DNS resolver.

**Predictable IP ID:** The predictability of IP ID may theoretically be used in some conditions to track devices. [6] describes a technique to predict the IP ID of a target, but requires the adversary to have a fully controlled device alongside it behind the same NAT. Also this technique only handles sequential increments (e.g. not time-based). As such, it is inapplicable to the more general scenarios handled in this paper. This technique is then used in [9] to poison DNS records.

**OS Fingerprinting:** [32] suggests using  $IPID = 0$  as a fingerprint for some operating systems.

**Measuring traffic:** [29] samples IP ID values from servers whose IP ID is a global counter, to estimate their outbound traffic.

**IP ID Algorithm Categorization:** [28] provides practical classification of IP ID generation algorithms and measurements in the wild.

**Fragmentation attacks:** While not directly related to the properties of the IP ID field, it should be noted that attack techniques abusing fragmentation are known. RFC 1858 [26] lists several such attacks, e.g. the “tiny fragment” attack and the “overlapping fragment” attack.

**Windows IP ID research:** In parallel to our research, Ran Menscher published on Twitter his research on Windows IP ID [23]. That research reverse-engineered part of the Windows IP ID generation algorithm (without revealing how the index to the counter array is calculated). The analysis of this algorithm is based on two assumptions: (1) that the technique is applied shortly after restart, when the relevant memory buffer contains zeroes in a large part of its cells; and (2) that the attacker controls or monitors traffic to pairs of IP addresses which differ in single, specific bit position (includ-

ing positions in the left half of the address). Based on these extreme assumptions, the attacker can extract the key easily, and use it to expose kernel 31-bit data quantities (though without learning where in the array this data resides).

The uninitialized memory issue exploited by this attack was fixed in Microsoft’s October 2018 Security Update [24], which invalidated assumption (1), rendering Menscher’s attack completely ineffective. Our attack and our demo, on the other hand, still work against systems that were patched with this update. Our work has multiple contributions over Menscher’s attack: (1) We provide the full details of the IP ID algorithm. (2) Our analysis does not rely on the array data, and is thus still in effect after applying the October 2018 Security Update which initializes the array with random data. (3) Our analysis does not require the extreme requirements on the relations between the addresses of the controlled/monitored IP addresses. (4) Our kernel data exposure provides positions of the data, not just data quantities (though our kernel exposure technique, too, was eliminated with the October 2018 Security Update). (5) It should also be noted that unlike our attack, Menscher’s technique could not be used for tracking, since as the cell arrays become non-zero when they are incremented, the attack becomes ineffective.

### 3.2 PRNG seed/key extraction

Our approach involves breaking the random number generator algorithm used by operating systems to generate the IP ID value and obtain the seed/key used by the algorithm. Similar strategies were used to different ends. For example, [17] broke the PRNG of the Witty worm to obtain the seed, from which they learned the infection time of the Internet nodes. [14] broke the Javascript `Math.Random()` PRNG of several browsers, obtained the seed and used it as a browser instance tracking ID. [15] broke the `Math.Random()` PRNG of Adobe Flash, obtained the seed and used it to extract the machine clock speed.

## 4 Tracking Windows 8 (and Later) Devices

In this section we first present the algorithm that is used for generating the IP ID in Windows 8 (and later) devices. The input to this algorithm includes a key which is generated at system restart. We then describe how a remote server can identify 45 bits of this key. This data enables to remotely and uniquely identify machines.

### 4.1 IP ID Generation

**IP ID prior to Windows 8** In versions of Microsoft Windows up to and including Windows 7, the IP ID was generated sequentially and globally. That is, for each outgoing IP packet, a global counter would be incremented by 1 and the

result (truncated to 16 bits) would be used [25]. These older Windows versions are out of scope for this paper.

The source code of the algorithm that is used for generating IP ID values in Windows is not public. However, we recovered the exact algorithm using reverse engineering, and verified its correctness by comparing its output to IP ID values generated by live Windows systems.

**Technical details** The algorithm was obtained by reverse-engineering parts of the `tcpip.sys` driver of 64-bit Windows 10 RedStone 4 (April 2018 Update, Build 1803). Apparently this algorithm is in use starting with Windows 8 and Windows Server 2012. Notice that the code is not specific to IPv4, and can be used with IPv6, which is why the key  $K$  is defined as 320 bits - more than required to support IPv4.<sup>7</sup> For IPv4 pre RedStone 5, only 106 key bits are used.

**Toeplitz hash** The IP ID generation is based on the Toeplitz hash function defined in [10]. Let us first define the *Toeplitz hash*,  $T(K, I)$ , which is a bilinear transformation from a binary vector  $K$  in  $GF(2)^{320}$ , and an input which is a binary string  $I$  (where  $|I| \leq 289$ ) to the output space  $GF(2)^{32}$ . For a binary vector  $V$ , denote by  $V_i$  the  $i$ -th bit in the vector, with bit numbering starting from 0. The  $i$ -th bit of  $T(K, I)$  ( $0 \leq i \leq 31$ ) is defined as the inner product between  $I$  and a substring of  $K$  starting in location  $i$ . Namely

$$T(K, I)_i = \bigoplus_{j=0}^{|I|-1} I_j \cdot K_{i+j} \quad (1)$$

**IP ID generation** The IP ID generation algorithm itself uses keys  $K$  (`tcpip!TcpToeplitzHashKey`) which is a 320 bit vector, and  $K1$  and  $K2$  which are 32 bits each. All these keys are generated once during Windows kernel initialization (using `SystemPrng` and `BCryptGenRandom`).

In addition to these constant keys, the algorithm uses a dynamic array of  $M$  counters, denoted  $\beta[0], \dots, \beta[M-1]$ , where  $M$  is a power of 2, and is specifically set to  $M = 8192$ .

Algorithm 1 describes how Windows 8 (and later) generates an IP ID for a packet delivered from  $IP_{SRC}$  to  $IP_{DST}$ , while updating a counter in  $\beta$ .

The algorithm uses the keys, and the source and destination IP addresses, to pick a random index  $i$  for a counter in  $\beta$ , and an offset. The algorithm outputs the sum of the counter  $\beta[i]$  and the offset, and increments the counter.

**Notation** We use the notation  $\text{Num}(a_0, a_1, \dots, a_{31})$  for the number represented in binary by the bits  $a_i$ , namely the number  $\sum_{i=0}^{31} a_i \cdot 2^{31-i}$ . (Network byte order is used throughout the paper for representing IP addresses as bit vectors, e.g. 127.0.0.1 is 01111111.00000000.00000000.00000001.)

**Properties of the Toeplitz hash** Our attack uses the following properties of  $T$ , which follow from the linearity of this transformation:

$$T(K, I || (0, 0, \dots, 0)) = T(K, I) \quad (2)$$

<sup>7</sup> Our tracking technique can be probably adapted to IPv6, but since IPv6 is out of scope for this paper, we did not test this.

Therefore the trailing zeros in the input of  $T$  in the computation of  $v$  on line 3 of Algorithm 1, have no effect on the output. Also,

$$T(K, I_1 || I_2) = T(K, I_1) \oplus T(K, 0^{|I_1|} || I_2) \quad (3)$$

Therefore it is possible to decompose the second input of  $T$  to two parts, and rephrase the computation as the XOR of two separate expressions.

## 4.2 Reconstructing the Key $K$

To reconstruct the key, the device needs to be measured. The measurements only take a few seconds, and are thus assumed to take place from the same network. I.e., the *device's* source IP address,  $IP_{SRC}$ , is fixed (though possibly unknown). A first set of measurements directs the client device to  $J$  IP addresses from the same class B network. A second set of measurements directs the client device to  $G$  pairs of IP addresses, each pair in the same class B network, with  $G$  different class B network pairs in the set.

Once the device is measured, the attack proceeds in two phases. The first phase of the attack recovers 30 bits of the key using the first set of measurements. The second phase of the attack reveals additional 15 bits of the key using the second set of measurements. Overall, the measurements reveal 45 bits of the key, which suffices to uniquely identify machines from a large population, with high probability.

Section 4.5 describes how to optimally choose the parameters  $J$  and  $G$  given limits on the number of IP addresses that are available ( $L$ ) and the processing time that is allowed ( $\mathcal{T}$ ). For  $L = 30$  IP addresses (typical low budget limit), and attack run time limit of  $\mathcal{T} = 1$  seconds on a single Azure B1s machine ( $\alpha = 0.001$  from Section 5.2), the optimal parameter values are  $J = 6, G = 12$ .

## 4.3 Extracting Bits of $K$ - Phase 1

Denote by  $IP^{g,j}$ ,  $IPID^{g,j}$  and  $\beta[i_g]^{g,j}$  the values of the destination IP address, the IP ID and  $\beta[i]$  (prior to increment) respectively, with respect to the  $j$ -th packet in the  $g$ -th class B network that is used in the attack ( $j$  and  $g$  are counted 0-based). The first phase of the attack uses only a single class B network, and therefore  $g$  is set to 0 in this phase. We thus use the following shorthand notation:  $IP^j = IP^{0,j}$ ,  $IPID^j = IPID^{0,j}$  and  $\beta_g = \beta[i_g]^{g,0}$ .

A major observation is that only the first half of  $IP_{DST}$  is used to calculate  $i$  in Algorithm 1. Therefore packets that are sent to different IP addresses in the same class B network, have an identical index  $i$  into the counter table, and use the same counter  $\beta[i]$ . Denote the value of  $i$  for the  $g$ -th class B network as  $i_g$ .

If these packets are sent in rapid succession (i.e. when no other packet is sent in-between with  $i = i_g$ ), then  $\beta[i_g]^{g,j} = \beta_g + j \pmod{2^{32}}$ , and therefore the output in line 5 of the

---

**Algorithm 1** Windows 8 (and later) IP ID Generation
 

---

```

1: procedure GENERATE-IPID
2:    $i \leftarrow \text{Num}(K2 \oplus T(K, (IP_{DST})_{0,\dots, \lfloor \frac{IP_{DST} \rfloor - 1})} \oplus T(K, IP_{SRC})) \bmod M$ 
3:    $v \leftarrow \beta[i] + \text{Num}(K1 \oplus T(K, IP_{DST} || IP_{SRC} || 0^{32})) \bmod 2^{32}$ 
4:    $\beta[i] \leftarrow (\beta[i] + 1) \bmod 2^{32}$ 
5:   return  $v \bmod 2^{15}$ 

```

$\triangleright v \bmod 2^{16}$  for Windows 10 RedStone 5

---

algorithm is calculated with  $\beta[i_g]^{s,j} = \beta_g + j \bmod 2^{15}$  (for simplicity, in Windows 10 RedStone 5, we discard the most significant bit of the IP ID).

We focus in this phase on the first class B network,  $b_0$ , with  $J$  destination IP addresses in it. Note that the offset that is calculated in line 3 is the difference between the IPID and the counter  $\beta[i_0]$  prior to its increment.

The attack enumerates over the values of the  $\beta_0 \bmod 2^{15}$  counter. For each possible value it calculates the differences between the observed  $J$  IPIDs and the corresponding values of the counter, arriving at the offsets calculated in line 3. By observing pairs of IPIDs, it is possible to identify the correct value of  $\beta_0 \bmod 2^{15}$  as well as 30 bits of the key.

In more detail, for each possible value of  $\beta_0 \bmod 2^{15}$  the attack calculates the difference

$$IPID^j - (\beta_0 + j \bmod 2^{15}) \bmod 2^{15}$$

which, for the right value of the counter should be equal to the offset that is calculated in line 3. Namely to

$$\text{Num}(K1 \oplus T(K, IP^j || IP_{SRC} || 0^{32})) \bmod 2^{15}$$

This value can be expressed as  $(K1 \oplus T(K, IP^j || IP_{SRC} || 0^{32}))_{17,\dots,31}$ . Applying eq. (2) and eq. (3), this expression is simplified into:

$$(K1 \oplus T(K, IP^j) \oplus T(K, 0^{32} || IP_{SRC}))_{17,\dots,31}$$

The attack takes two different  $j$  values and computes the XOR of the two corresponding such quantities. This results in the following expression (where we denote by  $\text{Vec}$  a representation of a number in  $[0, 2^{32})$  as a vector in  $GF(2)^{32}$ ):

$$\begin{aligned} & (\text{Vec}(IPID^j - (\beta_0 + j) \bmod 2^{15}) \oplus \\ & \text{Vec}(IPID^{j'} - (\beta_0 + j') \bmod 2^{15}))_{17,\dots,31} = \\ & T(K, IP^j \oplus IP^{j'})_{17,\dots,31} \end{aligned}$$

This yields 15 linear equations ( $i = 17, \dots, 31$ ) on  $K$  since (from eq. (1)):

$$T(K, IP^j \oplus IP^{j'})_i = \bigoplus_{m=0}^{31} (IP^j \oplus IP^{j'})_m \cdot K_{i+m}$$

Since all  $IP^j$  belong to the same class B network,  $IP^j \oplus IP^{j'}$  always has 0 for its first 16 bits, and therefore  $m$  can start at

16. Due to obvious linear dependencies, only  $J - 1$  sets of such equations are useful (e.g. all pairs with  $j' = 0$ ), with a total of  $15(J - 1)$  linear equations for bits  $K_{33}, \dots, K_{62}$ . That is, for  $j = 1, \dots, J - 1$  and  $i = 17, \dots, 31$ , the equations are:

$$\begin{aligned} & \bigoplus_{m=16}^{31} (IP^j \oplus IP^0)_m \cdot K_{i+m} = \\ & (\text{Vec}(IPID^j - (\beta_0 + j) \bmod 2^{15}) \oplus \\ & \text{Vec}(IPID^0 - (\beta_0) \bmod 2^{15}))_i \quad (4) \end{aligned}$$

**Speeding up the computation using preprocessing** The coefficients of  $K$  in eq. (4) are controlled by the server and are known at setup time. Therefore it is possible to preprocess the computation of Gaussian elimination. Namely, compute a matrix  $Z$  that, when multiplied by the observed values, reveals bits of the key. This preprocessing is only important for efficiency, therefore we defer the details to the extended paper.

### Attack summary

1. The tracker needs to control  $J$  IP addresses in the same class B network.
2. During setup time, the tracker calculates, using Gaussian elimination, a matrix  $Z \in GF(2)^{15(J-1) \times 15(J-1)}$ , based on the values of these IP addresses.
3. In real time, the tracker gets IP ID values from the device, from packets sent to the  $J$  destination IP addresses under the tracker's control.
4. The tracker then guesses 14 bits ( $\beta_0 \bmod 2^{14}$  - the most significant bit of  $\beta_0 \bmod 2^{15}$  cancels itself in eq. (4)) of the counter that is used for these IP addresses, calculates vectors  $D^j$  ( $j = 1, \dots, J - 1$ ), where  $D^j = (\text{Vec}(IPID^j - (\beta_0 + j) \bmod 2^{15}) \oplus \text{Vec}(IPID^0 - (\beta_0) \bmod 2^{15}))_{17,\dots,31}$ , and performs a matrix-by-vector multiplication of  $Z$  and the vector  $(D^0, \dots, D^{J-1})$ .  
For the correct value of  $\beta_0 \bmod 2^{14}$  this computation results in a vector of  $15(J - 1)$  bits, whose first 30 bits are  $K_{33}, \dots, K_{62}$  and the remaining bits are zero.
5. The attacker identifies the right value of the counter by comparing to zero the  $15(J - 1) - 30$  bits starting at position 31: if  $15(J - 1) - 30 \gg 14$ , this verification statistically guarantees the correctness of the solution (up to a flipped most significant bit in  $\beta_0 \bmod 2^{14}$ , see the extended paper.)

Overall this process reveals 30 bits of the key as well as the value  $(\beta_0 \bmod 2^{14})$ .

The attack takes  $2^{14} \cdot (15(J-1))^2$  bit operations (for enumeration over the possible key values and for the matrix-by-vector and  $(15(J-1))^2$  memory bits (for  $Z$ ). As explained in Section 4.5, we set  $J = 6$  and therefore this overhead is very small.

The tracker obtains the (correct) value  $\beta_0 \bmod 2^{14}$ , which will be used in the next phase. While it is guaranteed that the correct  $K$  and  $\beta_0 \bmod 2^{14}$  will be found, the algorithm may emit additional candidates (with incorrect  $\beta_0 \bmod 2^{14}$ ). The false positive probability of both phases of the attack is analyzed in the extended paper.<sup>8</sup>

#### 4.4 Extracting Bits of $K$ - Phase 2

Given 30 bits of  $K$  ( $K_{33}, \dots, K_{62}$ ) and the value  $(\beta_0 \bmod 2^{14})$ , recovered in Phase 1, the attack can be extended to learn a total of up to 45 key bits ( $K_{18}, \dots, K_{62}$ ). This is done in the following way. The offset for  $IPID^0$  computed in line 3 of Algorithm 1 is:

$$\text{Num}(K1 \oplus T(K, IP^0) \oplus T(K, 0^{32} || IP_{SRC})) \bmod 2^{15} = (IPID^0 - \beta_0) \bmod 2^{15}$$

The following equation follows from the previous one:

$$(K1 \oplus T(K, 0^{32} || IP_{SRC}))_{17, \dots, 31} = T(K, IP^0)_{17, \dots, 31} \oplus \text{Vec}(IPID^0 - \beta_0 \bmod 2^{15})_{17, \dots, 31}$$

The tracker looks at pairs of IP addresses in the remaining B classes ( $b_1, \dots, b_G$ , each pair in a different class B network. Denote each such pair as  $(IP^{g,0}, IP^{g,1})$ , with the order inside the pair conforming to the order of packet transmission, and the packets being transmitted in rapid succession. Substituting the above into the definition of  $IPID$  yields:

$$IPID^{g,j} = \beta_g + j + \text{Num}(T(K, IP^0)_{17, \dots, 31} \oplus \text{Vec}(IPID^0 - \beta_0 \bmod 2^{15})_{17, \dots, 31} \oplus T(K, IP^{g,j})_{17, \dots, 31}) \bmod 2^{15}$$

Using the linearity of  $T$ , this is simplified into:

$$IPID^{g,j} = \beta_g + j + \text{Num}(T(K, IP^0 \oplus IP^{g,j})_{17, \dots, 31} \oplus \text{Vec}(IPID^0 - \beta_0 \bmod 2^{15})_{17, \dots, 31}) \bmod 2^{15}$$

Let us use the notation

$$S^{g,j} = \text{Num}(T(K, IP^0 \oplus IP^{g,j})_{17, \dots, 31} \oplus \text{Vec}(IPID^0 - \beta_0 \bmod 2^{15})_{17, \dots, 31}) \bmod 2^{15}$$

<sup>8</sup>Note: Throughout the paper, we assume that  $\text{rank}(C) = 30$ . This results in a single key vector per guessed  $\beta_0 \bmod 2^{14}$ . We discuss the conditions on  $IP^0, \dots, IP^{j-1}$  to meet this assumption in the extended paper. If  $\text{rank}(\ker(C)) > 0$ , then each guess of  $\beta_0 \bmod 2^{14}$  yields  $2^{\text{rank}(\ker(C))}$  possible keys. Thus small values of  $\text{rank}(\ker(C))$  are acceptable.

Then this equation becomes

$$IPID^{g,j} = \beta_g + j + S^{g,j} \bmod 2^{15}$$

Subtracting the IPIDs of the two consecutive packets in the same B class (with  $j = 0$  and  $j = 1$ ) cancels the value of the counter  $\beta_g$ , and yields:

$$(IPID^{g,1} - IPID^{g,0}) \bmod 2^{15} = 1 + S^{g,1} - S^{g,0} \bmod 2^{15} \quad (5)$$

The left side of the equation is observed by the tracker. The right side can be computed based on  $\beta_0 \bmod 2^{15}$  and  $K_{17}, \dots, K_{62}$ . The tracker already knows these values except for  $K_{18}, \dots, K_{33}$ , and therefore only needs to enumerate over the  $2^{15}$  possible values of  $K_{18}, \dots, K_{32}$  and eliminate all values which do not agree with the equation. We discuss this procedure in depth in the extended paper.

#### Attack summary:

1. The tracker needs to control additional  $G$  pairs of IPs (each pair in its own class B network).
2. Given IP IDs for these pairs, the tracker enumerates over additional 15 key bits, and then, for each pair of IP addresses, calculates both sides of eq. (5) and compares them. For this calculation the tracker can choose  $K_{17}$  and the leftmost bit of  $\beta_0 \bmod 2^{15}$  arbitrarily, as they will both cancel themselves.
3. In theory, each IP pair should yield a  $2^{15}$  elimination power for identifying the right key, but see the extended paper for a more accurate analysis.
4. In the calculation, the leading term (in terms of run time) is computing  $T(K, I)_{17, \dots, 31}$  (where  $|I| = 32$ ), which takes  $14|I|$  bit operations, and is used twice. Thus, the run-time is roughly  $2^{15} \cdot 2 \cdot 14 \cdot 32$  bit operations (there is no multiplication by  $G$  since the first pair is likely to eliminate almost all false guesses).

At the end of Phase 2, the tracker obtains:

- A partial key vector (or some candidates)  $K_{18}, \dots, K_{62}$  (45 bits), which is specific to the device since it was set during kernel initialization, and does not depend on  $IP_{SRC}$ . These bits serve as a device ID.
- The value

$$(K1 \oplus T(K, 0^{32} || IP_{SRC}))_{18, \dots, 31} = T(K, IP^0)_{18, \dots, 31} \oplus \text{Vec}(IPID^0 - \beta_0 \bmod 2^{14})_{18, \dots, 31}$$

This value allows the tracker to calculate (assuming  $K_{18}, \dots, K_{62}$  are known) the value of the counter  $\beta[i] \bmod 2^{14}$  for any destination IP address whose IP ID is known (provided the source IP is  $IP_{SRC}$ ).<sup>9</sup>

<sup>9</sup>This is useful for reconstructing the table  $\beta$  of counters – this table is not correctly initialized (pre October 2018 Security Update), and therefore is populated with kernel data that happens to be (in build 1803) data structures containing kernel address pointers.

## 4.5 Choosing Optimal $G$ and $J$

For Windows, we assume budget-oriented constraints, namely  $L$  available IP addresses and  $\mathcal{T}$  CPU time per measurement. We need to set the number  $J$  of IP addresses from the same class B network to which the client is directed in the first set of measurements, and the number  $G$  of pairs of IP addresses, each pair in the same class B network, used in the second set of measurements.

Our goal is to optimize for minimum false positives. The first constraint can be expressed as  $J + 2G \leq L$ . As for the second constraint, the leading term of the time of the attack run is  $\alpha \cdot (J!)$  (Appendix A.1.2), where  $\alpha$  expresses the computing platform's strength. Therefore, we can approximate the second constraint as  $\alpha \cdot (J!) \leq \mathcal{T}$ . Additionally, there are inherent constraints:  $J - 1 \geq 3$  to let Phase 1 suggest a single key candidate to Phase 2 (most of the time), and  $G \geq 2$  to let Phase 2 provide a single final key (most of the time).

Given these constraints, we want to minimize the leading term in false positives,  $2 \cdot 2^{-\frac{G+J-1}{2}}$  (Appendix A.2), i.e. we need to maximize  $G + J$ . Since we “pay” two IP addresses for each increment of  $G$  and only one IP address for each increment of  $J$ , we should make  $J$  as large as possible (as long as  $G$  is valid), so the solution is:

$$J = \min(\max(\{J \mid \alpha J! \leq \mathcal{T}\}, L - 4)$$

(As stated in Section 4.2, for  $L = 30$ ,  $\mathcal{T} = 1$  sec., and  $\alpha = 0.001$ , the optimal combination is  $J = 6$ ,  $G = 12$ .)

## 4.6 Practical Considerations

We discuss in Appendix A.1 different issues that appear when deploying the attack. These issues include ways to emit the needed traffic from the browser, handling packet loss and out-of-order packet transmission, handling interfering packets, and limiting the false-positive and false-negative error probabilities.

The run time of the key extraction attack is less than a second even on a very modest machine. The *dwell time* (time duration in which the page needs to be loaded in the browser) is 1-2 seconds for a WebSocket implementation. It is possible to minimize the dwell time by moving to WebRTC (STUN).

Longevity: the device ID is valid until the machine restarts (mere shutdown+start does not invalidate the device ID due to Windows' Fast Start feature). A typical user needs to restart his/her Windows machine only for some Windows updates, i.e. with a frequency of less than once per month.

The attack is scalable: with 41 bits, the probability of a device to have a unique ID is very high, even for a billion device population; false positives are also rare ( $2.1 \times 10^{-6}$  – Table 3), and false negatives can be made negligible (Appendix A.1.4). From resource perspective, the attack uses a fixed number of servers, RAM/disk and ( $L = 30$ ) IPs. The

required CPU power is linear in the number of devices measured per time unit, and in the Windows case is negligible. Network consumption per test is also negligible (assuming WebRTC/STUN implementation – 1.5KB at the IP layer.)

## 4.7 Attack Improvements and Variants

A **fast-track identification of already-seen keys** can be obtained in the following way: Once bits of a key  $K$  are extracted, they will be stored for comparison against future connections. When a device is to be measured, the tracker first goes through all stored  $K$  bit strings, and tests the measured data for compatibility with each one of them. This amounts to guessing the bits of  $\beta_0$  one by one, starting from the least significant, and eliminating via eq. (5), using  $\text{mod } 2^n$  where  $n$  is the number of  $\beta_0$  bits guessed so far. The CPU work per key is thus almost negligible.

The original attack can also be sped up using **incremental evaluation**. The details are in the extended paper.

## 4.8 Environment Factors

We demonstrate here that the tracking attack can be deployed in almost every setting that can be reasonably expected.

**HTTPS:** In essence, there should be no problem in having the snippet use WebSocket over HTTPS (`wss://` URL scheme) for TCP packets.

**NAT:** Typically NAT (Network Address Translator) devices do not alter IP IDs, and thus do not affect the attack.

**Transparent HTTP Proxy / Web Gateway:** Such devices may terminate the TCP connection and establish their own connections (with IP ID from their own network stack) and thus render our technique completely ineffective. However, typically these devices do not interfere with HTTPS (TCP port 443) traffic, and UDP traffic, so these alternatives can be used by the tracker.

**Forward HTTP proxy:** When a browser is configured to use a forward proxy server, even HTTPS traffic is routed to it by the browser. However, it may still be the case that UDP traffic (which is not handled by HTTP forward proxies) can be used by the technique.

**Tor-based browsers and similar browsers:** Browsers that forward TCP traffic to proxy servers (and disallow or forward UDP requests) are incompatible with the tracking technique as they do not expose IP header data generated on the device. Since “Tor transports TCP streams, not IP packets”,<sup>10</sup> this applies to all Tor-based products, such as the Tor browser and Brave's “Private Tabs with Tor” and therefore they are not covered by our technique.

**Windows Defender Application Guard (WDAG):** This new technology in Windows 10 enables the user to launch the Edge browser in a virtual environment. While the device ID

<sup>10</sup><https://www.torproject.org/docs/faq.html.en#RemotePhysicalDeviceFingerprinting>

in this virtual environment is independent of the device ID of the main operating system, it is consistent among all WDAG Edge instances. Furthermore, unlike the “main” Windows device ID, the WDAG device ID does not change with operating system restart, hence the WDAG device ID lives longer than the main Windows device ID. It should be noted that WDAG is only available for Edge browser in Windows 10 Enterprise/Pro edition, and requires high-end hardware.

**IP-Level VPN:** We experimented with F-Secure FreeDome ([www.f-secure.com/en/web/home\\_global/freedome](http://www.f-secure.com/en/web/home_global/freedome)) and PureVPN ([www.purevpn.com/](http://www.purevpn.com/)). Both VPNs supported our technique.

**IPv6 and IPsec:** We do not know whether IPv6 or IPsec packets use the same IP ID generation mechanism. This requires further research.

**Javascript disabled:** Tracking can also work when Javascript (or any client side scripting) is not available, e.g. with the NoScript browser extension [20]. We discuss this in the extended paper.

## 4.9 Possible Countermeasures

We list here some obvious ways of modifying Algorithm 1 and their impact:

- Increasing  $M$  (the size of the table of counters) – surprisingly, this has very little effect on the basic tracking technique, since no assumptions were made on  $M$  in the first place. It does affect the  $\beta$  reconstruction technique.
- Changing  $T$  into a cryptographically strong keyed-hash function – while this change eliminates the original attack, it is still possible to mount a weaker attack that only tracks a device while its  $IP_{SRC}$  does not change. In fact, this applies to the entire abstract scheme proposed in [7, Section 5.3]. See the extended paper for details.
- Changing the algorithm altogether (this is our recommendation). A robust algorithm relies on industrial-strength cryptography, large enough key space, and strong entropy source for the key, and uses them to generate IP IDs which (a) have guaranteed non-repetition period; (b) are difficult to predict; and (c) do not leak useful data. The algorithm used in macOS/iOS [30] is a good example. This eliminates the attack altogether.

## 5 Field Experiment – Attacking Windows Machines in the Wild

We set up a fully operational system to test the IP ID behavior in the wild, as well as to verify that the technique for extracting device IDs for Windows machine works as expected.

### 5.1 Setup

As explained in Appendix A.1.3, in order to avoid false positives (which almost always happen due to false keys that dif-

fer from the true key in a few most significant bits), we need to trim the most significant bits from the key – i.e. use the key’s tail. For the full production setup (30 IP addresses), we calculated that a tail of 41 bits will suffice. Due to logistic and budgetary constraints, in our experiment we used only 15 IP addresses (rather than 30) for the key extraction (and 2 more IPs for verification), with  $J = 5, G = 5, Q = 1$ . Thus we lowered the tail length to 40, and used the 40 bits  $K_{23}, \dots, K_{62}$  as a device ID. That is, for this experiment, we traded the device ID space size for a smaller probability of false positives.

We then used WebSocket traffic to the additional pair of IP addresses (from a class B network that is different than those in the initial set of 15 IPs) to verify the correctness of the key bits extracted. In this experiment, since we do not extract  $K_{17}, \dots, K_{22}$  we can only compute the least significant 9 bits of the IPID, adapting eq. (5) into:

$$IPID^{g,1} \bmod 2^9 = IPID^{g,0} \pm 1 + S^{g,1} - S^{g,0} \bmod 2^9$$

(We need to use  $\pm 1$  since we cannot know the order of packet generation. Thus given knowledge of  $IPID^{g,0}$  we have two candidates for  $IPID^{g,1}$ , out of a space of  $2^9 = 512$  values.) A random choice of two values yields a success rate of  $1/256$ . We deem our algorithm to be valid if it consistently yields the correct value (in one of the candidates) in all tests.

We asked “Friends and Family” to browse to the demo site using Windows 8 or later, from various networks.

## 5.2 Results

**Network distribution** The experiment was conducted from July 22<sup>nd</sup>, 2018 to October 20<sup>th</sup>, 2018. We collected data on 75 different class B networks. The networks are well dispersed across 18 countries and 4 continents. The networks are also usage-diverse (home networks, SMB networks, corporate networks, university networks, public hotspots and cellular networks). We asked the users who connected to our demo site to use multiple regular browsers and networks, and connect at different times, and verified that the device ID remained the same in all these connections.

**Failures to extract a key – IP ID modification** In only 6 networks out of 75 (8%) we could not extract the key and therefore concluded that the IP ID was not preserved by the network. These six networks did not include any major ISP and seem to be used by relatively few users: they included an airport WiFi network, a government office, and a Windows machine connecting through one cellular hotspot (hotspots that we tested in other cellular networks did not change the IP ID). Of those six networks, in 3 networks we had clear indication that a transparent proxy or a web security gateway was in path. In such cases, moving to WebSocket over HTTPS, or to UDP would probably have addressed the issue. Another case was a forward proxy (moving to UDP would have possibly addressed it). In the two final cases, the exact

nature of interference was not identified. We can say then that optimistically, only 2 networks out of 75 (2.7%) are incompatible with the tracking technique, maybe even less (as it is still quite possible these two TCP gateways are actually transparent proxies).

**Positive results** In the remaining 69 networks, for 4 networks we did not keep traffic for the additional two IPs, thus we could not verify the key extraction. For the rest 65 networks, our algorithm extracted a single 40-bit key, and correctly predicted the least significant 9 bits of the IPID of the second IP in the last pair (i.e. the correct value was one of the two candidates computed by the algorithm). This verifies the correctness of the algorithm and the key bits it extracts.

**Lab verification** We tested a machine in the lab with the above test setup to obtain 40 bits of  $K$ . Then, using WinDbg in local kernel mode, we obtained `tcpip!TcpToepplitzHashKey`, extracted the 40 bits from it and compared to the 40 bits calculated by the snippet – as expected, they came out identical.

**Actual run time** We estimate the overall runtime for  $J = 6, G = 12$  on a single Azure B1s machine to be 0.73 seconds.

**Packet loss and false negatives** We analyzed 79 valid tests and found only 3 cases wherein the analysis logic failed to provide a device ID (additional test from the same devices succeeded in extracting a key). In all such cases a manual analysis indicates that this is due to packet loss. Appendix A.1.4 describes additional logic that can be used to reduce false negatives to a negligible level.

## 6 Linux and Android

The scope of our research is Linux kernel 3.0 and above. Also, we only investigated the x64 (typical desktop Linux) and ARM64 (Android) CPU architectures, although almost all of the analysis is not architecture-specific.

### 6.1 Attack Outline

In order to track a Linux/Android device, the tracker needs to control several hundred IP addresses. The tracking snippet forces the browser to rapidly emit UDP packets to each such IP (using WebRTC and specifically the STUN protocol, which enables sending bursts of packets closely spaced in time to controlled destination addresses). It also collects the device’s source IP address (using WebRTC as well or a different approach described in the extended paper.)

The tracker collects IP IDs from all IP addresses, and identifies bucket collisions by looking for IP pairs whose IP IDs are in close proximity. Recall that the choice of the bucket is a function of the source and destination IP addresses, and a device key. The tracker enumerates over the key space to find the (correct) key which generates collisions for the same pairs for which collisions were observed. The key that is found is the device ID.

## 6.2 IP ID Generation in Linux

The Linux kernel implementation of IP ID differs between TCP and UDP [16]. The TCP implementation always used a counter per TCP connection (initialized with a hash of the connection endpoints and a secret key, combined with a high resolution timer) and as such, is not interesting to us (collisions are meaningless). The implementation of IP ID for stateless over-IP protocols (e.g. UDP) has gone through an interesting evolution process. We focus on short datagrams, i.e. datagrams shorter than MTU (maximum transmission unit), that do not undergo fragmentation. We designate the IP ID generation algorithms as  $A_0, A_1, A_2$  and  $A_3$ , in their order of evolution.

**$A_0$ :** In early Linux kernels, the IP ID for short datagrams was simply set to 0.

**$A_1$  and  $A_2$ :** In Linux kernel 3.16.0 (released August 2014), IP ID for short datagrams became dynamic (just like it has always been for long UDP datagrams).<sup>11</sup> This was back-ported to various active Linux 3.x branches (see Table 2). The generation algorithm in general has an array of  $M = 2048$  buckets, each containing a value  $0 \leq \beta < 2^{16}$  and a time-stamp  $\tau$  of the last time this bucket was used. The bucket array is initialized at boot time with random data (using a PRNG). The algorithm also uses the following parameters

- *key* – a 32-bit key (`ip_idents_hashrnd`) which is initialized upon first IP transmission with random data.
- *h* – a hash function. Older and newer versions of Linux used different hash functions ( $A_1$  and  $A_2$ , resp.) The details of the hash functions are described in the extended paper since they not important for understanding the attack.
- *protocol* – the IP “next level” protocol number (for UDP, this value is 17). Nominally 8-bit field, extended to 32-bit by zero-filling the most significant bits.
- $\text{RANDOM}(x), x > 0$  – a PRNG (a 96/128 bit Tausworthe Generator) which receives  $x$  as a parameter and provides a random integer in the range  $[0, x)$ . (We define  $\text{RANDOM}(0) = 0$ ). Note that  $\text{RANDOM}(1) = 0$ .

The IP ID generation algorithm is defined in Algorithm 2. The procedure picks an index to a counter as a function of the source and destination IP address, the protocol and the key. It picks a random value which is smaller than or equal to the time that passed (measured in ticks, with tick frequency of  $f$  per second) since the last usage of this counter, increments the counter by this value, and outputs the result.

**$A_3$ :** Starting with Linux 4.1, the net namespace of the kernel context, *net* (a 64-bit *pointer* in kernel space) is included in the hash calculation, conditional on a compilation flag `CONFIG_NET_NS` (which is on by default for Linux 4.1

<sup>11</sup>See function `__ip_select_ident` in <https://elixir.bootlin.com/linux/v3.16/source/net/ipv4/route.c>.

---

**Algorithm 2** Linux IP ID Generation ( $A_1/A_2$ )

---

```
1: procedure GENERATE-IPID
2:    $i \leftarrow h(IP_{DST}, IP_{SRC}, protocol, key) \bmod M$ 
3:    $hop \leftarrow 1 + \text{RANDOM}(t_{now} - \tau[i])$ 
4:    $\beta[i] \leftarrow (\beta[i] + hop) \bmod 2^{16}$ 
5:    $\tau[i] \leftarrow t_{now}$ 
6:   return  $\beta[i]$ 
```

---

and later, and for Android kernel 4.4 and later). The modification is for step 2, which now reads:

$$i \leftarrow h(IP_{DST}, IP_{SRC}, protocol \oplus g(net), key) \bmod M$$

where  $g(x)$  is a right-shift (by  $\rho$  bits) and a truncation function that returns 32 bits from  $x$ . We designate this algorithm as  $A_3$ .

To summarize, there are four flavors of IP ID generation (for short stateless protocol datagrams) in Linux:

1.  $A_0$  - IP ID is always 0 (in ancient kernel versions)
2.  $A_1 / A_2$  - Both versions use Algorithm 2, with the different implementations of  $h$ .
3.  $A_3$  - Algorithm 2, adding net namespace to the calculation.

Of interest to us are algorithms  $A_1$  to  $A_3$ . We focus mostly on UDP, as this is a stateless protocol which can be emitted by browsers.

The resolution  $f$  of the timer  $t$  in the algorithm is determined by the kernel compile-time constant `CONFIG_HZ`. A common value for older Android Linux kernels is 100(Hz). Newer Android Linux kernels (4.4 and above) use 300 or 100 (or rarely, 250). The default for Linux is  $f = 250$ .<sup>12</sup> In general, for tracking purposes, a lower value of  $f$  is better.

Note that  $key$  and  $net$  are generated during the operating system initialization, which, unlike Windows, happens during restart *and* during (shutdown+)start.

### 6.3 Setting the Stage

Our technique for tracking Android (and Linux) devices uses HTML5's WebRTC[1] both to discover the internal IP address of the device and to send multiple UDP packets. It works best when the WebRTC STUN [21] traffic is bursty. In order to analyze the effectiveness of the technique we investigated the following features, focusing on Android devices.

**Android Versions and Linux Kernel Versions** The Android operating system is based on the Linux kernel. However, Android versions do not map 1:1 to Linux kernel versions. The same Android version may be built with different Linux kernel versions by different vendors, and sometimes

<sup>12</sup><https://elixir.bootlin.com/linux/v4.19/source/kernel/Kconfig.hz>

by the same vendor. Moreover, when an Android device updates its Android operating system, typically its Linux kernel remains on the same branch (e.g. 3.18.x). Android vendors also typically use somewhat old Linux kernels. Therefore, many Android devices in the wild still have Linux 3.x kernels, i.e. use algorithm  $A_1$  or  $A_2$ .

**Sending Short UDP Datagrams to Arbitrary Destinations, or “Set Your Browsers to STUN”** The technique requires sending UDP datagrams from the browser to multiple destinations. The content of the datagrams is immaterial, as the tracker is interested only in the IP ID field. We use WebRTC (specifically – STUN) to send short UDP datagrams (with no control over their content) to arbitrary hosts. The `RTCPeerConnection` interface can be used to instruct the browser's WebRTC engine to use a list of presumably STUN servers, and even allows setting the UDP destination port per each host. The browser then sends STUN “Binding Request” (UDP short datagram) to the destination host and port.

To send STUN requests to multiple servers (in Javascript), create an array `A` of strings in the form `stun:host:port`, then invoke the constructor `RTCPeerConnection({iceServers: A}, ...)` in a regular WebRTC flow e.g. [13] (applying the fix from [8]).

Another option (specific to Google Chrome) is to send requests over gQUIC (Google QUIC) protocol, which uses UDP as its transport. This is less ideal since the traffic is less bursty, its transmission order isn't deterministic, and there is an overhead in HTTPS requests and in gQUIC packets.

**Browser Distribution in Android** We want to estimate the browser market share of “supportive” browsers (Chrome-like and Firefox) in the Android OS. Based on April 2018 figures for operating systems,<sup>13</sup> combined with mobile browsers distribution in April 2018,<sup>14</sup> we conclude that the Chrome-like browsers (Google Chrome, Opera Mini, Baidu, Opera) comprise 90% of the browser usage in Android. Adding Firefox (even though its STUN traffic is less bursty, Firefox can still be tracked at least for  $f = 100$ ) gets this figure up to 92%.

**Chrome's STUN Traffic Shape** Chrome sends the STUN requests to the list of supposedly STUN servers, in bursts. A single burst may contain the full list of the requested STUN servers (in ascending order of destination IP address), or a subset of the ordered list (typically with a missing range of destination hosts). We measured 1014 bursts (to  $L = 400$  destination IP addresses) emitted by a Google Pixel 2 mobile phone (Android 8.1.0, kernel 4.4.88), running Google

<sup>13</sup><https://netmarketshare.com/operating-system-market-share.aspx>

<sup>14</sup><https://netmarketshare.com/browser-market-share.aspx>

Chrome 67 browser. The vast majority of bursts last between 0.1 seconds to 0.2 seconds, and the maximal burst duration was 0.548 seconds. Thus we use an upper bound of  $\delta_L = 0.6$  seconds for a single burst duration.

Chrome emits up to 9 bursts with increasing time delays, at the following times (in seconds, where  $t = 0$  is the first burst): 0, 0.25, 0.75, 1.75, 3.75, 7.75, 15.75, 23.75, 31.75.<sup>15</sup> We label these bursts  $B_0, \dots, B_8$  respectively, and we will be interested in  $B_4$  and  $B_5$ , as they're sufficiently far from their neighbors. Thus, we are only interested in the first 8-9 seconds of the STUN traffic.

**UDP Latency Distribution** While WebRTC traffic is emitted by the browser in well defined, ordered bursts, one cannot assume the traffic will retain this “shape” when arriving to the destination servers. Indeed, even order among packets within a burst is not guaranteed at the destination. Understanding the latency distribution in UDP short datagrams is therefore needed in order to simulate the in-the-wild behavior, and consequently the efficacy of various tracking techniques. The latency of UDP datagrams is gamma-distributed according to [18] and [19]. However, for simplicity, we use normal distribution to approximate the in-the-wild latency distribution. On May 1<sup>st</sup>-6<sup>th</sup> 2018, we measured the latency of connections to a server in Microsoft Azure “East-US” location (in Virginia, USA) from 8 different networks located in Israel, almost 10,000km away. The maximum standard deviation was 0.081 seconds. Hereinafter, we will use a standard deviation value  $\sigma = 0.1$  seconds as a worst case scenario for UDP jitter.

**Packet Loss** We identified two different packet loss scenarios:

- Packet loss during generation: the WebRTC packet stream (in Chrome-like browsers) is bursty in nature. In some bursts, we noticed large chunks of missing packets. These are quite rare (in the STUN traffic measurement experiment we got 29 such cases out of 1014 – 2.9%, though they are more common in Androids whose kernel is 4.x and have  $f = 100$ ) and easily identified. We can safely ignore them because the tracker can detect a burst with a lot of missing packets, reject the sample and run the sampling logic again, or use a more sophisticated logic incorporating information from more than two bursts. Additionally, with  $f = 100$  there are far less false pairs, which helps the analysis.
- Network packet loss: the UDP protocol does not guarantee delivery, and indeed packets get lost over the Internet. The loss rate is not high, however, and we estimate it to be  $\leq 1\%$ . This is also backed by research.<sup>16</sup>

<sup>15</sup>See <https://chromium.googlesource.com/external/webrtc/+master/p2p/base/stunrequest.cc>.

## 6.4 The Tracking Technique

The technique that we use is different than prior art techniques in focusing on bucket *collisions*. That is, in cases wherein UDP datagrams for two different destination IP addresses end up with IPID generated using the same counter.

The tracker needs to control  $L$  Internet IPv4 addresses, such that the IP-level traffic to these addresses (and particularly, the IP ID field) is available to the tracker. Ideally the IPs are all in the same network, so that they are all subject to the same jitter distribution. The tracker should be able to monitor the traffic to these IP addresses with time synchronization resolution of about 10 milliseconds (or less) - e.g. by having all the IPs bound to a single host.

With  $L$  different destination IP addresses and  $M$  buckets ( $M = 2048$  in Algorithm 2), there are  $\binom{L}{2}/M$  expected collisions, assuming no packet loss. In reality, the tracker can only obtain an *approximation* of this set. The goal is to reduce those false negatives and false positives to levels which allow assigning meaningful tracking IDs.

The basic property that enables the attacker to construct the approximate list is that in an IP ID generation the counter is updated by a random number which is smaller than 1 plus the multiplication of the timer frequency  $f$  and the time that passed since the last usage of that counter. Therefore for a true pair  $(IP^i, IP^j)$  where the IP ID generation for  $IP^i$  and  $IP^j$  used the same bucket (counter), the following inequality almost always holds:

$$0 < (IPID^j - IPID^i) \pmod{2^{16}} < f\Delta t + 10$$

(We use  $f\Delta t + 10$  instead of  $f\Delta t + 1$  to support up to 10 IPs colliding into the same bucket, as each collision may increment the counter by  $\leq 1 + f\Delta t$  where  $\Delta t$  is from the *previous* collision. So the counter can end up incrementing no more than  $f\Delta t + 10$  where  $\Delta t$  is the sum of the time difference between collisions, i.e. the time duration between the first collision and the last collision in the burst.)

Since we are looking at datagrams from the same burst we have an upper bound  $\delta_L$  such that  $\Delta t < \delta_L$ , and therefore:

$$0 < (IPID^j - IPID^i) \pmod{2^{16}} < f\delta_L + 10$$

For two IP addresses which are *not* mapped to the same counter, the likelihood of this inequality to hold is only  $\frac{(f\delta_L+10)-1}{2^{16}}$  which is  $\ll 1$  when  $f\delta_L \ll 2^{16}$ . The key extraction algorithm (Section 6.6) will examine IP ID values in two different communication bursts, and this will further reduce the likelihood of a false positive. Note that the probability of a false positive pair in a given burst to survive into the next burst is roughly  $\frac{f\delta_L+10}{f\Delta t} \approx \frac{\delta_L}{\Delta t}$  where  $\Delta t$  is the time between the consecutive bursts, whereas a true pair will occur in all bursts. Thus for the intersection of 2 consecutive bursts  $\Delta t = 4$  seconds apart, the amount of false positives (in both bursts) will be  $\approx 0.15$  of their amount in a single burst.

## 6.5 Attack Phase 1 – Collecting Collisions

The tracking snippet needs to be rendered for at least 8.5 seconds, enough time for the browser to send the first 6 STUN bursts ( $B_0, \dots, B_5$ ) – see Section 6.3. The tracking server splits the STUN traffic to bursts, based on the datagrams’ time of arrival, and on the expected burst time offsets (see Section 6.3). For simplicity and ease of analysis, we henceforth only use traffic from bursts  $B_4$  and  $B_5$ , which can be easily and unambiguously determined (since they are well separated in time from other bursts). We note that in some cases, requests in  $B_4$  or in  $B_5$  may be unsent, and in such cases we may need to resort to using e.g.  $B_3$  and  $B_5$  or similar combinations, but as long as these are “late” bursts (i.e. separated from their neighboring bursts by a enough  $\sigma$  units, where  $\sigma$  is the UDP jitter, see above), they can be separated without errors (or almost without errors) and the following analysis remains valid. If there are too many missing requests in a burst, the Tracking Server communicates with the Tracking Snippet, instructing it to retest the device.

Assuming no (or few) missing requests in  $B_4$  and  $B_5$ , the Tracking Server starts analyzing the data per burst (in  $B_4$  and  $B_5$ ). For each burst the Tracking Server calculates a set of pair candidates by collecting pairs of IP addresses ( $IP^i, IP^j$ ) for which  $IP^i < IP^j$  and  $0 < (IPID^j - IPID^i) \bmod 2^{16} < \lambda_L$  where  $\lambda_L = f\delta_L + 10$ . It then identifies pairs which appear in the candidate sets of *both* bursts, and adds them to a set  $U$  of full candidates. This set forms a single *measurement* of a device. The tracker calculates the tracking ID based on  $U$  in Phase 2.

## 6.6 Attack Phase 2 – Exhaustive Key Search

In the second phase the tracking server runs an exhaustive search on the key space  $W$  where the key is 32 bits long for algorithms  $A_1$  and  $A_2$ , 41 bits long for algorithm  $A_3$  (Linux) and 48 bits for  $A_3$  (Android). For each candidate key, the algorithm counts how many IP pairs in  $U$  are predicted by the candidate key. It is expected that only in one (the correct) key, this number will exceed a threshold  $v$ , and in such case, this will be returned as the correct key (and the device ID). See Algorithm 3 for details (the algorithm uses the notation  $h'(\dots, k) = h(\dots, protocol \oplus g(net), key)$  where  $k$  is split into  $g(net), key$ ).

We assume here knowledge of the version of the algorithm ( $A$ ) used –  $A_1, A_2$  or  $A_3$ . For  $A_1$  and  $A_2$ , the key space size is  $|W| = 2^{32}$ , and for  $A_3$ , it is  $2^{41}$  for the x64 architecture and  $2^{48}$  for the ARM64 architecture (see Section 6.7.)

As explained in Section 6.11, false positives ( $|X| > 1$ ) are very rare – they can be handled but as this complicates the analysis logic, it is left out of the paper.

**Attack run time** Where  $|U| = P$  pairs, the run time of Algorithm 3 is proportional to  $|W|P$ .  $P$ ’s distribution depends on  $f$ ; Table 1 summarizes the expectancy and standard deviation

---

```

---

Table 1: Approximated  $P$  distribution

$f$ [Hz]	$E(P)$	$\sigma(P)$	$\sigma(P)/E(P)$
100	50.59	7.39	0.146
250	65.47	8.60	0.131
300	70.45	8.79	0.125

for common  $f$  values. These were approximated by a computer simulation (100 million iterations.)

**Time/memory optimization** When the number of devices to measure is much smaller than  $|W|$  it is possible to optimize the technique for repeat visits. The optimization simply amounts to keeping a list  $\Lambda$  of already encountered *key* values (or  $(g(net), key)$  values), and trying them first. If a match is found (i.e., this is a repeat visit), there is clearly no need to continue searching the rest of the key space. Otherwise, the algorithm needs to go through the remaining key space.

**Targeted tracking** Even if the key space  $W$  is too large to make it economically efficient to run large scale device tracking, it is still possible to use it for targeted tracking. The use case is the following: The tracking snippet is invoked for a specific target (device), e.g. when a suspect browses to a honeypot website. At this point, the tracker (e.g. law enforcement body) extracts the key, possibly using a very expensive array of processors, and not necessarily in real time. Once the tracker has the target’s key, it is easy to test any invocation of the tracking snippet against this particular key and determine whether the connecting device is the targeted device. Moreover, if the attacker targets a single device (or very few devices), it is possible to reduce the number of IP addresses used for re-identifying the device, by using only IP addresses which are part of pairs that collide (into the same counter bucket) under the known device key. Thus we can use a single burst with as few as 5 IP pairs per device to re-identify the device. The dwell time in this case drops to

near-zero.

## 6.7 The Effective Key Space in Attacking Algorithm $A_3$

In Algorithm  $A_3$ , 32 bits of the net namespace are extracted by a function we denote as  $g()$ , and are added to the calculation of the hash value. The attack depends on the effective key space size  $|W| = |\{key\}| \times |\{g(net)\}| = 2^{32} \cdot |\{g(net)\}|$ .

We analyzed the source code of Linux kernel versions 4.8 and above on x64, and 4.6 and above on ARM64, and found that if KASLR is turned off then the effective key space size is 32 bits in both x64 and ARM64. If KASLR is turned on, then the effective key space size is 41 bits in x64 and 48 bits in ARM64.

## 6.8 KASLR Bypass for Algorithm $A_3$

By obtaining  $g(net)$  as part of Attack Phase 2 (Section 6.6), the attacker gains 32 bits of the address of the `net` structure. In single-container systems such as desktops and mobile devices, this `net` structure resides in the `.data` segment of the kernel image, and thus has a fixed offset from the kernel image load address. In default x64 and ARM64 configurations, the 32 bits of  $g(net)$  completely reveal the random KASLR displacement of `net`. This suffices to reconstruct the kernel image load address and thus fully bypass KASLR.

## 6.9 Optimal Selection of $L$

Since IP addresses are at premium, we choose a minimal integer number  $L$  of IP addresses such that at the point  $v$  where  $Prob(FN) + Prob(FP)$  is minimal,  $Prob(FP) + Prob(FN) \leq 10^{-6}$ . We assume  $f = 300$  (worst case scenario). For simplicity, at this stage we neglect packet loss, and assume that  $\delta_L = \frac{L}{400} \delta_{400}$  (we assume  $\delta_L \propto L$ , and we measured  $\delta_{400}$ ). For false negatives, we use the Poisson approximation of birthday collisions [3] with  $\lambda = \binom{L}{2}/M$ . Therefore:

$$Prob(FN) \approx \sum_{i=0}^{v-1} \frac{\lambda^i e^{-\lambda}}{i!}$$

For false positives, we also assume that a burst contains the average number of false pairs and true pairs  $A = \lfloor \frac{f\delta_L+10}{f\Delta t} \binom{L}{2} \frac{f\delta_L+10}{2^{16}} + \frac{\binom{L}{2}}{M} \rfloor$ . We note that the probability for a single false key to match exactly  $k$  pairs is  $\binom{A}{k} (\frac{1}{M})^k (1 - \frac{1}{M})^{A-k}$ . The probability of  $|W| - 1$  false keys to generate at least one false positive key is therefore:

$$Prob(FP) \approx 1 - \left( \sum_{i=0}^{v-1} \binom{A}{i} \left(\frac{1}{M}\right)^i \left(1 - \frac{1}{M}\right)^{A-i} \right)^{|W|-1}$$

Assuming  $|W| = 2^{48}$  (worst case – Android), we enumerated over all  $v$  values for each  $L$  in  $\{200, 250, \dots, 500\}$  to find the

optimal  $v$  (per  $L$ ). We found that  $L = 400$  (with  $v = 11$ ) is the minimal “round”  $L$  satisfying  $Prob(FP) + Prob(FN) \leq 10^{-6}$  at its optimal  $v$ .

## 6.10 A More Accurate Treatment for $L = 400$

Using a computer simulation, we approximated the distributions of all collisions  $p_A(n)$  (using  $10^8$  simulation runs), and of true collisions  $p_T(n)$  (using  $10^9$  simulation runs). The simulations took into account 1% packet loss. With these, we can calculate more accurate approximations:

$$Prob(FN) \approx \sum_{i=0}^{v-1} p_T(i)$$

$$Prob(FP) \approx 1 - \sum_n p_A(n) \left( \sum_{i=0}^{v-1} \binom{n}{i} \left(\frac{1}{M}\right)^i \left(1 - \frac{1}{M}\right)^{n-i} \right)^{|W|-1}$$

(We use the convention  $\binom{n}{k} = 0$  where  $k > n$ .) We enumerated over values  $1 \leq v \leq 20$  for  $L = 400$  and  $|W| = 2^{48}$  (worst case – Android.) The minimal  $Prob(FP) + Prob(FN)$  is at  $v = 11$ , where  $Prob(FP) = 6.2 \times 10^{-10}$  and  $Prob(FN) = 4.2 \times 10^{-8}$ . We get the same optimal  $v$  value for  $L = 400$  as we got in Section 6.9, which means that the approximation steps we took there are reasonable.

## 6.11 Practical Considerations

**Controlling packets from the browser** As explained in Section 6.3, it is possible to emit UDP traffic to arbitrary hosts and ports using WebRTC. The packet payload is not controlled. The tracker can use the UDP destination port in order to associate STUN traffic to the same measurement.

**Synchronization and packet transmission/arrival order** Unlike the Windows technique, in the Linux/Android tracking technique there is no need to know the exact transmission order of the packets within a single burst.

**False positives and false negatives** Using a computer simulation with  $L = 400$  destination IP addresses, a burst length of  $\delta_L = 0.6$  seconds, and packet loss rate of 0.01, we calculated an approximation of for the false negative rate of  $4.2 \times 10^{-8}$  for  $v = 11$ , and an approximation for the false positive rate of  $6.2 \times 10^{-10}$ . These approximations were computed assuming  $|W| = 2^{48}$  (worst case – Android). See Section 6.10 for more details.

**Device ID collisions** The expected number of pairs of devices with colliding IDs, due to the birthday paradox, and given  $R$  devices and a key space of size  $|W|$ , is  $\binom{R}{2}/|W|$ . For Algorithms  $A_1$  and  $A_2$  the key space size is  $|W| = 2^{32}$ , and will cause device ID collisions once there are several tens of thousands of devices. For  $R = 10^6$  this will affect 0.00023 of the population (2 out of every 10,000 devices). For Alg.  $A_3$ , the key space size (with KASLR) is  $\geq 2^{41}$ , so collisions start showing up with  $R$  in the millions. Even for  $R = 128 \cdot 10^6$ , collisions affect only 0.00006 of the population.

**Dwell time** In order to record  $B_5$ , the snippet page needs to be loaded in the browser for 8-9 seconds. Navigating away from the page will immediately terminate the STUN traffic.

**Environment factors** All the UDP-related topics in Section 4.8 are applicable as environment factors on the Linux/Android tracking technique.

**Longevity** The device ID remains valid as long as the device is not shutdown or restarted. Mobile devices are rarely shut down, and are typically restarted only on updates, which happen once every several months, or even less frequently.

**Scalability** The attack is scalable. Device ID collisions are rare even with many millions of devices (see above). False positives and false negatives are also rare (less than  $4.3 \times 10^{-8}$  combined). From a resource perspective, the attack uses a fixed number of IPs and servers, and a fixed-size RAM/disk. The required CPU power is proportional to the number of devices measured per time unit. Network consumption per test is negligible – approx. 13.5KB/s (at the IP level) during measurement.

## 6.12 Possible Countermeasures

**Increasing  $M$**  Changing the algorithm to use a larger number  $M$  of counters, will reduce the likelihood of pairs of IP addresses using the same counter. In response to such a change the tracker can increase the number  $L$  of IP addresses that it uses. The expected number of collisions is  $\binom{L}{2}/M$ , and therefore increasing  $M$  by a factor of  $c$  requires the attacker to increase  $L$  by only a factor of  $\sqrt{c}$ .

On the other hand,  $\delta_L$  also grows (probably linearly in  $L$ ), and when  $f\delta_L \geq 2^{16}$  no information is practically revealed to the tracker. It is probably safe to assume that the tracker can handle an increase of  $L$  by a factor of  $\times 10$ , which means that in order to stop the attacker the IP ID generation algorithm must increase  $M$  by more than  $\times 100$ , making it too memory expensive to be practical.

**Increasing the key size ( $W$ )** This can be an effective counter-measure for the exhaustive search phase, though the pair collection phase is unaffected by it. Yet some choices of the hash function  $h$  might still allow fast cryptanalysis.

**Strengthening  $h$**  Our analysis does not rely on any property of the hash function  $h$ , except that it is more-or-less uniform. Thus, changing  $h$  will not affect our results.

**Replacing the algorithm** See the last item in Section 4.9.

## 7 Experiment – Attacking Linux and Android Devices in the Lab

In order to verify that we can extract the key used by Linux and Android devices, we need to control hundreds of IP addresses. Controlling such a magnitude of Internet-routable IP addresses was logistically out of scope for this research. Therefore we had to settle for an in-the-lab setup, which naturally limited the number of devices we could test.

## 7.1 Setup

We connected the tested devices to our own WiFi access point, which advertised our laptop as a network gateway. Then we launched a Chrome-like browser inside the Linux/Android device, and navigated to a page containing a tracking snippet. The tracking snippet used WebRTC to force UDP traffic to a list of  $L = 400$  hosts, and this traffic passed through our laptop (as a gateway) and was recorded.

We then ran the collision collection logic (Phase 1), and fed its output (IP pairs whose IP IDs collide) to the exhaustive key search logic (Phase 2). For KASLR-enabled devices, we also provided the algorithm with the offset (relative to the kernel image) of `init_net`, which we extracted from the kernel image file given the build ID (can be inferred e.g. from the User-Agent HTTP request header). We expected that the algorithm will output a single key, which will match a large part of the collisions.

## 7.2 Results

We tested 2 Linux laptops and 6 Android devices, together covering the vast majority of operating system and hardware parameters that regulate the IP ID generation. The results from all tests were positive - our technique extracted a single key and a kernel address of `init_net` where applicable (which was identical to the address in `/proc/kallsyms`). Note that due to hardware availability constraints, for the Pixel 2XL case ( $|W| = 2^{48}$ ), we provided the algorithm with the correct 16 bit kernel displacement to reduce the key search to  $2^{32}$ . Table 2 provides information about the common kernel versions, their parameter combinations and the tested devices.

The Attack time column is the extrapolated attack time in seconds with 10,000 Azure B1s machines, based on  $E(P_f)$  from Table 1, i.e. the average attack time is  $r \cdot |W| \cdot E(P_f)$  where  $r$  is the time it takes a single B1s machine to test a single key with a single pair, divided by 10,000. The standard deviation of the attack time for a given  $f$  is  $r \cdot |W| \cdot \sigma(P_f)$ , which is  $\sigma(P_f)/E(P_f)$  in Table 1 times the average attack run time in Table 2. From a calibration run (single B1s machine, 10 pairs,  $2^{32}$  keys, 294.83 seconds run time) we calculated  $r = 6.8645 \times 10^{-13}$ , and populated the Attack Time column in Table 1 with  $r \cdot |W| \cdot E(P_f)$ .

**Applicability in-the-wild** While our tests were carried out in the lab, we argue that the results are representative of an in-the-wild experiment with the same devices. We list the following potential differences between in-the-lab and in-the-wild experiment, and for each difference, we note why our experiment can be projected to an in-the-wild scenario.

- Packet loss: our technique is not sensitive to packet loss. We ran false positive/negative computer simulations (assuming 1% packet loss) supporting this fact.

Table 2: Common Linux/Android Kernels and Their Parameter Combinations

O/S	Kernel Version	Alg.	$f$ [Hz]	KASLR	NET_NS	$\rho$	$\log_2  W $	Tested System	Attack Time [s]
Linux (x64)	4.19+	$A_3$	250	Yes	Yes	12	41	Dell Latitude E7450 laptop	99
Linux (x64)	4.8-4.18.x	$A_3$	250	Yes	Yes	6	41	Dell Latitude E7450 laptop	99
Android (ARM64)	4.4.56+, 4.9, 4.14	$A_3$	300/100	Yes	Yes	6/7	48	Pixel 2XL ( $\rho = 6$ )	13,612/9,775
Android (ARM64)	3.18.17+ 3.4.109+	$A_2$	100	No	No	Don't care	32	Redmi Note 4 Xiaomi Mi4	0.15
Android (ARM64)	3.18.0-3.18.6 3.10.53+ 3.4.103-3.4.108	$A_1$	100	No	No	Don't care	32	Samsung J7 prime Samsung S7 Meizu M2 Note	0.15

- Network latency: our technique is not sensitive to network latency (which is just a constant time-shift, from our perspective).
- UDP jitter: this only affects correctly splitting the traffic into bursts. Our technique uses the “late” bursts, thus assuring that the bursts are well separated time-wise and that a jitter of  $\sigma = 0.1s$  does not affect tracking.
- Network interference (IPID modification): this issue was already evaluated in-the-wild in the Windows experiment, and the Windows results can be applied to the Linux/Android use case.
- Packet reordering (within a burst): Our technique does not rely on packet order within a burst.

Thus we conclude that our results (and henceforth, the practicality of our technique) are applicable in-the-wild.

## 8 Conclusions

Our work demonstrates that using non-cryptographic random number generation of attacker-observable values (even if the values themselves are not security sensitive), may be a security vulnerability in itself, due to an attacker’s ability to extract the key/seed used by the algorithm, and use it as a fingerprint of the system.

We stress that any replacement cryptographic algorithm must not be hampered by using a key that is too short, in order to avoid a key enumeration attack. Also, as a security measure, we strongly recommend generating unique keys for such cryptographic usage, without resorting to using secret data that is used for other purposes (which – in case of a cryptographic weakness in the algorithm – can leak out).

## 9 Acknowledgements

This work was supported by the BIU Center for Research in Applied Cryptography and Cyber Security in conjunction

with the Israel National Cyber Directorate in the Prime Minister’s Office.

We would like to thank the anonymous reviewers for their feedback, Assi Barak for his help to the project, as well as Avi Rosen, Sharon Oz, Oshri Asher and the Kaymera Team for their help with obtaining a rooted Android device.

## A Details of the Attack on Windows

### A.1 Practical Considerations

#### A.1.1 Controlling Packets from the Browser

**UDP:** As explained in Section 6.3, it is possible to emit UDP traffic to arbitrary hosts and ports using WebRTC. The packet payload is not controlled. The tracker can use the UDP destination port in order to associate STUN traffic to the same measurement.

**TCP:** WebSocket [22] emits TCP traffic in a controlled fashion once a circuit is established, thus can be used by the snippet to fully control packet transmission. The downside of using TCP-based protocols is the TCP-level retransmission, which can introduce loss of synchronization between the device and the server side, regarding how many packets were sent. The tracker can use the packet payload to mark packets that belong to the same measurement.

Table 3: Common tail length probability - measured with 1000 randomly chosen sets of 30 IPs ( $J = 6, G = 12, Q = 3$ ), 10,000 tests each ( $10^7$  tests altogether).

Common tail [bits]	Prob.	Common tail [bits]	Prob.
45	0.9937579	42	$2.6 \times 10^{-5}$
44	0.0058328	41	$2.9 \times 10^{-6}$
43	0.0003783	$\leq 40$	$2.1 \times 10^{-6}$

### A.1.2 Packet Transmission Order

We encountered cases in the wild where the packet payload generation order is not identical to packet transmission order. Specifically, Microsoft IE and Edge are prone to this behavior. This is only relevant in the same class B network (since there the original extraction algorithm makes an assumption on the order of the packets). Therefore, the tracker should try all possible permutations of packet order (per class B network IPs). In Phase 1, this means enumerating over all  $\pi \in S_J$  ( $J!$  permutations). For each permutation, use the following definition of  $D^j$  (instead of the original one):

$$D^j = (\text{Vec}(IPID^j - (\beta_0 + \pi(j)) \bmod 2^{15}) \oplus \text{Vec}(IPID^0 - (\beta_0 + \pi(0)) \bmod 2^{15}))_{17, \dots, 31}$$

It follows that enumerating over all possible orders will increase the run time of Phase 1 by a factor of  $J!$ . In Phase 2, for each pair of IP addresses, there are only  $2!$  permutations, and since the elimination is so powerful, this will only affect the run time due to the first pair, i.e. will double the run time.

### A.1.3 Handling False Positives

The issue of false positive keys is covered in the extended paper. As mentioned there, the vast majority of false positive keys only differ from the correct key by a few leftmost bits. Table 3 demonstrates that with an optimal choice of 30 IP addresses, if the tracker keeps only 41 bits of the key tail, he/she will get multiple keys with probability  $2.1 \times 10^{-6}$ , which is sufficiently small even for a large scale deployment.

In the case where multiple keys are emitted by the algorithm (even after truncation, e.g. to 41 bits), two strategies can be applied: either (a) determining that this particular device cannot be assigned an ID (at the price of losing  $2.1 \times 10^{-6}$  of the devices); or (b) assigning multiple IDs to the device (which makes tracking the device more complicated and more prone to ID collisions).

### A.1.4 Handling False Negatives and Interference

It is important to note that while there may be false positives, there are no algorithmic false negatives, i.e. the algorithm always emits the correct key (possibly along with incorrect

keys), given the correct data. However, it is possible for the algorithm to receive incorrect data, in the sense that IP IDs are provided which are not (even after re-ordering) derived from an incrementing counter – i.e. there are “gaps” in the counter values associated with the IP IDs. This can happen either due to packet loss or due to interference.

**Packet loss:** In TCP, when a packet from the client to the server is lost, the client will note a missing ACK and will eventually retransmit the original data (with incremented IP ID). This will cause a gap in the counter values, which can be enumerated by the analysis logic (our analysis logic does not currently implement this). Another packet loss scenario is wherein the ACK packet from the server to the client is lost, and the client retransmits the original data. The server however receives two such packets, and can simply discard the one with incremented IP ID. Thus the “problematic” scenario is the one wherein the original data packet is lost.

**Interference:** Theoretically, an unrelated packet sent by the Windows device in between measurement packets may interfere with the measurement. However, this is very unlikely. First, the interfering packet must fall into the same counter bucket as that of the measurement packets – this happens with probability of  $1/8192$  for a given bucket. Second, the timing is delicate – the interfering packet should be sent between the first and the last measurement packet. This time window is below 1 second, so overall the likelihood for interference is very low. When such an interference happens, it creates a gap in the IP ID values, which can be addressed as explained below.

**Addressing “gaps”:** The analysis logic can compensate for up to  $l$  lost packets in the first class B network ( $g = 0$ ) by enumerating over all possible  $\sum_{d=0}^l \binom{J-2+d}{J-2}$  gap configurations (each addendum counts all weak compositions of  $d$  into  $J - 1$  parts). In our experiment, we measured  $l = 4$  for some “difficult” networks, so for  $J = 6$  there are 126 gap configurations, thus a  $\times 126$  factor in the runtime. Note that a gap in the transmissions for  $g > 0$  is much easier to handle, as  $(IPID^{g,1} - IPID^{g,0})$  in eq (5) may now take values in  $\{1, \dots, l + 1\}$ , so there is no runtime factor for this case. When the total gap space is larger than  $l$ , the algorithm will yield no key. In such a case, the server can instruct the snippet to run another test. Therefore the actual false negative probability can be reduced to as small as necessary.

## A.2 Optimizing the IP Set for Minimum False Positives

Since (from Table 3) keys with flipped  $K_{18}$  are the source of most false positives, the tracker should choose a set of IP addresses that minimizes (over  $Q$ ) this false positive probability,  $2^{-(J-1)-Q} + 2^{-(G-Q)}$  (this calculation can be found in the extended paper.) The said minimum is at  $Q = G - (J-1)/2$ , and yields false positive leading term of  $2 \cdot 2^{-\frac{G+J-1}{2}}$ . For  $G = 12, J = 6$ , the optimum is at  $Q = 3$  or  $Q = 4$ .

# When the Signal is in the Noise: Exploiting Diffix’s Sticky Noise

## Abstract

Anonymized data is highly valuable to both businesses and researchers. A large body of research has however shown the strong limits of the de-identification release-and-forget model, where data is anonymized and shared. This has led to the development of privacy-preserving query-based systems. Based on the idea of “sticky noise”, Diffix has been recently proposed as a novel query-based mechanism satisfying alone the EU Article 29 Working Party’s definition of anonymization. According to its authors, Diffix adds less noise to answers than solutions based on differential privacy while allowing for an unlimited number of queries.

This paper presents a new class of noise-exploitation attacks, exploiting the noise added by the system to infer private information about individuals in the dataset. Our first differential attack uses samples extracted from Diffix in a likelihood ratio test to discriminate between two probability distributions. We show that using this attack against a synthetic best-case dataset allows us to infer private information with 89.4% accuracy using only 5 attributes. Our second cloning attack uses dummy conditions that conditionally strongly affect the output of the query depending on the value of the private attribute. Using this attack on four real-world datasets, we show that we can infer private attributes of at least 93% of the users in the dataset with accuracy between 93.3% and 97.1%, issuing a median of 304 queries per user. We show how to optimize this attack, targeting 55.4% of the users and achieving 91.7% accuracy, using a maximum of only 32 queries per user.

Our attacks demonstrate that adding data-dependent noise, as done by Diffix, is not sufficient to prevent inference of private attributes. We furthermore argue that Diffix alone fails to satisfy Art. 29 WP’s definition of anonymization. We conclude by discussing how non-provable privacy-preserving sys-

tems can be combined with fundamental security principles such as defense-in-depth and auditability to build practically useful anonymization systems without relying on differential privacy.

## 1 Introduction

Personal data holds a significant potential for researchers and organizations alike, yet its large-scale collection and use raise serious privacy concerns. While scientists have compared the impact of modern large-scale datasets of human behaviors to the invention of the microscope [1], numerous scandals, such as the recent Cambridge Analytica debacle [2] highlight the importance of privacy and data protection for the general public and modern societies.

Historically, the balance between using personal data and preserving people’s privacy has relied, both practically and legally, on the concept of data anonymization. Anonymization, also called de-identification, is the process of transforming personal data to mask the identity of participants, e.g. by removing identifiers, coarsening data, or adding noise. The recent European General Data Protection Regulation (GDPR) defines anonymous information as “information which does not relate to an identified or identifiable natural person or to personal data rendered anonymous in such a manner that the data subject is not or no longer identifiable” [3]. Similar definitions exist in other protection laws around the world, such as the HIPAA privacy rule for medical data in the US and the ePrivacy regulation. These all state that anonymized data does not require consent from participants to be shared widely, as it cannot be traced back and potentially used against them.

While de-identification algorithms are widely used in industry and academia to transform and release anonymous datasets, a large body of research has shown that these practices are not resistant to a wide range of re-identification attacks [4–9]. Exposure of the limits of de-identification have led to less than happy conclusions by policy makers: for instance, the [US] President’s Council of Advisors on Sci-

ence and Technology concluded that data anonymization “is not robust against near-term future re-identification methods. PCAST do not see it as being a useful basis for policy” [10].

**Query-based systems.** In response to the limits of de-identification, privacy researchers and companies have proposed query-based systems as an alternative. Such systems typically offer data analysts a remote interface to ask questions that return data aggregated from several, potentially many, records. Granting access to the data only through queries, without releasing the underlying raw data, mitigates the risk of typical re-identification attacks. Yet a malicious analyst can often submit a series of seemingly innocuous queries whose outputs, when combined, will allow them to infer private information about participants in the dataset.

**Differential privacy.** Privacy research has been increasingly focused on providing provable privacy guarantees to defend query-based systems against such attacks. Differential privacy [11] is the main privacy guarantee considered by researchers. Intuitively, a randomized algorithm is differentially private if the output does not depend on any single individual’s record in the dataset. It has been shown that algorithms that satisfy differential privacy are robust to a very large class of attacks [12]. Yet, efficient differential privacy mechanisms are generally very use case-specific and, even if a large range of differentially private mechanisms have been proposed, there is still no practical widely deployed differential privacy solution for general-purpose data analytics [13]. To achieve strong privacy guarantees, practitioners must often sharply limit the data utility by adding large amounts of noise and restrict the total number of requests that the system is allowed to answer [14]. Moreover, while differential privacy is a strong guarantee, the risk of data breaches because of implementation issues remains, exposing systems to attacks that differential privacy should in theory rule out [15, 16]. Overall, with some rare exceptions, the complexity of correctly implementing differential privacy and choosing the right privacy budget often prevents practitioners from using it.

**Alternatives to differential privacy.** Diffix, a patented commercial solution that acts as an SQL proxy between an analyst and a protected database [17, 18], has recently been proposed by researchers affiliated with Aircloak and the Max Planck Institute for Software Systems as a practical alternative to differential privacy, based on the [EU] Article 29 Working Party (Art. 29 WP)’s definition of anonymous data. It defines a dataset as anonymous if the anonymization mechanism used protects against *singling out* (identify one user), *linkability* (match users across datasets), and *inference* (learn participants’ records) attacks [18, 19]. Diffix relies on a novel noise addition framework called “sticky noise”, which aims to give analysts a rich query syntax, minimal noise addition, and an infinite number of queries, all while satisfying the WP29 definition of anonymous.

The authors claim that data produced by Diffix (*i*) falls

outside of the scope of the new European GDPR regulation; (*ii*) has been determined by the French National Commission on Informatics and Liberty (CNIL) to offer “GDPR-level anonymization” for all cases; and (*iii*) has been certified by TÜViT as fulfilling “all requirements for data collection and anonymized reporting” [20, 21]. Diffix is used in production and Aircloak reports working with partners such as Telefonica, DZ Bank and Cisco.

**Exploiting Diffix’s noise.** In this paper we present a new class of attacks, called noise-exploitation attacks. The attacks work in three parts: (*i*) canceling out part of the sticky noise using multiple queries, (*ii*) exploiting the noise Diffix adds to one query in order to learn information about the query set associated to this query, and (*iii*) using logical equivalence between queries to obtain independent noise samples for the same query. We develop two noise-exploitation attacks that take advantage of the structure of Diffix’s sticky noise to infer private (also called secret) attributes of individuals in the dataset, violating the inference requirement from the Article 29 WP definition of anonymization [19]. Our first attack, the differential attack, uses samples obtained by the difference between two queries’ outputs, to discriminate between two distributions, depending on the value of the private attribute. We show that, under specific conditions, this attack potentially allows an attacker to infer private information of unique users with up to 96.8% accuracy knowing only 5 pieces of auxiliary information we call attributes.

Our second noise-exploitation attack, the cloning attack, uses dummy conditions that affect the output of queries conditionally to the value of the private attribute. This attack relies on weaker assumptions and automatically validates them with high accuracy, without the need for an oracle. It proceeds in two steps: (*i*) a *validation* step, searching for subsets of known attributes to use for the attack, that will satisfy the assumptions required for its success, and (*ii*) an *inference* step that uses the attributes found to predict users’ private attribute’s value. We perform the attack against four real-world datasets, and show that it can infer the private attributes of between 87.0% and 97.0% of all records across datasets. We then present an optimized cloning attack that targets 55.4% of the users and achieves the same accuracy using as little as 32 queries. This proves that introducing limits for the number of allowed queries would not protect against our attacks.

**Contributions.** This paper makes the following contributions:

- By developing and implementing two attacks, we demonstrate that Diffix alone does not currently satisfy the *inference* requirements of the Art. 29 WP. We make the datasets and code for the attacks and experiments available to other researchers.
- We show, using a collection of four previously published datasets that the assumptions made by our attacks are realistic. We establish that, across all datasets, between

93% and 100% of all users are value-unique (i.e. all records sharing the same set of attributes have the same private attribute).

- We make a range of defense-in-depth proposals, which can be used to improve the practical privacy guarantees of both Diffix and other non-differentially private data anonymization tools. While these measures will not result in differential privacy guarantees, they might provide adequate practical solution in many settings.
- We show, using the Diffix mechanism as our primary example, that anonymization mechanisms that do not rely on differential privacy might not be GDPR-compliant alone, and that naive data-dependent noise can lead to powerful attacks.

**Paper organization.** The rest of the paper is organized as follows. Section 2 describes the Diffix mechanism. Section 3 presents two attacks exploiting the noise added by the system to infer private attributes of individuals in the dataset. Section 4 shows, on real-world datasets, how an attacker can accurately attack the Diffix mechanism. Section 5 discusses the assumptions of the attacks and potential solutions for Diffix to thwart noise-exploitation attacks moving forward. Sections 6 and 7 summarize related work and provide our conclusions to build practically useful anonymization systems. Appendix A provides some details for the statistical tests used by the attack. Appendix B describes how to optimize the cloning attack to reduce the number of queries.

## 2 Summary of the Diffix framework

Here we summarize the Diffix framework as described in [18] and introduce notations for our attack. Diffix acts as an SQL proxy between an analyst and a *protected database*  $D$  where each row is an individual record and each column one attribute. The analyst can send SQL queries to Diffix, which will process the queries and then output a noisy answer.

We denote with  $\mathcal{A}_D$  the set of attributes in the database  $D$ . For instance,  $\mathcal{A}_D$  could contain 4 attributes  $\mathcal{A}_D = \{gender, age, zip, HIV\}$  with *HIV* a binary attribute (0 or 1). A record  $x$  is a row of  $D$  with values for the attributes in  $\mathcal{A}_D$ . For example, with  $\mathcal{A}_D$  as above, we could have  $x = (M, 27, 55416, 1)$ . We assume, for simplicity, that there is one and only one record for every user in  $D$ .

While Diffix can process a large part of the SQL syntax, we here focus on simple count queries:

```
SELECT count(*)
FROM table
WHERE condition1 AND condition2 [AND ...]
```

where every condition is an expression of the form “*attribute*  $\square$  *value*” with  $\square$  being  $=, \neq, \leq, <, \geq,$  or  $>$ .

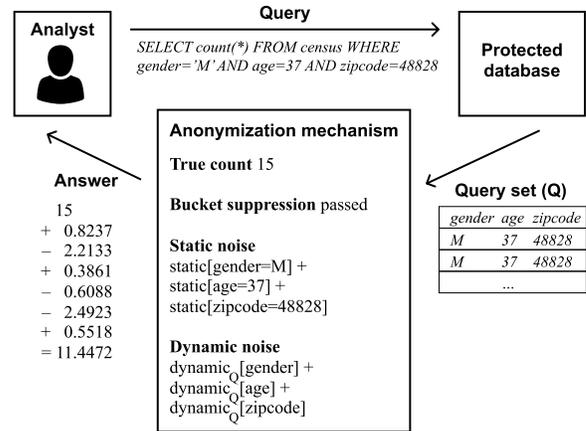

Figure 1: Diffix privacy-preserving architecture

For simplicity, we use a shorter notation for queries using “ $\wedge$ ” for the logical AND:

$$Q \equiv \text{count}(\text{condition}_1 \wedge \text{condition}_2 \wedge \dots).$$

The following query would, for example, count the number of individuals in the database who are male, 37 years old, and live in the area with ZIP code 48828:

$$Q \equiv \text{count}(\text{gender} = M \wedge \text{age} = 37 \wedge \text{zip} = 48828)$$

**Diffix’s privacy-preserving mechanism.** Diffix protects privacy through *sticky noise* addition (static and dynamic noise) and bucket suppression (see Fig. 1). Let  $Q \equiv \text{count}(C_1 \wedge \dots \wedge C_h)$ , and denote by  $Q(D)$  the true result of  $Q$  evaluated on  $D$  (without noise). Diffix’s output for  $Q$  on  $D$  (without bucket suppression, see below) is:

$$\tilde{Q}(D) = Q(D) + \sum_{i=1}^h \text{static}[C_i] + \sum_{i=1}^h \text{dynamic}_Q[C_i] \quad (1)$$

with  $\text{static}[C_i]$  the *static noise* for condition  $C_i$ ,  $\text{dynamic}_Q[C_i]$  the *dynamic noise* for condition  $C_i$  in  $Q$ .

**Static noise.** Let  $C$  be a condition, for example  $\text{age} = 34$ . The *static noise*  $\text{static}[C]$  associated to  $C$  is a random number drawn from a normal distribution  $\mathcal{N}(0, 1)$ . The value is generated by a pseudo-random number generator (PRNG), whose seed is a salted hash of the string literal  $C$ :

$$\text{static\_seed}_C = \text{XOR}(\text{hash}(C), \text{salt})$$

This ensures that the static noise associated with  $C$  is always the same independently of the query where  $C$  appears. The noise is “sticky” thereby preventing an attacker to send the same query multiple times, average out the results, and obtain a precise estimate of the private value (*averaging attack*) [18].

**Dynamic noise.** In the Diffix framework, every record in  $D$  is associated with a user ID, a unique string for that user.

These pseudonyms are used to compute the dynamic noise. Let  $Q \equiv \text{count}(C_1 \wedge \dots \wedge C_h)$  be a query and  $C$  any condition  $C_i$ . The dynamic noise depends not only on  $C$ , but also on the *query set* of  $Q$  in the dataset  $D$ , i.e. the set of users which satisfies *all* conditions  $C_1, \dots, C_h$ . More precisely, if the query set for  $Q$  on  $D$  is  $S = \{\text{uid}_1, \text{uid}_2, \dots, \text{uid}_m\}$ , the dynamic noise for  $C$  ( $\text{dynamic}_Q[C]$ ) is generated from a normal distribution  $\mathcal{N}(0, 1)$  by the PRNG seeded with:

$$\text{dynamic\_seed} = \text{XOR}(\text{static\_seed}_C, \text{hash}(\text{uid}_1), \dots, \text{hash}(\text{uid}_m))$$

Note that we don't include  $D$  in the notation  $\text{dynamic}_Q[C]$ , as the dataset is usually fixed and clear from the context.

The output  $\tilde{Q}(D)$  is therefore the realization of a random variable distributed as a normal distribution  $\mathcal{N}(\mu, \sigma^2)$ , with mean  $\mu = Q(D)$  and variance  $\sigma^2 = 2h$ .

**Example.** Consider again the query

$$Q \equiv \text{count}(\text{gender} = M \wedge \text{age} = 37 \wedge \text{zip} = 48828).$$

Diffix's output for  $Q$  on the database  $D$  is

$$\begin{aligned} \tilde{Q}(D) = & Q(D) \\ & + \text{static}[\text{gender} = M] + \text{dynamic}_Q[\text{gender} = M] \\ & + \text{static}[\text{age} = 37] + \text{dynamic}_Q[\text{age} = 37] \\ & + \text{static}[\text{zip} = 48828] + \text{dynamic}_Q[\text{zip} = 48828] \end{aligned}$$

where  $\tilde{Q}(D)$  is a random value drawn from a normal distribution  $\mathcal{N}(Q(D), 6)$ .

Static and dynamic noise layers are both needed to prevent *intersection attacks* [17, 18], a class of attacks that combine multiple queries to infer private attributes of records.

**Bucket suppression.** In addition to static and dynamic noise, Diffix implements another security measure called *bucket suppression*, similar to the classic query set size restriction. If the size of the query set is smaller than a certain threshold, the bucket suppression rejects the query. Previous research has shown that a fixed threshold constitutes a risk for privacy [22]. Diffix addresses this issue by using a *noisy* (and sticky to the query set) *threshold*. Specifically, suppose Diffix processes a query  $Q \equiv \text{count}(C_1 \wedge \dots \wedge C_h)$ . If  $Q(D) \leq 2$ , then the query gets suppressed. If  $Q(D) > 1$ , then Diffix computes a noisy threshold  $T \sim \mathcal{N}(4, 1/2)$ , using the seed:

$$\text{threshold\_seed} = \text{XOR}(\text{salt}, \text{hash}(\text{uid}_1), \dots, \text{hash}(\text{uid}_m))$$

If  $Q(D) < T$ , the query is suppressed; otherwise, the noisy output  $\tilde{Q}(D)$  is computed and sent to the analyst. In the original Diffix mechanism [17], the queries are said to be “silently suppressed” when censored by bucket suppression. This could mean that (1) a value of 0 is returned as result, (2) a random value is returned or (3) Diffix displays an error message. In this paper, we assume that a bucket-suppressed query will

return a value of zero. This gives less information to a potential attacker than an error message, as a value of zero can be the result of either noise addition or bucket suppression. We consider that returning a random result affects utility too significantly to be applied in practice.

### 3 Noise-exploitation attacks

Our noise-exploitation attacks, which we call *differential* and *cloning*, are both based on three observations. First, since the noise is sticky, it is possible to *cancel out* part of it using multiple queries. Second, since the noise depends on the query set, the noise itself leaks information about the query set. Third, exploiting logical equivalence between some queries, it is possible to circumvent the “stickiness” of the noise by repeating (almost) the same query and consequently obtain independent noise samples. Our differential attack uses samples in a likelihood ratio test to discriminate between two probability distributions depending on the value of the private (also called secret) attribute. Our cloning attack relies on dummy conditions that conditionally strongly affect the output of the query depending on the value of the secret attribute.

#### 3.1 Differential noise-exploitation attack

We first define further notations: with  $A \subseteq \mathcal{A}_D$  a set of attributes,  $x^{(A)}$  is the *restriction* of the record  $x$  to  $A$ , i.e. the vector one obtains after removing from  $x$  every entry for attributes that are not in  $A$ . For example, if  $\mathcal{A}_D = \{\text{gender}, \text{age}, \text{zip}, \text{HIV}\}$ ,  $x = (M, 27, 55416, 1)$  and  $A = \{\text{gender}, \text{age}, \text{HIV}\}$ , then  $x^{(A)} = (M, 27, 1)$ . If  $A$  contains a single attribute  $a$ , we simply write  $x^{(a)}$ . So, for example,  $x^{(\text{gender})} = M$ .

For this attack, we make the following assumptions:

- H1 The attacker wants to find out some information about Bob, the victim. The attacker knows that Bob's record is in the dataset. We denote Bob's record by  $x$ . The attacker has access to the protected dataset only through Diffix.
- H2 The attacker knows all of Bob's attributes for some set of attributes  $A$ . Our *background knowledge* (also called auxiliary information in the literature) is the restricted record  $x^{(A)}$ . This is a standard assumption in the literature on re-identification attacks [23, 24].
- H3 The attacker wants to infer a secret attribute  $s$  about Bob, the victim. That is, she wants to infer the value of  $x^{(s)}$ , where  $s \notin A$ . For simplicity of notation,  $s$  is a binary attribute, i.e.  $x^{(s)} \in \{0, 1\}$ . This means that the attack can be seen as a classifier, with the output of the attack being negative if the algorithm returns  $x^{(s)} = 0$  and positive if it returns  $x^{(s)} = 1$ . While we here focus on the binary case, our results fairly easily extend to non-binary cases.
- H4 There exists an oracle *Unique* that takes as input any restricted record  $z^{(R)}$  and outputs whether  $z^{(R)}$  is *unique*.

(resp. negate) other conditions  $a_j = x_j$  for  $j \leq k$ , obtaining queries  $Q_j$  (resp.  $Q'_j$ ) for  $j \leq k$ . In our notation:

$$Q_j \equiv \text{count} \left( \bigwedge_{\substack{i=1 \\ i \neq j}}^k a_i = x_i \wedge s = 0 \right) \quad (7)$$

$$Q'_j \equiv \text{count} \left( \bigwedge_{\substack{i=1 \\ i \neq j}}^k a_i = x_i \wedge a_j \neq x_j \wedge s = 0 \right) \quad (8)$$

Running all queries  $\{(Q_j, Q'_j)\}_{j \leq k}$ , the attacker collects a vector of realizations  $\{q_j\}_{j \leq k}$  where  $q_j = \tilde{Q}_j(D) - \tilde{Q}'_j(D)$ . All  $q_j$  values are computed from different queries, which generate different noises. Hence, the noises all have different values (with probability 1). Nevertheless, the equation (6) is still true for each  $q_j$ , so we can combine them as  $k$  different samples from the same distribution, and estimate the value of  $Q(D)$ .

Finally, replacing the “ $s = 0$ ” condition with “ $s = 1$ ” in every pair  $(Q_j, Q'_j)$  defines  $k$  new pairs of queries  $\{(R_j, R'_j)\}_{j \leq k}$ . This allows us to obtain  $k$  more samples  $\{r_j\}_{j \leq k}$  (with different noises and inverted results in equation (6)). This gives us a total of  $2k$  samples before bucket suppression (see Appendix A), generated by issuing  $4k$  queries.

On a technical note, observe that in principle we cannot be certain that the  $q_j$ 's (resp.  $r_j$ 's) are all independent samples, because two different queries  $Q_j$  and  $Q_l$  (resp.  $R_j$  and  $R_l$ ) with  $j \neq l$  might have the same query set. In that case, the dynamic noise layers associated to the same conditions would have the same values, and hence the total dynamic noises of the two queries would be heavily correlated. While this affects the accuracy of the likelihood ratio test, the impact is negligible in practice. Hereafter, we always assume that the samples are independent.

**Full differential attack.** For larger values of  $k$ , the queries used by the differential attack contain many conditions, and hence potentially select a low number of records. Depending on the dataset, this might result in a large fraction of queries being bucket suppressed, leaving the attacker with few or no samples for the likelihood ratio test. To counteract this effect, we integrate the attack with a subset exploration step to obtain a *full differential attack*. Assume that the attacker knows a set  $A^*$  of the correct attributes for the victim with  $|A^*| = k^*$ , i.e. the background knowledge is  $x^{(A^*)}$ . The full attack proceeds as follows. The algorithm selects random subsets of  $A^*$  until it finds a subset  $A \subseteq A^*$  such that  $\text{Unique}(x^{(A)})$  returns True. It then performs the differential attack using  $x^{(A)}$  as background knowledge. For the likelihood ratio test, the attack considers only query pairs  $(\tilde{Q}_j(D), \tilde{Q}'_j(D))$  or  $(\tilde{R}_j(D), \tilde{R}'_j(D))$  which have outputs larger than zero in both entries. If no such pair exists, the algorithm samples a new subset  $A$  and iterates the procedure. If no feasible subset is found, the algorithm outputs NonAttackable. The subsets of  $A^*$  are sampled by decreasing size, as bucket

suppression is less likely for lower values of  $k$  (but on the other hand the likelihood ratio test is less accurate).

The procedure `FullDifferentialAttack` presents in detail the algorithm outlined above.

---

### 3.2 Cloning noise-exploitation attack

In this section, we present an extension of the differential noise-exploitation attack, which we call *cloning attack*. This attack adds dummy conditions, that don't affect the query set, to queries, in such a way that several queries with different dummy conditions will have either identical or very different results conditional to the secret attribute's value.

We first introduce some new notations and definitions. Denoting by  $x$  the victim's entire record, the attacker's background information is now  $x^{(A)} = (x^{(A')}, x^{(u)})$  with  $A = A' \cup \{u\}$  and  $|A| = k$ . We use the shorthand  $(A', u)$  for  $A' \cup \{u\}$ . We also define a restricted record  $z^{(A)}$  to be *value-unique* for the attribute  $s$  in  $D$  if  $y^{(A)} = z^{(A)}$  implies  $y^{(s)} = z^{(s)}$ . That is,

---

**Procedure** FullDifferentialAttack( $A^*, x^{(A^*)}, s$ )

---

**Input:** known attributes (names  $A^*$  and values  $x^{(A^*)}$ ),  
secret  $s$

**Output:** True if  $x^{(s)} = 1$ , False if  $x^{(s)} = 0$ ,  
NonAttackable if  $x^{(A^*)}$  is not attackable

```
1 for  $k \leftarrow |A^*|$  to 1 do
2   for  $iter \leftarrow 1$  to 100 do
3      $A \leftarrow \text{RandomSubsetOfSize}(A^*, k)$ 
4     if Unique( $x^{(A)}$ ) and
       DifferentialAttack( $A, x^{(A)}, s$ )  $\neq$  NoSamples
       then
5       return DifferentialAttack( $A, x^{(A)}, s$ )
6     end if
7   end for
8 end for
9 return NonAttackable
```

---

every record that shares the same attributes of the restricted record  $z^{(A)}$  holds the same value for the secret attribute  $s$ . To simplify the notation, we write  $A' = x^{(A')}$  to indicate the condition that all attributes in  $A'$  must match the ones in  $x^{(A')}$ , i.e.  $\bigwedge_{a \in A'} a = x^{(a)}$

The attack addresses several limitations of the differential attack, making it much stronger in practice.

First, the cloning attack does not require an oracle to confirm that the background information uniquely identifies a user. Instead, it replaces the oracle with a heuristic to automatically validate the assumptions.

Second, the differential attack has to ignore any pair  $(\tilde{Q}_j(D), \tilde{Q}'_j(D))$  where at least one of the entries is not positive, as it cannot tell whether the null output comes from noise addition or from bucket suppression. This significantly reduces the total number of samples used. Our cloning attack instead uses “dummy conditions” that do not impact the user set. As queries now only differ in the dummy conditions, the corresponding query sets will always be identical. This allows us to rule out bucket suppression in case at least one output is greater than zero.

Third, while the differential attack requires records to be unique, the cloning attack only requires records to be value-unique. This is a weaker condition and makes the cloning attacks effective on a larger set of users.

Fourth, the cloning attack only requires that the set of users who share all attributes in  $x^{(A')}$  is “large enough” to not be bucket suppressed. This is a weaker assumption than for the differential attack, where this needed to hold for a large number of subsets of  $A$  with one attribute removed. Furthermore, the cloning attack validates this automatically (and thus prevents bucket suppression) with high confidence.

While much stronger, the attack relies on the attacker being able to produce a set of distinct *dummy conditions*

$\Delta = \{\Delta_j\}_{1 \leq j \leq |\Delta|}$ , where each  $\Delta_j$  is an SQL statement such that the set of users matching  $A' = x^{(A')}$  is the same as the set of users matching  $A' = x^{(A')} \wedge \Delta_j$ . In section 5, we discuss how dummy conditions are easy to obtain, slow to detect, and how automatically filtering them might introduce new vulnerabilities.

**Description of the attack.** For each dummy condition  $\Delta_j$ , we define the two queries:

$$Q_j \equiv \text{count} \left( A' = x^{(A')} \wedge \Delta_j \wedge s = 0 \right) \quad (9)$$

$$Q'_j \equiv \text{count} \left( A' = x^{(A')} \wedge \Delta_j \wedge u \neq x^{(u)} \wedge s = 0 \right) \quad (10)$$

With  $q_j = \tilde{Q}_j(D) - \tilde{Q}'_j(D)$ , we have:

$$\begin{aligned} q_j = & Q_j(D) - Q'_j(D) \\ & - \text{static}[u \neq x^{(u)}] - \text{dynamic}_{Q_j}[u \neq x^{(u)}] \\ & + \sum_{i \in A'} \text{dynamic}_{Q_j}[a^{(i)} = x^{(i)}] + \text{dynamic}_{Q_j}[s = 0] \\ & - \sum_{i \in A'} \text{dynamic}_{Q'_j}[a^{(i)} = x^{(i)}] - \text{dynamic}_{Q'_j}[s = 0] \\ & + \left( \text{dynamic}_{Q_j}[\Delta_j] - \text{dynamic}_{Q'_j}[\Delta_j] \right) \end{aligned}$$

By the same argument we presented for the differential attack, if  $x^{(s)} = 1$  then  $Q_j(D) = Q'_j(D)$  and most dynamic and static noises cancel out, giving:

$$q_j = -\text{static}[u \neq x^{(u)}] - \text{dynamic}_{Q_j}[u \neq x^{(u)}] \quad (11)$$

As this value does not depend on the dummy condition used, we have that  $q_1 = q_2 = \dots = q_{|\Delta|}$ .

On the contrary, if  $x^{(s)} = 0$ , then the noise layers do not cancel out with probability 1. As the noise values given by  $\text{dynamic}_{Q_j}[\Delta_j]$  and  $\text{dynamic}_{Q'_j}[\Delta_j]$  depend on  $\Delta_j$ , the probability that all (or any)  $q_j$  are equal is zero.

We can therefore complete the attack by inferring that  $x^{(s)} = 1$  if  $q_1 = \dots = q_{|\Delta|}$ , and  $x^{(s)} = 0$  otherwise. Under the current assumptions, the attack always infers the correct value with 100% confidence (up to pseudo-random collisions in Diffix’s noise addition mechanism).

**Robustness against rounding.** In the previous section, we follow the Diffix papers [17, 18] and assume that  $\tilde{Q}(D)$  is returned directly without any rounding, admitting also negative values. We now consider the case where results are rounded to the nearest nonnegative integer, and propose a simple modification of our attack that accounts for this.

When the results of the queries  $Q_j$  and  $Q'_j$  are rounded, the corresponding  $q_j$  might not be identical if  $x^{(s)} = 0$ . However, the  $q_j$ s will vary less if  $x^{(s)} = 1$  than if  $x^{(s)} = 0$ . Hence, instead of checking if  $q_1 = \dots = q_{|\Delta|}$ , we check if the  $q_j$  values are “similar” to one another. While for high values of  $k$  this is easy to detect, the total variance of the noise for low values

of  $k$  is small, making it harder to distinguish between the two hypotheses (i.e. whether the  $q_j$  values are “similar” or not). To overcome this issue, we “amplify” the noise for each query: instead of adding a single dummy condition  $\Delta_j$  to the queries for  $Q_j$  and  $Q'_j$ , we add the conjunction  $\bigwedge_{l \neq j} \Delta_l$ :

$$Q_j \equiv \text{count} \left( A' = x^{(A')} \wedge \bigwedge_{l \neq j} \Delta_l \wedge s = 0 \right) \quad (12)$$

$$Q'_j \equiv \text{count} \left( A' = x^{(A')} \wedge \bigwedge_{l \neq j} \Delta_l \wedge u \neq x^{(u)} \wedge s = 0 \right) \quad (13)$$

This increases the total variance of the noise in  $q_j$  in the  $x^{(s)} = 0$  case, making it easy to distinguish between the two hypotheses: all the  $q_j$  values will be very similar if  $x^{(s)} = 1$  and fluctuate heavily if  $x^{(s)} = 0$ . Measuring the sample variance  $S^2$  of  $\{q_j\}_{1 \leq j \leq |\Delta|}$ , we infer that  $x^{(s)} = 1$  if  $S^2 \leq \sigma^*$ , and  $x^{(s)} = 0$  otherwise with a cutoff threshold  $\sigma^*$  chosen by the attacker. We include an empirical analysis of  $\sigma^*$  in the full version of this manuscript. The cloning attack is described in detail in the procedure [CloningAttack](#).

---

**Procedure CloningAttack**( $A', u, x^{(A',u)}, \Delta, s, v$ )

---

**Input:** known attributes (names  $A', u$  and values  $x^{(A',u)}$ ), dummy conditions  $\Delta$ , secret  $s$  and target value  $v$

**Output:** True if  $x^{(s)} = v$ , False if  $x^{(s)} \neq v$

```

1 for  $j \leftarrow 1$  to  $|\Delta|$  do
2    $\phi \leftarrow A' = x^{(A')} \wedge \bigwedge_{l \neq j} \Delta_l$ 
3    $\tilde{Q} \leftarrow \text{count}(\phi \wedge s \neq v)$ 
4    $\tilde{Q}' \leftarrow \text{count}(\phi \wedge u \neq x^{(u)} \wedge s \neq v)$ 
5    $q_j \leftarrow \tilde{Q} - \tilde{Q}'$ 
6 end for
7  $\bar{r} \leftarrow \frac{1}{|\Delta|} \sum_{j=1}^{|\Delta|} q_j$ ,  $S^2 \leftarrow \frac{1}{|\Delta|-1} \sum_{j=1}^{|\Delta|} (q_j - \bar{r})^2$ 
8 return  $S^2 \leq \sigma^*$ 

```

---

**Automated validation of the assumption.** The cloning attack relies on two assumptions on the attacker’s background knowledge  $x^{(A',u)}$ :

1. The queries  $\{Q_j\}_{1 \leq j \leq |\Delta|}$  and  $\{Q'_j\}_{1 \leq j \leq |\Delta|}$  in equations (12) and (13) are not bucket suppressed.
2. The user is value-unique in the dataset according to  $(A', u)$  for the secret attribute  $s$ .

We here propose procedures for an attacker to determine whether  $(A', u)$  satisfies the two assumptions with high probability.

Validating the first assumption can be done easily by submitting queries  $\{Q_j\}_{1 \leq j \leq |\Delta|}$  and  $\{Q'_j\}_{1 \leq j \leq |\Delta|}$  to Diffix. Recall that the threshold for bucket suppression for a query depends only on the corresponding query set. All the queries in

$\{Q_j\}_{1 \leq j \leq |\Delta|}$  have the same query set, and the same applies for  $\{Q'_j\}_{1 \leq j \leq |\Delta|}$ . Hence, if *any* query  $Q_j$  is bucket suppressed (i.e. has output zero), then *all* queries in  $\{Q_j\}_{1 \leq j \leq |\Delta|}$  must have output zero, and similarly for  $\{Q'_j\}_{1 \leq j \leq |\Delta|}$ . Thus, if *any* query  $Q_j$  and *any* query  $Q'_j$  have output higher than zero, we are sure that no query was bucket suppressed, and hence all  $q_j$ ’s are valid samples. The test is considered passed in this case, and failed otherwise. See the algorithm [NoBucketSuppression](#) for an implementation example.

Validating the second assumption relies on a heuristic. We run the query:

$$\text{count}(A' = x^{(A')} \wedge u = x^{(u)})$$

and consider the assumption validated if the output is zero, and not otherwise. The idea is that if the output is larger than zero, then the query was not bucket suppressed, and many users are likely share the same attributes  $x^{(A',u)}$ , meaning that  $x^{(A',u)}$  is unlikely to be value-unique. Experiments in section 4 show that this heuristic works very well on real-world datasets.

---

**Procedure NoBucketSuppression**( $A', u, x^{(A',u)}, \Delta, s, v$ )

---

**Input:** known attributes (names  $A', u$  and values  $x^{(A',u)}$ ), dummy conditions  $\Delta$ , secret  $s$  and target value  $v$

**Output:** True if  $(A', u)$  passes the tests and is deemed to satisfy assumption 1, False otherwise

```

1  $ok_Q \leftarrow 0$ ,  $ok_{Q'} \leftarrow 0$ 
2 for  $j \leftarrow 1$  to  $|\Delta|$  do
3    $\phi \leftarrow A' = x^{(A')} \wedge \bigwedge_{l \neq j} \Delta_l$ 
4    $\tilde{Q} \leftarrow \text{count}(\phi \wedge s \neq v)$ 
5    $\tilde{Q}' \leftarrow \text{count}(\phi \wedge u \neq x^{(u)} \wedge s \neq v)$ 
6   if  $\tilde{Q} > 0$  then
7      $ok_Q \leftarrow 1$ 
8   end if
9   if  $\tilde{Q}' > 0$  then
10     $ok_{Q'} \leftarrow 1$ 
11  end if
12 end for
13 return  $ok_Q = 1$  &  $ok_{Q'} = 1$ 

```

---

---

**Procedure ValueUnique**( $A', u, x^{(A',u)}$ )

---

**Input:** known attributes (names  $A', u$  and values  $x^{(A',u)}$ )

**Output:** True if  $(A', u)$  passes the tests and is deemed to satisfy assumption 2, False otherwise

```

1  $\tilde{Q} \leftarrow \text{count}(A' = x^{(A')} \wedge u = x^{(u)})$ 
2 return  $\tilde{Q} = 0$ 

```

---

The procedures [CloningAttack](#) and [NoBucketSuppression](#) both issue (the same)  $2|\Delta|$  queries, while [ValueUnique](#) uses

only one query. Validating the assumptions and performing the attack thus requires only  $2|\Delta| + 1$  queries, for a given set of attributes  $(A', u)$ . We empirically obtain accuracy above 93.3% with  $|\Delta|$  as low as 10 (see section 4 and Appendix B).

**Full cloning attack.** Combining procedures [CloningAttack](#), [NoBucketSuppression](#) and [ValueUnique](#), we design a fully fledged procedure [FullCloningAttack](#) that performs the entire attack under the following assumptions:

- H1 The attacker knows that the victim’s record  $x$  is in the dataset.
- H2 The attacker knows a set  $A^*$  of the correct attributes for the victim with  $|A^*| = k^*$ , i.e. the background knowledge is  $x^{(A^*)}$ .
- H3 The secret attribute  $x^{(s)}$  is a binary attribute.

The full cloning attack includes a subset exploration step similar to the one used in the full differential attack. The algorithm selects random subsets  $A'$  of  $A^*$  (and an element  $u$  from  $A^* \setminus A'$  at random) by decreasing size until it finds a subset that passes both tests, upon which it then performs the attack using  $x^{(A', u)}$  as background knowledge. If no feasible subset is found, the algorithm outputs NonAttackable.

---

```

Procedure FullCloningAttack( $A^*, x^{(A^*)}, \Delta, s, v$ )

---

Input: known attributes (names  $A^*$  and values  $x^{(A^*)}$ ),
         dummy conditions  $\Delta$ , secret  $s$  and target value  $v$ 
Output: True if  $x^{(s)} = v$ , False if  $x^{(s)} \neq v$ 
1 for  $k \leftarrow |A^*|$  to 1 do
2   for  $iter \leftarrow 1$  to 100 do
3      $A' \leftarrow \text{RandomSubsetOfSize}(A^*, k - 1)$ 
4      $u \leftarrow \text{RandomElement}(A^* \setminus A')$ 
5     if NoBucketSuppression( $A', u, x^{(A)}$ ,  $\Delta, s, v$ ) and
6       ValueUnique( $A', u, x^{(A^*)}$ ) then
7         return CloningAttack( $A', u, x^{(A)}$ ,  $\Delta, s, v$ )
8       end if
9   end for
10 return NonAttackable

```

---

**Reducing the number of queries.** While Diffix allows each analyst to send arbitrarily many queries, we study how many queries are required to perform the cloning attack in practice. In Appendix B we present a heuristic that reduces the median number of queries by a factor of 100. Using this heuristic, the attack targets 55.4% of the users in the dataset, achieving 91.7% accuracy with a maximum of 32 queries per user in our experiments.

## 4 Experiments

In order to assess the effectiveness of our attacks, we implemented Diffix’s mechanism for counting queries as described

in the original paper [18]. The implementation outputs zero when queries are bucket-suppressed and results are rounded to the nearest nonnegative integer. We apply our attacks to four datasets and an additional synthetic dataset on which the assumptions of the differential attack are always validated.

### 4.1 Description of the datasets

In our experiments, we use the following datasets:

1. ADULT: U.S. Census dataset with 30,162 records and 11 attributes, incl. salary class as secret attribute [26].
2. CREDIT: credit card application dataset with 690 records and 16 attributes, incl. accepted credit as secret attribute [27].
3. CENSUS: U.S. Census dataset with 199,523 records and 42 attributes, incl. total personal income (digitized, null income as negative condition) as secret attribute [28].
4. CDR: synthetic collection of phone metadata with 2,000,000 records generated using real-world data for human behaviour and the geography of the UK for the location of antennas. Every user is a record of 11,674,870 binary attributes (an attribute being whether a user was geographically present at a certain place and time, and placed a call or received a text message). As the vast majority of the attributes in a record are null, the distribution of values for a random attribute is heavily skewed towards zero. To obtain a balanced experiment, for 50% of runs we select as the secret attribute a pair (*location, time*) where the user was present, and for the other 50% we select a pair where the user was absent.

### 4.2 Differential noise-exploitation attack

**Evaluation of the attack alone.** We first test the differential attack on a synthetic dataset where all users satisfy the uniqueness assumption.

In the  $\text{Complete}_k$  dataset, every user is unique according to  $k$  attributes (excluding the secret attribute), whereas  $k - 1$  attributes always identify a *larger* set of users. This ensures that (i) every user is vulnerable to the attack and (ii) bucket suppression is unlikely to be triggered by the attack queries. To create the dataset, we fix an integer  $B$  and generate every possible  $k$ -tuple whose values are in  $\{1, \dots, B\}$ . We then append to each tuple a random value of either 0 or 1 for the secret attribute.  $\text{Complete}_k$  contains  $B^k$  records, one for each combination of  $k$  attributes. For our experiments, we set  $B = 12$ , to ensure that close to no bucket suppression occurs. For computational reasons, as the size of the dataset in memory grows as  $B^k$ , the maximum  $k$  we can use is limited to 6.

Fig. 2 compares the accuracy  $\text{acc}(k)$  of the attack, knowing  $k$  attributes, on  $\text{Complete}_k$  with the theoretical accuracy. The procedure we use here is [DifferentialAttack](#), which does *not* include subset exploration and has no access to the oracle.

Hence, this experiment simulates a realistic attacker. We report the empirical fraction of users whose secret attribute is correctly predicted, estimated by performing the differential attack on a sample of 1000 users. We also report the theoretical distribution of accuracy, (i) without rounding (closed-form expression, see Appendix A) and (ii) with rounding (numerical simulation, see Appendix A). For the  $\text{Complete}_k$  dataset, the accuracy reaches 92.6% for 5 points. Even knowing only  $k = 2$  attributes, the accuracy is above 66% both theoretically and empirically. While rounding has close to no effect on the theoretical accuracy of the attack, comparing the  $\text{Complete}_k$  with the Theoretical (rounding) curves shows that bucket suppression and potential correlations between the samples in empirical experiments noticeably decrease the accuracy.

**Evaluation on real-world datasets.** We now evaluate the accuracy of the differential attack on 1,000 users selected at random in each of the four datasets. Contrary to the synthetic experiment, bucket suppression is more prevalent on real-world datasets. Therefore, we run the **FullDifferentialAttack** algorithm, knowing  $k^*$  attributes  $A^*$  that are selected at random for each record. If the attack outputs **NonAttackable**, the secret attribute is predicted at random (uniformly).

Fig. 3 shows, for each dataset and knowing  $k^*$  attributes, the percentage of unique individuals and the percentage of individuals, in each dataset, for which the secret is correctly inferred. The latter divided by the the former gives us the accuracy of our attack. Our attack realizes an accuracy of 68.4% for ADULT with  $k^* = 10$ , 64.0% for CREDIT with  $k^* = 15$ , 68.8% for CENSUS with  $k^* = 40$ , and 68.8% for CDR with  $k^* = 6$ .

Observe that the fraction of correctly inferred attributes

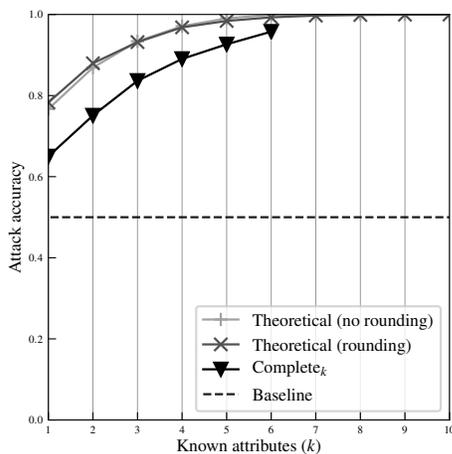

Figure 2: Accuracy of the differential attack when the uniqueness assumption is always validated and with balanced truth values. The baseline accuracy is 0.5 and represents the expected success rate when randomly predicting the secret attribute using a uniform prior.

Dataset	Attributes ( $k^*$ )	Value-unique	Predicted attackable	accuracy <sub>pa</sub>	accuracy <sub>all</sub>
ADULT	10	93.0%	96.8%	93.3%	87.0%
CREDIT	15	100.0%	100.0%	97.0%	97.0%
CENSUS	40	99.7%	94.6%	97.1%	91.6%
CDR	6	100.0%	100.0%	91.3%	91.3%

Table 1: Empirical results of the cloning attack on four real-world datasets.

plateaus with larger  $k^*$  for the CREDIT, CENSUS and CDR datasets. The reason is that, on these datasets, most users are unique for larger values of  $k^*$ . As explained in section 3, this makes bucket suppression more prevalent and reduces the total number of samples for the likelihood ratio test, which is a limitation of the differential attack.

### 4.3 Cloning noise-exploitation attack

We implement the attack as described by algorithm **FullCloningAttack**. As before, for each value of  $k^*$  we select 1,000 users at random, and for each user a random subset  $A^*$  of their attributes of size  $k^*$ .  $A^*$  represents the total number of attributes known to the attacker about the victim.

We set a threshold  $\sigma^* = 0.7$  for the variance cutoff (see full version). We generate  $|\Delta| = 10$  dummy conditions for  $x_1 = a_1$  of the form  $x_1 \neq b_j$  for  $j \leq |\Delta|$ , with  $b_j$  being some plausible values for  $x_1$  different from  $a_1$ . We present the results when the attacker knows enough attributes ( $k^*$ ) to identify every user, or up to all available attributes in the dataset.

Table 1 shows the proportion of records that are value-unique (third column) and fraction of the value-unique records that are predicted as attackable by procedures **NoBucketSuppression** and **ValueUnique** (fourth column). We then perform the cloning attack on all records that are predicted as attackable and report accuracy<sub>pa</sub>, the fraction of predicted attackable records whose secret attribute was successfully inferred (fifth column). For completeness, we also report accuracy<sub>all</sub>, the fraction of all records in the datasets (including the ones deemed **NonAttackable**) whose secret attribute was successfully inferred (last column).

Table 1 shows that the cloning attack—including the assumption validation step—performs really well on all datasets considered, between 87.0 and 97.0% of secret attributes and 97.0% on the CREDIT dataset when knowing 15 attributes.

Fig. 4 shows, knowing  $k^*$  attributes, the fraction of all records that are value-unique, predicted attackable, and correctly inferred. The curves for value-unique users and for predicted attackable users are always very close, suggesting

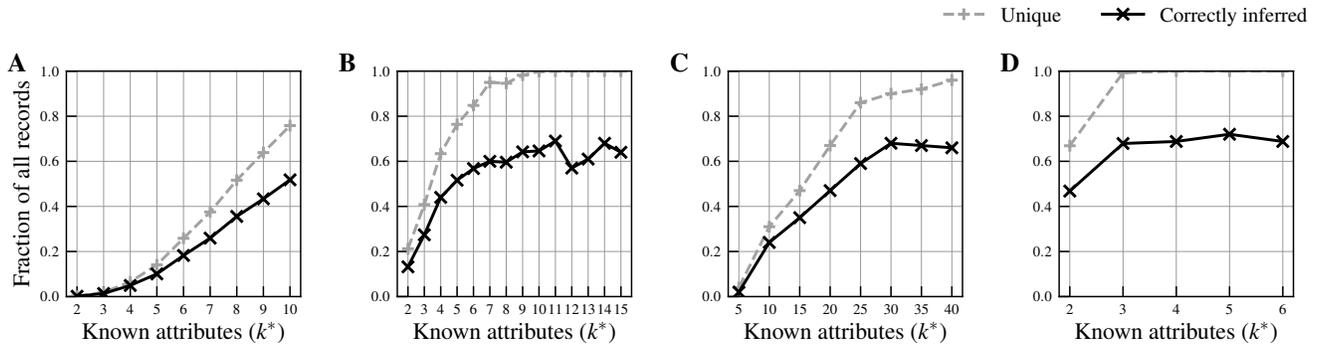

Figure 3: Results of the differential attack for the (A) ADULT, (B) CREDIT, (C) CENSUS, and (D) CDR datasets.

that the assumption validation step is effective. Out of all records predicted as attackable, most of them are correctly inferred, demonstrating that the attack works on targeted records across all  $k$ . For the CREDIT dataset, with only six attributes, the attack reaches the inference step for 95% of the users in the dataset, and correctly infers the secret attribute for 93% of the total records.

## 5 Discussion

### 5.1 Value-uniqueness and attribute predictability

Value-uniqueness plays an important role in the cloning attack. As Fig. 4 shows, it is a valid assumption for real-world datasets.

Value-uniqueness means that a group of people who share the same attributes also share the same secret attribute. If this group were to be large enough, the noise added by Diffix might not be enough to hide the secret attribute, which could then be revealed by using a simple count query. While this might be true for some datasets, it is not the case for any of the datasets we considered. For instance, the average size of the value-unique class (i.e. the set of value-unique users sharing the same restricted record) in the ADULT dataset is 1.44, with no class containing more than 4 users and similar numbers for the other datasets. This means that, most of the times, value-unique users are simply *unique*.

If secret attributes are predictable from the other attributes, a trained machine learning classifier could predict them with potentially high accuracy<sup>2</sup>. Despite our datasets coming from the machine learning literature, our attack does not rely at all on the predictability of secret attributes and performs equally well if no correlation at all exists between attributes and the secret attribute. We run our attack on a modified version of the ADULT dataset where sensitive attributes have been randomly sampled, thereby theoretically destroying any correlation. Our attacks perform as well on this modified dataset as on the

<sup>2</sup>Whether this would constitute a privacy attack is debated [29].

original dataset. These results are included in the full version of this manuscript.

### 5.2 Producing and detecting dummy conditions

The cloning attack requires the attacker to provide a set of dummy conditions that affect the noise addition without affecting the query set. These conditions can be syntactic (e.g.,  $age \geq 15$  for the query  $age = 23$ ), semantic (e.g.,  $status \neq retired$  for  $age = 23$ ), or pragmatic (e.g.,  $age \neq 15$  against a database containing only adult individuals).

When the language is rich enough, detecting redundant clauses is not a trivial task. At the same time, the richer the syntax is, the more utility an analyst gets out of the system. Diffix offers a fairly rich syntax including boolean expression, GROUP BY, JOIN, seven aggregation functions, set membership, fourteen string functions, and ten maths functions. In this context, automatically detecting dummy conditions would likely require iterating recursively through every condition and evaluating the query with and without them, a costly operation. Moreover, if dummy conditions are detected by evaluating them on the dataset, filtering them might not be safe. Removing semantic and pragmatic dummy conditions from a query would indeed reduce the total variance of the added noise and leak information about the dataset itself (e.g., only adult individuals are present if the condition  $age \neq 15$  is always removed).

### 5.3 Improving the attacks

The cloning attack can be modified to run a double **NoBuck-etSuppression** test: once with  $v = 0$  and once with  $v = 1$ . If both pass and the **ValueUnique** test is passed as well, the attack proceeds with the actual inference procedure **CloningAttack** for both  $v = 0$  and  $v = 1$ . The attack then makes a guess only if both inferences return the same value, and continues with the subset exploration otherwise (deeming the user NonAttackable if no working set of attributes is found).

We found that this modified attack improves the accuracy<sub>pa</sub> figure on all datasets (e.g. from 93.3% to 97.3% for ADULT,

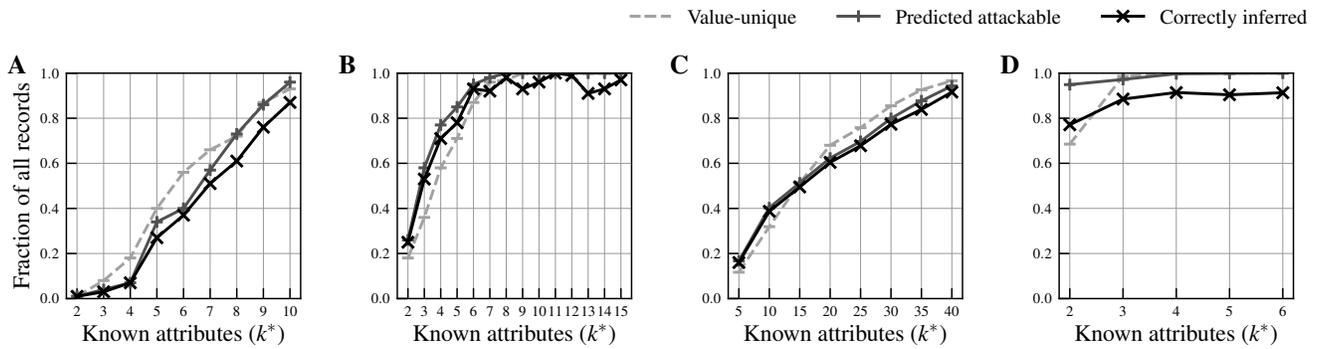

Figure 4: Results of the cloning attack for the (A) ADULT, (B) CREDIT, (C) CENSUS, and (D) CDR datasets.

all results available in the full version). However, double tests are more likely to fail, meaning that less users are predicted as attackable (from 96.8% to 87% in ADULT). Because of bucket suppression, this effect is particularly strong for datasets where the overall distribution of the secret attribute is very skewed, such as the CDR dataset where the number of predicted attackable users goes from 100% to 8.5%. Depending on the aims of the attacker (precision versus coverage), she might prefer the original or the double version of the cloning attack.

**Other improvements.** To properly quantify the strength of our attacks, none of them use prior knowledge on the distribution of the secret attribute. In practice, an attacker might want to use this information, e.g. obtaining it by querying Diffix. We discuss this in the full version of the manuscript. We also discuss how to generate more samples for the differential attack and outline how to generalize both attacks to infer non-binary attributes.

## 5.4 Defenses

In this section, we briefly outline some of the approaches that may be used to mitigate the effects of our noise-exploitation attacks – and other attacks – against Diffix and other privacy-preserving query-based systems. Overall, it is our belief that practical secure design principles apply here just as they do in many other contents. Specifically, privacy-preserving query-based system such as Diffix (regardless of whether they have provable guarantees or not) would benefit from a defense-in-depth approach, by monitoring the query stream for queries that are likely to lead to exploitation.

**Intrusion detection.** The set of queries generated by our attacks follow a specific template. Learning this pattern may help prevent noise-exploitation attacks, as well as potentially related attacks. A more sophisticated attacker might however vary the shape of the queries and interleave them with other more natural-looking queries, including over long periods of time.

**Auditability.** If the user of such a system is authenticated, then a suspicious-looking query stream can lead to temporary account suspension and further investigations of their activity, including after the fact, as new attacks are being uncovered.

**Increased friction.** Another strategy involves imposing time delays or financial charges on queries, for instance by charging by the number of queries, instead of using a subscription-based model. This strategy can be refined to, for instance, charge more or create longer delays for suspicious queries. This would make it more difficult to automate the inference process at scale.

**Limited expressiveness.** Instead of a rich syntax, the mechanism could allow only for a small set of conditions that are easier to validate. This could also include a limit to the number of conditions per query, or to the total number of conditions that may be used by the authenticated system user during a specific interval of time. This involves a compromise between rough data summarization and fine-grained queries, and limits the utility of the system in practice.

## 5.5 Disclosure

After we discovered and prototyped our differential attack, we reached out to the authors of Diffix and shared with them our manuscript, which subsequently appeared on ArXiv.org. A week later, the authors of Diffix published a blog post on their website [30] discussing our results. While they acknowledge our attack, they claim that it is not practical as the necessary assumptions are rarely met in the datasets they analyzed.

We disagree with this claim. First, the existence of the attack, *independently* of the dataset, contradicts both the spirit and the letter of GDPR’s Art. 29 WP. Second, we showed that, albeit correct, the authors’ analysis was insufficient. In this paper, we give an example of a dataset on which the differential attack is very effective, even without an oracle. Moreover, we demonstrate that there exist real-world datasets on which the necessary assumptions are met for a significant fraction of users. Third, the cloning attack, which we developed after-

wards, is able to validate its assumptions automatically and performs very well on a large range of real-world datasets.

The code of our differential and cloning attacks, as well as the experiments performed in this paper, are available at <https://cpg.doc.ic.ac.uk/signal-in-the-noise>.

## 6 Related work

**Attacks on query-based systems.** Diffix is an example of query-based system: the individual-level (often pseudonymous) data is stored on the data curator’s server. Users access the data exclusively by sending queries that only return information aggregated from several records. While this setup prevents traditional re-identification attacks [4–9], a large range of attacks on query-based systems have been developed since the late 70’s [25, 31]. Most of these attacks show how to circumvent privacy safeguards (for instance, query set size restriction and noise addition) in specific setups. In 2003, Dinur et al. [32] proposed the first example of an attack that works on a large class of query-based systems. In what they called a reconstruction attack, they showed that if the noise added to every query is at most  $o(\sqrt{n})$ , where  $n$  is the size of the dataset, then an attacker can reconstruct almost the entire dataset using only polynomially many queries. Sankararaman et al. [33] realized the first formal study of tracing attacks, introducing a theoretical attack model based on hypothesis testing. While reconstruction attacks aim at inferring one or more attributes of some record in the dataset (violating the inference requirement of the Art. 29 WP), the goal of tracing attacks is only to determine whether the data about a certain individual (more precisely, their record) is present in the dataset. Numerous reconstruction and tracing attacks have been proposed in the literature. These attacks address different limitations of previous ones, particularly the computational time required to perform them. A recent survey from Dwork et al. [34] gives a detailed overview of attacks on query-based systems.

**Attacks on differential privacy.** Differential privacy is a privacy guarantee that can be enforced by query-based systems. Differential privacy has been mathematically proven to be robust against a very large class of attacks [12] when used with an appropriate privacy budget  $\epsilon$ . However, research has shown that attacks on *implementations* of differentially private systems exist. We give an overview in the full version.

**Differential privacy for general-purpose analytics.** Diffix was specifically created as an alternative to differential privacy to provide a better privacy/utility tradeoff for general-purpose analytics [35, 36]. Specifically, Diffix allows for infinitely many queries with little noise added to outputs.

General-purpose analytics usually refers to systems that allow analysts to send many queries of different type, and ideally permit to join different datasets. Some solutions based on differential privacy have been proposed, the main ones being PINQ [37], wPINQ [38], Airavat [39], and GUPT [40]. All

of these systems however present limitations, e.g. simplicity of use and support for various operators that join different datasets [13]. In 2017, Johnson et al. [13] proposed a new framework for general-purpose analytics, called FLEX, developed in collaboration with Uber. FLEX enforces differential privacy for SQL queries without requiring any knowledge about differential privacy from the analyst. However, the actual utility achieved – level of noise added – by the current implementation of FLEX has been questioned [41].

**Attacks on data-dependent noise.** Values of Diffix’s dynamic noise for a query depend on the query set (i.e. the set of users selected by the query), and hence on the data. This is what allows for our noise-exploitation attack to work. Data-dependent noise, also called instance-based noise, has been shown to provide significantly better accuracy than data-independent noise [42]. However, naive implementations of data-dependent noise can leak information about the data, a result Nissim et al. theorized as a potential way to attack the system [42]. To the best of our knowledge, our noise-exploitation attack is the first instance of an attack exploiting specifically data-dependent noise on deployed systems.

### 6.1 Other attacks on Diffix

We published the first version of our paper on ArXiv.org in April 2018, describing the differential attack. We updated it with a cloning attack in July 2018. Two months later, in October 2018, two other attacks on Diffix were disclosed. A membership attack by Pyrgelis et al. [43], based on a previous paper [44], and a reconstruction attack by Cohen and Nissim [45], based on previous work by Dinur et al. [32] and Dwork et al. [46]. These attacks are very different from ours and require a large number of queries in a typical setting, while our cloning attack can work with only 32 queries (see Appendix B). These are, to the best of our knowledge, the only three attacks specifically targeting Diffix.

**Membership attack on location data.** The attack by Pyrgelis et al. [43] is as follows: the attacker trains a machine learning algorithm on a *linkability* dataset (the attacker’s background knowledge) to infer the presence of a user in a *protected* dataset (accessible only through queries on Diffix). Both datasets contain the full trajectories of users and half of the users are present in both datasets. The classifier is trained on the linkability dataset and queries on Diffix that count the number of people transiting in a certain area at a given time. The experimental results focus on the top 100 users with the highest number of reported locations in the linkability dataset. Out of 62 users present in both datasets, the classifier correctly infers the presence for 50 of them.

This attack presents three limitations. First, it is a membership attack and only allows an attacker to infer whether a person is in the protected dataset or not. Second, it assumes a strong adversary who has access to the full trajectory of a user exactly as it exists in the protected dataset, for a large number

of users. Third, the attack requires about 32,000 queries to assess the presence of a user. Membership attacks are however very useful when combined with inference attacks like ours, allowing an adversary to effectively verify our assumption that the victim is in the dataset.

**Linear program reconstruction attack.** The attack by Cohen et al. [45] focuses on reconstructing the dataset. In its simplest form, the attack assumes that the dataset contains  $n$  records, and each user  $i \in [n]$  has a binary attribute  $s_i$ . The attack then selects random subsets of users and, for each subset  $I \subseteq [n]$ , queries Diffix for the result of  $\sum_{i \in I} s_i$ . This allows the attacker to produce a noisy linear system that can be solved using linear programming techniques to reconstruct the entire set of secret attributes  $\{s_1, \dots, s_n\}$  with perfect accuracy in polynomial time.

While this attack can successfully reconstruct the entire dataset, it presents two limitations compared to our attack.

First, it requires that the system allows queries of the type  $\sum_{i \in I} s_i$ , i.e. queries that select any analyst-defined set of users  $I \subseteq [n]$ , the “row-naming problem”. The authors here exploit SQL functions supported by Diffix to define hash functions which they then use to select “random enough” sets of users. Following the disclosure, Aircloak restricted the available SQL functions to prevent the attack [47].

Second, to target a specific user, the attack would require a number of queries proportional to the number of records. Since the attacker does not know *which* name  $i \in [n]$  corresponds to the victim’s record, it is necessary to fully reconstruct at least a few columns entirely. The attacker would then perform a uniqueness attack on the reconstructed dataset to infer the secret attribute of the victim.

On the contrary, the number of queries used by our attacks is independent of the number of records in the dataset.

## 7 Conclusion

The Diffix mechanism has recently been proposed as an alternative to data anonymization methods and differential privacy, and is currently used in production. The mechanism is claimed to allow an analyst to submit an unbounded number of queries, while thwarting inference attacks, as defined by EU’s Art. 29 WP. In this paper, we show that Diffix’s anonymization mechanism is vulnerable to a new class of attacks, which we call noise-exploitation attacks. Our attacks leverage design flaws in Diffix’s data-dependent noise to infer private attributes of an individual in the dataset, solely from prior knowledge about other attributes of this individual. In our opinion, Diffix alone and in its present state likely fails to satisfy the EU’s Art. 29 WP requirements for data anonymization. Furthermore, our results show that naive data-dependent noise leads to highly vulnerable systems.

Our differential noise-exploitation attack, given little auxiliary information about the victim, combines specific queries and estimates how the noise is distributed to infer the value

of the private attribute. In a synthetic best-case dataset, the attacker can predict with 92.6% accuracy private attributes, using only 5 attributes.

Our cloning noise-exploitation attack extends the first one by adding “dummy” conditions that do not change the selected query set. It relies on weaker assumptions, that are automatically validated with high accuracy by our algorithm. We evaluate its performances on four real-world datasets and find that it infers private attributes of between 87.0% and 97.0% of all records across datasets.

We finally recommend four defense-in-depth principles to defeat the de-anonymization attacks we describe.

## A Likelihood ratio test

Let  $X$  and  $Y$  be independent random variables. Suppose that we have two hypotheses about the distributions of  $X$  and:

$$\begin{aligned} H_0 : X &\sim \mathcal{N}(\mu_0, \sigma_0^2) \quad \text{and} \quad Y \sim \mathcal{N}(\mu_1, \sigma_1^2) \\ H_1 : X &\sim \mathcal{N}(\mu_1, \sigma_1^2) \quad \text{and} \quad Y \sim \mathcal{N}(\mu_0, \sigma_0^2) \end{aligned}$$

where  $\mu_0, \mu_1, \sigma_0, \sigma_1$  are known and fixed values such that  $\mu_0 < \mu_1$  and  $\sigma_0^2 < \sigma_1^2$ .  $\mathcal{N}(\mu, \sigma^2)$  denotes the the normal distribution with mean  $\mu$  and variance  $\sigma^2$ .

Suppose we have a vector of  $n$  realizations  $\mathbf{x} = (x_1, \dots, x_n)$  of  $X$  and a vector of  $n$  realizations  $\mathbf{y} = (y_1, \dots, y_n)$  of  $Y$ . We assume that all the  $2n$  realizations are mutually independent. The standard frequentist way to accept the preferred hypothesis  $H_0$  or refute it (in favor of  $H_1$ ) would use a likelihood ratio test with a pre-defined confidence level from which to derive critical regions [48]. In our case we do not have a preferred hypothesis, and hence we define a slightly different test.

Let  $f$  and  $g$  denote the probability density functions of  $\mathcal{N}(\mu_0, \sigma_0^2)$  and  $\mathcal{N}(\mu_1, \sigma_1^2)$  respectively. We define the likelihood ratio function  $\Lambda$  as follows:

$$\Lambda(\mathbf{x}, \mathbf{y}) = \prod_{j=1}^n \frac{f(x_j)}{g(x_j)} \prod_{j=1}^n \frac{g(y_j)}{f(y_j)}.$$

We accept  $H_0$  if  $\Lambda(\mathbf{x}, \mathbf{y}) \geq 1$ , and we accept  $H_1$  if  $\Lambda(\mathbf{x}, \mathbf{y}) < 1$ .

**Theoretical accuracy of the test.** The test will sometimes yield the wrong result. It is possible to determine what is the probability that this happens. Such probability depends on mean and variance of the two specific normal distributions.

**Fact.** Let  $p_{err_0} = \Pr[\Lambda(\mathbf{x}, \mathbf{y}) < 1 \mid H_0]$  and  $p_{err_1} = \Pr[\Lambda(\mathbf{x}, \mathbf{y}) \geq 1 \mid H_1]$ . Then

$$p_{err_0} = p_{err_1} = \Pr[\alpha_0 Z_0 - \alpha_1 Z_1 < 0]$$

where, for  $i = 0, 1$ ,  $Z_i$  is a noncentral chi-squared distribution with  $n$  degrees of freedom and noncentrality parameter

$$\lambda_i = n \left( \frac{\mu_i}{\sigma_i} + \frac{\mu_0 \sigma_1^2 - \mu_1 \sigma_0^2}{\sigma_i (\sigma_0^2 - \sigma_1^2)} \right)^2$$

and

$$\alpha_i = \frac{\sigma_0^2 - \sigma_1^2}{2\sigma_{1-i}^2}.$$

To prove the fact, one considers the log-likelihood ratio function  $\log \Lambda(\mathbf{x}, \mathbf{y})$  and applies elementary algebra to the obtained expression to derive a linear combination of noncentral chi-squared distributions. We omit the details.

Since  $p_{\text{err}0} = p_{\text{err}1}$ , we refer to this quantity simply as  $p_{\text{err}}$ . The accuracy of the test is  $\text{acc} = 1 - p_{\text{err}}$ .

We now show how to apply the fact to our differential noise-exploitation attack. For simplicity, we suppose that Diffix's outputs are not rounded to the nearest nonnegative integer and bucket suppression is never triggered for the queries in the attack, so that every pair of queries  $(\tilde{Q}_j, \tilde{Q}'_j)$  and  $(\tilde{R}_j, \tilde{R}'_j)$  yields a valid sample. Thus, for  $k$  known attributes, we have two vectors of samples  $\mathbf{q} = (q_1, \dots, q_k)$  and  $\mathbf{r} = (r_1, \dots, r_k)$  and for every  $j \leq k$ :

$$q_j \sim \begin{cases} \mathcal{N}(0, 2) & \text{if } x^{(s)} = 1 \\ \mathcal{N}(1, 2k+2) & \text{if } x^{(s)} = 0 \end{cases}$$

$$r_j \sim \begin{cases} \mathcal{N}(1, 2k+2) & \text{if } x^{(s)} = 1 \\ \mathcal{N}(0, 2) & \text{if } x^{(s)} = 0 \end{cases}$$

We assume that the  $2k$  samples in  $\mathbf{q}$  and  $\mathbf{r}$  are mutually independent. As discussed in section 3, this is not always guaranteed to be true, but it has close to no effect on the actual accuracy of the test. Let

$$H_0 : x^{(s)} = 1$$

$$H_1 : x^{(s)} = 0.$$

Let  $f$  and  $g$  denote the probability density functions of  $\mathcal{N}(0, 2)$  and  $\mathcal{N}(1, 2k+2)$  respectively. Observe that  $H_0$  holds if and only if every  $q_j \sim f$  and every  $r_j \sim g$ . Similarly,  $H_1$  holds if and only if every  $q_j \sim g$  and every  $r_j \sim f$ . Then we can apply the test defined above. Define

$$\Lambda(\mathbf{q}, \mathbf{r}) = \prod_{j=1}^k \frac{f(q_j)}{g(q_j)} \prod_{j=1}^k \frac{g(r_j)}{f(r_j)}.$$

Our test concludes that  $x^{(s)} = 1$  if  $\Lambda(\mathbf{q}, \mathbf{r}) \geq 1$ , and  $x^{(s)} = 0$  if  $\Lambda(\mathbf{q}, \mathbf{r}) < 1$ .

To measure the theoretical accuracy of the attack for  $k$  known attributes, we can apply the fact to  $\Lambda(\mathbf{q}, \mathbf{r})$  with  $\mu_0 = 0, \sigma_0^2 = 2, \mu_1 = 1, \sigma_1^2 = 2k+2$  and  $n = k$ , and finally find  $\text{acc}(k) = 1 - p_{\text{err}}(k)$ .

Fig. 2 shows the values of  $\text{acc}(k)$  for increasing values of  $k$ . Computing the value of  $p_{\text{err}}$  requires an approximation of the cumulative distribution function of a linear combination of noncentral chi-squared distributions, for which an exact closed-form expression is not known [49]. We compute these values using the R package `sadists`<sup>3</sup> version 0.2.3.

**Numerical simulation with rounding.** If we suppose that Diffix's outputs are rounded to the nearest nonnegative integer, no simple expression can be determined for the error rate. To estimate the accuracy in this case, we numerically simulate the values of  $\tilde{Q}_j(D)$  and  $\tilde{Q}'_j(D)$  that would result from querying Diffix (without bucket suppression), for different values of the secret attribute  $x^{(s)}$ . We then obtain each sample as the difference of the rounded results:

$$q_j = \text{round}(\tilde{Q}_j(D)) - \text{round}(\tilde{Q}'_j(D)).$$

Finally, we perform the likelihood ratio test as for the continuous case (considering also null outputs) and check whether the result is correct. We use balanced truth values for  $x^{(s)}$ , and perform 1000 experiments (on different queries) for each value of  $x^{(s)}$ . The results are shown in Fig. 2.

## B Reducing the number of queries

One of the main features of Diffix is that it allows analysts to send an unlimited amount of queries. Many privacy attacks work by issuing a relatively large number of queries (see also 6.1). Limiting the number of queries allowed by Diffix would thwart or significantly affect these attacks. While our actual attack procedures require a small number of queries ( $2|\Delta| + 1$  for the cloning attack), the subset exploration step can sometimes explore many sets of attributes before finding an exploitable one. To minimize the number of queries, we replace the iterative exploration with a greedy heuristic that selects only one subset which is likely to work. We focus only on the cloning attack, as it does not require an oracle and achieves much better accuracy.

The cloning attack requires a set of attributes  $(A', u)$ , where the restricted record  $x^{(A', u)}$  uniquely identifies the victim, but the vector  $x^{(A')}$  is shared across a larger population (to avoid bucket suppression). The `FullCloningAttack` starts with a larger set of attributes  $A^*$  and iteratively explores subsets of  $A^*$  to find a candidate  $(A', u)$ . We replace this iterative process with a single deterministic step.

Intuitively, we want  $u$  to be as discriminative as possible, while for the attributes in  $A'$  to select as many users as possible. This is what the procedure `GreedySelectSubset` does. First, it computes the (approximate) fraction of users that share the same value  $x^{(a)}$ , for each attribute  $a \in A^*$ . Then it selects as  $u$  the attribute associated with the lowest fraction. Now suppose that  $N$  is the estimated total number of users in the dataset. The set  $A'$  is selected as the smallest set of attributes

<sup>3</sup><https://github.com/shabbychef/sadists>

associated with the highest fraction, additionally requiring that the product of all the fractions for  $(A', u)$  is smaller than  $1/N$ . This ensures that, with high probability, the victim is uniquely identified by  $x^{(A', u)}$ .

---

**Procedure GreedySelectSubset** $(A^*, x^{(A^*)}, s, v)$

---

**Input:** known attributes (names  $A^*$  and values  $x^{(A^*)}$ ), secret  $s$  and target value  $v$   
**Output:** a set of attributes  $(A', u) \subseteq A^*$

- 1  $N \leftarrow \text{count}()$  // approx. tot. number of users
- 2 **foreach**  $a \in A^*$  **do**
- 3      $C_a \leftarrow \text{count}(a = x^{(a)} \wedge s \neq v)$
- 4      $\rho_a \leftarrow \frac{C_a}{N}$
- 5 **end foreach**
- 6  $\{\rho_1, \dots, \rho_{|A^*|}\} \leftarrow \text{SortDescendingOrder}(\{\rho_a\}_{a \in A^*})$
- 7  $u \leftarrow a_{|A^*|}$
- 8  $i \leftarrow 1, A' \leftarrow \emptyset$
- 9 **while**  $\rho_u \prod_{a_i \in A'} \rho_{a_i} > \frac{1}{N}$  **do**
- 10      $A' \leftarrow A' \cup \{a_i\}$
- 11      $i \leftarrow i + 1$
- 12 **end while**
- 13 **return**  $(A', u)$

---

We can modify the [FullDifferentialAttack](#) replacing the subset exploration with this heuristic. The modified full attack is described in the [GreedyFullCloningAttack](#) procedure.

---

**Procedure GreedyFullCloningAttack** $(A^*, x^{(A^*)}, \Delta, s, v)$

---

**Input:** known attributes (names  $A^*$  and values  $x^{(A^*)}$ ), dummy conditions  $\Delta$ , secret  $s$  and target value  $v$   
**Output:** True if  $x^{(s)} = v$ , False if  $x^{(s)} \neq v$

- 1  $(A', u) \leftarrow \text{GreedySelectSubset}(A^*, x^{(A^*)}, s, v)$
- 2 **if**  $\text{NoBucketSuppression}(A', u, x^{(A)}, \Delta, s, v)$  and  $\text{ValueUnique}(A', u, x^{(A^*)})$  **then**
- 3     **return**  $\text{CloningAttack}(A', u, x^{(A)}, \Delta, s, v)$
- 4 **end if**
- 5 **return** NonAttackable

---

Observe that the [GreedySelectSubset](#) procedure issues ex-

Subset selection	Median n. queries	Max n. queries	Predicted attackable	accuracy pa
Iterative	304	5310	96.8%	93.3%
Heuristic	32	32	55.4%	91.7%

Table 2: Empirical results of the cloning attack with iterative subset exploration and with the heuristic subset selection.

actly  $|A^*| + 1$  queries. The differential attack with the assumption validation step issues at most  $2|\Delta| + 1$  queries. So, the [GreedyFullCloningAttack](#) algorithm requires at most  $|A^*| + 2|\Delta| + 2$  queries.

We compared the performances of the [FullCloningAttack](#) and [GreedyFullCloningAttack](#) on the ADULT dataset, with the salary class as secret attribute and the other 10 attributes as  $A^*$ . As in section 4, we used  $|\Delta| = 10$  dummy conditions and ran the attack on 1000 random users. The results are summarized in Table 2.

The maximum (and median) number of queries used by [GreedyFullCloningAttack](#) for a single user is  $10 + 2 \times 10 + 2 = 32$ . The median number of queries used by [GreedyFullCloningAttack](#) is about 10 times higher, and the maximum is 100 times higher.

[GreedyFullCloningAttack](#) effectively attacks more than half of the users, as opposed to 96.8% of the users for the [FullCloningAttack](#). This is due to the fact that the first attack tries a single subset of attributes per user. However, this figure is still remarkably high, given the huge reduction of required queries. Finally, the accuracy of the inference for the attacked users is almost the same.

We believe that these results give additional evidence of the power, extendability and practicability of our noise-exploitation attacks. Introducing additional optimizations, the accuracy could be improved and the number of queries could be further reduced (see full version).

# FIRM-AFL: High-Throughput Greybox Fuzzing of IoT Firmware via Augmented Process Emulation

## Abstract

Cyber attacks against IoT devices are a severe threat. These attacks exploit software vulnerabilities in IoT firmware. Fuzzing is an effective software testing technique for vulnerability discovery. In this work, we present FIRM-AFL, the first high-throughput greybox fuzzer for IoT firmware. FIRM-AFL addresses two fundamental problems in IoT fuzzing. First, it addresses compatibility issues by enabling fuzzing for POSIX-compatible firmware that can be emulated in a system emulator. Second, it addresses the performance bottleneck caused by system-mode emulation with a novel technique called augmented process emulation. By combining system-mode emulation and user-mode emulation in a novel way, augmented process emulation provides high compatibility as system-mode emulation and high throughput as user-mode emulation. Our evaluation results show that (1) FIRM-AFL is fully functional and capable of finding real-world vulnerabilities in IoT programs; (2) the throughput of FIRM-AFL is on average 8.2 times higher than system-mode emulation based fuzzing; and (3) FIRM-AFL is able to find 1-day vulnerabilities much faster than system-mode emulation based fuzzing, and is able to find 0-day vulnerabilities.

## 1 Introduction

The security impact of IoT devices on our life is tremendous. By 2020, the number of connected IoT devices will exceed the number of people [10]. This creates an unprecedented attack surface leaving almost everybody at danger. Even currently, the hackers leverage the lack of security in IoT devices to create large botnets (e.g., Mirai, VPNFilter and Prowli). These malware attacks exploit the vulnerabilities in IoT firmware to penetrate into the IoT devices. As a result, it is crucial for defenders to discover vulnerabilities in IoT firmware and fix them before attackers.

Fuzzing, a software testing technique that feeds a program with random inputs, has approved to be very effective in finding vulnerabilities in real-world programs. In particular, AFL [34], a coverage-guided greybox fuzzing tool, has been used widely in both industry and academia. For instance, most of the finalists in DARPA Cyber Grand Challenge used AFL as the primary vulnerability discovery component [2].

**Challenges in IoT firmware fuzzing.** Despite the effectiveness of fuzzing for programs on general-purpose platforms, it is generally not feasible to directly apply fuzzing on IoT firmware, due to its strong dependency on the actual hardware configuration. For instance, simply extracting a user-level program from a Linux-based firmware and fuzzing this program with AFL would not work in most cases.

To this end, recent researches propose a series of solutions, ranging from directly fuzzing the IoT devices (e.g., IoTFuzzer [14]), a hybrid solution that combines hardware and software emulation (e.g., AVATAR [33]), to a full system emulation (e.g., Firmadyne [13]). As a recent study by Muench et al. [28] points out, full system emulation yields the highest throughput, because IoT devices are much slower than a desktop workstation or a server.

Throughput is a key factor for the effectiveness of fuzzing. However, even for full system emulation, its performance is far from being ideal. According to our evaluation (§5), full system emulation is about 10 times slower than user-mode emulation (which is used by AFL). 10 times slowdown means approximately 10 times more computing resources are needed to find a vulnerability in an IoT program than its desktop counterpart. According to our analysis (§2.4), part of the enormous runtime overhead of full-system emulation comes from software implementation of memory management unit (i.e., SoftMMU) that is used to translate a guest virtual address into a host virtual address for every single memory access happening in the virtual machine. The other part of the overhead comes from the system calls emulation overhead.

†Corresponding author

**Our solution: greybox fuzzing via augmented process emulation.** In this work, we present, to the best of our knowledge, the first greybox fuzzer for IoT firmware, that achieves two design goals simultaneously: (1) *transparency* that is no modification should be needed for the program in firmware to be fuzzed, and (2) *efficiency* that is the fuzzing throughput of the overall system should come close to that of the user-mode emulation. Our key insight is to find a novel combination of full-system emulation and user-mode emulation to achieve the best of two worlds: generality from full-system emulation and efficiency from user-mode emulation.

More specifically, we propose a new technique called “augmented process emulation”. As the name suggests, its main idea is to augment process (or user-mode) emulation with full system emulation. The program to be fuzzed is mainly run in user-mode emulation to achieve high efficiency, and switches to full system emulation only when necessary to ensure correct program execution, thus achieving generality.

To evaluate the feasibility of this technique, we implement a prototype system called FIRM-AFL, on top of AFL [34] and Firmadyne [13]. From a user’s perspective, using FIRM-AFL, we can conduct coverage-guided greybox fuzzing on a user-specified program from an IoT firmware, the same as fuzzing a normal user-level program using AFL. Under the hood, FIRM-AFL occasionally switches to the full system emulation mode in Firmadyne, to ensure the given program can be correctly emulated.

We have evaluated FIRM-AFL with standard benchmarks and a set of real-world IoT firmware images. The evaluation results showed that (1) FIRM-AFL can faithfully emulate the target programs as if they were running in full-system emulation; (2) compared to a full-system emulation based fuzzer (TriforceAFL [29] with lightweight snapshot enabled), the throughput of FIRM-AFL is 8.2 times higher on average and (3) FIRM-AFL can find 1-day vulnerabilities 3 to 13 times faster than full-system emulation based fuzzer, and was able to find two 0-day vulnerabilities within 8 hours on a single machine.

**Contributions.** In summary, we make the following contributions in this paper:

- We point out that full system emulation exerts significant runtime overhead, and is far from ideal to serve as the base for IoT firmware fuzzing. We further investigate the root cause of this runtime overhead.
- We propose a novel technique called “augmented process emulation”, to reconcile the contradictory characteristics of full-system emulation (high generality and low efficiency) and user-mode emulation (low generality and high efficiency).
- We design and implement the first coverage-guided greybox fuzzing platform for IoT firmware, FIRM-AFL.

- We extensively evaluate our system and show the overhead for each part of our system. Our improvements lead to 8.2 times speedup on average. As a result, FIRM-AFL could find 1-day vulnerabilities 3 to 13 times faster than full-system emulation, and was able to find two new vulnerabilities within 8 hours on a single machine.
- The current implementation of FIRM-AFL supports three CPU architectures, including mipsel, mipseb and armel, which cover 90.2% firmware images in the Firmadyne datasheet [4]. The source code of FIRM-AFL can be found at <https://github.com/zyw-200/FirmAFL>.

## 2 Background and Motivation

### 2.1 Fuzzing

Fuzzing is a software testing technique that aims to find bugs by executing the target program with random inputs and looking for interesting program behaviors such as the crashes. Based on how much information is collected and used from the execution, fuzzers can be categorized into blackbox, whitebox and greybox. A blackbox fuzzer treats the target program as a blackbox and does not utilize any feedback from the execution to guide the generation of random inputs. This approach was originally used to test Linux utilities [26]. On the other hand, a whitebox fuzzer selects the inputs based on a deep insight into the target program. This is usually achieved through expensive program analysis techniques like dynamic taint analysis and symbolic execution [22]. Finally, a greybox fuzzer improves the testing by utilizing limited information collected with lightweight monitoring techniques (e.g., code coverage).

The most popular greybox fuzzers are coverage-guided fuzzers. These fuzzers instrument the target program to collect code coverage information. The collected information is then used to guide the input generation—inputs that explore new execution paths will be used as *seeds* to generate new inputs while inputs that did not yield new coverage will be discarded. This simple strategy is extremely effective in practice. In fact, greybox fuzzers can even outperform whitebox fuzzers when targeting real-world applications. Their secret is *speed*, the lightweight instrumentation allows greybox fuzzers to execute hundreds or thousands times more inputs than whitebox fuzzers [32]. In other words, throughput is paramount for greybox fuzzers.

AFL [34] is a well-known greybox fuzzer. It can instrument the program either statically or dynamically. Static instrumentation is preferred when the source code is available. When the source code is not available, e.g., when fuzzing commercial off-the-shelf (COTS) programs, AFL utilizes a binary translator (i.e., user-mode emulation provided by QEMU [12]) to perform the instrumentation. For most IoT devices, because source code and design documents are often proprietary and

only firmware image might be available, dynamic instrumentation is the only viable option. As a matter of fact, even extracting the binary from the firmware is not always straightforward [14].

## 2.2 QEMU

QEMU [12] is a fast processor emulator based on dynamic binary translation. Unlike traditional emulators that interpret the target program instruction-by-instruction, QEMU translates several basic blocks at a time. More importantly, it caches translated blocks and uses block chaining to link them together. This allows the execution to remain inside the code cache (i.e., the logic of the target program) for the most of the time thus minimizes the overhead of the translation. Dynamic instrumentation can be performed during the translation to introduce new functionalities, such as branch monitoring [34] and taint propagation [19, 23].

Besides the translation of instructions, the next most important task is address space translation. The translation is done very differently based on the execution mode. In system mode, QEMU implements a software Memory Management Unit (MMU) to handle memory accesses. The software MMU maps Guest Virtual Addresses (GVAs) to the Host Virtual Addresses (HVA). This mapping process is transparent to the guest operating system (OS) meaning that QEMU still allows the guest OS to set up the GVA to Guest Physical Address (GPA) mapping through the interface of page tables and to handle page faults. Under the hood, QEMU inserts a GVA to GPA translation logic for every memory access. To speed up the translation, QEMU uses a software Translation Lookaside Buffer (TLB) to cache the translation results. Moreover, to avoid invalidating the code cache and block chaining whenever the address translation changes, all translated blocks are indexed using GPA and the block chaining is only performed when the two basic blocks are within the same physical page. GPA to HVA mapping is done using a linear mapping (i.e.,  $HVA = GPA + OFFSET$ ).

In contrast to system-mode emulation, in user-mode emulation, the Host Virtual Address (HVA) is calculated as the Guest Virtual Address (GVA) plus a constant offset. So this translation is much faster than the one in system-mode emulation.

## 2.3 Testing IoT Firmware

As IoT devices become a popular attack target, testing IoT programs to find vulnerabilities also becomes important. There are two main challenges in testing IoT programs. The first challenge is compatibility: many IoT programs depend on special hardware components of the device thus cannot be tested without proper support. The second challenge is code coverage: blackbox fuzzers are known to have low code coverage while whitebox fuzzers cannot scale to slightly larger

code base [20]. Table 1 compares some representative efforts on IoT firmware testing using these two metrics.

Avatar [33] aims to enable dynamic program analysis for embedded firmware by providing better hardware component support. It achieves this goal through constructing a hybrid execution environment consists of both a processor emulator (QEMU) and real hardware where Avatar acts as a software proxy between the emulator and the real hardware. This allows Avatar to utilize the emulator to execute and analysis the instructions while channeling the I/O operations to the physical hardware. As a demonstration, the authors have applied S2E [15], a whitebox fuzzing tool to find vulnerabilities in the Redwire Econotag Zigbee sensor. Due to the involvement of whitebox fuzzing and slow hardware, the throughput of Avatar is expected to be very low.

IoTFuzzer [14] performs blackbox fuzzing directly on the real device. Its main advantage over previous blackbox fuzzing based approaches is that it performs the fuzzing through the companion mobile app of the target device. By automatically analyzing the data flow in the companion app to better understand the communication protocol, IoTFuzzer can generate better test cases that are more likely to trigger a bug. That said, based on its evaluation, IoTFuzzer never exceeds a throughput of 1 test case per second, which is slow (based on Table III in [14]).

Although it does not perform fuzzing, Firmadyne [13] adds hardware support for IoT firmware to the system mode QEMU. It provides support for both ARM and MIPS architectures that are popular among the IoT manufacturers. For hardware support, Firmadyne fully emulates the system by modifying the kernel and drivers to handle the IoT exceptions due to the lack of actual hardware. Compared to the former two solutions, this solution is easier to adapt to new IoT firmware and programs. The throughput of full-system emulation is usually better than the native execution [28].

Muench et al. [28] compare the throughput of a blackbox fuzzer [24] under different configurations, including native execution (directly sending inputs to the hardware), partial emulation (redirecting only hardware requests to the hardware), and full emulation. Their emulation is based on image replaying capability provided by PANDA [19]. They concluded that full emulation (FE) has the highest throughput mainly because the IoT processors are much slower than desktop processors. However, even in the best case, the throughput did not exceed 15 test cases per second<sup>1</sup>.

AFL [34] is a well-known greybox fuzzer that can support binary-only fuzzing through user-mode QEMU. Unfortunately, lacking special hardware support, user-mode QEMU can not successfully emulate most IoT programs. For example, AFL with user-mode QEMU failed on all the programs used in our evaluation (Table 3). Moreover, simply adopting a full system emulator (e.g., Firmadyne) does not fully solve

<sup>1</sup>They reported 53390 cases/hour which is equal to 15 cases/second

	Avatar [33]	IoTFuzzer [14]	Firmadyne [13]	Muench et al. [28]	AFL [34]
Technique	Whitebox fuzzing	Blackbox fuzzing	PoC	Blackbox fuzzing	Greybox fuzzing
Compatibility	High	High	High	High	Low
Hardware Support	Hybrid	Real	Emulation	Mixed	None
Code Coverage	Medium	Low	N/A	Low	High
Throughput	Very Low	Low	Medium	Low to Medium	High
Zero-day Detection	Yes	Yes	No	Yes	Yes

Table 1: Comparison of IoT firmware testing tools.

the problem because the throughput is low.

In summary, existing IoT firmware testing tools do not provide satisfying code coverage yet state-of-the-art fuzzers (e.g., AFL) cannot be easily applied to test IoT programs. So far, there is no greybox IoT fuzzer, not to mention a greybox IoT fuzzer with good throughput.

## 2.4 Motivations

Given the unsatisfying status-quo of IoT firmware testing tools, we aim to enable high-throughput greybox fuzzing for IoT programs. To this end, we decide to build the fuzzer based on emulation. This choice is based on two reasons. First, greybox fuzzing requires collecting execution information (e.g., branch coverage) to guide test case generation. As mentioned in §2.1, this is usually done through lightweight instrumentation. Since most IoT programs are only distributed in binary format, emulator-based instrumentation is the best available option. The second reason is performance. Although it might be possible to run instrumented binaries directly on the device, Muench et al. [28] have shown that full-emulation-based approach is actually faster than the real device, because the desktop processors are much faster.

Unfortunately, simply adopting a full system emulator (e.g., Firmadyne [13]) does not fully solve the problem because the throughput is not enough. For example, even with the full-emulation configuration, the fuzzer used in [28] never exceeded 15 test cases per second. To understand the bottleneck, we profiled the execution time of two networking tools (`basename` and `uptime`) under full-system emulation (with lightweight snapshot) and user-mode emulation. The results are shown in Table 2. Based on this measurement, we can see that the throughput of fuzzing can be significantly boosted if we can apply user-mode emulation to the target program. There are several bottlenecks that contribute to the execution time difference.

- *B1. Memory address translation.* In full-system emulation, QEMU uses a software MMU to perform address translation for *every* memory access. In contrast, in user-mode emulation, the address translation is much simpler. So even if we just consider time spent in user-mode execution, user-mode emulation uses much less time.

- *B2. Dynamic code translation.* The code translation process in user-mode emulation is faster than the full-system mode. In full-system mode, block chaining is limited to basic blocks in the same physical page, which means the translator is invoked more often than in user-mode emulation.
- *B3. Syscall emulation.* In user-mode emulation, system calls are handled directly by the host OS and hardware. Therefore, it is significantly faster than full-system emulation where the OS also runs in the emulator and the hardware devices are also emulated. Although hardware emulation is necessary to allow the target program to run correctly, not all system calls would rely on the special hardware. In other words, not all system calls require emulation.

In this work, we address all three bottlenecks to improve the throughput of IoT program fuzzing.

## 3 Augmented Process Emulation

### 3.1 Overview

The goal of this work is to enable high-throughput greybox fuzzing for IoT programs. As discussed in §2, to achieve this goal, we need to overcome two challenges: compatibility and performance. The first challenge can be solved through full-system emulation but this would result in poor performance. The second challenge can be solved through user-mode emulation but would result in poor compatibility. In this section, we present *augmented process emulation*, a new approach that brings the best of both full-system emulation and user-mode emulation.

**Problem statement.** Generally speaking, the goal of augmented process emulation is to correctly execute a program of an IoT firmware in a user-mode emulator, given the following requirements are satisfied:

- (1) The firmware can be correctly emulated in a system emulator (e.g., system-mode QEMU). Fortunately, with the help of Firmadyne [13], a large portion of IoT firmware images are able to meet this requirement.

program	system mode (ms)					user mode (ms)			
	overall	sys exec	sys code trans	user exec	user code trans	overall	sys exec	user exec	user code trans
basename	4.08	1.79	0.53	1.41	0.35	0.34	0.02	0.11	0.22
uptime	7.48	2.39	0.76	2.79	1.55	0.89	0.04	0.31	0.54

Table 2: Runtime performance of system mode and user mode emulation

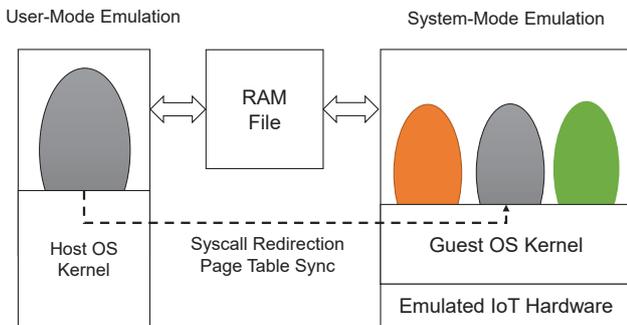

Figure 1: Overview of Augmented Process Emulation

- (2) The firmware runs a POSIX-compatible operating system (OS). Fortunately, many IoT firmware images use Linux as the OS hence satisfy this requirement.

With augmented process emulation, we aim to achieve the following design goals:

- *Transparency.* The user-level program running in the augmented process emulation should behave as if it were run in the system-mode emulation.
- *High efficiency.* Since throughput is a dominating factor for fuzzing, the augmented process emulation needs to be as efficient as possible. Ideally, it should approximate the performance of pure user-mode emulation.

**Solution overview.** To achieve the design goals mentioned above, we resort to combine user-mode emulation with system-mode emulation in a novel manner. Figure 1 illustrates the overview of our solution.

At first, the IoT firmware boots up in the system-mode emulator and the user-level programs (including the one to be fuzzed) are launched properly inside the emulator. After the program to be fuzzed has reached at a predetermined point (e.g., the entry point of main function, or after receiving the first network packet), the process execution is then migrated to the user-mode emulation in order to gain high execution speed. Only at rare occasions, the execution is migrated back to the system-mode execution to ensure the correctness of execution.

To minimize the migration cost, the memory state is shared between these two emulation modes. More concretely, the physical memory of the virtual machine for the system-mode

emulation is allocated as a memory-mapped file, called RAM file. This RAM file is also mapped into the address space of the user-mode emulation. Note that system-mode emulation and user-mode emulation access this RAM file in different ways. System-mode emulation treats the RAM file as physical memory, and thus accesses it by physical address, while user-mode emulation accesses the shared memory by virtual address. Therefore, the physical pages in the RAM file need to be mapped into the address space of user-mode emulation by their virtual addresses at a page granularity. As a result, when a page mapping is not established in the user-mode emulation, the process execution needs to be migrated to the system-mode emulation to establish this mapping. We will discuss more details about the memory mapping in §3.2.

With a proper memory mapping, the process should be able to execute correctly in the user-mode emulation, until it reaches a system call. Directly executing the system call locally on the host OS would not work in general, because the host OS and the OS in IoT firmware are different and the underneath hardware layers are also different. To ensure transparency, we need to migrate the execution to the system-mode emulation to process this system call. When the system call returns, we migrate the execution back to the user-mode emulation. More details will be discussed in §3.3.

## 3.2 Memory Mapping

**Bootstrapping.** When fuzzing a program with AFL, the program executes to a predetermined point, and then the fork server of AFL will repeatedly fork a new program instance on this point (which is referred to as fork point) and feed random inputs. Similarly, in this setting, we will boot up the IoT firmware in system-mode emulation and further launch the specified IoT program. Using Virtual Machine Introspection (VMI) provided by DECAF [23] (a system emulation based dynamic analysis platform), we are able to monitor the execution of the specified IoT program and get notified when the execution reaches to the predetermined fork point.

At this moment, we will walk the page table of the specified process and collect the virtual to physical page mapping information and send it over to the user-mode emulation side. Then for each mapping of virtual address ( $va$ ) to physical address ( $pa$ ), the user-mode emulation side establishes a mapping by calling `mmap` as below:

```
mmap(va, 4096, prot, MAP_FILE, ram_fd, pa);
```

The code above is self-explanatory. Essentially, we map a page of the RAM file with the physical address as offset into a specified virtual address. The argument `prot` is determined by the protection bits from the corresponding page table entry.

From this point onward, the execution in system-mode emulation is paused, the CPU state is sent over to user-mode emulation, and the execution resumes there.

**Page fault handling.** During the process execution in user-mode emulation, if the accessed memory addresses have already been mapped in this address space, the execution should proceed successfully. Otherwise, the host processor will raise a page fault. We register a signal handler for page fault in user-mode emulation, so the host OS will pass along the page fault event to the user-mode emulation. On receiving this signal, the user-mode emulation records the CPU state at the faulting instruction, pauses the execution, and passes the CPU state to the system-mode emulation side, expecting that the page fault can be handled in the system-mode emulation and a new mapping for the faulting virtual address can be established.

When the system-mode emulation receives the CPU state and resumes execution, the emulated processor will raise a page fault, since the page is not present. The page fault handler in the OS of the IoT firmware will respond to this page fault and attempt to establish the mapping. Most likely, this mapping will be established by the OS sooner or later (depending on the scheduling of numerous kernel threads and interrupt handlers) and the instruction that causes the page fault will be re-executed. In very rare cases, if the OS cannot establish a mapping for various reasons, it will kill the process.

A key question here is to determine when the page mapping has been established or an error occurs, so we can switch back to the user-mode emulation to maximize execution speed. The answer to this question is in fact non-trivial, because the OS is handling multiple tasks simultaneously and enormous amount of context switches may happen in the meantime.

To capture the right moment when a mapping is established, we instrument the end of each basic block. If the execution is currently within the specified process (or thread), it means the execution has returned from the kernel to the user space to resume the faulting instruction. The mapping must be present in the software TLB. So we can just directly find the mapping there. At this moment, we pass the mapping information and the CPU state back to the user-mode emulation, which will create this new mapping by calling `mmap` and resume the execution.

If for some reasons, an error occurs and the process gets killed, we can rely on the VMI (Virtual Machine Introspection) capability provided by DECAF [23] to get notified, and then the whole execution on both sides get terminated.

**Preload page mapping.** Modern operating systems load memory pages in a lazy manner. Although when a new pro-

cess starts, all code pages are assigned into its address space, a mapping from each virtual page to its physical page is not really established until a page fault caused by the first memory access to it.

This lazy design has adverse effect on fuzzing performance. As we will discuss in §4.1, a child process is repeatedly forked from the parent process for each fuzzing iteration, and thus there are always a series of page faults caused by un-mapped code pages. This is especially harmful for our system, because the overhead of page fault handling is much more expensive than handling it locally on the host OS.

To solve this problem, we decide to preload the code pages of the given process in the physical memory and perform the mapping between the two modes. This helps us avoid repeatedly loading the code pages at every fuzzing iteration, and hence speed up the fuzzing throughput. To do that, we simulate the access to each program code page in the system-mode emulation during the bootstrap, to force the OS to map each page into the process' address space. As a result, we can reduce the number of page faults caused by these pre-loaded pages.

### 3.3 System Call Redirection

System calls and their implementation in IoT programs are different because of the underlying IoT hardware, firmware and requirements. Consequently, user-mode emulation of an IoT program will likely fail if the exceptions caused by the system calls are not properly handled (see §2). For example, most IoT devices have network interfaces that are not available on a local emulator. When an IoT program in the user-mode emulation executes a system call that needs to interact with a specific network interface in the IoT system, there will be a fault that needs to be handled. Another example is a system call that accesses NVRAM that is undefined for a desktop computer.

Therefore, to ensure execution correctness, we must redirect the system calls from the user-mode emulation to the system-mode emulation. More specifically, when the user-mode emulation encounters a system call, it pauses the execution, saves the current CPU state, and sends it over to the system-mode emulation. The system-mode emulation receives the CPU state and resumes execution. This will cause a mode switch into the kernel mode in the guest system to process the corresponding system call. Again, since the guest OS kernel is multi-tasking, there might be many context switches happening before the system call returns. So similar to how we handle page faults, we will instrument the end of each basic block. If the current basic block is in the kernel space, but next program counter is in the user level, and the current execution context is for the thread that makes the system call, we detect the moment when the system call returns. Then at this moment, we pause the execution in the system-mode emulation, save the CPU state, and pass it back to the user-mode

emulation, which will then resume the execution.

**Optimizing filesystem-related system calls.** While examining the system calls made by a set of IoT programs, we realize that many system calls are related to the file system. The IoT programs either attempt to access files or directories that already exist in the firmware or are newly created for only temporary uses. We propose an optimization for this set of system calls. We map the file system from the firmware image, and mount it as a directory in the host OS, such that the user-mode emulation can directly access it. In this way, the user-mode emulation can directly pass through the file-system related system calls to the host OS, instead of redirecting them to the system-mode emulation.

As shown in §5.3, filesystem-related system calls take a significant portion among all system calls, and thus this optimization makes a significant contribution for the final performance.

## 4 Firm-AFL Design and Implementation

Leveraging the technique described in §3, we design and implement FIRM-AFL, an enhancement of AFL [34] for fuzzing IoT firmware. In §4.1, we first describe the workflow of AFL, and then in §4.2, we present how we integrate augmented process emulation into the workflow of AFL.

### 4.1 Workflow of AFL

AFL is a coverage-guided greybox fuzzer. It maintains a seed queue that stores all the seeds, including the initial seeds chosen by the user as well as the ones that are mutated from the existing seeds and cause the program to reach unique code coverage.

The main program that drives the fuzzing process is `afl-fuzz`. It picks a seed from the seed queue, performs a random mutation, generates an input, and feeds this input to the target program (assuming it is a binary executable).

In order to collect the code coverage information from the execution of the target program, AFL starts the program using the user-mode QEMU, and instruments the branch transitions of the target program, and the code coverage information is encoded and stored in a bitmap.

Since during fuzzing we need to execute the target program repeatedly, AFL utilizes “fork” as a mechanism to speed up this process. It first runs the target program up to a certain point (e.g., the entry point of the main function) such that the program’s code and data have been properly initialized, and then repeatedly forks a child process from it. In this way, the initial setup of a new process is skipped. For this reason, the parent process is called `fork-server`. Then the input is fed into the forked child process, and the coverage information is collected and stored in the bitmap, which is shared among

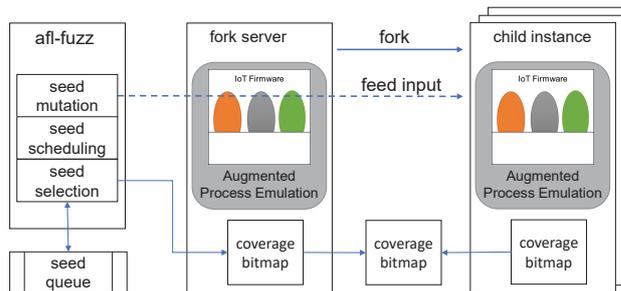

Figure 2: Overview of FIRM-AFL

all three processes (`afl-fuzz`, `fork-server`, and the child instance). `afl-fuzz` will compare the bitmap from the child instance and the accumulative bitmap from all past executions to determine if this mutated input should be kept as a new seed and stored in the seed queue.

### 4.2 AFL with Augmented Process Emulation

We would like to keep the workflow of AFL intact, but allow AFL to fuzz a target program in an IoT firmware image. To do so, we replace the user-mode QEMU with augmented process emulation, and the rest of the components remain unchanged. The new workflow is illustrated in Figure 2.

**Bootstrapping.** To fuzz a program in the IoT firmware image, we need to boot up the firmware image and launch the program after the system boots up. This is done in the system-mode emulation within `fork-server`.

We leverage Firmadyne [13] to correctly emulate a firmware image. We further integrate DECAF [23] with Firmadyne to make use of its VMI (Virtual Machine Introspection) capability. In this way, we are able to capture the precise moment when the target program is started or terminated. We can also know when the execution of the target program has reached the pre-determined fork point.

**Forking.** The default fork point chosen by AFL is the entry point of the main function. In our case, we are interested in finding vulnerabilities in the IoT programs that are triggered through the network interface. Therefore, we hook the network-related system calls. And the first invocation of any of these system calls becomes the fork point.

In the standard workflow of AFL, we can simply leverage the `fork` system call to fork a child process and start the next fuzzing instance. In our case, we not only need to fork a child process for the user-mode emulation, but also “fork” a new virtual machine instance for the system-mode emulation, because two modes must synchronize with each other.

Actually forking a new virtual machine would be too expensive. Instead, we can make a snapshot of the virtual machine

at the fork point, and when one fuzzing execution is finished, we can restore the snapshot. System-mode QEMU offers `save_snapshot` function that saves all the CPU registers and the memory space to a specific file. However, file write/read operations would still be very slow.

In our system, we implement a lightweight snapshot mechanism based on the Copy-on-Write principle. More concretely, we first mark the RAM file mapped into the system-mode QEMU as read-only. Then a memory write will cause a page fault. We make a copy of the page, and then mark this page as write-able. As such, we record all memory pages that have been modified during one fuzzing execution. When restoring the snapshot, we only need to write these recorded pages back.

**Feeding input.** The inputs are fed through instrumenting system calls. For the IoT programs that are receiving input from network interface, we instrument the network-related system calls in the user-mode emulation directly, so we don't need to redirect these system calls to the system-mode emulation.

**Collecting coverage information.** Since most of execution happens in the user-mode emulation and system-mode emulation is only needed for handling page faults and some system calls, we can simply instrument the branch transitions in user-mode QEMU to compute the coverage bitmap, just like how the original AFL does it in user-mode QEMU.

## 5 Evaluation

In this section, we evaluate the prototype implementation of our fuzzer FIRM-AFL. The purpose of this section is to test whether our approach has resolved the performance bottlenecks and achieved the two design goals. In short, we would like to answer following questions:

- *Transparency.* Can FIRM-AFL fuzz programs extracted from IoT firmware as if they are running inside a full-system emulator?
- *High efficiency.* How close is FIRM-AFL's throughput (executions/sec) to the throughput of a pure user-mode emulation based fuzzer?
- *Effectiveness of optimization.* Do our optimization techniques successfully resolved the performance bottlenecks we identified?
- *Effectiveness in vulnerability discovery.* How effective is FIRM-AFL in finding real vulnerabilities in IoT firmware?

**Experiments setup.** We used three sets of programs in our evaluation. The first set of programs are two standard benchmarks: `nbench` [9] and `lmbench` [7]. They are used to access the correctness of the emulation and the overhead of the emulation. The second set of programs consist of seven IoT programs from four different vendors (Table 3). We selected these program since they are the key service programs that handle network requests thus are good targets for remote attacks. They are used to access the performance of greybox fuzzing. The third dataset is the Firmadyne dataset which includes firmwares whose HTTP and uPnP services are related to 15 1-day exploits (Table 6). We collected them to evaluate the transparency and effectiveness of FIRM-AFL in vulnerability discovery.

Experiments (except the ones in §5.4) are conducted on a 8-core Intel(R) Core(TM) i7-3940XM 3.00GHz CPU machine with 23.5GB of RAM 1TB hard disk . The operating system is Ubuntu 16.04.5 LTS. The version of QEMU and AFL is 2.10.1 and 2.06b. We obtain each measurement value after every ten iterations. Our final reported numbers are the average value of 20 measurements. By default, we set fork point at the position after the network data received, and feed the random input provided by AFL engine.

### 5.1 Transparency

To evaluate the transparency of our augmented process emulation, we first evaluated our emulator with the `nbench` test suite. After generating the output, the benchmark will compare the outputs with expected outputs. If the generated outputs are wrong, then it implies the emulation is not correct. The results showed that our system can finish all the benchmarks without errors.

We also empirically evaluated the transparency of FIRM-AFL using the Firmadyne dataset [4]. We collected 120 firmware images with HTTP services and unique device models. We first tried to run HTTP service programs in them directly using user-mode QEMU. We extracted the file systems from the firmware images and used `chroot` to mount the file systems. However, all these programs crashed at the very beginning due to the lack of expected system environment. Then we tried to run them with normal inputs (the initial seeds) under full-system emulation, as well as under augmented process emulation. We observed that in both settings, all the programs could run properly. For each program, we further compared the system call sequences generated under full-system emulation as well as augmented process emulation, and confirmed that the system call sequences were identical.

Finally, we evaluated a set of exploits targeting known vulnerabilities listed in Table 6. For each vulnerability, we fed a proof-of-concept (PoC) exploit in both full-system emulation and augmented process emulation and compared the execution traces. We confirmed that the collected two traces are

Program	Size (KB)	Description	Vendor	Devices	Model	Version	CPU Arch
cgibin	129.4	CGI binary program	DLINK	Router	DIR-815	1.01	MIPSEL
httpd	90.2	Embedded HTTP server					
dnsmasq	162.3	Embedded DNS server					
dropbear	307.3	Embedded SSH server	TPLINK	Router	TL-WR940N	V4_160617	MIPSEB
httpd	1692	Embedded HTTP server					
jjhttpd	103.3	Embedded HTTP server	Trendnet	Router	TEW-813DRU	v1(1.00B23)	MIPSEB
lighttpd	327.3	Embedded HTTP server	Netgear	Router	WNAP320	3.0.5.0	MIPSEB

Table 3: IoT programs used for evaluation

identical.

In summary, this evaluation showed that FIRM-AFL can provide transparent emulation as if the program is executing in full-system emulation.

## 5.2 Efficiency

Benchmark	Augmented mode	User mode	Slowdown
Numeric sort	679.12	686.56	1.08%
String sort	78.36	79.54	1.48%
Bitfield	3.47E+08	3.45E+08	0.00%
FP emulation	163.85	161.72	0.00%
Fourier	1383.6	1,384.00	0.00%
Assignment	20.45	20.75	1.40%
IDEA	4,864.10	4,854.10	0.00%
Huffman	1,749.00	1,743.10	0.00%
Neural Net	1.93	1.95	0.60%
LU Decomp	61.26	61.92	1.00%

Table 4: `nbench` results, the unit is iterations/second. The last column shows the slowdown of augmented mode.

Syscall	Augmented mode	User mode	Overhead
null	0.48	0.48	0.00%
read	0.62	0.60	3.33%
write	0.57	0.52	9.62%
stat	1.31	1.24	5.64%
fstat	0.63	0.61	3.28%
open	2.61	2.50	4.40%
select file	3.52	3.48	1.15%
select tcp	32.74	12.64	159%
pipe(latency)	6.73	6.57	2.44%

Table 5: `lmbench` syscall testing results, the unit is microsecond. The last column shows the overhead of augmented mode.

**Standard benchmarks.** We evaluated the efficiency of our approach from two angles. First, we evaluated the performance overhead of augmented process emulation using standard performance benchmarks. The result of `nbench` is shown in Table 4. `nbench` is a CPU-bound benchmark suite. On

this benchmark, the augmented mode did not impose much overhead, largely due to the fact that these benchmarks are relatively simple, so they do not require many memory synchronization operations and syscall redirection. To evaluate the overhead of syscall redirection, we used the `lmbench`. The result is shown in Table 5. As we can see, for syscalls that are executed locally (e.g., file related syscalls), the overhead is almost negligible. For syscalls that still require redirection (e.g., TCP related), the overhead is much higher.

**Fuzzing throughput.** In the second performance evaluation, we measured the throughput of FIRM-AFL, under different optimization levels:

- (a) *Baseline*: we used TriforceAFL [29] as the baseline. TriforceAFL uses full-system emulation to support fuzzing IoT programs. To avoid rebooting the virtual machine, in this configuration, we added support for QEMU’s stock snapshot mechanism (`qemu_savevm` and `qemu_loadvm`) to TriforceAFL. We also use VMI provided by DECAF [23] to capture the precise moment when program is started and terminated.
- (b) *Lightweight snapshot*: in this configuration, we changed the snapshot mechanism to our lightweight snapshot (§4).
- (c) *Augmented process emulation*: in this configuration, we switched the emulation mode from full-system mode to our augmented process emulation mode (§3).
- (d) *Full*: in this configuration, we applied all optimization techniques, including selective syscall redirection.

Figure 3 shows the throughput improvement. Overall, lightweight snapshot boosted the throughput for about 9.3 times (b vs. a). Augmented process emulation boosted the throughput for about 3 times on average (c vs. b). With selective syscall redirection, the throughput had another boost for about 2.9 times on average (d vs. c). So compared with the best result on full-system emulation based fuzzing (b), FIRM-AFL (d) provided an average improvement of 8.2 times.

## 5.3 Effectiveness of Optimization

In §2.4, we identified three major bottlenecks of full-system emulation: memory address translation, dynamic code trans-

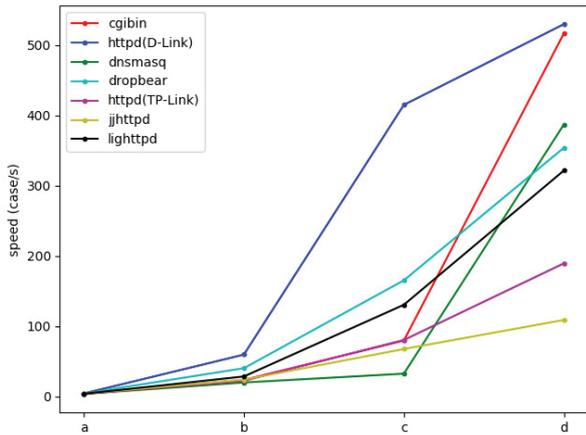

Figure 3: Fuzzing throughput of FIRM-AFL under different optimization level. The x-axis is the optimization level: (a) baseline, (b) w/ lightweight snapshot, (c) w/ augmented process emulation, and (d) w/ selective syscall redirection. Fuzzing throughput for each program is shown in a different color.

lation, and syscall. In this section, we evaluated whether our optimization techniques successfully addressed these bottlenecks. For this purpose, we break down the total execution time into five parts:

- *User execution time*: the total time spent in executing the logic of the target program, this includes the time spent on software address translation.
- *Memory synchronization time*: in augmented emulation mode, time spent on setup the memory mapping between the user-mode emulator and the full-system emulator.
- *Code translation time*: total time spent on translating the target program.
- *Syscall execution time*: total time spent on system calls in an iteration of execution.
- *Syscall redirection time*: in augmented emulation mode, time spent on redirecting the system call to the full-system emulator.
- *Snapshot time*: the total time spent on storing and restoring memory and CPU states in an iteration of fuzzing. Note that different snapshot mechanisms have different time overhead values. We record the starting and ending time for each page store and restore operations.

**Lightweight snapshot.** Snapshot overhead only exists for the system-mode emulator. In augmented process emulation, a synchronization mechanism is required to ensure the consistency of snapshot between system and user mode. For these

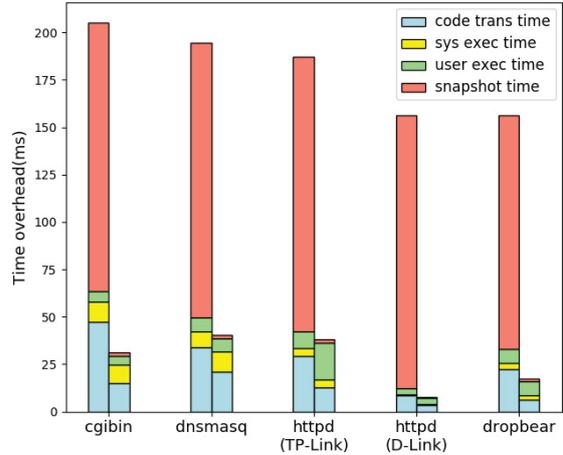

Figure 4: Execution time breakdown: system-mode emulation w/o and w/ lightweight snapshot.

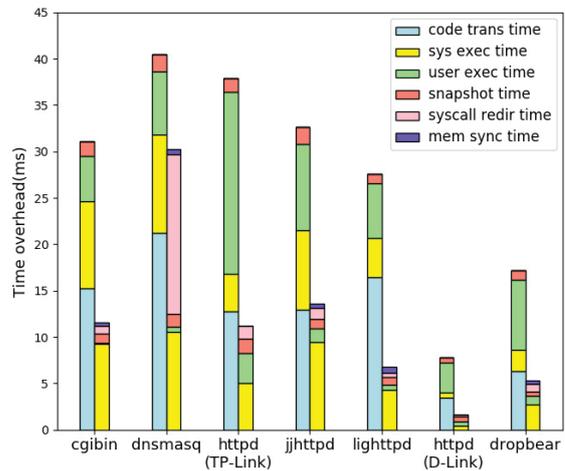

Figure 5: Execution time breakdown: augmented process emulation vs. full-system emulation.

experiments, we measure the snapshot synchronization cost and add it to the snapshot overhead. When comparing the snapshot overhead in Figure 4 and Figure 5, we can see that the lightweight snapshot mechanism leads to more than 100x reduction in the snapshot overhead.

**Augmented process emulation.** Figure 5 shows the execution time breakdown of full-system emulation and augmented process emulation for the seven IoT programs. The total execution time on average reduces more than 50% except for dnsmasq. When analyzing breakdown of execution time, we can see huge reduction on user execution time and code translation time. On average, the user execution time (green bar) was reduced by about 9 times. This is mostly due to the elimination of software address translation. Even if we combine

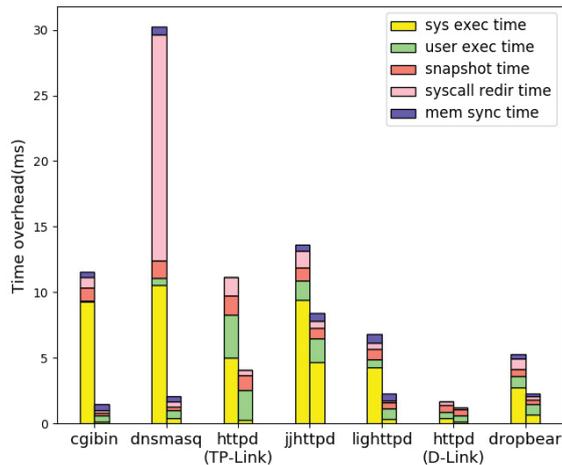

Figure 6: Execution time breakdown: augmented process emulation w/o and w/ selective syscall redirection.

the memory synchronization time (purple bar), the execution time was still reduced by about 5 times.

Another huge reduction is the code translation time. As briefly mentioned in §2, this is due to two optimization techniques. First, when running in full-system mode, QEMU only performs block chaining for basic blocks within the same physical page. This means the emulator has to be invoked to resolve control transfer between pages. In augmented process emulation, QEMU can link any basic blocks as long as they are translated. Second, when using full-system mode for fuzzing, the fuzzer (Triforce) will reset the virtual machine after processing each input. Although we have optimized this step with lightweight snapshot, the code cache will be reset during the restore. This means the same basic block could be translated repeatedly for every fuzzing iteration. In augmented process emulation, we can utilize the code cache pooling technique from AFL to avoid this re-translation. As a result, the amortized code translation time became very small.

Unfortunately, the reduction on user execution time and code translation time is at the cost of increase in overall syscall time, i.e., the combination of syscall execution time and syscall redirection time. In general, the more syscalls the target program issues, the higher the redirection overhead. This is why `dnsmasq` spent significantly more time on syscall redirection than the other programs: it issued more than one thousand system calls which caused more than two thousand state transitions between system mode and user mode. This highlights the necessity of selective syscall redirection.

**Selective syscall redirection.** Figure 6 shows the execution time breakdown with and without selective syscall redirection. Recall that the goal of redirecting system calls to the full-system emulator is to ensure correct emulation. However, not all system calls require special kernel or hardware sup-

port. Therefore, by locally executing system calls that can be fully supported by the host system (e.g., file system related syscalls), we reduce most of the syscall time without jeopardizing correctness. As shown in the figure, after applying this optimization, we observed a huge reduction in system call execution time, because many system calls are now executed by the host OS without address/code translation and device emulation. At the same time, we also observed reduction in syscall redirection time, which has a great impact on programs that issue many syscalls, like `dnsmasq`. A majority of syscalls issued by `dnsmasq` were file operations which can be handled locally by mounting the IoT firmware file system in the host OS. By doing so, the total execution time of `dnsmasq` can be reduced by another 14 times.

To summarize, this evaluation showed that our solutions (augmented process emulation and selective syscall redirection) have successfully addressed the three bottlenecks we identified in §2.4.

## 5.4 Vulnerability Discovery

In this section, we aim to evaluate how effective FIRM-AFL is in finding vulnerabilities in real-world IoT firmware images.

**Data collection.** We started with the Firmadyne dataset [4]. We collected these firmware images and tested the emulation condition and network reachability, and then checked the liveness of HTTP and uPnP services by probing their ports. Eventually, we obtained 288 firmware images with active HTTP and uPnP services. We then used `getsploit` [1] to collect exploits targeting HTTP and UPnP services from online resources, such as `exploit-db` [3], `metasploit` [8], and `Packet Storm` [6]. Then we fed these exploits into the 288 images, and eventually identified 15 exploits that can be launched successfully against 51 firmware images. Table 6 lists these 15 exploits.

We further ran the programs related to these 15 exploits in user-mode QEMU, and observed that only one program `tcapi` that is related to the last five exploits can continue to work in user-mode QEMU. This result once again confirms the necessity of augmented process emulation.

**Experiment setup.** As our focus in this case study is on fuzzing HTTP and uPnP services, which have well-structured protocol formats. To expedite fuzzing, we made use of the dictionary option “-x” in AFL. We collected keywords for HTTP (from `honggfuzz` [5]), uPnP and HTTP CGI services (extracted directly from binary programs) respectively. For each service, we then provided a normal service request as the initial seed.

Moreover, to avoid underestimating the performance of full-system emulation with its default snapshot implementation, we enabled lightweight snapshot in it.

Exploit ID	Vendor	Model	Version	Device	Program	Full-System Time to crash	FIRM-AFL Time to crash
CVE-2018-19242	Trendnet	TEW-632BRP	1.010B32	Router	httpd	21h43min	6h2min

Table 6: 1-day exploits

The experiments were conducted on a server with 40-core Intel Xeon(R) E5-2687W(v3) 3.10GHz CPU and 125GB of RAM.

Finally, to ensure our evaluation results on fuzzing performance are statistically significant, as suggested by Klees et al. [25], we ran each fuzzing experiment ten instances in parallel for 24 hours. In addition to FIRM-AFL, we also evaluated full system emulation with lightweight snapshot support. We report cumulative number of unique crashes found over time, using `plot_data` in AFL output files.

**Evaluation results.** We calculate the median time to first crash in full-system emulation and augmented process emulation respectively and record them in the last two columns of Table 6. We can see that FIRM-AFL can find a crash at least 3.6 times faster than full-system emulation, and in many cases more than 10 times faster.

We also plot cumulative number of unique crashes found over time by FIRM-AFL (blue), and fuzzing with full emulation (red) in Figure 7. In each plot, the solid line represents the median result from 10 rounds while the dashed lines represent the lower and upper bounds of 95% confidence intervals for a median. Since last five cases in Table 6 are related to the same program and the results are similar, we just plot the case for CVE-2018-10749 as the representative.

From the result, we can see that in spite of large variations across fuzzing runs, FIRM-AFL was able to find significantly more unique crashes and find them multiple times faster than full emulation. We further investigated these crashes and confirmed that most of these crashes were caused by the same known vulnerabilities. We indeed found two new vulnerabilities, which we will describe next.

**0-day vulnerabilities.** We discovered two 0-day vulnerabilities using FIRM-AFL, after 7.5 hours and 6 hours respectively. We also tried fuzzing these two programs with full-system emulation using the same initial seeds, and no crash was found within 24 hours. we reported them to IoT manufacturers and MITRE corporation. The details about these two vulnerabilities are described as below.

- CVE-2019-11417: Buffer overflow in Trendnet TV-IP110WN (firmware version: v.1.2.2 build 68). Attackers can exploit the device by using ‘`languse`’ parameter in `system.cgi`.
- CVE-2019-11418: Buffer overflow in Trendnet TEW-632BRP (firmware version: v.1.010B32). Attackers can exploit the device by crafting the `soapaction` HNAP interface.

## 6 Discussion

In this section, we discuss the limitations in our system and shed some light for future work.

**Limitation on supported CPU architectures.** The current implementation of FIRM-AFL supports the following CPU architectures: `mipsel`, `mipseb` and `armel`, which already account for 90.2% images in the Firmadyne dataset. We expect that supporting more CPU architectures is relatively easy, because the majority of the emulation logic in QEMU is implemented in an architecture-independent manner.

**Limitation on supported IoT firmware.** Even after more CPU architectures are supported, FIRM-AFL can only fuzz a

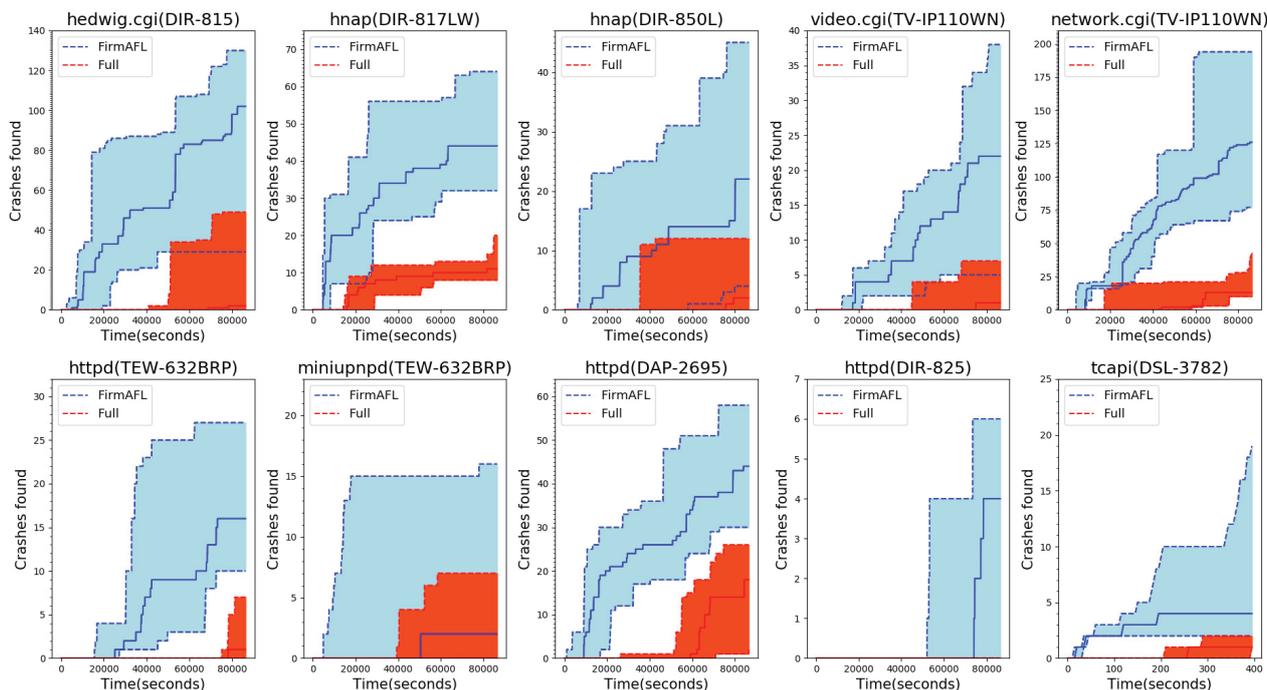

Figure 7: Crashes found over time

program in a firmware image that can be properly emulated by Firmadyne and runs a POSIX-compatible OS (e.g., Linux). This limitation stems deeply from the design of FIRM-AFL, and thus there is no simple solution. An improvement on IoT firmware emulation is orthogonal to this paper. We will leave it for future work. Supporting a non-POSIX program would require a virtualization layer, such that they can run properly within a POSIX process. We are not aware of an existing solution for this. Thus, it can be an interesting future work.

## 7 Related Work

With the increasing number of IoT devices and their security issues, several techniques are proposed to find the IoT devices vulnerabilities in an automatic manner. These techniques can be categorized into static or dynamic analysis. Lacking the source code of the IoT firmware, static analysis often relies on the binary image and reverse engineering techniques.

**Static analysis.** Costin et al. presented a large scale analysis of IoT firmware by coarse-grained comparison of files and modules [17]. Their approach is able to find a lot of known bugs within the common third-party projects used by different vendors. Cojocar et al. proposed another approach to heuristically identify parsers and complex processing logics from IoT firmware, and they find several vulnerabilities [16]. That said, these approaches suffer from high false positives and cannot find completely new vulnerabilities. Feng et al. pre-

sented a cross-platform bug search technique for firmware images [21]. The technique is based on high-level numeric features comparison, and only takes 0.1 second on average to finish all 154 vulnerabilities searching. Xu et al. further proposed a novel neural network-based approach to detect cross-platform binary code similarity [31]. It can significantly reduce training time and feature vector generation time, as well as improve search accuracy.

Firmallice is another IoT binary analysis framework that employs static analysis techniques [30]. Firmallice utilizes symbolic execution on the firmware binary and uses backward slicing to make the vulnerability analysis tractable. Firmallice focuses only on one slice of the program based on an analyst’s specification. The specification provides a clue about the privileged program code. Isolating the potential vulnerable code, Firmallice makes the analysis scalable while also capable of finding new vulnerabilities. That said, Firmallice can only find the authentication vulnerabilities and relies on manual analysis for the slice specification.

**Dynamic analysis.** On the other hand, dynamic analysis techniques for IoT firmware require either the real devices or an emulation of some sort. Black-box fuzzing is a common approach to discover vulnerabilities by directly interacting with devices. Recently, several works have developed dynamic emulators for IoT devices. For example, Zaddach et al. developed a dynamic analysis framework for IoT devices by redirecting hardware requests from the emulator to

the actual hardware [33]. Based on it, Marius et al. developed a dynamic multi-target orchestration framework that can enable interoperability between different dynamic binary analysis framework, debuggers, emulators and real physical devices [27]. However, the large number of hardware limits its scalability, and also imposes a large overhead.

Chen et al. proposed a robust software-based full system emulation. Their emulation is based on kernel instrumentation [13]. Their goal is to perform automatic vulnerability verification that has no ability to find unknown vulnerabilities. Both Avatar and Firmadyne do not use techniques such as fuzzing that are capable of finding completely new vulnerabilities in real applications. Anderi et al. conducted dynamic analysis to achieve automated vulnerability discovery within embedded firmware images [18]. The tool aims at discovering web-interface related vulnerabilities by using web pentesting tools. However, it cannot find vulnerabilities of other modules in IoT firmware.

**IoT fuzzing.** For IoT fuzzing, and closest to our work, Muench et al. developed six live analysis heuristics including call stack tracing and call frame tacking [28]. Muench et al. built their system on top of Avatar [33] and PANDA [19], and their system can effectively detect memory corruption for IoT devices. However, this system takes target systems as black-box and feeds input from outside which imposes overhead on the devices startup and rebooting for each fuzzing session. Further, unlike greybox fuzzing, the input space exploration is very blind, and hence the chance of finding a bug is very low. In our work, we utilize greybox fuzzing, and aim to minimize each fuzzing iteration overhead so that the fuzzer can test more test cases in the same unit of time. In addition, Alimi et al. proposed to use fuzzing techniques and specific simulators (JCOP) to discover vulnerabilities in programs hosted into smart cards [11]. The methodology does not scale due to emulation problems of various kinds of IoT firmware.

## 8 Conclusion

Coverage-based greybox fuzzing has proven to be an effective way to find vulnerabilities in real-world programs. Yet, applying greybox fuzzing to IoT firmware has not been realized due to two main challenges. Firstly, state-of-the-art greybox fuzzers like AFL fail to run many IoT programs due to specific hardware dependencies. Secondly, solutions that can tackle the first challenge (e.g., by employing full-system emulation) yield very low throughput. We proposed a novel technique, augmented process emulation to address both challenges at the same time. With augmented process emulation, we achieve high throughput fuzzing by running the target program in a user-mode emulator and switch to a full-system emulator when the target program invokes a system call that has specific hardware dependencies.

We evaluated the transparency and the efficiency of FIRM-AFL, our prototype implementation of greybox IoT fuzzing based on the augmented process emulation. The results showed that our system is transparent and its throughput outperforms all the state-of-the-art IoT firmware fuzzers by one order of magnitude. Our case study further showed that FIRM-AFL could indeed find both 1-day vulnerabilities much faster than full-system emulation and was able to find two new vulnerabilities within only two hours on a single machine.

## Abstract

Devices with high energy consumption such as air conditioners, water heaters, and electric vehicles are increasingly becoming Internet-connected. This new connectivity exposes the control of new electric loads to attackers in what is known as Manipulation of demand via IoT (MadIoT) attacks. In this paper we investigate the impact of MadIoT attacks on power transmission grids. Our analysis leverages a novel cascading outage analysis tool that focuses on how the protection equipment in the power grid as well as how protection algorithms react to cascading events that can lead to a power blackout. In particular, we apply our tool to a large North American regional transmission interconnection system consisting of more than 5,000 buses, and study how MadIoT attacks can affect this power system. To help assess the effects of such cyber attacks, we develop numerical experiments and define new and stronger types of IoT demand attacks to study cascading failures on transmission lines and their effects on the system frequency. Our results show that MadIoT attacks can cause a partition of the bulk power system, and can also result in controlled load shedding, but the protections embedded in the operation of the transmission grid can allow the system to withstand a large variety of MadIoT attacks and can avoid a system blackout.

## 1 Introduction

The vulnerability of Internet of Things (IoT) devices is a well-known problem [11, 25, 46]. Previous work has demonstrated that devices from cameras to door locks can be compromised directly or through their designated smart phone applications [29, 43]. A large-scale compromise of these devices can enable attackers to affect network infrastructures, as exemplified by the Distributed Denial of Service (DDoS) attacks by the Mirai botnet—which consisted of more than six hundred thousand IoT devices [13].

The collective effect of compromised IoT devices can go beyond traditional computer network infrastructures. Recent

work proposed a novel form of attack called Manipulation of demand via IoT (MadIoT) [47], and showed that if an attacker compromised hundreds of thousands of high-energy IoT devices (such as water heaters and air conditioners), the attacker could cause various problems to the power grid, including (i) frequency instabilities, (ii) line failures, and (iii) increased operating costs. These attacks paint a dire picture of the security of the power grid as they show that a 30% increase in demand can trip all the generators in the US Western interconnection causing a complete system blackout, and a 1% increase of demand in the Polish grid results in a cascade of 263 transmission line failures, affecting 86% of the load in the system.

In this paper we re-evaluate the potential impact of MadIoT attacks by modeling in detail the protection equipment and the operational responses to sudden load changes in the power grid. Our analysis leverages a novel cascading outage analysis tool that focuses on how the protection equipment already embedded in the power grid reacts during cascading events, where multiple protection equipment is activated one after the other.

Our analysis shows that while MadIoT attacks can create negative consequences on the power grid, the negative impact on the grid will not be as dire as originally thought. In particular, while the most powerful MadIoT attacks (assuming the attacker compromises more than 8 million air conditioners) might cause the power system to partition and operate as separate islands, or can also cause some controlled load shedding, our results show that creating a system blackout—which would require a black start period of several days to restart the grid—or even a blackout of a large percentage of the bulk power grid will be very difficult.

This paper is organized as follows. Section 2 introduces the background necessary to understand power systems and how our tool compares to state-of-the-art practices for cascading analysis. Section 3 presents the details of our simulations and models. Section 4 illustrates why our cascade analysis tool has advantages over competing alternatives in a simplified model used in previous work. Our main results focusing on the analysis of a large-scale North American interconnec-

tion undergoing **MadIoT** attacks are presented in Section 5. Section 7 summarizes related work and Section 8 provides conclusions, limitations, and future work.

## 2 Power Systems Background

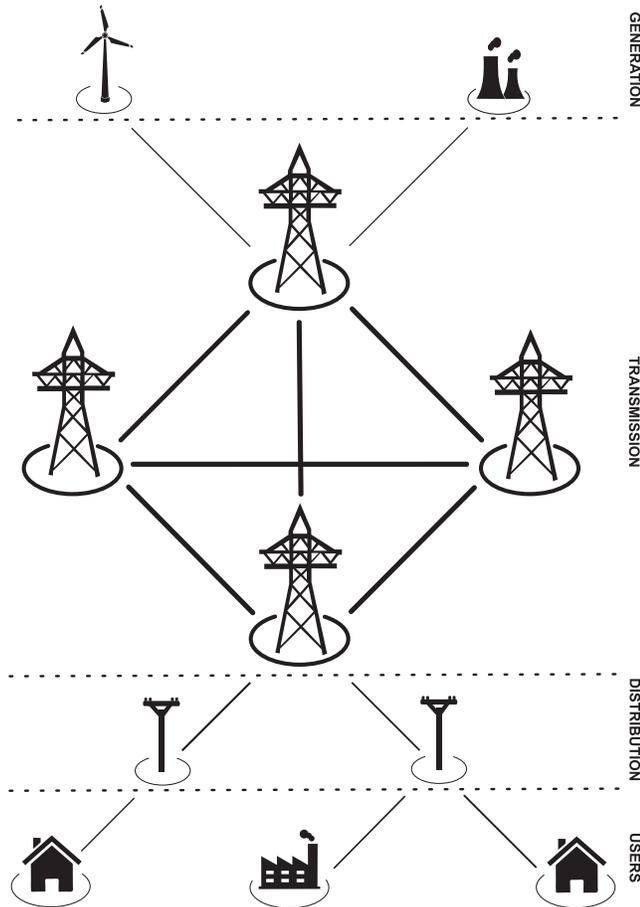

Figure 1: Generation and Transmission form the Bulk of the Power Grid. Transmission systems are redundant and have to satisfy the N-1 operation criterion, while Distribution systems are radial systems (non redundant) and affect a very small percentage of the system.

The objective of engineers and researchers in the power system industry is to deliver increasing amounts of electrical energy in a safe, clean, and economical manner [31]. The power grid has three major parts: (1) generation, (2) transmission, and (3) distribution. Electric power is generated wherever it is convenient and economical, and then it is transmitted at high voltages (100kV-500kV) in order to minimize energy losses—electrical power is equal to voltage times electrical current ( $P = VI$ ), and given a constant power, high voltage lines have less electrical current, and therefore there is less energy lost as heat as the current moves through the transmis-

sion lines. Geographically, a distribution system is located in a smaller region thereby energy losses are less of a concern while safety (preventing accidents, fires, electrocutions, etc.) is more important, therefore they are operated at lower voltages. Figure 1 illustrates these three main parts of the grid. A distribution system is connected to a transmission system in a substation and the conductor that completes the connections is usually represented in electrical diagrams by nodes called **buses**.

Operators have to keep the nominal frequency (e.g., 60Hz in the Americas) and the transmission lines at their operating range (at a fixed voltage like 500kV, and with currents below a safety threshold) in order to ensure reliable operation of the grid. If there is a sudden increase in the demand of electricity, the frequency of the power grid tends to slow down, and automatic controls ramp up generation of electricity to take the frequency back to 60Hz. If there is a sudden decrease in the demand of electrical power, then the frequency of the grid tends to increase, and automatic controls then decrease generation of electrical power to reduce the frequency to the nominal level. Similarly sudden changes in electricity consumption might overload transmission lines and activate protection equipment (relays that prevent the flow of electricity through the line), and if this happens, the power is then distributed to other transmission lines.

### 2.1 Transmission vs. Distribution Outages

Large generation plants and the transmission network are usually referred to as the **Bulk Power System**, and this bulk power system is responsible for the reliable delivery of electricity to large areas. The bulk power system is an interconnected, redundant network that spans large regions—usually one country, but in North America there are three bulk systems: the Eastern Interconnection, the Western Interconnection, and Texas. In contrast, distribution systems are geographically smaller and their networks are mostly radial (i.e., non-redundant).

The **bulk** power system is designed and operated to satisfy the N-1 security criterion, which means that the system can lose any one of its N components (such as generators or transmission lines) and continue operating safely and serving the power supply to the customers in the large area. This operating criterion is mandatory and enforced by government entities, and therefore bulk power system operators have the incentives to make sure that their systems satisfy the N-1 criterion at any point in time, otherwise they get massive sanctions. In contrast, since distribution systems are usually non-redundant and serve customers in a regional area, they do not have to meet the same operating criterion.

The reason distribution systems do not have to meet the N-1 criterion is the scale of a system failure. A disruption in the **bulk** power grid will be the topic of national news headlines because it causes a blackout in a large part of the country

(sometimes even the whole country), while a disruption in the distribution system will usually only cause a localized outage (e.g., a neighborhood will be without electricity). Electric power in the distribution grid can also be more easily restored, while a system blackout of the bulk power system will require days of coordination in what is called **black start period**.

While distribution systems are not required to follow the N-1 criterion, there are separate criteria applied to them. For example, the hours of successful power supply to consumers as percentage of the total hours in a year is required to meet certain standard e.g. 99.999%. Other details of the distribution system will not be discussed as they go beyond the scope of this paper.

As we will show later in the paper, one of the protections embedded in the power system to prevent a bulk power outage is called **Under Frequency Load Shedding (UFLS)**, which is a mechanism where predetermined blocks of customers in the distribution system are automatically dropped from the system. This is a carefully selected procedure where electricity is not cut to safety-critical loads like Hospitals. We will show that some of the most severe MadIoT attacks will activate this protection and therefore can cause some controlled outages, but at the same time, these small outages are done in order to prevent that the bulk system goes into a cascading failure resulting in a system blackout.

## 2.2 Failure Analysis in the Bulk Power Grid

The power grid analysis tool we use in this paper was developed to address the limitations for modeling and analyzing cascading failures identified by the task force from the IEEE Power Engineering Society [14, 15]. As stated in these reports, most of the research in cascading failure analysis focuses on independent phenomena, but these interactions are often ignored. In our recent work on cascading failures [33, 53–56] we have been developing a tool that captures the time interdependencies of all relevant protection equipment and stability studies in the power grid when multiple simultaneous (or quasi-simultaneous) contingencies occur. In this paper we adapt our tool to model MadIoT attacks. Before we discuss our approach in more detail, we now present related work in the analysis of failures in the power grid and discuss how our system compares to these approaches.

Cascading failure analysis has attracted a lot of attention from the research community [14, 44, 52]. There are two main approaches for studying cascading failures: stochastic models, and fine-grained simulations.

Stochastic models are used to evaluate the likelihood of a cascading event by giving us the probability of having incorrect settings for protection equipment in a given power system [26, 45]. To build these estimates, stochastic models perform a forensic analysis of previous cascading failures by looking at the properties of power systems just before they experienced a system blackout. Although these models pro-

vide a probabilistic insight of cascading events, they cannot be used to model the operation of a power system undergoing a cascade, which is particularly important when we want to understand how the system reacts to incidents in general (and cyber-attacks in particular). To understand the operation of the power system undergoing cascading failures we need to turn to detailed simulation models.

### 2.2.1 Power System Simulations

There are two main behaviors that we need to study when a system undergoes a failure:

1. **Transient Analysis** finds the behavior of the frequency in the power grid in the immediate aftermath of the incident. If the frequency deviates too far from 60Hz, some protection equipment will be activated. There are two options for transient analysis.
  - (a) **No System Dynamics:** This is a very fast computational method where the behavior of all generators is simplified to only one generation machine. This allows us to evaluate how the frequency of the system behaves with big changes in electricity consumption. Several cascading studies use this method [35, 41]. This simplification cannot capture the frequency at every bus in the system (therefore it cannot model if a power system is partitioned into islands), nor model how each generator will react differently to cascading incidents (therefore it cannot model how the protection mechanism in each generator will activate).
  - (b) **System Dynamics:** In this type of transient analysis we model all generators in the power system and all the frequencies in all the buses of the system. This is in line with one of the main objectives of a transient stability study—to determine whether the resulting angular separation between the machines in the system remains within certain bounds so that the system maintains synchronism [36]. Cascading analysis models with system dynamics are considered in [28, 34, 40].
2. **Steady-State Analysis** finds the voltages and currents of the system after all frequency equipment has tripped and can help us understand if the system ends up in a configuration where voltage protection or overcurrent protection equipment will activate. To compute these values, a power flow program uses Kirchhoff's physical laws to obtain the voltage magnitudes and phase angles at each bus of a power system. As a by-product of this calculation we can also compute real and reactive power flows in equipment such as transmission lines and transformers, as well as equipment losses [31]. There are two ways to perform steady state analysis:

- (a) **DC Power Flow:** Direct Current (DC) Power Flow is a very fast way to compute voltages and phase angles. There are several cascading analysis studies that use DC Power Flow models [22, 27, 57]. DC power flow models however are approximations to AC models, and they do not show the variations on voltages that might trigger protection equipment, therefore DC methods are only valid when voltages are close to their nominal values, which rules out their use for modeling large-scale events such as MadIoT attacks.
- (b) **AC Power Flow:** Alternating Current (AC) Power Flow is a more accurate (but computationally more expensive) way to analyze the steady state behavior of the power system. The only way to model voltage protection systems is with the use of AC power flow. Cascading analysis with AC power flow methods include [35, 41].

### 2.2.2 Power System Protections

In the previous subsection we have argued that the best practices for an accurate portrayal of power system behavior under *large-scale* events (i.e., events where voltages go beyond nominal values, and where individual generators might go beyond safety limits) is to use (1) System Dynamics for transient analysis, and (2) AC Power flow for steady-state analysis. In this section we describe how the results of our transient and steady-state simulations are used to evaluate how protection equipment in the power grid will react to changes in the operation of the system.

In particular, we model four protection mechanisms that are relevant for cascading analysis studies:

1. **Protection of Generators:** when the frequency of the system is too low or too high, the generator will be automatically disconnected from the power grid to prevent permanent damages to the generator.
2. **Under Frequency Load Shedding (UFLS):** if the frequency of the power grid is too low, controlled load shedding will be activated. As discussed before, this disconnection of portions of the distribution system is done in a controlled manner, while avoiding outages in safety-critical loads like hospitals. UFLS is activated in an effort to increase the frequency of the power grid, and prevent generators from being disconnected (as discussed in the point above).
3. **Overcurrent Protection:** if the current in a transmission line is too high, a protection relay will be triggered after time  $T$ . This activation time is based on an equation for current relays [10]. We will discuss in detail this equation when we describe our cascade outage analysis model.

4. **Over/Under Voltage Protection:** if the voltage of a bus is too low or too high, a voltage relay will be triggered after time  $T$ . This activation time depends on an equation modeling configuration thresholds and over/under voltage relay pick-up values [2].

### 2.2.3 Industry Practices

For day-to-day operations related to power grid failures, power operators focus on satisfying the N-1 criterion as this is the most important failure condition that is regulated and enforced by most electric regulatory agencies. Large-scale events such as a massive natural disaster, a terrorist attack, or a cyber-attack have not been a major priority for industry practices because the likelihood of these events is very small, and investment in preparing for these events has higher costs than responding to them when they happen [49].

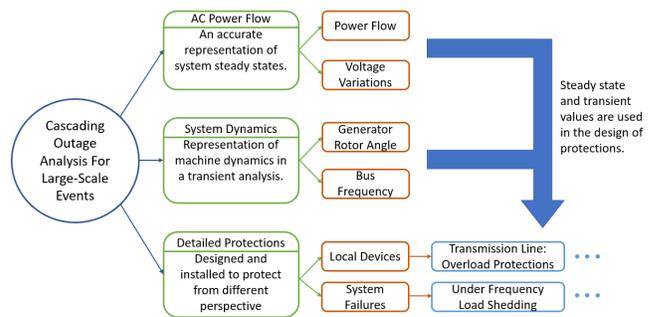

Figure 2: Analysis of Cascading Outages.

Therefore most of the industry efforts on cascading studies focus on smaller-scale events that initiate a cascade, and where the transient dynamics do not affect the cascade analysis too much. These efforts include the Transmission Reliability Evaluation of Large-Scale Systems (TRELSS) [32, 39] and the Oak Ridge-PSERC-Alaska (OPA) [18]. Similar problems have been studied by system operators like ERCOT [3]. Our tool on the other hand is designed for the study of the large disruptions in the operation of a power system like a deliberate cyber attack which can take hundreds of lines out in a short time, and therefore transient analysis has to be coupled with steady-state analysis.

The integration of (1) System dynamics, (2) AC power flow, and (3) the timing of protection equipment gives our tool a level of fidelity that goes beyond the current state-of-the-art practices [22, 27, 28, 34, 35, 35, 40, 41, 41, 57]. These three analysis techniques and their relationship are shown in Figure 2.

## 2.3 Contributions

Our contributions to the study of a MadIoT attacks compared to recent work [24, 47] include the following:

First, previous work considered transient and steady state simulation as separate use-cases (and in different inconsistent power systems), and as a result, the transient impacts on generators and system frequencies are not present in the power flow simulations. Therefore the predictions of cascading outages can differ between the two simulations. As we explain in Section 4.1, without the transient effect, the power flow solution will indicate a system blackout, while in reality Under Frequency Load Shedding will activate before generators start tripping and will prevent a system blackout.

Second, including the exact timing for the activation of a protection relay captures the realistic behavior of equipment in the power grid. Previous works on IoT attacks to the power grid [28, 34] do not represent the delay characteristic of protection equipment, but rather use models that appear to be based only on the immediate removal of an element after any amount of overload. Such a model violates NERC criteria for overload protection [1]. Our model is instead a discrete event simulator that does not assume that all relays will trip at the same time. In particular, we model equipment under stress, such as current overloads of 50-100% of the line rating. This model is based on the curves from manufacturers [2, 10] that relate the overload of the device to the time until it trips—e.g., if the overload of the line increases significantly, the trip time would be much shorter.

Third, we also perform the first large-scale transient analysis of MadIoT attacks on a real-world North American regional system with over 5,000 buses. This large-scale analysis shows that the most powerful MadIoT attacks can partition the bulk power system into three or more isolated islands. The power grid does not go into a system blackout, but each island will be more vulnerable to future contingencies. This is a new effect that has not been considered before.

Because by repeating the same attack conditions from previous work did not cause any blackout in our system, we introduce new variations of the MadIoT attacks where for example, the attacker systematically tries to create oscillations of demand in order to drive the system into a more vulnerable state before launching the second stage of the attack.

Finally, all our simulations are done in PowerWorld [4], which is an industry-standard transient and AC steady-state solver, as its basic building block, so the basic physics of the system are represented with industry-accepted fidelity.

These contributions are summarized in Table 1.

### 3 Cascading Outage Analyzer

This section summarizes our Cascading Outage Analyzer (COA) tool. The COA model considers both steady-state and transient stability analysis in different time scales but coordinated so the transition of system stability from one steady-state operating point to another is present. The basic model checks for conditions that would trigger protective relays, and assesses the time when relays will be triggered.

Table 1: Contributions

Contributions	Our Work	Previous Work [24, 47]	
Simulations	Transient	PowerWorld	
	Steady-state	Matlab	
	<b>Combined transient and steady-state analysis</b>	Yes	No
Transient Analysis	<b>Under Frequency Protection</b>	Yes	No [47]
	<b>Frequency in all buses</b>	Yes	No [24]
Steady-state Analysis	<b>Power Flow</b>	AC	Not Specified
	<b>Time for Over Current Protection</b>	Yes	No
	<b>Time for Voltage Protection</b>	Yes	No
New MadIoT Attacks	<b>IoT Demand Increase and Decrease</b>	Yes	No
	<b>IoT Repeat</b>	Yes	No
Scale of Analysis	<b>Case used in Transient Simulation</b>	A North American regional system with over 5,000 buses	Up to WSCC 9-bus system
	<b>Case used in Steady-state Simulation</b>	A North American regional system with over 5,000 buses	Polish system with 3,120 Buses

The framework of the COA is described in Figure 3. The simulation has both transient and steady state parts. For each contingency, a transient simulation is run using the PowerWorld transient simulation tool. If the system reaches a stable state, then simulation results are sent to the steady state simulation as initial values, where an AC power flow is run. Based on the resulting line flows and voltage magnitudes, the timing for activating protection equipment is then computed.

If there are any new protection equipment activated from this steady state simulation, the new outage will be modeled and the next iteration of simulation will start using the PowerWorld transient simulation tool. This multi-time scale process continues until no outage occurs in both the transient and steady-state parts of the simulation, or until the transient simulation is unable to solve the problem, in which case an “algorithmic non-convergence” is declared to have occurred as a proxy to a system blackout.

We now describe how each of the four protection systems we consider are modeled.

#### 3.1 Protection of Generators

If a mismatch between generation and load occurs, there will be a frequency deviation from the desired nominal value (if there is more load than generation, the frequency of the system will decrease, and if there is more generation than load, the frequency of the system will increase). A big frequency deviation may trigger generator under- and over frequency-protections.

Transient stability or rotor angle stability is the ability of

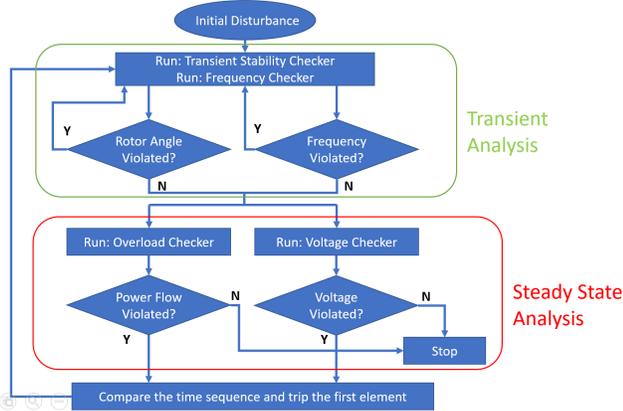

Figure 3: Overview of our Cascading Outage Analysis Tool.

the power system to remain in synchronism when subjected to large transient disturbances [37]. We choose to use time-domain simulation because the time-domain simulation takes into account the full system dynamic model and constantly checks that inter-machine rotor angle deviations lie within a specific range of values.

We use the PowerWorld transient stability solver to numerically calculate the system response after a fault. If the rotor angle deviation of a generator is bigger than a certain threshold, e.g., 100 degrees, the generator will be automatically tripped and removed from the power grid to prevent permanent damages. The disconnection of the generator won't be immediate after crossing a threshold, but it will be dependent on the amount of time that it remains in the unsafe region. We will discuss the exact configuration parameters for disconnecting a generator later in the paper.

### 3.2 Preventing the Tripping of Generators

When the system loses a generator or when there is a sudden increase in the load, the frequency of the power grid decreases rapidly. A countermeasure to prevent the activation of (more) under-frequency generator protections is a mechanism called Under Frequency Load Shedding (UFLS). The predominant system condition addressed by IEEE C37.117 involves the use of protective relays for under frequency shedding of connected load in the event of insufficient generation or transmission capacity within a power system. Therefore, we include UFLS along with over/under frequency generator tripping as frequency outage checkers in the COA model. Taking into consideration these protections embedded in power systems is one of the reasons we obtain different results when compared to previous work.

### 3.3 Overcurrent Protection

Disconnecting transmission lines because of a thermal limit violation is one of the most common events in cascading outages [53]. We trigger overcurrent protections based on the results from our steady-state results. The status and dispatch set points of units at the end of the PowerWorld transient analysis are used as starting points for the PowerWorld AC power flow simulator. An inverse-time overcurrent equation described in the Siemens SIPRO-TEC 5 Current Relay [10] is implemented in our model. The time when the over current relay trips the element is determined by equation (1),

$$T = \frac{0.14}{\left(\frac{I}{I_{th}}\right)^{0.02} - 1} T_p [s], \quad (1)$$

where  $I_{th}$  is the current threshold value of the relay, and  $T_p$  is the setting value of the relay. Both values are set by the relay operator.  $I$  is the current on the monitored component such as a transmission line or a transformer. The value of  $T$  in (1) determines when the protection will be activated. It is important to understand that overloading the line past its nominal rating does not immediately result in a transmission outage. Simplified models that do not account for the detailed behavior of protection equipment are likely to consider that a line gets out of service when in reality it keeps operating (it just sags). This is another of the reasons we obtain different results from previous work.

### 3.4 Over/Under Voltage Protection

Another typical pattern associated with cascading outages is an under (or over) voltage problem. When the system is highly stressed, the voltage profiles of power systems may decline. Even if the AC power flow calculation converges, if a bus voltage stays below the lower limit in our simulations, a load-shedding protection mechanism will be triggered in order to return the bus voltages to their limits [53].

The bus voltages are required to be on a range for the safe operation of the connected generators. A generator may also be disconnected if the voltage of the connected bus goes out of limits for too long.

We implement in our simulator a standard inverse time characteristic equation described in ABB RXEDK 2H time over/under voltage relay [2] to find the timing for the activation of voltage protection equipment. The time duration until the under or over voltage relay trips is determined in equations (2) and (3),

$$T = \frac{k}{\left(\frac{U}{U_{th}}\right) - 1} [s], \quad (2)$$

$$T = \frac{k}{1 - \left(\frac{U}{U_{th}}\right)} [s], \quad (3)$$

where  $k$  is the inverse time constant,  $U_{th}$  is the over/under voltage relay pick-up value, and  $U$  is the user defined relay operating value. The values of  $T$  in equations (2) and (3) determine when the protection will activate. As with the line overload model, over/under voltages do not immediately result in a bus outage.

## 4 Considerations for Modeling the Impact of IoT Attacks

This section will demonstrate the contribution of applying our cascading outage analyzer in the study of IoT demand attacks and in particular, this section will compare our results with previous work in order to show why we obtain different results. We will start our analysis with a relatively simple but standard Western System Coordinating Council (WSCC) model with 9 buses and 9 lines, as this is a model that has been used in previous work. We will also discuss in more detail some of our considerations for modeling the impact of IoT attacks. In the next section we will provide a detailed study on a model of a real-world North American system.

In this section we use the over/under frequency generation protection and Under-frequency load shedding parameters from Table 2 and Table 3. In the next section we will explain in more detail these parameters.

### 4.1 The Need for Combining Transient and Steady-State Simulations

Since the operation of a power system after a disturbance is a continuous process over a long time frame, a closed-loop structure of the cascading outage analyzer can better approximate the operations of the power system over various time scales after a disturbance. As previously discussed, the results and states of the system after the transient simulation are stored and set as the starting point of the steady-state simulations. The cascading outage generated from steady state simulations, if there is any, is then used as the initial condition in the transient simulation for the next loop.

Previous work considered transient and steady-state simulations as separate, and as a result, the transient impacts on generators and system frequencies are not present in the power flow simulations. Therefore the predictions of cascading outages can differ when compared to our work. Let us look at an example to see a possible inconsistency, while emphasizing the importance of a combined transient/steady-state simulation for the analysis of cascading outages caused by IoT demand attacks.

Figure 4 shows the WSCC 9-bus system considered by Soltan et al. [47]. Consider an IoT demand attack that increases all loads by 15% in the system. Now let us see what happens if a transmission line is removed if the power flow is over its rated capacity [20]. If the transient impacts of this

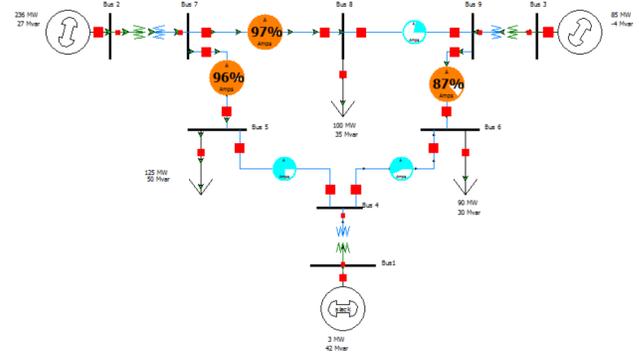

Figure 4: PowerWorld 9-bus system.

attack are not considered, the results from the steady-state power flow would indicate a line outage between bus 7 and bus 8, as highlighted with a red circle (shows the percentage of the rated capacity) in the top left corner in Figure 5.

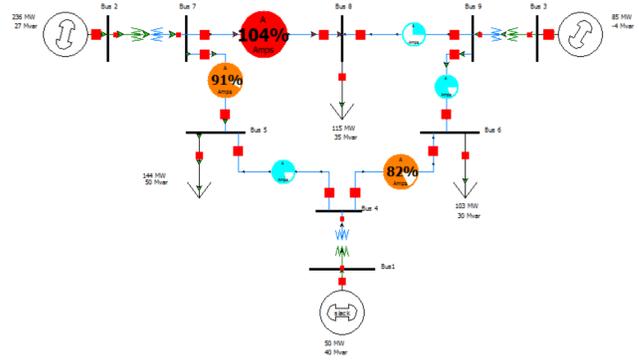

Figure 5: Power flow results of 15% of load increase.

However, because of the sudden load increase caused by the MadIoT attack, load and generation are not balanced and the frequency of the system will be affected. A frequency protection relay would disconnect a generator from the system if the frequency of the system stays lower or higher than the generator's threshold values for too long in order to prevent permanent damage to the generator. Figure 6 shows the frequency responses to the 15% load increase. We can see that the system frequency starts to decline after the attack starts (the attack starts after one second). The frequency relays then disconnect all the generators in the system two seconds after the frequency drops below the threshold of 58 Hz (table 2). Therefore, this results in a blackout in the transient simulation of the IoT demand attack. These transient stability results are different from the steady state stability study, which identified only one cascading line outage as discussed in the previous paragraph.

This is a motivating reason to include transient and steady state analysis together in a single simulation. Because transient and steady-state simulations are connected in a closed

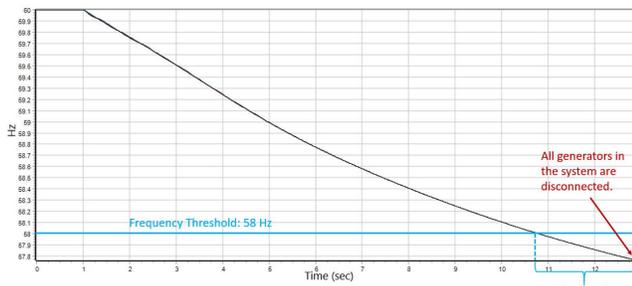

Figure 6: Frequency responses to the 15% of load increase in the transient simulation.

loop in our model, the transient solution at the end of the simulation time will be used as an initial condition for the steady-state power flow simulation. In this example, if the under frequency load shedding is not considered, which will be discussed in Section 4.2, the transient solution would include the fact that all three generators were disconnected from the system. Thus, the power flow solution would indicate a system blackout.

## 4.2 Under Frequency Load Shedding

Under Frequency Load Shedding (UFLS) is a countermeasure applied by bulk power system operators [5] to reduce the incidence of generator under-frequency tripping, which is a great danger to the reliable operation of the power systems. UFLS is a coordinated disconnection of small and non-critical (e.g., no Hospitals are ever disconnected) loads to prevent a large blackout.

To illustrate why it is important to consider UFLS in the simulation of IoT demand attacks, let us first take a second look at Figure 6. As observed, after the 15% load increase attack, the system frequency starts to decrease. Because there is no action that could relieve the imbalance between the increased load and unchanged generation, the system frequency declines fast until it drops below the thresholds of frequency protections at generators. Because the frequency stays below the thresholds for longer than the delay time set at the frequency protections, the generators are disconnected and there is a system blackout.

Now, let us compare the simulation results when we incorporate UFLS as defined by the parameters in Table 3. Figure 7 shows the frequency response to the 15% system demand increase attack on the WSCC 9-bus system. The system frequency declines after the IoT load increase attack starts at one second of the simulation time. The frequency of the system then reaches the first UFLS threshold at 59.3 Hz, and as a result, 5% of the system load is disconnected. However, this is not enough and the system frequency keeps declining until it reaches the second threshold: 58.9 Hz, and at that time a total of 15% of the system demand is disconnected and the

frequency stops decreasing and starts to stabilize to its desired state. The system frequency reaches a new stable state and there are no generator disconnections from the system.

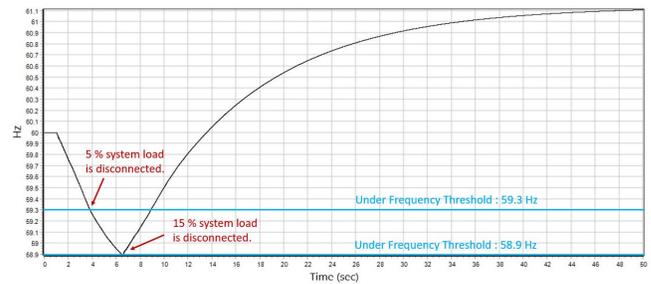

Figure 7: Frequency responses with Under Frequency Load Shedding to the 15% of load increase in the transient simulation.

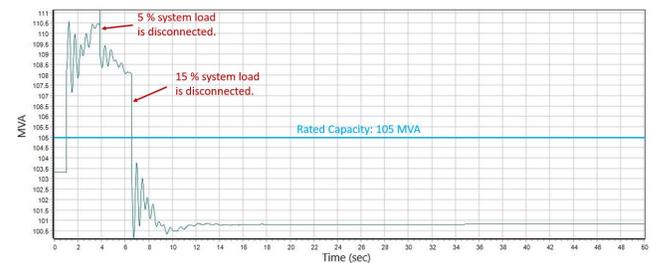

Figure 8: Power flow on the transmission line connected between bus 7 and bus 8 in the transient simulation

What is more, because of UFLS, the system load is reduced to a level where no transmission line is overloaded, and therefore there are no cascading outages. In Figure 8, we can see that the transmission line between bus 7 and bus 8 in Figure 4 is overloaded after the IoT demand increase attack begins at one second. However, the power flow on the line soon decreases following the load shedding event caused by UFLS and remains below its rated capacity at the end of the transient simulation. As discussed in Section 4.1, a power flow steady state simulation starts based on the solution of the transient simulation; the results of this new steady state stability analysis are shown in Figure 9. We can see that no line is overloaded and the combined transient and steady-state simulations end.

The example in this subsection shows that the simulation results will be significantly affected if UFLS protections are considered. In fact, by including UFLS, the closed-loop transient and steady state simulations used in this work generates a result suggesting that the system would shed some demand, but all the system transmission lines and generators will remain in operation. This result is different from the cascading line outage suggested by our steady-state simulation illustrated in Figure 5 and the complete system blackout suggested by previous work.

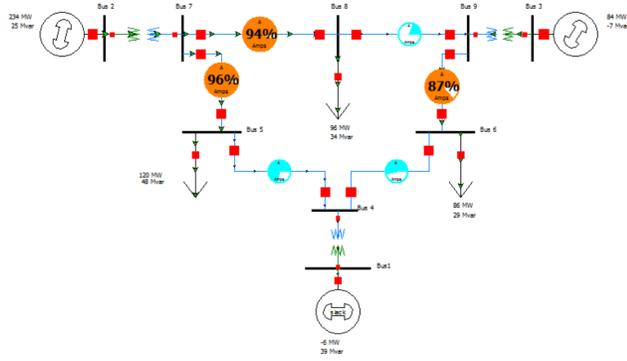

Figure 9: Power flow results after the transient simulation with UFLS.

### 4.3 Frequency Response Model

UFLS protections are indeed considered in some previous work [24]. However, the simplified frequency response model used by the authors is not a good fit to analyze IoT demand attacks. The system frequency responses used by Dabrowki et. al [24] model the power grid as a single large machine that represents an “aggregation” of all the synchronous generators in the system.

A synchronous machine is associated with a rotating magnetic field winding that induces alternating voltages in a armature windings of the stator. The frequency of the induced alternating voltages and of the resulting currents that flow in the stator windings when a load is connected depends on the speed of the rotor. The frequency of the stator electrical quantities is thus synchronized with the rotor mechanical speed, hence the designation “synchronous machine” [37]. When two or more synchronous machines are interconnected, the stator voltages and currents of all the machines must have the same frequency and the rotor mechanical speed of each is synchronized to this frequency. Therefore, the rotors of all interconnected synchronous machines must be in “synchronism” [37].

In contrast, the assumption of Dabrowski et. al [24] is that every generator in the system will respond to a disturbance exactly the same. In other words, the implicit assumption of this model is that all the generators in the system will always keep synchronism and respond identically. However, when the system is under a significant disturbance, generators will respond differently to the disturbance and the system will have the risk of losing synchronism in a short time after the disturbance. In some scenarios, the frequency protections will contribute to a lack of synchronism, and therefore, the frequencies at different buses will diverge from synchronism. All of this frequency diversity can not be reflected in the single machine mode [24]. A detailed discussion of why this phenomenon is important will be demonstrated in subsection 5.4, where we show how different parts of the grid start operating at different

frequencies and therefore the system becomes a set of islands operating semi-independently.

### 4.4 Line Overloads

The line overload outage models also play an important role in understanding the impact of MadIoT attacks. Previous work [47] relied on the criteria described by Cetinay et al. [20], where a line will be removed from the system if the steady-state results indicate that the power flow on the line is greater than its rated capacity. When a transmission line is overloaded, the heat generated from the extra power flow on the line will sag the transmission line. Although it exposes the line to a possible outage from faults associated with ground element or vegetation, it does not necessarily cause any immediate real danger to the system. In fact, under an emergency, the system operator is allowed to use overloaded transmission lines for additional transmission capacity [6]. Therefore, instead of immediately removing the overloaded lines, we utilize a model that calculates the time of tripping given the overload level. The details are described in Section 3.3. The time inverse calculation in the outage protection mechanism will result in a quick tripping time for the lines that are heavily overloaded. In this way, we approximate the different actions taken at different levels of overload on transmission lines.

### 4.5 IoT Demand Attacks

In addition to fixed demand increase (or decrease) attacks, we also consider attacks that increase and then decrease the load. The intuition for this attack is that the first part of the attack will force automatic responses from the grid (such as UFLS) and therefore when the system starts operating with a reduced load, a reversal in the load (a big decrease) can drive the system to a potentially unstable state. After initial attack increasing the demand, the attackers will decrease the demand when they think the system frequency reverses due to UFLS and intend to overshoot the system frequency over the thresholds of generator frequency protections in the hopes of causing a generator disconnection.

This demand increase and decrease attack was studied by Dabrowski et al. [24]. However, our results will differ because of their simplification of the frequency model, as discussed in Section 4.3. In addition, if the attacker can cyclically increase and then decrease demand, it is reasonable to assume that the attacker is capable of repeating this attack. The simulation results and detailed discussions of the experiments are shown in Section 5.

## 5 Simulation Results in a Large Power System

The study case we use to analyze the impact of the IoT demand attacks is a large North American regional system with more than 5,000 buses, and as such it is the largest study

Table 2: Over/Under Frequency Generator Tripping. Source: Section 2.6.1 of [5].

Over Frequency Threshold	Time Delay	Under Frequency Threshold	Time Delay
60.6 Hz	9 min	59.4 Hz	9 min
61.6 Hz	30 sec	58.4 Hz	30 sec
61.8 Hz or above	0 sec	58.0 Hz	2 sec
		57.5 Hz	0 sec

done on the impact of IoT attacks on power systems. Unfortunately, because our close collaboration with the operator of this power systems we are required to maintain the confidentiality of this system and we are not allowed to share the name of the system or details of their network topology. Before we describe our simulation results we clarify our assumptions.

## 5.1 Assumptions

We state three main assumptions about an IoT demand attack:

1. IoT attackers have full and unlimited ability to control the compromised portion of loads;
2. The actions of attackers to increase or decrease the compromised loads are simultaneous;
3. The portion of the system demand compromised by the cyber attackers are evenly distributed at each demand connection point in the transmission system.

The third assumption is a speculation about the scalability of an IoT attack. For example, if the adversary is able to compromise one brand of air conditioner, they can systematically apply the attack to as many air conditioners as possible in the target system. Thus, if the total energy capacity of all such air conditioners is 10% of the system demand, this 10% of demand is likely to be spread to every demand connection point in the transmission system.

### 5.1.1 Parameters Used for Protection Equipment

There are two protections implemented in the transient simulation, namely Over/Under Frequency Generator Tripping (O/UFGT) and Under Frequency Load Shedding (UFLS). If the frequency at a bus deviates from a predefined threshold for more than a specific time period, the generator connected to that bus will be tripped, and a certain percentage of load connected to the bus will be shed. The details of O/UFGT and UFLS are shown in Table 2 and Table 3 specifically.

Since the current and voltage responses in the system are normally slower than frequency responses, the Time Inverse Overload, Time Inverse Under Voltage Load Shedding, and Time Inverse Over Voltage Generator Tripping are modeled

Table 3: Under Frequency Load Shedding. Source: Section 2.6.1 of [5].

Frequency Threshold	System Load Relief	Time Delay
59.3 Hz	5 %	0 sec
58.9 Hz	15 %	0 sec
58.3 Hz	25 %	0 sec

in the steady state simulation. Each protection checker will calculate tripping times once the current flow on branches or the voltage at buses exceed the thresholds. The element (branch, generator, or load) with the shortest tripping time will be tripped as the initial conditions for the next iteration of transient simulation. The parameters of the steady state protection models described in equations (1-3) are listed in Table 4.

Table 4: Steady State Protections. Source: [53]

	Over Load	Over/Under Voltage	
		over	under
Threshold	$I_{th} = 2 \times \text{line limit [amps]}$	$U_{th} = 1.3 \text{ [pu]}$	$U_{th} = 0.8 \text{ [pu]}$
Parameters	$T_p = 0.05$	$k = 0.5$	$k = 0.5$

## 5.2 Demand Increase Attacks

The most intuitive MadIoT attack against the power grid is a sudden increase of demand. This will attempt to overload the transmission lines and potentially cause cascading failures.

### 5.2.1 1% Demand Increase Attack

Previous work showed that a 1% increase attack against the Polish power grid in 2008 caused cascading failures. In their system, a 1% load increase corresponded to 210MW, requiring the adversary to compromise about 210,000 air conditioners. In our system, one percent of the load is equivalent to 822.7 MW, which would require the attacker to compromise approximately 822,000 air conditioners.

Figure 10 shows the bus frequency responses after 1% of load increase at second 1 and Figure 11 shows the power flow on branches as a percent of the branch rated capacity. We can observe that the bus frequencies shown in Figure 10, decline after the attack at second 1 except for very few buses that are connected to the region outside of the system with DC tie lines (the ones that remain at 60Hz on top of the diagram) and thereby remain less affected.

The rest of the frequencies decline from 60 Hz to 59.875 Hz in about 9 seconds and settle to a new stable state towards the end of the transient simulation. As indicated in table 2 and table 3, the system frequency doesn't violate any thresholds of

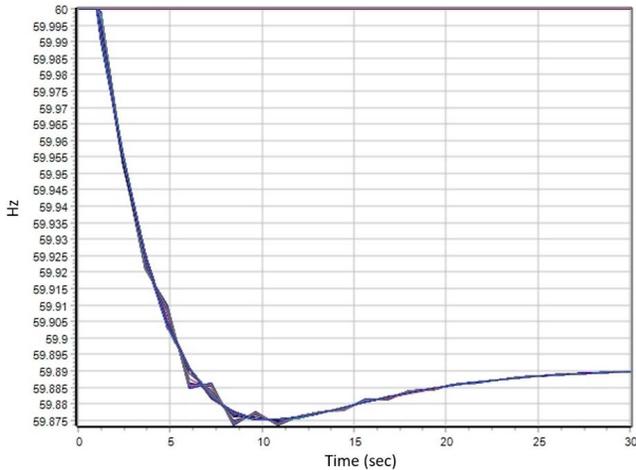

Figure 10: Frequency Response to 1% System Load Increase.

frequency protections on generators and loads. Notice that we focus our study in a short time window, since 30 seconds of transient simulation is enough to display the moving trends of the frequency in this case. In short, we can see the how the frequency is affected after the attack; however, as long as the bus frequency converges to a stable level, driving the frequency back to 60Hz can be accomplished either automatically or manually over a longer time scale.

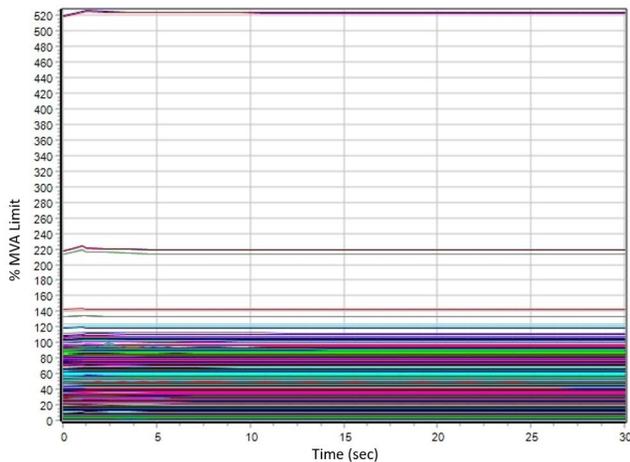

Figure 11: Branch Flow after 1% System Load Increase.

In Figure 11, we can see that the power flow of some branches slightly increases after the attack at second 1. However, no transmission line is overloaded resulting from the IoT 1% load increase attack. Note that some branches are initially overloaded before the simulation and remain unchanged during the simulation and the overload outage checker is not activated on those lines under the assumption that protection in the actual system would not have been activated under these conditions.

In summary, a 1% load increase attack does not affect our system and there is no need to activate any protection equipment as the transmission lines remain operating in their nominal values and the frequency of the system does not reach thresholds to activate any protection.

In contrast to our results, Soltan et al. [47] find that with a 1% increase in load there could be cascading outages in the summer peak of the Polish grid. We are surprised that a sudden 1% increase in load can lead to cascades in a power system. The reason for our surprise is the N-1 security criterion.

The N-1 criterion requires that electricity systems be operated to be able to withstand sudden step changes in the supply-demand balance due to outages of generation. The NERC disturbance control performance standard [8] requires any system to be able to withstand “the most severe single contingency” which may include certain common-model double outages. For ERCOT, for example, (the Power Grid of Texas) this amounts to always having 2700 MW or more of reserves to cope with a simultaneous outage of nuclear units having total production of around 2700 MW. To put that in perspective, peak load in ERCOT is around 70GW, and 1% of 70GW is 700MW, which is much smaller than the 2700MW of reserves carried in ERCOT to satisfy the N-1 criterion.

While an increase by 700MW in load due to an IoT attack (and the reaction by generation reserves) would result in somewhat different changes in transmission flows compared to the effect of a 700MW decrease in generation (and the reaction by generation reserves), we believe that it is unlikely that an increase in load of 1% would result in any unacceptably adverse conditions on the transmission system. This is because load is geographically distributed around the system, so that it is unlikely for there to be a more than a 1% increase in most transmission flows, and it is unlikely that the system is operating such that a 1% increase in current would immediately trigger the overload protection.

In the Eastern and Western Interconnections of North America, the total load is much larger (several hundred GW) but even 1% of this would only amount to slightly more than the double outage of a nuclear unit (plus it would require millions of compromised IoT devices). To summarize, the results of the Polish power grid reported by Soltan et al. [47] suggest that the system being modeled is not N-1 secure.

### 5.2.2 10% Demand Increase Attack

Ten percent of system load in our case study is equivalent to 8,227.3 MW, which would be equivalent to an adversary controlling over eight million air conditioners. Figure 12 shows the bus frequency responses after a 10% load increase attack at 1s and Figure 13 shows the power flow on branches as a percent of the branch rated capacity.

To better understand the variations of power flow depicted in Figure 13, let’s first take a look at Figure 12. From Figure 12, we can observe that the bus frequencies plummet after the

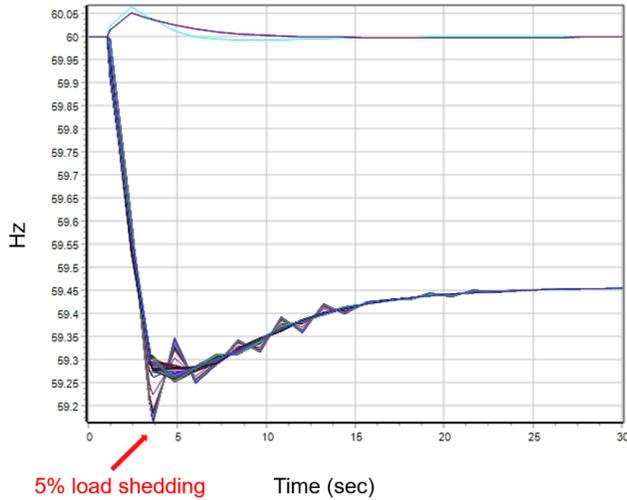

Figure 12: Frequency Response to 10% System Load Increase.

attack begins (1s). The only lines that are not affected are the few buses that connected our power grid to another region outside the system with DC tie lines (the frequencies at the top of the figure).

In contrast to the previous 1% attack, with a 10% demand increase the power system needs to activate protection algorithms; in particular, 5% UFLS is activated at 3.5 seconds by shedding 5% of the system load. Again, as long as the bus frequency converges to a stable level, the differences between the converged value and its initial value of 60 Hz can be fixed either automatically or manually over a longer time scale.

Although the under frequency shedding has no deliberate time delay as indicated in Table 3, a 0.02 second of relay operation time is included in the simulation. Therefore, the load shedding occurs 0.02 seconds after the time frequency falls below the first UFLS threshold of 59.3 Hz.

In Figure 13, we can see that the power flows of some branches increase after the attack starts (1 sec.). However, the power flows of those branches drop to or gradually decrease to roughly their initial values after the under frequency load shedding protection is activated at 3.5 seconds. Therefore, at the end of the simulation there is no additional transmission line overloaded. Note that some branches are initially overloaded before the simulation and remain unchanged during the simulation and so, as in the previous example, the protection mechanisms for these transmission lines are not activated.

Even with the assumption of millions of compromised IoT devices to affect 10% of our load, our results show that the power grid protections to prevent generators from disconnecting from the system are effective in mitigating any further problem. The amount of UFLS is intended to reflect ERCOT standards. The Eastern and Western Interconnections may

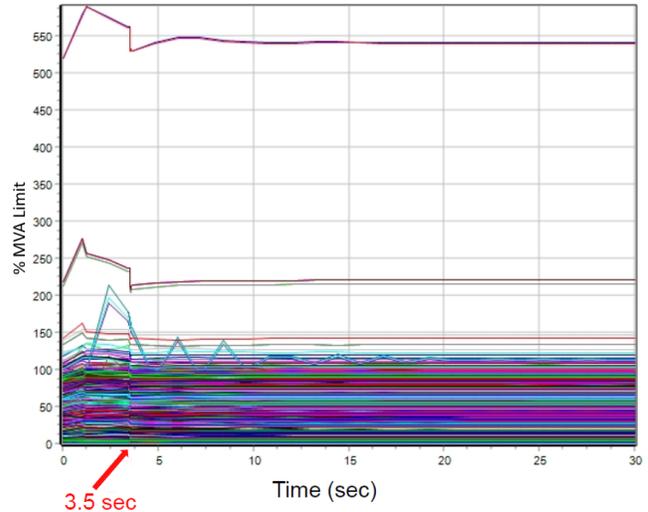

Figure 13: Branch Flow after a 10% System Load Increase.

have overall lower levels of UFLS than ERCOT; however, they have much larger levels of inertia than ERCOT.

### 5.3 Increase and Decrease Attack

One of the characteristics of IoT attacks, is that they are highly distributed they are hard to detect. Once the load is compromised, the compromised devices are unlikely to be removed from the grid (or the Internet) in a short time after they launch the first attack. Therefore attackers can launch a sequence of attacks, the first as an attempt to drive the system to a vulnerable state, and the second to exploit that vulnerability.

In the last attack we saw how under frequency load shedding successfully prevented a cascading failure of transmission lines from a single 10% load increase attack. However, a sophisticated attacker can identify when the system frequency starts rebounding after the initial drop, and can attempt to make this trend continue by immediately decreasing electricity consumption. This can cause a frequency overshoot that may trigger the action of over-frequency protection relays on the generators and disconnect them from the power grid; creating another cycle of frequency decrease along with new load shedding etc.

A straightforward approach in this experiment is to increase the load at the first attack and decrease the same amount of load at the second attack. However, we investigate a potentially worse scenario where in the second attack, we decrease by twice the amount of the load increase in the first attack (minus the percentage of the load that the attacker loses control of after the under frequency load shedding implementation).

The result in Figure 14 shows that the frequency does overshoot after the loads decrease at second 20, however the system frequency tends to stabilize at 61.7 Hz, which happens about 10 seconds later. From Table 2, we can observe that

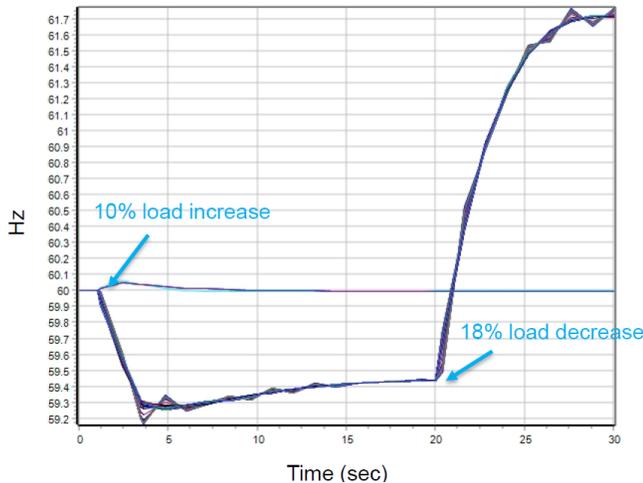

Figure 14: Frequency Response to a Cycle of Load Increase and Decrease

61.7 Hz will not cause an immediate generation trip by the frequency protections at the generators.

As mentioned in Section 5.2, a 10% system load compromised by the adversary is already a pessimistic assumption. We take this even further to 20% of the system load in this simulation to see if the IoT attack can cause a cascading result. However, we still do not observe an immediate generation trip after this demand increase and decrease attack in a system that is intended to reflect ERCOT standards for UFLS.

### 5.3.1 Under Frequency Load Shedding in a Repeated IoT Attack

We have explored the results of an attack “cycle” of load increase and decrease. The adversary could continue repeating this attack cycle of increasing and reducing the compromised load as long as their capabilities are not disabled by the load shedding mechanism.

The under frequency load shedding would disconnect some amount of demand each time when the IoT attack causes the frequency drop below any thresholds. Once the load is disconnected by Under-Frequency Load Shedding (UFLS) systems, the restoration of shed load is coordinated between the Independent System Operator (ISO), Transmission Service Providers (TSPs) and Distribution Service Providers (DSPs) [5]. It is fair to assume that such restoration, which requires coordination between different entities may take a relatively long time to complete. Therefore, a potential negative effect of such repeated attacks is that they can deplete the under frequency load shedding resources before they are restored, which might eventually lead to having no more UFLS protections against the attacks and will eventually cause a generator to trip.

The result in Figure 12 shows that although the system

frequency needs additional measures to be brought back to its initial frequency of 60 Hz, the frequency decline caused by 10% of system load increase can be stopped by only 5% of system load shedding. In Table 3 we can see that in ERCOT, 25% of the system load is contracted as UFLS. Under this condition, the adversary needs to apply the attack at least five times to deplete the UFLS resources. What is more, additional under-frequency relays may be installed on transmission facilities with the approval of the ISO provided the relays are set at 58.0 Hz or below in the real system [5]. That means, in reality, the adversary may need to apply the attack even more times to deplete the UFLS and cause a possible system failure.

Therefore, it may take many cycles of IoT demand increase and decrease attacks to deplete the UFLS resources, and these cycles will not only deplete the resources from a defensive stand point, but also the resources available to the adversary as each activation of UFLS will remove loads controlled by the attacker. Therefore, the efficiency, even the feasibility of the approach of using up the UFLS by such repeated IoT demand attack remains unclear.

## 5.4 Bifurcations, and Generator Tripping

### 5.4.1 30% Load Increase Attack

In Section 5.3, we briefly discussed the potential threats of generator disconnections caused by over frequency protections. In this section, we extend this discussion to IoT attacks that specifically target disturbing frequency and causing generator disconnections by frequency protection. In order to observe the response of frequency protection at generators, we study the impact of a MadIoT attack consisting of a load increase or decrease by 30%.

In previous work [47], this 30% load change attack was able to disconnect all generators of the (simplified) North American Western Interconnection, causing a complete system blackout. In our system, a 30% load increase attack would require the attacker to compromise about 24 million air conditioners.

Figure 15 shows the frequency response of our system to a MadIoT attack that increases the system load by 30%. First, we can observe that due to the sudden load increase, the bus frequencies decline dramatically and some of them drop quickly below the first UFLS threshold of 59.3 Hz. At this point 5% of the system load is disconnected by UFLS.

We notice that the frequency in some buses decline at a slower rate than others and they do not reach any UFLS thresholds. For convenience, we name this set of buses Group 1. The buses with DC tie lines are again less affected, and we call this set of buses Group 2. The group of buses whose frequencies decline faster and drop below UFLS thresholds are named Group 3. The group names are indicated in Figure 15.

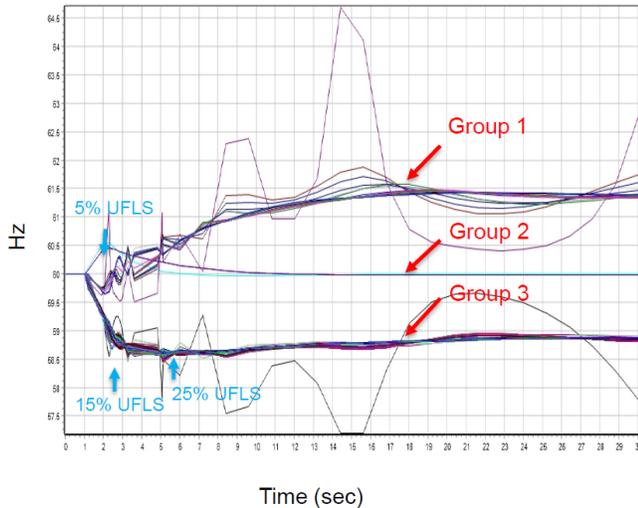

Figure 15: Frequency Response to 30% Load Increase.

Notice that, even within a group, the frequency responses are not exactly the same. Because of the first UFLS action, the frequency deviation between buses increases. After the 5% load shed, the frequency of Group 1 starts to increase—potentially this group has more generators in their region—while the frequency of Group 3 keeps declining—indicating that this region of the grid has insufficient generation of electrical power.

Shortly afterwards, the frequency of Group 3 declines to the point where the second and third UFLS thresholds, 58.9Hz and 58.3Hz, need to be activated (at around 2.6 seconds and 5.6 seconds respectively). An additional 10% of system load is disconnected in each occasion. The frequency deviation between Group 1 and Group 3 gets larger after the two UFLSs. What is more, the frequency deviation between buses in a group, especially in Group 1, increases after the actions of UFLS.

After the three activations of UFLSs for group 3, which disconnect a total 25% of system load, the frequency decline at Group 3 is stopped. Because there is no additional load shedding, the frequency at Group 1 stops increasing as well. Thus, although the bus frequencies have not converged at the end of the simulation, they stop diverging and there is no need to activate frequency protections to disconnect generators.

#### 5.4.2 30% Load Decrease Attack

We now study what happens if instead of increasing the load by 30%, we decrease the load by 30%. In this case we expect the frequencies in all buses to increase dramatically; furthermore, because UFLS can only be activated when the frequency is decreasing, then we know that there are no immediate protections to prevent a generator from disconnecting from the grid because of its over-frequency protections.

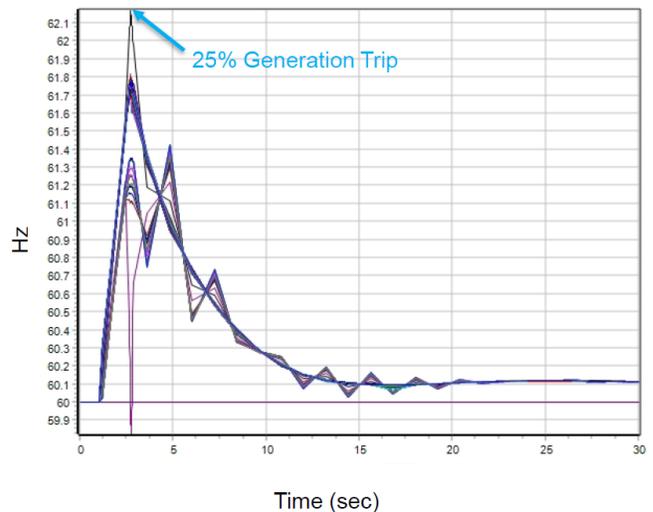

Figure 16: Frequency Response to 30% Load Decrease.

Figure 16 shows the system frequency response to a Ma-IoT attack that decreases the system load by 30%. We can see that the bus frequencies increase after the attack and a few of them go above the threshold of immediate over frequency protections at generators, which is 61.8 Hz within 5 seconds. The over frequency protections then disconnect generators, resulting in a 25% reduction of system generation. After the tripping of generators, the bus frequencies reduce and converge to a value close to 60 Hz and no more protection actions or failures are observed.

Because we model the time in which each generator is disconnected, we can see that not all of them are disconnected synchronously, as suggested in prior work, but at different times, depending on their configuration settings. When some generators are disconnected, then the frequency drops and is stabilized by the remaining generators.

Compared to the system frequency response to an IoT attack that increases the system load, we find that the bus frequencies react differently to the IoT attack that decreases the system load. In Figure 16, although the frequencies of some buses increase faster than those in some other buses, the frequencies gradually converge after 25% of the system generation is tripped. One of the conclusions we can draw from this comparison is that a quick protection reaction in big scales like the generation tripping in Figure 16 performs better than the gradual protection actions like the load shedding in Figure 15 in terms of the system frequency restoration.

We also find that the tripped generations in this simulation consist of a significant amount of wind generation. The benefit of disconnecting the wind generation or any generation that doesn't provide inertia in this condition is that the system loses less inertia after the over frequency protection action. Therefore, the system doesn't become weaker in terms of

maintaining frequency stability. This phenomenon suggests that generation that doesn't provide inertia could be included in the over frequency protection to protect the system against any following attacks targeted at disturbing the system frequency after an IoT attack.

## 6 Limitations

Our results also assume that all grid operators satisfy the N-1 security criterion. This is the general practice and should be expected as operators can get massive fines if they are found to be in violation of this criterion. Having said that, some blackouts have occurred because operators believe they are satisfying the N-1 criterion but a misconfigured protection device that should have been activated during an event was not activated, and this created an unanticipated N-2 event that initiated a cascading failure. As discussed in our summary of related work on cascading analysis, stochastic models can complement our approach by establishing the risk or likelihood that one of our protection devices does not work as expected and causes a series of cascading events.

We believe the type of protections considered in this study is the subset of the protections in power systems that would contribute to a cascading outage the most after a disturbance in the system. However, future work can be done to explore the impacts from other protections that are commonly equipped in the power systems e.g. differential and distance protections on buses [31]. In addition, in this study, we considered only an IoT demand attack that is evenly distributed across all the load points in the system. However, in future work, we will consider how feasible it is to compromise a large-scale set of high wattage IoT devices in a specific geographical area such that that target only a part of the system.

## 7 Related Work

The importance of stronger cyber security requirements in SCADA systems is highlighted by recent experiences in Ukraine. On December 23rd 2015, a third party illegally accessed the computer and Supervisory Control and Data Acquisition (SCADA) systems of three regional electricity distribution companies in Ukraine. Investigations revealed that a malware named BlackEnergy had infected the SCADA systems after successful spear phishing attacks. Seven 110 kV and twenty-three 35 kV substations were disconnected for three hours resulting in several outages that caused approximately 225,000 customers to lose power across various areas [19]. The following year, on December 17th 2016, a second power outage occurred in Ukraine and deprived part of its capital, Kiev, of power for over an hour. An assessment was made that a more advanced form of malware called "Industroyer", was used in the second cyber attack against the power grid in Ukraine [23].

While both security researchers and industry practitioners have worked on the security of the power grid for a decade, their focus has been on understanding and preventing attacks to devices in the bulk of the power grid [7, 17, 38, 48, 51], i.e., the components controlling the operation of the electrical transmission system in large geographical areas and the Supervisory Control and Data Acquisitions (SCADA) systems.

While in the U.S. the bulk power system is regulated to maintain a minimal set of cybersecurity standards [7], there is a growing push to start improving the security of systems in the distribution network. On October 19th 2017, the Federal Energy Regulatory Commission (FERC) proposed new mandatory cybersecurity controls to address the risk posed by, for example, smaller grid control centers that are typically less critical than major control centers, but which are nonetheless vulnerable to attacks [9].

Load-altering attacks have been previously studied in demand-response systems [12, 16, 21, 30, 42, 50]. Demand-response programs provide a new mechanism for controlling the demand of electricity to improve power grid stability and energy efficiency. In their basic form, demand-response programs provide incentives (e.g., via dynamic pricing) for consumers to reduce electricity consumption during peak hours. Currently, these programs are mostly used by large commercial consumers and government agencies managing large campuses and buildings, and their operation is based on informal incentive signals via as phone calls by the utility or by the demand-response provider (e.g., a company such as Enel X) asking the consumer to lower their energy consumption during the peak times. As these programs become more widespread (targetting residential consumers) and automated (giving utilities or demand-response companies the ability to directly control the load of their customers remotely) the attack surface for load altering attacks will increase.

## 8 Conclusions

This paper presents a study of the impacts of IoT demand attacks on power systems using the cascading outage analysis in a North American Regional Interconnection System.

From the simulation results, we show that, 1% of load increase attack does not interrupt any generator, load, or transmission line in the system. We also find that, thanks to under frequency load shedding protections, a 10% of sudden IoT load increase does not cause a cascading failure on the transmission lines.

A "frequency swing attack" is defined as a cycle of load increase and decrease attacks with the aim to push the frequency outside the safety limits of the generators. However, the frequency swing attack doesn't show an ability to cause an immediate disconnection of generators. We also discussed a possible repeated frequency swing attack and the potential impact of depleting the UFLS resources. Our analysis shows that the effectiveness of such attack would be impacted by

any additional frequency protection measures in the system, and by the diminishing resources that the adversary would have to continue the attacks.

We also considered high-impact attacks with control of 30% of the system load. The simulation results show that under a sudden IoT attack increasing 30% of the system demand, load shedding by UFLS would split the frequencies of the buses into islands of different operating regions of the grid. In contrast, a 30% decrease of the load would cause the frequency of the system to increase above the thresholds for over-frequency protections, and will result in the disconnection of some (but not all) generators. Our results show that the actions of UFLS and over frequency protection are sufficient to prevent an immediate system failure over a short time after the attack. Additional actions may be needed over a longer time scale to restore the stable operation of the system, but the main point is that a system blackout will likely not occur in this situation. In addition, we discover that including generations that are not providing inertia in the over-frequency protections would benefit the system in case of following IoT attacks targeted at disturbing the system frequency.

Our results show a different perspective on the risks of IoT attacks to the power grid and will hopefully serve as a starting point for new discussions to assess this threat. We show that while immediate cascading failures or a total system blackout will be very hard to achieve, the power system will still suffer negative consequences. First, UFLS will disconnect various consumers from the power grid. This is done to prevent further damage to the grid, but several consumers will be affected. Second, our attacks show that with millions of high-energy IoT devices, the attacker can potentially cause a bifurcation of the frequency in the power grid, forcing the grid to operated as separate islands and driving it to a more vulnerable state.

## Abstract

A smart home connects tens of home devices to the Internet, where an IoT cloud runs various home automation applications. While bringing unprecedented convenience and accessibility, it also introduces various security hazards to users. Prior research studied smart home security from several aspects. However, we found that the complexity of the interactions among the participating entities (i.e., devices, IoT clouds, and mobile apps) has not yet been systematically investigated. In this work, we conducted an in-depth analysis of five widely-used smart home platforms. Combining firmware analysis, network traffic interception, and black-box testing, we reverse-engineered the details of the interactions among the participating entities. Based on the details, we inferred three legitimate state transition diagrams for the three entities, respectively. Using these state machines as a reference model, we identified a set of unexpected state transitions. To confirm and trigger the unexpected state transitions, we implemented a set of phantom devices to mimic a real device. By instructing the phantom devices to intervene in the normal entity-entity interactions, we have discovered several new vulnerabilities and a spectrum of attacks against real-world smart home platforms.

## 1 Introduction

With the development of the Internet of Things (IoT), smart home technology has become widely used in many applications including safety and security [33], home appliances [5], home healthcare [13], etc. According to Statista research, more than 45 million smart home devices were installed in 2018, and the annual growth rate of home automation is 22% [51]. To manage the ever-increasing number of diverse smart home devices in a consolidated way, many companies have proposed their smart home platforms (e.g., Samsung SmartThings [52]). With IoT clouds playing a central role in building smart homes, real-world smart home platforms essentially engage **three (kinds of) entities** that interact with

each other: an IoT cloud, smart home devices and a mobile app. Briefly speaking, the mobile app provides users with an interface to facilitate the initial setup of devices including WiFi provision. After getting Internet access, each device negotiates its login credential(s) with the IoT cloud. In this way, it can build a connection with the IoT cloud to routinely report its status and execute the received remote control commands, which are usually generated by certain home automation applications running in the IoT cloud. At the same time, the mobile app is able to monitor and control each device through the IoT cloud.

While bringing substantial convenience to our lives, smart home technology also introduces potential security hazards. Since smart home devices directly process user-generated data, once compromised, they could introduce serious consequences. For example, user privacy can be harmed [28, 42]; property can be destructed [22, 38]; life safety and psychological health are also threatened [26, 54]. Imagine a smart home which is programmed in such a way that whenever the home temperature rises to a given threshold, the windows will be automatically opened. If an attacker obtains access to a smart heater, he could easily break into the home by keeping the heater at the highest temperature [21].

Although an increasing number of research studies have focused on smart home security, we found that existing research on the insecurity of interactions (e.g. inter-operations) in smart home platforms is still quite limited. First, the existing studies usually focus on individual parts of smart home platforms. For instance, there are studies disclosing the security problems with device firmware [44, 41, 28], communication protocols [14, 50, 27], and home automation applications [23, 40, 16]. Focusing on individual parts, the revealed vulnerabilities have little to do with the interactions among the three entities engaged in a smart home platform. Second, the existing studies seem to pay most attention to classic security issues such as privacy protection [24, 57], authentication [44, 41] and permission models [25, 23, 40], and leave the potential risks of the entity-entity interactions largely uninvestigated.

\*Corresponding author: zhangyq@nipc.org.cn

Third, one kind of interaction in the Samsung SmartThings platform has recently been studied in [17, 16], finding that the interaction between multiple home automation applications (i.e. IoT apps) can lead to unsafe device states. While this finding is inspiring, other essential kinds of interactions in smart home platforms have not yet been (systematically) studied in the literature. In this paper, when we use the word “interactions”, we are specifically referring to the inter-operations involved among the aforementioned three entities, with a focus on high-level pairing of devices, handshaking between IoT clouds and devices, etc.

To systematically discover and understand the security hazards in the interactions involved in smart home platforms, we have analyzed several widely-used smart home platforms and conducted the following investigations in this work. First, because all the communications among the three entities are encrypted, we combined several techniques including firmware reverse-engineering and man-in-the-middle (MITM) monitoring (to break SSL) to work out the details of the interactions among the three entities. Second, based on the interactions among the three entities, we inferred three legitimate state transition diagrams for the three entities, respectively. Using the inferred state machines as a reference model, we identified unexpected state transitions in several widely-used smart home platforms. Finally, to confirm and trigger unexpected state transitions, we implemented a *phantom* device that mimics a real device. A phantom device is essentially a computer program. By instructing the phantom device to intervene in the normal interactions among legitimate smart home devices, IoT clouds, and a mobile app, we have identified several new vulnerabilities and attacks in major smart home platforms.

In summary, the main contributions are as follows:

**New insights are provided:** (a) Real-world smart home platforms do not strictly guard the validity of the involved state transitions. For example, we found that an IoT cloud can accept some device requests without checking whether such a request should be allowed or not in its current state. (b) The three entities can sometimes stay in unexpected state combinations, which brings potential risk. (c) IoT clouds do not always perform adequate authorization checks on interaction requests. We found that an IoT cloud sometimes simply accepts and executes sensitive device-side commands without any permission checking. (d) By carefully constructing attacks that exploit a particular combination of the above security flaws, we showed that serious new security hazards can occur. This *new* finding proves that high risk attacks are rarely caused by a single factor. Accordingly, stake holders should conduct integrated insecurity analysis on interactions among the three entities.

**New hazards are discovered:** (a) An adversary can remotely replace a victim’s real device with a non-existing phantom device under his control. As a result, all the con-

trol commands from the victim user are exposed to the phantom device and further to the adversary, leading to privacy breaches. The adversary can also leverage the phantom device to manipulate the data to be sent to the victim user, thus deceiving or misleading the victim user. (b) An adversary can remotely take over a device. As a result, he can harvest the sensor readings to monitor the victim’s home or even manipulate the smart home devices, causing data breaches and endangering the victim. (c) An adversary can remotely unbind an authorised user through a phantom device. As a result, the user can no longer control the device with his account. (d) An adversary can leverage a phantom device to mislead an IoT cloud and occupy the identity of a real device before the device is sold. When a consumer buys the device, he cannot bind the device with his account. (e) An adversary can utilize a phantom device to automatically send update requests to an IoT cloud to steal various proprietary firmware on a large scale.

The newly discovered hazards have significantly enlarged the previously-known attack surface of smart home platforms; they also provide essential new understandings about the security and privacy hazards in smart homes.

*Responsible Disclosure.* All the vulnerabilities described in this paper have been reported to the corresponding vendors, and they have confirmed our disclosures. We have shared the technical details with the vendors. And most of the vulnerabilities have been fixed by them.

## 2 Background

### 2.1 Terminology

To make the presentation more clear, we first define several key terminologies.

**Device ID.** The *Device ID* of an IoT device uniquely identifies the device. Since device IDs are used to authenticate a device, they should be kept secret at all time. The attacks discovered in this study create fake IoT devices by occupying the device ID of a real victim device.

**Identity Information.** By “identity information,” we mean the information items whose values are used to generate (i.e. calculate) a device ID. A typical use case of identity information is as follows: a device first provides the IoT cloud it belongs to with its identity information, then the cloud generates and returns the corresponding device ID to the device. Frequently used identity information includes MAC address and device model. Since device IDs should be kept secret, identity information should also be kept secret. Unfortunately, we found that this rarely holds in practice and attackers can easily obtain device identity information.

**Legitimacy Information.** By “legitimacy information,” we mean the information items whose values are used to conduct certain legitimacy checking of a device, but are not used to

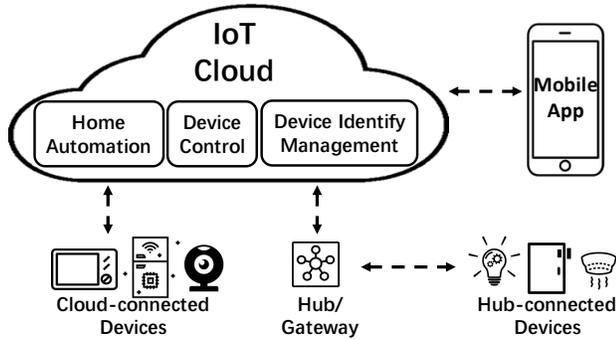

Figure 1: Smart Home Platform Architecture

generate any device IDs. We found that such information can also be easily acquired by hackers.

**Phantom Devices.** A phantom device is used by us to analyze the smart home interactions and to launch attacks. It is essentially a computer program that is instructed to intervene in the normal interactions among legitimate smart home devices, IoT clouds, and mobile apps.

## 2.2 Overview of Smart Home Platforms

The architecture shown in Figure 1 is widely adopted by major cloud-based smart home platforms. There are three key entities interacting with each other on a smart home platform: the IoT devices, the mobile app, and the IoT cloud.

The IoT cloud is the brain of a smart home platform. It is usually responsible for three kinds of services, denoted as Device Identify Management, Device Control, and Home Automation as shown in Figure 1. First, in order to ensure that only the device owner and delegated users have access to a device, the device identify management service needs to maintain a one-to-one mapping between the owner’s account and the device. This binding happens at the time when the device is firstly deployed. As soon as the device is undeployed, the binding relationship should be revoked. Second, in order to allow authorized users to remotely control a device, the device control service serves as a “proxy” when users send remote commands to the device. Lastly, most smart home platforms provide home automation services, in which users can customize automation rules that define the interoperability behaviors of smart home devices. For example, a home owner can craft an automation rule that turns on the air conditioner if the indoor temperature goes above 70°F. When a thermometer detects that the temperature exceeds the specified threshold, it sends the event to an in-cloud home automation application, which then sends a command to turn on the air conditioner.

The second type of entities in a smart home platform are IoT devices. IoT devices are equipped with embedded sensors and actuators that interact with the physical world and send sensor readings to an IoT cloud. There are two typical mechanisms for devices to connect to an IoT cloud. (a)

Table 1: Two Types of Smart Home Platforms and Their Differences

	Platform	Device Registration	Device Binding/Unbinding
<i>Type I Platform</i>	Alink, Joylink	Device ID Generated by Cloud	Authorization Checking Performed by Cloud
<i>Type II Platform</i>	SmartThings KASA, MIJIA	Skipped	Authorization Checking Performed by Device

WiFi-enabled devices can connect to the Internet and thus directly communicate with the IoT cloud. We call these devices *cloud-connected devices*. (b) Energy-economic devices are not equipped with a WiFi interface to directly interact with the IoT cloud. Instead, they first connect to a hub/gateway using energy-efficient protocols such as Z-Wave and ZigBee. Then the hub connects to the IoT cloud on behalf of the IoT devices. We call the devices connected to a hub as *hub-connected devices*. It is worth noting that the hub itself is one kind of cloud-connected device. Some platforms support both cloud-connected and hub-connected devices, while some only support one kind. The third kind of entities on a smart home platform are mobile apps. They provide users with an interface for device management (e.g., binding a device with its owner’s account) and customization of the in-cloud home automation services.

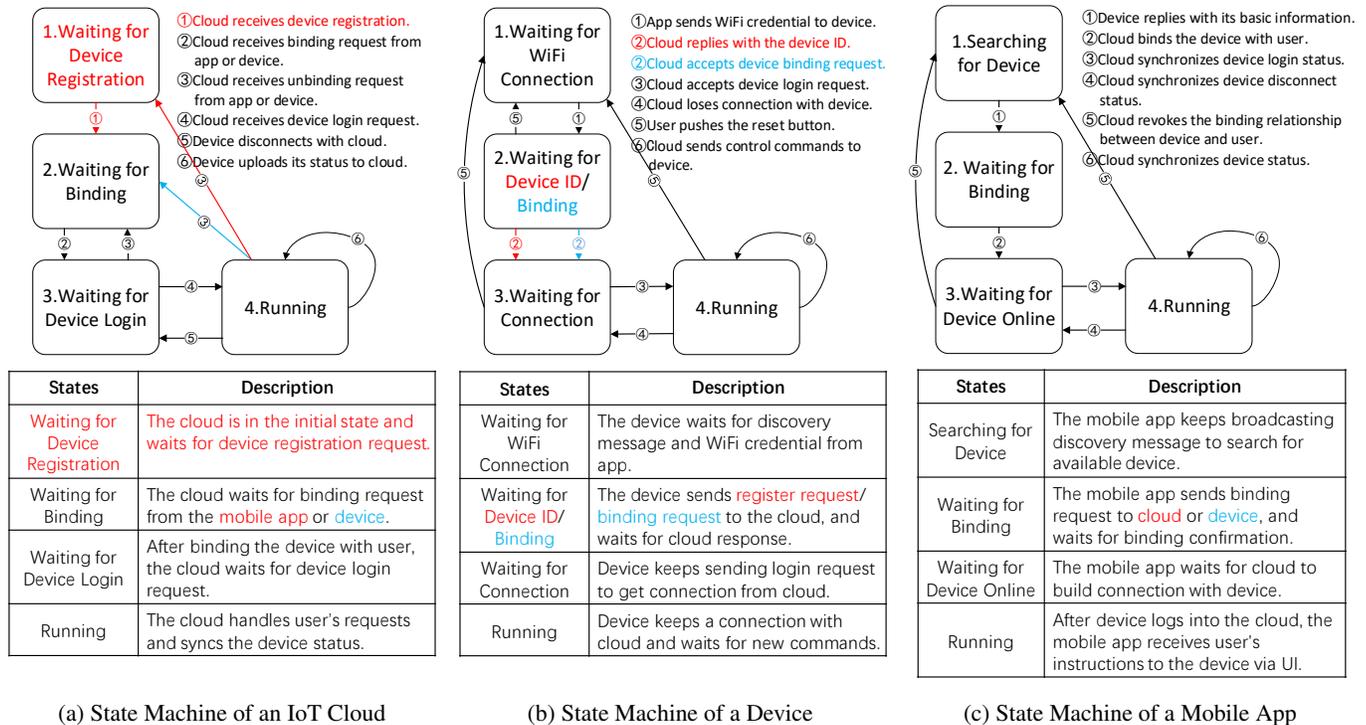

**Deployment.** To standardize and simplify the deployment of IoT services, smart home platform providers often provide collaborating partners with software development kits (SDKs). With SDKs, the adopting manufacturers only need to focus on device-specific initialization procedures and core application logic. Features such as over-the-air (OTA) update are also integrated in the SDKs.

## 2.3 Overview of the Interactions on Smart Home Platforms

In this section, we depict the interactions among the three entities during the life-cycle of a smart home device from the viewpoint of a consumer (rather than a manufacturer, supplier or retailer). To make the description more clear, the description focuses on cloud-connected devices. Hub-connected devices follow a similar model except that they use a hub as an intermediate node.

*Type I vs. Type II:* Depending on how the device ID of a device is generated, we classify the smart home platforms investigated in this work into two types. How a device ID is generated further influences device registration and device binding/unbinding. In Table 1, we list the investigated platforms for each type and the key differences between the two types. These differences lead to different attack preconditions in attacking a smart home platform.

In the following, we try to abstract an interaction model for *Type I* and *Type II* smart home platforms. When there is a difference between the two types, we also explicitly report it. In Appendix C, the complete interaction diagrams for all

Note: The states and transitions specific to *Type I* platforms are shown in red; the states and transitions specific to *Type II* platforms are shown in blue; and the shared states/transitions are in black.

Figure 2: High-Level State Machines of the Three Entities

the studied platforms are given.

**1. Device Discovery:** The life-cycle of a newly bought smart home device starts with device discovery. After the home owner (i.e. the customer) clicks the “Add Device” button on the designated mobile app, the app establishes a local connection with the device through broadcasting a discovery message or through the device’s access point. Then, the device reports its basic information, such as its MAC address and device model, to the mobile app.

**2. WiFi Provisioning:** To access the Internet, the IoT device needs to join the same LAN as the mobile app. To obtain WiFi credentials, there are several mechanisms such as Access Point Mode [18], WiFi direct [4] and SmartConfig [29].

**3. Device Registration:** After device registration, the IoT device is given a unique device ID. Different types of platforms provide device IDs in different ways. For *Type I* platforms, the device sends its device identity information to the IoT cloud it belongs to. The cloud then generates a device ID and returns it to the device. The device then writes the device ID to its persistent storage. The cloud also keeps a record of the device ID for future authentication. For *Type II* platforms, the device’s device ID is generated by the device’s platform beforehand and hard-coded into the device during fabrication. Therefore, device registration is skipped.

**4. Device Binding:** The IoT cloud binds the device’s device ID with the user account of the home owner. As a result, only authorized users can access the device via the cloud. The two types of smart home platforms adopt different device binding methods. For *Type I* platforms, the binding request is directly sent by the mobile app to the IoT cloud, which is responsible for maintaining the binding information and performing the permission checks (i.e., whether a user account should have access to a device). For *Type II* platforms, the mobile app first sends the account information to the device. The device, having the device ID and the user account, issues the binding request to the IoT cloud. It is worth noting that here the cloud unconditionally accepts the binding request from the device. This design is based on the natural assumption that the customer who physically owns a device should have full control over it.

**5. Device Login:** The device uses its device ID to log into the IoT cloud. Then it establishes a connection with the cloud to keep the status updated and ready itself to execute remote commands. In addition, when a device loses connection with the cloud for a long time, it tries to re-login automatically.

**6. Device in Use:** After successful registration and login, the device performs designed functions. Specifically, the home owner can monitor the real-time status of the device and ex-

PLICITLY control the device locally or remotely via the “control panel” on the mobile app.

**7. Device Unbinding & Device Reset:** When the home owner no longer uses the device, she can unbind or reset it. When the user requests for unbinding, for *Type I* platforms, the cloud directly erases the binding information. For *Type II* platforms, however, since the binding information is also stored on the device locally, one additional command is sent from the cloud to the device to erase the binding information.

In the life-cycle of an IoT device, although most of the time is spent in the sixth phase, i.e., the device-in-use phase, the interactions that occur during the other phases are the most complex and critical. Any oversight in these phases could lead to serious security problems and harm the normal use of devices.

## 2.4 State Transitions

In this subsection, we describe the state transitions inferred from our analysis of five widely-used smart home platforms (i.e., Samsung SmartThings [52], TP-LINK KASA [53], Xiaomi MIJIA [56], Ali Alink [2], and JD Joylink [31]). A smart home platform is a special kind of distributed system. In this viewpoint, the aforementioned interactions among IoT devices, mobile apps, and IoT clouds unavoidably cause state transitions. Based on our analysis of the aforementioned five platforms, we infer three state transition diagrams for the three entities, respectively. The three state machines are shown in Figure 2. In each sub-figure, an interaction with other entities (denoted by an edge) causes a state transition. The definitions for each state and each transition are annotated in the corresponding sub-figure. Note that *Type I* and *Type II* platforms behave slightly differently and we highlight the differences using different colors. Specifically, the states and transitions specific to *Type I* platforms are shown in red while the states and transitions specific to *Type II* platforms are shown in blue. The shared states and transitions are shown in black. In addition, since *Type II* platforms use hard-coded device ID, state 1 is absent in the state machine of an IoT cloud.

**State Correlation.** The three state machines are closely related to one another. Whenever an interaction takes place, the three entities as a whole may transfer from one 3-tuple state combination (i.e., the current state of the IoT cloud, the current state of the device, and the current state of the mobile app) to another 3-tuple. We identify all the legitimate 3-tuple state combinations and show them in the table presented in Appendix A. If a 3-tuple does not appear in the table, the corresponding state combination is illegal and might be exploited. To avoid the potential attacks, the three entities should always stay in a legitimate state combination. Unfortunately, we found that none of the investigated smart home platforms strictly maintain a three-entity state machine.

## 2.5 Scope of Empirical Vulnerability Analysis

Real-world cloud-based smart home platforms can be classified into two categories. The first category is the platforms *dedicated* to building a smart home (e.g., Samsung SmartThings [52]). The second category is general-purpose IoT platforms (e.g., Amazon Web Services IoT [6]) which could be customized for smart home usage. Since smart home platforms of the second category usually differ from each other in terms of device management and interaction, we leave studying common security issues with them as our future work. In addition, smart home platforms that are not cloud-based, such as HomeKit [8] and HomeAssistant [10], are out of the scope of this study, although we will discuss the implications of our research findings to platforms that are not cloud-based in Section 7.2.

In this work, we focus on five leading cloud-based smart home platforms. As mentioned earlier, they are SmartThings, KASA, MIJIA, Alink, and Joylink. To attract more cooperative manufacturers, some smart home platform providers such as Samsung, JD, and Ali make their platforms open and even open-source the corresponding device-side SDKs. Thus, the collaborative manufacturers can easily follow the documentation and assemble platform compliant devices through proper use of the SDKs. Over 200 well-known smart home device manufacturers (e.g., Philips, ECOVACS, and Media) are actually fabricating products running on these platforms [3, 30].

Some other cloud-based smart home platform providers, including TP-LINK and XiaoMi, adopt a closed “ecosystem”. They fabricate smart home devices by themselves. On North America and Europe markets, TP-LINK’s smart home devices, such as smart WiFi plugs and smart LED bulbs, rank in the top 10 in the category of home improvement on Amazon [19]. XiaoMi is the world’s largest intelligent smart home device manufacturer. More than 85 million smart home devices have been sold under the brand of XiaoMi all over the world [34], especially in Asia-Pacific [43].

## 3 Threat Model and Feasibility Assessment

### 3.1 Threat Model

In contrast to network-based exploits (e.g., MITM) and firmware-based reverse-engineering, the adversary in our threat model seeks to exploit the design flaws in the interactions among the three entities. Therefore, we *do not* assume any forms of software bugs or protocol vulnerabilities. The targets of the attack are cloud-connected devices which directly communicate with IoT clouds. The adversary’s goal is to take control of the device or to monitor/manipulate the data collected/generated by the device.

We *do* assume that the adversary has the capability to collect necessary information, including device *identity information* and *legitimacy information*. For different platforms, the difficulty levels of collecting these information items dif-

Table 2: Device Identity/Legitimacy Information

	Platform	Identity Info	Legitimacy Info
<b>Type I Platform</b>	Alink	MAC (G), CID (P), Device Model (P)	Key (P), Sign (P)
	Joylink	MAC (G), SN (H), Device Model (P)	NULL
<b>Type II Platform</b>	SmartThings	Device ID (H)	NULL
	KASA	Device ID (H)	MAC (G), hwID (P)
	MIJIA	Device ID (H)	TagKey (H)

P: Public information    G: Guessable information    H: Hard-coded information

fer. For example, for *Type II* platforms, we assume the adversary has local access to the victim device beforehand, whereas for *Type I* platforms, we do not have such an assumption. As a result, the discovered exploits may exhibit different levels of feasibility depending on which type of platform is being attacked, who is the platform provider, etc.

In the following, for both types of platforms, we analyze the feasibility of obtaining these information items case by case. The reason is that different platforms may designate and use individual information items in different ways. Correspondingly, the adversary faces different challenges in collecting them.

### 3.2 Prerequisites and Feasibility Assessment

In this subsection, we describe the specific identity and legitimacy information items the adversary has to obtain, and evaluate the feasibility of obtaining them in practice.

As mentioned earlier, a device is identified by a unique device ID. In essence, the discovered exploits fake a phantom device by using the victim device’s device ID. Thus, the adversary needs to get the device ID of the victim device. For *Type I* platforms, given that the device ID is determined solely by the victim device’s identity information, the adversary only needs to collect all the identity information.

For *Type II* platforms, the device ID is hard-coded in the victim device. So the adversary has to have local access to the victim device (e.g., connect to the same LAN or physically possess the device) to obtain the device ID. Although this seems to be a strong assumption, we note that once the hard-coded information is leaked, the victim device becomes remotely vulnerable forever.

Furthermore, some platforms use pre-configured legitimacy information (e.g., a key) as additional authentication requirements.

Depending on the way to obtain a particular identity/legitimacy information item, we classify these information items into three categories: public information (**P**), guessable information (**G**) and hard-coded information (**H**). For each platform investigated in this study, we list the needed identity/legitimacy information items plus their categories in Table 2. Note that the same information item may be used differently. For example, MAC addresses are used by Alink devices as identity information, but are used by KASA de-

vices as legitimacy information.

**Public information** is the easiest to obtain. Information items in this category are often publicly available or can be easily inferred. For example, device model and device chip id (CID) are public information. Moreover, legitimacy information items in this category are sometimes not uniquely bound with a device but shared by multiple devices. For example, in the Alink platform, the legitimacy information is a tuple which consists of two “confidential” numerical strings, namely Key and Sign. We found that obtaining the tuple is extremely easy – a bunch of such credentials are available in the official GitHub repositories of both the Ali company<sup>1</sup> and the cooperative manufacturers<sup>2</sup>.

**Guessable information** is the information which can be guessed by brute-force. MAC addresses are a typical kind of guessable information, because the first three bytes in a MAC address are usually fixed for a manufacturer [32]. Moreover, manufacturers often allocate a block of consecutive MAC addresses to the products of the same device model. Thus, there remains only two or three bytes for the attacker to brute-force. We detail an experiment on Alink devices in Section 6.1, in which we successfully guessed more than 7,181 valid MAC addresses. Moreover, if the adversary can be in the WiFi-range of a victim device, he can simply eavesdrop the MAC address of the device by sniffing wireless probe requests [37]. Note that this is a fundamental drawback of the WiFi protocol.

**Hard-coded information** is unpredictable, immutable, and inherent to a device. For example, a long device ID embedded in the device hardware is a typical kind of hard-coded information for *Type II* platforms. In addition, for some *Type I* platforms, hard-coded information (e.g., a serial number (SN)) is also incorporated in the generation of a device ID. Although hard-coded information cannot be obtained easily, it is immutable. Once this information is leaked, the victim device becomes vulnerable forever.

To get this information, the adversary needs local access to the victim device. For example, the adversary can get the device’s hard-coded device ID by sniffing the device-app traffic in the device’s LAN during the device discovery phase (Section 2.3). In case the adversary is using the device on behalf of the home owner, he can find the hard-coded device ID in a log maintained by the mobile app.

We now discuss the feasibility of physically accessing a victim device and the adversary’s incentive to employ the discovered exploits. First, the ownership of a device can be changed if the device gets resold or decommissioned [36]. For example, increasingly popular smart home manufacturers such as Samsung and Apple provide certified refurbished devices on the on-line outlet stores or through Amazon. The

<sup>1</sup> <https://github.com/alibaba/AliOS-Things>

<sup>2</sup> <https://github.com/espressif/esp8266-alink-v1.0>

previous owner can easily extract the hard-coded credentials before re-selling the device. We have successfully obtained the device ID of a Samsung POWERbot R7040 Robot Vacuum in our experiments. If we resell or return this device, we can control this device remotely even after it is sold to another user.

Second, a recent study shows that 60% of guests would actually pay more for a vacation rental home with smart home features [15]. Thus, vacation rentals and hospitality service providers like Airbnb.com and Zillow.com have been collaborating with smart home providers to equip an increasing number of smart home devices (e.g., smart locks, cameras and TVs) in their apartments and hotels [7]. For instance, JD has worked with Zillow to deploy Joylink smart home devices in Zillow rental rooms [47]. If the adversary “legitimately” rents a vacation home for one night and extracts the device ID of the home’s smart lock, he could remotely open the lock at will in the future. This poses a serious threat to the safety of other tenants. We have successfully conducted such a remote hijacking attack against an Alink device (i.e., a KAADAS smart lock with model KDSLOCK001) in lab environment.

## 4 Analysis Methodology

The discovered exploits leverage a set of design flaws in the interactions among the three entities. This section elaborates the vulnerability analysis methodology we used to identify these design flaws.

### 4.1 Deciphering Communication

To protect user privacy, smart home platforms usually encrypt the communication among IoT devices, mobile apps, and IoT clouds. We must decrypt the communication traffic before we can study the interactions. This imposes significant challenge for us because some platforms are close-sourced (e.g., XiaoMi and TP-LINK).

**Cloud-App Communication.** A simple network sniffer confirms that most platforms adopt TLS, and mobile apps are required to verify the validity of the cloud (server) certificate. The MITM attack on the mobile app side is an obvious choice in deciphering the communication. However, to launch a MITM attack, we must replace the cloud certificate with one controlled by us. After analyzing a number of mobile apps, we found that a mobile app usually hard-codes the cloud certificate in its APK file without relying on the trust store provided by Android [39] (a.k.a. certificate pinning). If we replace the hard-coded certificate in an APK, the corresponding app would fail to run due to integrity checking. We have addressed this problem by rooting our test smartphone and installing an Xposed module<sup>3</sup>. This Xposed module is able to hook the certificate checking function so that we can

dynamically manipulate the certificate without compromising the app integrity.

**Device-App Communication.** We have analyzed the APK files of a number of mobile apps and found that some platforms such as Joylink and MIJIA use a symmetric encryption algorithm to protect device-app communication. Thus, we can easily extract the communication keys by analyzing the APK files. Other platforms such as SmartThings adopt TLS for device-app communication. To deal with TLS, we have used the same method as used for deciphering cloud-app communication.

**Device-Cloud Communication.** Again, device-cloud communication is protected by TLS. However, we cannot easily replace the cloud certificate embedded in the firmware on a device to launch a MITM attack as is done in mobile apps. We had to perform static analysis on the device firmware. In particular, we have physically dumped the firmware images of the target devices<sup>4</sup>. We have manually followed the data and control flows of the cryptographic functions, and were able to locate the hard-coded certificates in the firmware images. We then replaced the hard-coded certificates with a set of certificates forged by us. However, we found that the devices enforce firmware integrity verification which denies executing any manipulated firmware. Fortunately, simple reverse engineering confirms that most devices only use the simple cyclic redundancy check (CRC) algorithm to check integrity. Therefore, we updated the CRC values to match the manipulated firmware and successfully booted the firmware images with the forged certificates. As a result, we were able to launch the MITM attack to decrypt the communication.

## 4.2 Understanding the Interacting Messages

Using the aforementioned approaches, we were able to reveal plain-text network traffic among IoT devices, mobile apps, and clouds. This greatly simplified our analysis. Although different platforms adopt different communication protocols, it is a common practice that messages are encoded using the JSON (JavaScript Object Notation) format, which is quite self-explanatory. For instance, we show a message sent from a device to the cloud of the Alink platform in Listing 1. As indicated by the *method* field, this message is used to register the device. The device legitimacy information being sent includes *Sign* and *Key*. The device identity information being sent includes *CID*, *model*, and *MAC*. The respond message is shown in Listing 2. As we can see, the device ID is returned in the *uuid* field.

## 4.3 Phantom Devices

We investigated the interactions from three aspects. First, we tested whether each entity strictly maintains its state machine, which means an entity should only accept interacting requests acceptable in its current state. For example, as shown in Figure 2a, when an IoT cloud is working in state 4, it should deny the request from a device to bind itself to another user account. Second, we tested whether the three entities always stay in a legitimate 3-tuple state combination (see Appendix A). Third, we adjusted the parameters, especially those used in authentication, of the normal interacting requests and observed the responses. Our goal is to discover whether the receiving entity of each request conducts proper authorization checking.

To make this happen, we need to be able to craft JSON messages and send them to the receiving entities. However, we cannot arbitrarily change the requests of a real device. To cross this barrier, we created and ran a phantom device (program) that mimics a real device to assist our analysis. A phantom device is constructed as follows. Some smart home platform providers like Samsung, JD and Ali open-source their device-side SDKs and demo programs, which include the same communication logic as a real product. We simply reused them to build our phantom devices. On the other hand, XiaoMi and TP-LINK use proprietary SDKs, and we had to reverse-engineer the firmware we obtained from real devices, and implement programs to imitate the original communication functions.

With the help of phantom devices, we could arbitrarily adjust the parameters of request messages. In this way, we could trigger unexpected state transitions and manipulate/remove the authentication fields of a request to perform black-box testing against an IoT cloud. We shortly report our findings in Section 5.

The phantom devices not only facilitated interaction analysis, but also helped us figure out the relevant internal logic

of an IoT cloud, which was completely opaque to us. For instance, we used a phantom device to test and confirm which device identity information is used in the generation of a device ID. Specifically, for the Alink platform, we changed the value of each field appeared in Listing 1 and recorded the corresponding returned device IDs from cloud. Finally, we compared the received device IDs to infer which fields influence the generation of a device ID. We concluded that the fields *model*, *MAC* and *CID* uniquely determine a device ID. In other words, there is a one-to-one mapping between the (*model*, *MAC*, and *CID*) tuples and device IDs in the Alink platform. We used a similar method to test all the studied platforms and the results are summarized in Table 2.

## 5 Identified Design Flaws

Using the analysis methodology presented in Section 4, we have discovered four kinds of design flaws, and we have shared them with the providers of the five platforms we investigated. These design flaws are summarized in Table 3.

**F1: Insufficient State Guard.** We found that none of the three entities correctly guard their state machines. This could lead to severe consequences. Since IoT clouds are responsible for security-critical services such as device identify management, IoT clouds can be most affected. In the state machine of an IoT cloud (Figure 2a), when the cloud is working in state 4 (running), ideally it should only accept status upload requests (edge 6) or device unbinding requests (edge 3). Unfortunately, we found that the IoT cloud also accepts other requests. Depending on which request is accepted incorrectly when the IoT cloud is in state 4, we break down flaw F1 into three sub-flaws.

**F1.1:** This flaw is specific to *Type I* platforms. An attacker, having all the device identify information, can use a phantom device to send a registration request to the cloud, which is fooled to return the corresponding device ID to the attacker (Figure 3F1.1).

**F1.2:** This flaw is specific to *Type II* platforms. An attacker can use a phantom device to send a binding request that links the device (identified by device ID) with the attacker's account (Figure 3F1.2). Note that in *Type II* plat-

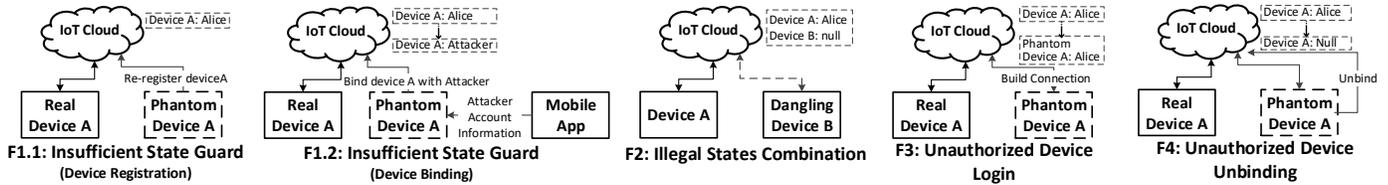

Figure 3: Identified Design Flaws

forms, the binding request is sent from the device and the cloud unconditionally accepts the binding request (see Section 2.3). As a result, the phantom device can bind the attacker’s account to the victim device.

**F1.3:** The IoT cloud accepts device login requests even if it is in state 4. This flaw is a pre-condition of flaw F3 which we will describe shortly.

**F2: Illegal State Combination.** We found that the three entities sometimes stay in unexpected and illegal state combinations. One root cause is flawed synchronization among them. When an illegal state combination is exploited, security can be violated. For instance, ideally, when a user retires a smart home device, he should reset and unbind the device, making all of the three entities go back to their initial states (i.e., state combination (S1, S1, S1)). However, for *Type I* platforms, if the user unbinds the device without firstly resetting it, a connection with the cloud is still retained and the state combination actually switches to (S1, S4, S1), which is illegal based on our table in Appendix A. Since the device is in this illegal state combination, we call it a dangling device (Figure 3F2). Now, since the IoT cloud is in state 1, if the attacker remotely issues a request to register this device, the request is allowed and the cloud transfers to state 2. For the same reason, if the attacker continues to send a request to bind the device, the cloud accepts the request and transfers to state 4 (state 3 is skipped because a connection is still maintained with the victim device). At this time, if the attacker sends a control command to the device, the cloud will mistakenly forward the command to the retired device. This essentially causes a device hijacking attack.

**F3: Unauthorized Device Login.** A connection is maintained between the device and the IoT cloud after device login. Ideally, the cloud should only allow a login request if the request is issued from the device that is bound with the owner account. However, we found that the IoT cloud does not perform any account-based authorization check during device login. In other words, the connection is decoupled from the user account. Consequently, when the attacker uses a phantom device to login with the device ID of the victim device, the cloud is fooled into establishing a connection with the phantom device (Figure 3F3). As a necessary condition of this flaw, the cloud must accept device login requests in state 4, which is exactly what Flaw f1.3 states.

**F4: Unauthorized Device Unbinding.** Ideally, only the

user who holds an account currently bound to a device has the privilege to unbind the device. This is true if unbinding operations are conducted on mobile apps, which indeed include user credentials in unbinding messages. Unfortunately, for *Type I* platforms, device unbinding can also be achieved on the device side. Based on our analysis, device-side unbinding commands do not included any user credentials. As a consequence, an attacker can build a phantom device to forge an unbinding request using device-side API. The binding relationship between victim user’s account and the device is then revoked without the user’s awareness (Figure 3F4).

## 6 Flaw Exploitation

Exploiting various combinations of the identified design flaws, an attacker can launch a spectrum of attacks, including remote device substitution, remote device hijacking, remote device DoS, illegal device occupation, and firmware theft. In the following, we first describe the experimental setup. Then we detail two most severe attacks revealed in this paper – how to remotely substitute and hijack a victim device, respectively. We also discuss the other attacks. In Table 3, we summarize the set of particular attacks, as well as the design flaws exploited by each attack. To visually demonstrate some of the discovered exploits, we also recorded two videos<sup>56</sup>.

### 6.1 Experimental Setup

All the PoC (Proof of Concept) attacks were conducted within lab environment without influencing legitimate users. The tested devices include smart plugs, IP cameras, WiFi bulbs, cleaning robots and smart gateways, covering all the studied platforms. These devices are shown in Figure 4 and we also list them in Appendix B.

**Obtaining Device Identity and Legitimate Information.** We need device identity and legitimacy information listed in Table 2 to forge a *phantom* device. As mentioned earlier, the difficulty of obtaining an information item differs. In the following, we use an Alink device (Philips smart plug with model SPS9011A) and a TP-LINK device (WiFi Bulb with model LB110) to represent *Type I* and *Type II* devices, respectively. We describe how to obtain their identity and legitimacy information. For other platforms, similar approaches can be adopted.

<sup>5</sup> [https://youtu.be/MayExk\\_PKhs](https://youtu.be/MayExk_PKhs)

<sup>6</sup> [https://youtu.be/fufEAtQq2\\_g](https://youtu.be/fufEAtQq2_g)

with the same device ID  $\mathcal{A}$ , but still keeps device ID  $\mathcal{A}$  bound with *Alice*. At this moment, *Alice* actually binds the phantom device and real device at the same time. Then *Trudy* could leverage the flaw F1.3 and F3 to log in a phantom device without *Alice*'s account information (Step T.2). Since the phantom device has the same device ID as the real device, the cloud disconnects the original connection with the real device and establishes a new connection with the phantom device. However, when the real device does not receive the heartbeat message for a while, it automatically logs into the cloud again and puts the phantom device offline. Now, the real device and the phantom device are in fact competing for connection with the cloud. To win the competition, *Trudy* configures the phantom device to login very frequently. As a result, the phantom device always wins. *Alice* now still appears to “control” a device through her mobile app, although this device has actually been replaced by the phantom device under the control of *Trudy*.

**Attack Workflow (Type II).** Similarly, the top part of Figure 6 (above the highest dashed red line) shows the normal workflow of how *Alice* uses her device on a *Type II* platform. After her mobile app sends her account information to the device (Step A.1), the device sends the binding request with device ID and legitimacy information, as well as the account information to the cloud (Step A.2). The cloud binds the device ID  $\mathcal{A}$  to *Alice*'s account. After the device logs in the cloud (Step A.3), *Alice* can control/monitor the device with her mobile app.

In the middle of the figure (between the two dashed red lines), *Trudy* launches the remote device substitution attack. Enabled by flaws F1.3 and F3, she lets the phantom device successfully log into the cloud with the same device ID (Step T.1). At this time, the device ID  $\mathcal{A}$  is still bound to *Alice*'s account. Like in the *Type I* platform, the phantom device maintains a connection with the cloud by periodically logging in. In this way, the attacker secretly substitutes *Alice*'s device with a phantom device under her own control.

**Attack Consequence: Privacy Breaches.** In normal operations, when *Alice* uses her mobile app to send a remote control command to the cloud, the cloud forwards the command to the “device”. Unfortunately, in the remote substitution attack, the real device has been replaced by a phantom device controlled by the attacker. As a result, all the control commands from *Alice* are exposed to the phantom device and further to *Trudy*, leading to a privacy breach. For example, if *Trudy* substitutes a smart plug, he could know when *Alice* turns on/off the smart plug. This information could be used to infer whether *Alice* is at home.

**Attack Consequence: Falsified Data.** In normal operations, the real device updates its sensor readings to the cloud and the result is reflected in *Alice*'s mobile app. Unfortunately, in the remote substitution attack, the sensor readings are sent from the phantom device. This gives *Trudy* an op-

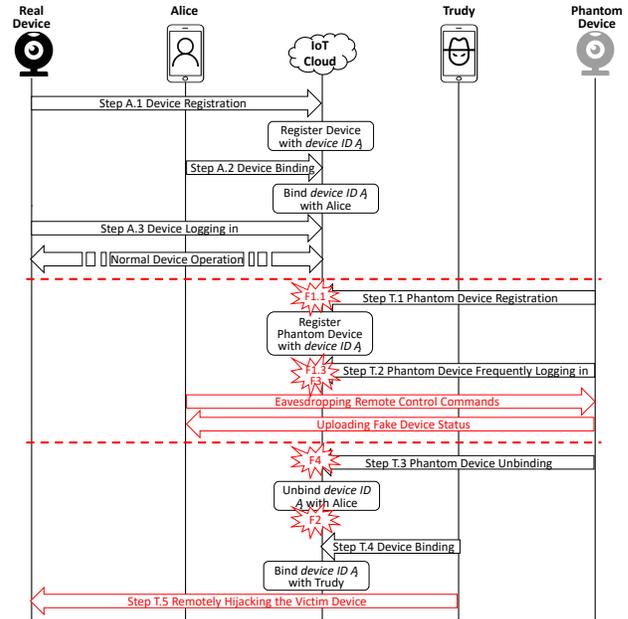

Figure 5: Remote Attacks on *Type I* Platforms

portunity to manipulate the sensor readings sent to *Alice*, thus deceiving or misleading *Alice*. For example, we tested a XiaoMi smoke alarm (model: Fire Alarm Detector) and a Alink smart lock (model: KAADAS KDSLOCK001). If the smoke alarm detects a thick smoke in the room, the smart lock will be unlocked automatically to open the window/door. We used remote device substitution attack to manipulate the sensor readings of smoke alarm and successfully unlocked the smart lock. This leads to serious consequence because *Trudy* can enter *Alice*'s room at will.

Our attack can also serve as a trigger for the flaws mentioned in previous works [17, 35]. Once a less-protected device is substituted by a phantom device and the device is in the chain of a “routine”, the phantom device can further influence other data sensitive devices. For example, as mentioned in [35], the Nest Cam monitor in a house will automatically switch off when the global “away/home” state changes from “away” to “home”. *Trudy* can take advantage of the substitution attack to change this state variable to disable the camera and burglarize the house without being recorded.

**Stealthiness Analysis.** Remote device substitution attack is highly stealthy. This is because *Alice* always sees the device to be online in her smartphone (although it is a phantom device). However, if *Trudy* feeds the phantom device with sensor readings that excessively deviate from normal, *Alice* (if she is security-savvy) might become suspicious of the dramatic change.

### 6.3 Remote Device Hijacking

*Trudy* can further remotely control *Alice*'s device by exploiting more flaws. We call this remote device hijacking attack.

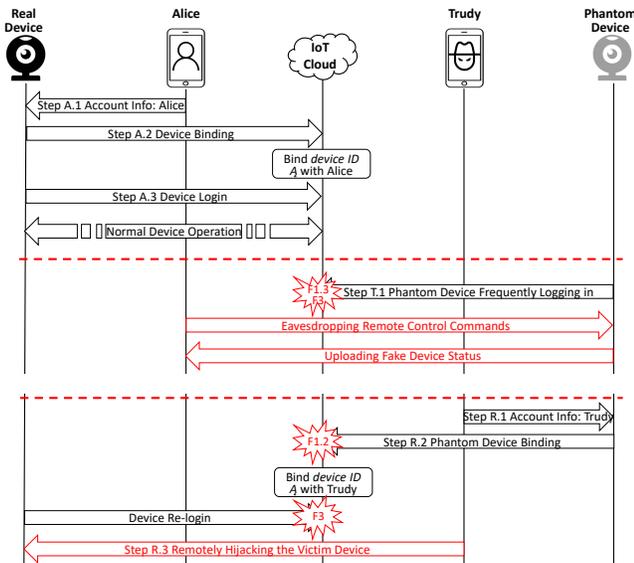

Figure 6: Remote Attacks on Type II Platforms

**Attack Workflow (Type I).** Continuing from Step T.2, device hijacking attack is depicted at the bottom of Figure 5 (below the lowest dashed red line). At this moment, the phantom device has already logged in the cloud. Due to flaw 4, *Trudy* is able to send a device-side unbinding request via her phantom device to the cloud (Step T.3), which puts the real device in dangling status (due to F2). Finally, *Trudy* binds the device with her account (Step T.4). As a consequence, *Alice*'s device is connected with the cloud whereas *Trudy* is able to control the device on her smartphone.

**Attack Workflow (Type II).** Unlike *Type I* platforms, to carry out a hijacking attack against *Type II* platforms, *Trudy* does not need to continue from the success of a remote substitution attack. Instead, she starts attacking from scratch, as depicted at the bottom part of Figure 6 (below the lowest dashed red line). *Trudy* starts by using her mobile app to send her account information to the phantom device (Step R.1). Next, the phantom device, which has *Alice*'s device and other legitimacy information, will send a binding request with *Trudy*'s account information (Step R.2) to the cloud. Due to F1.2, the cloud is fooled into accepting the binding request. Now, the ownership of the device has changed to *Trudy* from the view point of the cloud. The cloud then terminates the connection from the real device. However, the real device has re-connecting mechanism that continuously restores lost connection to the cloud. Due to F3, the cloud does not verify whether the account information (*Alice*) matches the current device owner (*Trudy*) or not. Therefore, the re-connecting request from the real device can be successful. At this point, *Trudy* could completely control *Alice*'s device (Step R.3).

**Attack Consequence.** The remote device hijacking attack allows *Trudy* to bind her account to *Alice*'s device. As a re-

sult, she can harvest the sensor readings in *Alice*'s home. She can also send remote commands to control *Alice*'s device. In our experiment, we successfully hijacked a Alink IP camera (model: RIWYTH RW-821S-ALY). As a result, we can view the victim's IP video feeds secretly, greatly threatening victim's privacy.

**Stealthiness Analysis.** Since *Alice*'s device has been hijacked, she can no longer talk to her device. It could raise an alert for *Alice* if she is security-savvy. Average Joe may simply regard it as a service failure and rebind his user account. It is worth mentioning that even for security-savvy users, it is not easy to trace back to the attacker. Only the IoT cloud has some clues to trace back to the attack origin.

## 6.4 Other Security Hazards

### 6.4.1 Remote Device DoS

As a basic security measure, IoT clouds only allows authorized users to control a device. If an attacker can unbind a target device from its legitimate user, the target device cannot be operated anymore, essentially leading to device denial of service (DoS) attack. To launch this attack, the attacker does not need to exploit many flaws. In particular, for *Type I* platforms, after the attacker sends the device-side unbinding command (Step T.3), as shown in Figure 5, the cloud directly revokes the binding relationship between the victim user and the device. For *Type II* platforms, as shown in Figure 6, after the attacker leverages flaw F1.2 to bind a phantom device with his account (Step R.2), the target device is unbound.

Note that since remote device DoS attacks require less flaws, the attack is applicable to more platforms. For instance, the Samsung SmartThings platform, which is immune to remote device substitution/hijacking attacks, is vulnerable to remote device DoS attacks. This is because the SmartThings platform is not subject to F3 which is essential for remote device substitution/hijacking attacks. However, F3 is not required in remote device DoS attacks. We will explain why SmartThings is not subject to F3 in Section 7.4.2.

### 6.4.2 Illegal Device Occupation

Although a device may be shared with multiple users, only one user account is allowed to be bound to a smart home device. If the attacker can predict the device IDs of unsold devices and use phantom devices to bind them with valid user accounts, these devices cannot be bound again after being sold. We call this attack illegal device occupation. In essence, this attack makes new devices unavailable to legitimate consumers. Note that this attack only applies to *Type I* platforms since attackers can predict device identity information. In *Type II* platforms, long and unpredictable device IDs are hard-coded in devices. Attacks can no longer learn anything about device IDs until the device is sold.

### 6.4.3 Firmware Theft

To protect intellectual property (IP), most IoT manufacturers employ certain tamper-resistant techniques to protect their products, including enforcing read-only property on flash chips that store proprietary firmware. However, with leaked-out firmware, the attacker can reverse-engineer it, causing IP theft and harming the corresponding manufacturers. By exploiting OTA updates available on most IoT devices, our firmware theft attack is able to bypass the aforementioned protections. By forging different kinds of phantom devices, the attacker can issue OTA update requests in bulk, and thus he can harvest hundreds of firmware images in seconds.

In the experiments, we created phantom devices to “emulate” 1,355 kinds of Alink devices, 543 kinds of Joylink devices, 118 kinds of XiaoMi devices, 23 kinds of SmartThings devices, and 18 kinds of TP-LINK devices. Eventually, we were able to collect 63 firmware images from the Alink platform, 37 from the Joylink platform, 89 from the MIJIA platform, and 16 from the KASA platform.

## 7 Discussion

Although we only studied five popular cloud-based smart home platforms, our findings can be generalized to other smart home devices (e.g., hub-connected devices), and have implications to platforms that are non-cloud-based. We also discuss the root causes of the identified vulnerabilities, and suggest several potential defensive approaches to mitigating the discovered exploits. Finally, we discuss the impact of the discovered exploits on commercial competitions.

### 7.1 Impact on Hub-Connected Devices

In this paper, we focus on cloud-connected devices. However, the discovered exploits are also applicable to hub-connected devices due to two reasons.

First, the attacker can leverage an already exploited hub to control hub-connected devices. For example, a XiaoMi smart gateway is a hub for MIJIA products. After hijacking the gateway, the attacker can further control all its connected devices. Note that Samsung SmartThings is not vulnerable to this attack because a SmartThings hub unbinds all the connected devices when the ownership of the hub is changed, which is inevitable in this attack.

Second, by forging a phantom hub-connected device, it is possible to launch firmware theft and illegal device occupation attacks. However, since the target devices are behind a hub, it is impossible to remotely hijack or substitute them.

### 7.2 Implications to Cloud-Free Smart Home Platforms

**HomeKit.** HomeKit [8] is Apple’s proprietary smart home platform. Compatible devices run the HomeKit accessory protocol to directly talk to mobile apps via WiFi or Bluetooth. Moreover, using the mobile app, users can access

home devices indirectly through a hub device (Apple TV, HomePod or even iPad). In this case, the cloud relays commands from the mobile app to the Apple TV or HomePod. Then the Apple TV or HomePod issue commands to home devices locally. Note outside the home LAN, there is no direct link to home devices [49]. As a result, our attacks are not applicable to HomeKit devices.

**DIY Platforms.** DIY smart home platforms such as Home Assistant [10] and OpenHAB [48] are open-source projects that focus on building local home automation. Due to controllable privacy and low cost (as low as the price of a Raspberry Pi), they are becoming more and more popular among DIY enthusiasts. In essence, they build private hubs that interact with different home devices. To support as many devices as possible, these platforms can be extended with components, which implement device specific logic [12]. While some devices can work by connecting to the hub locally (e.g., Philips Hue), others cannot work without relying their own cloud backends. To this end, Home Assistant classifies the smart devices into two types: devices that interact with third-party clouds, and devices that respond to events that happen within Home Assistant. For the former type, the hub serves as a proxy of other third-party clouds. For example, if a user wants to use a SmartThings device through Home Assistant, he first registers and binds the device with the SmartThings cloud. Then he needs to install a SmartThings plugin for Home Assistant to connect the device to the hub [11]. The plugin stores the user’s SmartThings account token and delegates all the device requests to the SmartThings cloud.

For smart home devices relying on their own cloud backends, Home Assistant is actually transparent to the devices and thus all the exploits discovered in this paper can be applied to them. However, our attacks cannot influence devices that only work locally.

### 7.3 Root Cause Analysis

Some of the vulnerabilities revealed in this paper are associated with inherent design flaws of smart home platforms. Some are themselves caused by design challenges of smart homes. Therefore, some of security flaws cannot be remedied in a straightforward way.

**Ownership Transfer.** A natural assumption that smart home manufacturers make is that a user who physically owns a device should have full control over it. Thus, in *Type II* platforms, each device takes charge of authorization checking and sending device binding requests. This allows a legitimate user to rebind a device with another account by physically resetting it. Note that the rebind operation unbinds the previous account automatically and happens regardless of whether the device has already been unbound or not. This design directly leads to flaw F1.2, allowing an attacker to use a phantom device to remotely unbind the original user.

**Device Reconnection.** Network congestion may cause ran-

dom connection loss between a device and an IoT cloud. The IoT cloud mitigates the problem by allowing the device to re-login itself automatically. However, at the time of re-login, the cloud does not do any account-based authentication checking on all the platforms we have investigated except for SmartThings. This design gives rise to F3 which allows an attacker to remotely control the device without user awareness.

**Cloud-Device State Inconsistency.** To avoid problematic state transitions, an IoT cloud should be aware of the status of the devices it manages. Unfortunately, this is very hard to achieve in practice. In the previous work, it has shown that 22 of 24 studied devices suffer from design flaws that lead to state inconsistency [45]. For one thing, intermittent network conditions make it very difficult to keep the state of a device and the state of the IoT cloud synchronized at all time. For another, a user may reset a device by pushing the physical reset button when the device's Internet connection is lost. As a result, the device binding information is cleared on the device but not in the cloud. In all cases, the synchronization between the cloud and the device is broken. This causes flaws F1.1, F1.2, F1.3, and F2.

## 7.4 Mitigation

In this section, we propose several defensive design suggestions to secure smart home platforms in the first place. It should be noticed that adopting only a subset of our suggestions is not enough, because the flaws involved in the interactions are multi-faceted and tangled together (e.g., F1.3 and F3). Platform providers should consider all the potential security issues introduced by the interactions, including authentication, authorization and validity of working state machines.

### 7.4.1 Strict Device Authentication

We have clearly shown that existing authentication is not adequate. By violating authentication, a phantom device is indistinguishable from a victim device. To ensure that every device an IoT cloud talks to is a genuine device, we suggest that the manufacturers embed a unique client certificate into each device for high-end devices powered by Intel or ARM Cortex-A processors. In addition, the IoT cloud should always examine the client certificate before accepting any device request. For resource-restricted devices powered by a microcontroller, the manufacturers should embed a read-only random number into each device. On the cloud side, the cloud should always check whether the random number matches the other identity or legitimacy information.

Because device IDs are used by IoT clouds to identify a device, we also suggest that platform providers retrofit the device ID provisioning mechanism so that the attacker cannot easily obtain a valid device ID. Hard coding the device IDs is a bad practice because once a device ID is leaked, the corresponding device becomes vulnerable forever. The de-

vice ID of a device should be generated by the IoT cloud during registration, and the generation algorithm should use harder-to-guess information, such as user ID/passwords, random numbers, etc.

### 7.4.2 Comprehensive Authorization Checking

Compared with mobile-side commands, we found that most IoT clouds do not enforce strict authorization checking of device-side commands and baselessly trust arbitrarily connected devices. For *Type I* platforms, when a device talks to an IoT cloud, the user account information is absent on the device. Thus, the IoT cloud directly accepts unauthorized logins (F3) or unbind (F4) commands. For *Type II* platforms, because the device takes charge of checking the binding relationship, the cloud skips performing further authorization checking on the requests from the device.

We suggest that both the device and the IoT cloud store and maintain the binding relationship as well as perform authorization checking. Moreover, on the cloud side, the account-based authentication should be performed on every device-side request, especially for critical operations such as device login. Samsung SmartThings follows this practice and thus is not vulnerable to flaw F3. In SmartThings, devices must explicitly include user credentials for every login request. This additional credential checking prevents the target device from reconnecting to the cloud.

### 7.4.3 Enforcing the Validity of State Transitions

As revealed by our findings, all the tested platforms failed to enforce the validity of the involved state transitions. In order to prevent the attacker from exploiting unexpected state transitions, smart home platforms should identify and formulate every legitimate interaction request as a 3-tuple in the form of (sender entity & its state, the request message, receiver entity & its state). In addition to checking every request, the sender entity should also verify if its current state allows the request to be sent out; and the receiver entity should verify if its current state is allowed to receive the request. For instance, the IoT cloud shown in Figure 2 should only accept a device registration request when it stays in state 1. Furthermore, in order to prevent the three entities from staying out of the set of legitimate state combinations, the three entities should formally define and maintain their own state machines. In the meantime, the IoT cloud of a platform should synchronize the three entities so that they stay in a legitimate state combination. Finally, if an unrecoverable system error occurs, the three entities should roll back to their initial states immediately.

## 7.5 Malignant Commercial Competitions

The discovered exploits could also be leveraged by unscrupulous merchants in commercial competitions.

**IP Theft.** As mentioned in Section 6.4.3, a company can steal a rival's firmware and reverse-engineer it to steal pro-

prietary IP. This kind of behavior harms fair competition and hinders technology advancement.

**Statistics Manipulation.** By churning out hundreds of thousands of phantom devices, a malicious company could rig the number of active devices in the market. This has two implications. First, by increasing the market share of its own products, the company can present an eye-catching year-end report. Second, by increasing the number of activated devices of its rival, its rival could be overcharged by the platform provider. This is because some platform providers bill cooperative manufacturers based on the number of activated devices connected to their clouds. An unscrupulous manufacturer can use phantom devices to register a large number of non-existing devices under the name of its rivals, causing financial loss to them.

**User Experience Disruption.** Leveraging the illegal device occupation attack, an unscrupulous manufacturer can potentially take over a large number of its rival's in-stock products. When these products are sold, the consumers will have a terrible user experience.

## 8 Related Work

We review the related work on smart home security from three perspectives: device security, communication security and IoT application security.

**Device Security.** Device security research emphasizes the vulnerabilities of individual devices. Ling *et al.* [41] studied a smart plug system and revealed a weak authentication vulnerability. After dissecting the behavior of several IoT devices such as Phillips Hue light bulbs and Nest smoke detectors, Notra *et al.* [44] revealed that basic security mechanisms such as encryption, authentication and integrity checking are absent in these devices. Several currently available smart hubs were investigated in [20] and [55], and numerous security flaws were identified. In contrast to analyzing individual devices, our study analyzes the complex interactions among the three entities engaged in a smart home platform.

**Communication Security.** Communication security research emphasizes the security and privacy issues in smart home communication protocols such as BLE, ZigBee, and Z-Wave [14, 1, 50, 27]. Agosta *et al.* [1] approached the security and privacy problems involved in the key derivation algorithm adopted by the widespread Z-Wave home automation protocol. Ronen *et al.* [50] described a worm attack which has the potential of massive spread by exploiting an implementation bug in the ZigBee Light Link protocol. Researchers also demonstrated that attackers can infer private in-home activities by analyzing encrypted traffic from smart home devices [9] or by extracting features of connection-oriented application data unit exchanges [46]. Instead of focusing on a particular algorithm or protocol, this study conducts comprehensive platform-wide vulnerability analysis.

**IoT Application Security.** Recently, increasing numbers of researchers have paid their attention to smart home platforms, but they usually focus only on in-cloud IoT applications (i.e. home automation applications). For instance, Fernandes *et al.* [23] revealed that the capabilities implemented in the SmartThings IoT application programming framework are too coarse-grained, which allows malicious third-party IoT applications to compromise the SmartThings platform. Celik *et al.* [16] proposed *SAINT*, a static taint analysis tool to find sensitive data flows in IoT applications. The same authors further studied whether an IoT application and its environment adhere to functional safety properties. They found that 9 out of 65 SmartThings apps violate 10 out of 35 properties [17]. Kafle *et al.* [35] revealed the feasibility and severity (e.g., privilege escalation) of misuse of smart home routines. Moreover, Ding *et al.* [21] presented a tool named *IoTMon* to discover risky interaction chains among IoT applications. Our work focuses on the interactions between the participating entities engaged in a smart home platform, instead of between home automation applications.

## 9 Conclusions

Smart home technology is playing a more and more important role in our digital lives. To seize a greater market share, smart home platform providers shorten the time-to-market by reusing existing architectures and incorporating open-source projects without rigorous review (of the potential security and privacy issues). In this work, we conducted an in-depth analysis of five widely-used smart home platforms, and found that the complex interactions among the participating entities (i.e., devices, IoT clouds, and mobile apps), though not being systematically investigated in the literature, are vulnerable to a spectrum of new attacks, including remote device substitution, remote device hijacking, remote device DoS, illegal device occupation, and firmware theft. The discovered vulnerabilities are applicable to multiple major smart home platforms, and cannot be amended via simple security patches. Accordingly, we propose several defensive design suggestions to secure smart home platforms in the first place.

## Abstract

Smart home IoT devices have increasingly become a favorite target for the cybercriminals due to their weak security designs. To identify these vulnerable devices, existing approaches rely on the analysis of either real devices or their firmware images. These approaches, unfortunately, are difficult to scale in the highly fragmented IoT market due to the unavailability of firmware images and the high cost involved in acquiring real-world devices for security analysis.

In this paper, we present a platform that accelerates vulnerable device discovery and analysis, without requiring the presence of actual devices or firmware. Our approach is based on two key observations: First, IoT devices tend to reuse and customize others' components (e.g., software, hardware, protocol, and services), so vulnerabilities found in one device are often present in others. Second, reused components can be indirectly inferred from the mobile companion apps of the devices; so a cross analysis of mobile companion apps may allow us to approximate the similarity between devices. Using a suite of program analysis techniques, our platform analyzes mobile companion apps of smart home IoT devices on market and automatically discovers potentially vulnerable ones, allowing us to perform a large-scale analysis involving over 4,700 devices. Our study brings to light the sharing of vulnerable components across the smart home IoT devices (e.g., shared vulnerable protocol, backend services, device rebranding), and leads to the discovery of 324 devices from 73 different vendors that are likely to be vulnerable to a set of security issues.

## 1 Introduction

Smart home IoT devices have become favored targets for attackers [41] as much for the lack of user awareness [35] as for their poor security design [46]. As the motivation for attackers grows (e.g. IoT botnets, personal data theft), security incidents for smart home devices are only expected to increase. Securing these devices is challenging on several fronts. First, a good

fraction of vendors in this space are small and medium-sized businesses that lack the budget for software quality control and security best practices, resulting in numerous insecure devices in the market. Second, many of these devices are relatively inexpensive (often less than \$100) and cannot afford to have support for expensive security infrastructure, such as monitoring agents, encryption and authentication hardware, etc. Consequently, when a device is found vulnerable, there is very little incentive and capability for the vendor to release a fix. Third, high vendor fragmentation makes it hard to manage and distribute software/firmware patches.

One way to address this issue is to identify vulnerable devices before they get deployed and take appropriate measures to protect the device. Examples of such measures may include upgrading the device firmware, identifying and blocking traffic that can exploit the vulnerability, or quarantining the device completely. To identify the vulnerable devices beforehand, multiple approaches have been proposed [10, 14, 16, 17, 19, 20, 24, 25, 27, 34, 42, 47, 49, 58]. One line of research [19, 27] focused on launching an Internet-scale scan to detect trivially vulnerable devices (e.g., devices with weak passwords, certificates, and keys) that are publicly accessible. However, these approaches often cannot help identify devices with more sophisticated vulnerabilities or devices hidden behind NAT. Another line of research [10, 14, 16, 17, 20, 24, 25, 34, 42, 47, 49, 58] focused on statically and/or dynamically analyzing an IoT device or its firmware to evaluate its security. Although these approaches tend to yield more comprehensive and accurate results for individual devices, they do not scale well for a large-scale analysis. First, getting physical access to all the devices on the market is not a viable option because of restricted availability of devices in certain geographies and their prohibitively high acquisition cost. Similarly, device firmware is not always available due to the highly fragmented market that involves a lot of small integration and distribution vendors<sup>1</sup>. Second,

<sup>1</sup>Integration vendors are the ones that integrate components, tools, and SDKs, provided by OEMs. Distribution vendors simply acquire the device from an OEM and re-brand with their own before selling in the market.

even with a device or its firmware, the analysis itself is often tedious, error-prone and difficult, especially considering the “device shell” that is often put in place by the device vendors (e.g., packing, obfuscation and encryption). As a result, the market would benefit from an approach where vulnerable devices can be quickly identified at scale and the scope of analysis can be narrowed down.

**Approach.** In this paper, we present a platform that accelerates vulnerable device discovery and analysis without requiring access to a physical device or its firmware. Our approach is based on two observations. First, smart home IoT device vendors, especially small and medium-sized ones, often rely on same components (e.g., software built from open source projects, hardware components from common suppliers) to build their devices. Consequently, the same vulnerabilities or bad security practices often transfer from one IoT device to another. We can thus propagate vulnerability information to an *unknown* device by evaluating its similarity with devices *known* to be vulnerable. Second, similarities of devices are often reflected in their mobile companion apps, which are widely accessible. Combining these two observations enables us to build a platform that identifies vulnerable devices in a scalable way without requiring the physical devices themselves or their firmware images.

In our platform, we try to expedite the process of identifying vulnerable devices by providing two functions: (1) *app analysis*: find the characteristics of a device by analyzing its companion app, and (2) *cross-app analysis*: find device families, i.e. cluster of devices, that have similarity in some of the characteristics found in app analysis by analyzing multiple apps. Clustering helps identify apps that have a similar set of vulnerabilities based on shared components [8].

**Results Overview.** For our experiments, we crawled Google Play Store [3] to search for potential IoT companion apps and downloaded 3,094 of them. After filtering out some noise, we were left with a dataset of 2,081 apps (see Section 2.2 for more details). These apps were then analyzed by our platform.

First, we found the device clusters, i.e., device families, containing devices that are similar in various aspects such as software or hardware components, back-end services, and network protocols. For instance, in our analysis, we found 19 device families covering 139 apps from 122 different vendors where devices in a family shared similar software components. As another example, we found 48 different families covering 460 devices that shared similar back-end services.

Second, we tried to identify devices that are impacted by a given vulnerability using the device families already identified. In one case, we were able to discover devices from four different vendors (apps of which is estimated to be installed by more than 215,000 users) that were previously not known to be vulnerable to a software vulnerability and independently confirm the existence of the vulnerability on 45 devices from four different vendors that were previously confirmed by other

sources. In another case, we were able to identify 67 devices from 16 different vendors that are impacted by a hardware security issue. In total, our platform has identified 324 potentially vulnerable devices from 73 different vendors. During the process of validation, we could reach a decision (confirm or disapprove) about 179 devices from 43 vendors, among which 164 (91.6%) are confirmed to be vulnerable.

**Contributions.** This paper makes the following contributions:

- It demonstrates how companion mobile apps for IoT devices can provide insights into the security of the devices themselves.
- It shows the effectiveness by using this approach to assess the security posture of IoT devices when neither the physical devices nor their firmware images are available.
- It proposes a platform to perform mobile app collection, filtering, analysis, and clustering at a large scale. It demonstrates its use by analyzing more than 2000 apps and clustering them in multiple dimensions.
- It reports the discovery of 324 devices from 73 distinct vendors that are likely to be vulnerable to a set of security issues.

## 2 System Design

### 2.1 Overview

Figure 1 presents an overview of our platform. The first component of our platform is the *IoT App Database*, which stores the companion apps of smart home IoT devices crawled from the Google Play Store [3]. The database is extended constantly by fetching more apps (e.g., when new IoT devices are on market or old apps get updated).

The apps stored in IoT App Database are then analyzed by the *App Analysis Engine*. The goal of the App Analysis Engine is to estimate the profile of an IoT device (i.e., what the device is like) based on code analysis. Specifically, the App Analysis Engine computes three things: the network interfaces of a device, the unique strings (called *imprints*) that a device may include, and code signature of the companion app. The results of App Analysis Engine are stored in the *App Analysis Database*.

A *Cross-App Analysis Engine* queries the App Analysis Database and identifies correlations across different devices in order to build a *device family*. A device family groups together different devices from different vendors based on their *similarity*. The similarity can be in terms of different dimensions (e.g., similar software, similar hardware, similar protocols, and similar cloud back-end services). The device family allows propagation of vulnerability information among similar devices. Specifically, it allows evaluation of IoT device

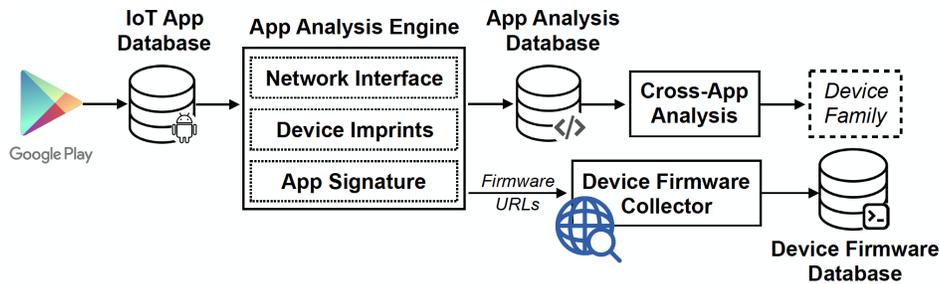

Figure 1: An overview of the platform

security from the perspective of either a device or a threat: 1) for a specific device, the similarity allows to quickly assess whether or not the device is vulnerable and if so to which vulnerabilities, and 2) for a specific vulnerability, find the set of devices on the market that might be affected by the vulnerability.

To facilitate vulnerability confirmation, our platform contains an additional component called *Device Firmware Collector*. It leverages the code analysis results output by the App Analysis Engine (e.g., Firmware URLs) as well as Internet search results to download firmware images into a *Device Firmware Database*. These firmware images later enable us to further confirm the vulnerabilities found by the Cross-App Analysis Engine. Note that the Device Firmware Collector is not an essential or required component of our platform. Rather, it is utilized as one of several means to help confirm the findings from the platform (See Section 3.2 for more details).

In the remainder of this section, we describe each component of our platform in detail.

## 2.2 App Collection

The first step of our platform is to gather mobile companion apps of smart home IoT devices for analysis. To achieve this goal, we crawled Google Play Store<sup>2</sup>. In total, we downloaded 3,094 Android apps, out of which 2,081 were included in the final dataset and analyzed by our platform.

The challenge during app collection is to identify apps that are mobile companion apps of IoT devices. To address this problem, we initialized the crawler with 281 seed apps manually selected from the online smart home products database *SmartHomeDB* [5], and used snowball sampling to collect more apps via the connections between the seed apps and other apps on Google Play (e.g., keywords, suggestions and categories). As a result, 3,094 candidate apps are initially downloaded. However, we observed that snowball sampling may sometimes introduce noise. For example, apps that manage phone camera are confused with the apps that manage

home security cameras. Apps that lock phone’s screen are confused with smart home locks. To eliminate such noise from the dataset, we performed filtering. The filtering is based on a clustering model (Affinity Propagation [26]) that clusters apps based on the permissions that the apps request on installation and the sensitive Android APIs that the apps may invoke at runtime. We deploy the filtering on apps that are nominated by the same seed sample and remain the largest cluster. This approach turns out to be effective: a random manual inspection of 200 apps after filtering shows that 98.5% of them are real mobile IoT companion apps. After further deduplication, 2,081 apps are left in the dataset and fed into the App Analysis Engine for analysis. Note at the first phase of the research, we worked with a relatively small dataset and focused more on validating the approach. Our platform is constantly running to collect more apps for future analysis at a larger scale.

## 2.3 App Analysis Engine

The *App Analysis Engine* analyzes mobile companion apps collected in order to build a device profile for individual devices. Unlike previous works [12, 32, 48, 60] that focused on apps themselves, the goal here is to compute what the *device* is like, indirectly from the app. We achieved this goal by independently applying three methods: a device interface analysis that computes the network interfaces of a device, an imprint analysis that computes unique strings a device might be related to, and a fuzzy hash analysis that computes code signature of a mobile companion app. In practice, we found that the first method is more comprehensive and informative. Nevertheless, the rest two methods are still useful in filling in gaps where the first method cannot easily apply.

### 2.3.1 Device Interface Analysis

The device interfaces are often a good reflection of what the device is like, e.g., the protocol that the device speaks, the service that the device runs, the function that the device supports, and sometimes the hardware components in use by the device. Without directly examining a device or its firmware, we estimate the device interfaces based on analysis of its mobile

<sup>2</sup>We based our analysis primarily on Android but most IoT device vendors provide mobile companion apps in both iOS and Android.

companion app, as the app and the device complement each other in their network interfaces. A peer-to-peer connection between the app and the device can benefit this estimation, as the app interfaces, in this case, are direct reflections of the device interfaces; however, this is not a necessary condition. For devices where a cloud or backend service is involved, popular backend services like Microsoft Azure IoT Hub [40] are often generic: they tend to relay the connection between the app and the device without much meddling. Such devices also work well with our approach since their app interfaces still closely reflect that of the devices. We performed a study over the online IoT device database (SmartHomeDB), and found that majority of the devices (76.3%) produced by small and medium-sized vendors support a peer-to-peer connection between the app and the device. Even large vendors like TP-Link support both cloud and peer-to-peer mode for network outage and privacy reasons. This enables us to have a good estimation of the device interfaces for many of the IoT devices, especially vulnerable ones, that are sold on the market.

We used a backward approach to compute the network interfaces of an app, starting from the network response messages that the app may receive, as these messages are information output by the device. We first identify message handling functions in the app and statically decide what the response message may look like. We then identify the request that may trigger the response. Finally, we partially instantiate and execute the app code to reconstruct the request [12, 56]. Figure 2 shows an example of the request and response extracted from the mobile companion app *com.Zengge.LEDWifiMagicColor* of Zengge Wi-Fi Bulb. With many different pairs of requests and responses (e.g., with UDP/48899, TCP/5577 of the bulb and also the cloud server *\*.magichue.net*), we obtain a good estimation of the device interfaces.

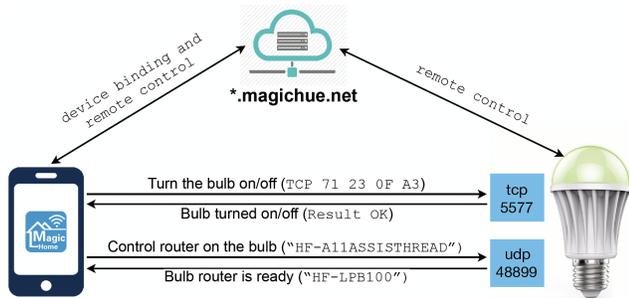

Figure 2: Interfaces of Zengge Wi-Fi Bulb

**Response Extraction.** We rely on symbolic execution [33] to estimate what the response messages from a device may look like, without actually running the device. We first built a Control Dependency Graph (CDG) and Data Dependency Graph (DDG) of a mobile companion app using Soot [51]. We then start from standard network receiving functions in Android (e.g., `<java.net.DatagramSocket: void`

`receive(java.net.DatagramPacket)>`) and forward execute the mobile companion app symbolically. Whenever we encounter a branch that is dependent on the content of a response message (e.g., fields of the response are checked against a value), we capture the check as a symbolic constraint and fork the execution. After all executions terminate, the conjunction of the symbolic constraints is stored as a “description” of the response message. In order for response messages from two devices to be similar, they have to satisfy the same set of symbolic constraints.

One practical issue is to decide when to terminate a symbolic execution. In our experience, we found that a valid response from the device (i.e., the response passes checks performed by the app) often triggers state changes of the app. Such state changes could be either UI element changes (e.g., updating device status displayed to the user) or modifications to the local registry (e.g., storing device information to configuration files, shared preferences or databases). To confirm this heuristic, we randomly sampled 200 response handling procedures that exist in 179 apps from our app set and evaluated manually the impact of valid responses. Among these responses, 162 of them had an influence on UI elements, and 76 of them resulted in modifications to the local registry (with some overlapping cases where responses changed both); only eight of them would not trigger such changes, but the app stored response content (e.g., login token) in global variables. This study shows that state changes can be a good approximation for the termination of valid response handling. We thus mark such state changes as the point where we terminate the symbolic execution and produce the conjunction of the symbolic constraints. In addition, we supplement this method with the observation that invalid responses are discarded quickly by the apps (i.e., within few lines of code). We thus also set a threshold on the number of procedures to execute before we terminate the execution. Utilizing these two heuristics, we could produce a small but meaningful set of constraints that closely describe a valid response that an IoT device may produce.

**Pairing Request and Responses.** The next step is to identify the request sent by the app that will trigger the response from the device. In many cases, the request is straightforward to identify: it co-locates with the response message handling functions. In other cases, however, it is trickier as the request can be located in a different procedure or class, especially when the communication between app and device is asynchronous. In these cases, static code analysis can be limited in identifying the matching request.

Fortunately, we observe that a matching pair of request and response often share a large code base of their handling functions (i.e., classes and methods used to process the request and response). Such similarities are reflected in the stack at runtime. To confirm this observation, we examined the paired requests and responses for the same set of 200

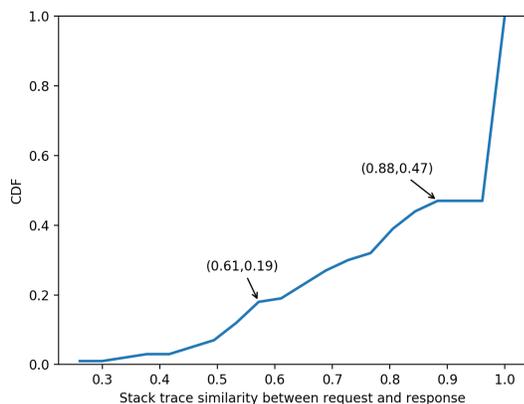

Figure 3: Cumulative Distribution Function (CDF) of request and response similarity

response handling procedures, and evaluated the similarities between stack traces of the responses and the requests. Figure 3 shows the Cumulative Distribution Function (CDF) of the Jaccard Similarity: 81% pairs of request and response share over 61% of their stack frames, and more than half (53%) of the request-response pairs have over 88% frames in common. For unpaired requests and responses, the similarity reduces to almost zero. Thus, by recording and comparing the execution stack of the app when the app is making requests (i.e., via concrete execution) and processing responses (i.e., via program dependence graph), we can pinpoint with good accuracy, among multiple request sending functions, the one that most likely will trigger the target response. As an example, Figure 4 shows the stack traces of a request and response that are used by Chuango Wi-Fi alarm system. The request and response are matched based on the common stack frames (e.g., those triggered by the same user click) despite being located in different classes that run in different threads.

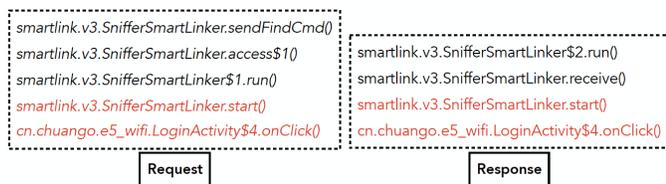

Figure 4: A matching asynchronous request and response in `cn.chuango.e5_wifi`

**Request Reconstruction.** After identifying a matching pair of request and response, the next step is to reconstruct the request string. Unlike responses, requests are produced by the app. Therefore, we may reconstruct a complete request string as compared to a set of symbolic constraints for responses. A number of techniques have been developed for

reconstructing program values via program slicing and execution [12, 29, 48, 56]. We adopted the *Instantiated Partial Execution (IPE)* technique developed in Tiger [12] in our platform. The advantage of using IPE is that it evaluates and instantiates variables to concrete values if they are found to be irrelevant to the request string thereby dramatically reducing the number of paths need to be explored. In addition, IPE also caches outputs of code slices and reuses the results if applicable, further reducing the analysis complexity. By using IPE, we were able to reduce the time needed to reconstruct a request to under a minute.

The result produced by device interface analysis is a set of request and response pairs. The requests are fully or partially<sup>3</sup> reconstructed request strings and responses are sets of symbolic constraints. A device is said to have a similar interface as another device if they both accept similar requests and output similar responses.

### 2.3.2 Imprints Analysis

Device imprints (i.e., unique strings) found in an app can help correlate different devices. We are particularly interested in imprints that show up in the communication between the app and the device, as they are indicative of the uniqueness of the *device*. In contrast, there are also app imprints, such as app developer emails or special class names, that identify an app or library. However, they are less indicative of the device.

Table 1: Examples of device imprints

Type	Imprints	Device
device keywords	"20140930073702357" (dir. name in firmware)	Homeboy Wi-Fi Security Camera
	"0622707c-da97-4286-cafe-" (UUID of the device family)	SensingTEK Cameras
cert and comm. keys	"Ztwy518518puy518" (AES key)	Zhongteng Smart Home Devices
user & pwd	"P0rtal@123!" (account pwd)	Pro1 Thermostats
special URLs	"qjg7ec".internetofthings .ibmcloud.com (MQTT <i>orgID</i> )	Max Smart Home Devices

Inspired by previous work done by Costin et al. [16] that directly extracts imprints from embedded firmware images, we also focus on four types of device imprints: device (backdoor) keywords, certificates and keys, non-trivial usernames and passwords, and special URLs. The method we used to identify imprints is simple: we build a Data Dependence Graph of an app and check backward from network APIs to find constant strings in the app that affect parameters of those APIs. Note that these APIs are used to communicate with the device. In other words, we only use unique strings as imprints if they are related to the device (i.e., they are part of either requests to or responses from the device). A parser later decides which category the constant strings fall into and

<sup>3</sup>Certain requests require user input (e.g., login request). In these cases, we partially reconstruct the request with <NONE> string replacing the missing user input.

whether or not they are commonly seen (e.g., *admin* for both username and password is ignored). Table 1 shows an example of a few imprints we collected in our dataset. When two apps have the same imprints (and both imprints affect the communication with devices), it serves as a strong indicator of the similarity between devices. For instance, by using imprint "*OBJ-000165-PBKMW*", we were able to correlate *VStarcam* and *OUSKI* IP Cameras (the latter is later confirmed to be a rebranding of the former).

Although imprints can serve as strong evidence of correlation, imprint analysis as a method is less applicable in general since many times imprints of a device do not manifest themselves in the app. For example, we were not able to spot the existence of any magic keyword, like the "*xmlset\_roodkcableoj28840ybtide*" (i.e., edit by 04882 joel backdoor in reverse) keyword used by a number of devices for debugging purposes reported by Constin et al. [16]. This makes sense since the magic keyword is built into the firmware images for debugging purposes, and device debugging is generally not a critical functionality required for customer facing apps. However, it highlights the limitation of imprint analysis, and the reason why we need a fully fledged device interface analysis.

### 2.3.3 Fuzzy Hash Analysis

Another method we used is to assess code similarity via fuzzy hash. Similar mobile companion apps often indicate similar devices. We thus compute *ssdeep* of objects found in an app, including classes, libraries, and other types of resources (e.g., texts), and compare the results across apps. The benefit of using fuzzy hash as compared to traditional hashing algorithm (e.g., *SHA1*) is that we can relate objects that are similar but are not exactly the same. Through this way, we were able to identify a few similar devices. For example, the companion apps of *CHITCO* and *EDUP* smart switches are found to have 50.7% objects matched with 80/100 similarity, and these two devices are later confirmed to share similar software. Note, however, similarities between devices do not necessarily mean similarities in the apps. We observed in many cases that similar devices have different apps (e.g., apps are developed independently), and therefore cause failures to fuzzy hash analysis. Code similarity is more useful for identifying obvious correlations as well as for cases where other analysis methods have some difficulties to apply (e.g., for native libraries).

### 2.3.4 Modularity

A special consideration we made while building the App Analysis Engine is the modularity of the analysis. The reason we took this extra step as compared with generating analysis result per app is to accommodate the *modular similarity* that often appear across IoT devices. It is common that IoT

device vendors, especially smaller ones, comprise their products from a number of existing modules on market, such as hardware components from common suppliers, software built from open source projects, binary driver code for protocols and etc. For example, the *HiFlying* Wi-Fi module is used by a number of vendors to manage Wi-Fi connectivity for their devices. Thus it is important for our analysis to be modular as well, in order to track device similarities and detect vulnerability propagation at a finer granularity of individual device components (Refer to Section 2.4 and Section 3.3 for more details of the components that we can track).

We based our design on the observation that device components are often managed by different code modules in the app (e.g., class, package). Taking the previous *HiFlying* Wi-Fi module as an example, devices such as *BeSMART* thermostat that uses the module often have two separate classes, *com.hiflying.smartlink.v3.SnifferSmartLinkerSendAction* and *com.besmart.thermostat.MyHttp*, for handling Wi-Fi connection and user interaction over HTTP, respectively. We thus infer such modularity from the app (e.g., based on class hierarchy and invocation stack) and apply the above analysis method on individual modules.

## 2.4 Cross-App Analysis Engine

The analysis results output by the App Analysis Engine are stored into the *App Analysis Database*, which is then queried by the *Cross-App Analysis Engine*. The Cross-App Analysis Engine is designed to detect modular similarities between different devices. In particular, the comparison is made to detect four types of similarities: similar software components, similar hardware components, similar protocol, and similar backend services.

**Similar Software Components.** Similar device interfaces, especially application interfaces, are indicative of strong connections between software components of different devices. For example, we were able to correlate 72 different smart home IoT devices from 16 distinct vendors that might have used the same version of GoAhead web server<sup>4</sup>. Such correlation is powerful, as in many times security weaknesses manifest them in software and security weakness found in one device can directly impact the security of others. For example, we were able to identify seven previously unreported devices that are vulnerable to a known vulnerability, as detailed in Section 3.3.

Another interesting phenomenon detected is device rebranding. In the smart home IoT industry, smaller vendors sometimes do not develop their own products. Instead, they customize IoT devices from OEMs and resell with their own branding. As reflected in the app analysis results, rebranded devices have almost identical device interfaces across multi-

<sup>4</sup>GoAhead is a simple web server specifically designed for embedded devices.

ple modules as the original OEM devices. Although device rebranding itself is not an issue, it complicates the security practices in firmware update and patching. In some cases, for example as shown in Section 3.3, a vulnerability is inherited by the rebranded devices from the OEM but the security patch that fixes the vulnerability is not.

**Similar Hardware Component.** Smart home IoT devices may be built upon similar hardware (e.g., Wi-Fi module). Such similarities in hardware components are sometimes reflected in device companion apps due to the need for the app to configure or interact with the hardware component. Due to the specialty of the hardware, such device-app interfaces can be unique, allowing a strong correlation of different devices using the same hardware. For example, we found that two Wi-Fi modules with a known security weakness of credential leakage are potentially being used by 166 devices from 35 different device vendors. The total downloads of these apps together are over 278,000 times.

**Similar Protocol and Backend Service.** A specific protocol often has its own request and response format. Similarly, a specific backend service often exposes standard APIs. Cross-App Analysis Engine can detect similarities in network interfaces and thus correlate devices that speak the same protocol or speak with the same backend service, even if such protocols or backend services are not documented. For example, we found that 39 different devices from 11 vendors are very likely to speak the SSDP protocol, which was known to be vulnerable as a reflector for DDoS attacks. As another example, we found that 32 devices from 10 vendors relied on the same cloud service to manage their devices, and the cloud service has a reported security weakness that allows attackers to take full control of the IoT devices by device ID and password enumeration.

**Future Work.** There are additional dimensions that security evaluation of an IoT device can benefit from similarity analysis. For example, previous works [16, 28] have shown that same developers or sub-contractor may follow a similar way of coding thus having the same set of bad security practices or vulnerabilities built into their devices. Similarly, the same development toolchain (e.g., compiler) may transform code in a similar way that leads to the same set of security issues [7, 52, 54]. As a future work, we plan to extend our analysis to cover more dimensions of similarities in order to obtain a more accurate and complete evaluation of smart home IoT devices.

## 2.5 Device Firmware Collector

Our platform features an additional component called *Device Firmware Collector* which enriches the *Device Firmware Database* through downloading firmware images of devices corresponding to the apps being analyzed. The purpose of the firmware images is to help us confirm the findings from the

cross-app analysis phase. In our current platform, we collect device firmware in two ways. First, we utilize the firmware downloading links that are embedded in the mobile companion apps. As IoT devices are usually headless (i.e., no keyboard or screen for user interaction), they often deploy firmware updates via the companion apps. As a result, links are sometimes built into the app by the vendor. Such links are often special URLs that can be extracted through imprint analysis. Second, we follow the app pages on Google Play, which often direct to device vendors, to crawl potential firmware files. Specifically, we used Google Custom Search API to programmatically search through vendor websites for firmware image files.

For the files collected, we filter out non-firmware files by checking their format using *Binwalk* [2]. Binwalk is a well-known firmware unpacking tool which extracts various data from a binary blob through pattern matching. Once a file is decided to be a firmware, a special effort is made to correlate firmware version with app version. As we will discuss in Section 3.3, this helps us to decide at which version a particular vulnerability is fixed and whether or not that fix has an impact on the app.

Note that not all device firmware could be downloaded. Even for the ones that we collected, there is still a considerable amount of firmware encrypted or obfuscated that renders the analysis difficult. This is a limitation yet to overcome in vulnerability confirmation, as discussed in Section 4.2.

## 3 Dataset and Results

### 3.1 Dataset and Platform Statistics

**Dataset.** In total, our dataset comprises of 2,081 apps collected through the method described in Section 2.2. The average size of the apps is 13MB (Min. 23KB and Max. 142MB). These apps spread globally (271 languages) and have a total download exceeding 1.2 billion. The apps cover 1,345 different device vendors and, by our estimate, about 4,720 different device models. We note that this dataset is still incomplete: by comparing certain types of devices in our dataset (e.g., IP camera) against online lists of devices [13, 21–23] of the same type, we estimate the dataset to cover ~5-20% of the total IoT companion apps.

**Testbed and App Processing.** Our app analysis platform ran on a 4 Core, 3.33GHz Ubuntu 16.04 server with 16 GB RAM and 1TB hard drive. The Android emulator is compiled from Android Open Source Project, AOSP 4.4.4.

In total, our platform needed ~68.3 hours to process the 2,081 apps, with an average processing time of 118.2 seconds per app. In our experiment, we set the maximum processing time to 10 minutes and the majority of the apps are processed successfully within this time frame. The platform was not able to fully analyze 73 (3.5%) apps within the timeout win-

down and therefore only partial analysis results are available for them. In addition, 43 (2.1%) apps were not analyzed by the platform because the tool we used (i.e., Soot) to build CDG and DDG failed to handle the app bytecode during interpretation. Overall, about 98% of the apps were either fully or partially analyzed.

One practical concern is the obfuscation of the app and its impact on the analysis. As reported in previous study, the majority (85.8%) of the device companion apps are produced by the standard tool in Android SDK (i.e., Proguard) [53], which mangles the apps by renaming classes, methods and fields. While Proguard introduces skews to the fuzzy hash analysis, it does not affect our main analysis method (i.e., network interface analysis) since it does not obfuscate network APIs, data-flow and control-flow. Another concern is the packing of the app—some developers use packers to encrypt their code, which would also have an impact on the network interface analysis. However, consistent with observations made by prior research [53], packers are often seen in malware, and less adopted by benign apps. In our dataset, only a handful of apps used commercial packers. Currently, we did not apply any special processing to these apps. There is an orthogonal line of research on developing better unpacking tools (e.g., DexHunter [59] and PackerGrind [57]) and our platform can be supplemented by these tools.

Table 2: IoT device families

Type	Number of Families	Covered Apps	Covered Vendors
Software	19	139	122
Rebranding	28	156	104
Hardware	14	61	51
Protocol	40	271	210
Backend	48	460	422

**Device Family.** Table 2 shows all the device families detected via our cross-app analysis. For example, we were able to identify 19 distinct device families covering 122 different vendors and 139 apps that were using similar software within the family. As another example, we were able to detect 14 distinct device families covering 51 different vendors that were using similar hardware components within the family. Note that these families are not mutually exclusive; a device might share software components with one device and hardware components with another. The largest device family we identified includes 31 device vendors and the smallest device family includes only 2 device vendors. Figure 5 shows a more intuitive illustration of the device family map.

### 3.2 Results Validation

Our platform is solely based on code analysis of mobile companion apps, without requiring the physical devices or their firmware images. This is the key to a large-scale security analysis of smart home IoT devices. However, the drawback

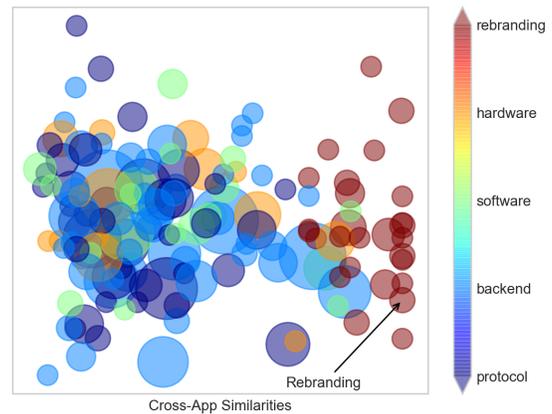

Figure 5: Device family map. Circle size indicates the number of device vendors in the family (the largest circle covers 31 vendors, while the smallest covers two).

of such approach is the accuracy of the result: the output from this analysis (e.g., a family of devices impacted by a particular vulnerability) is a conjecture that points to potential security issues that need to be validated with real devices.

In this paper, we validate and report some of the results we obtained from our analysis to demonstrate the value of the approach. We took a hybrid validation route, taking into consideration practical limitations such as the budget. First, we try to acquire the real device and test it in a local environment (Figure 6 shows the devices we purchased for validation). Second, if we do not have the device, we try to simulate, or in some cases statically analyze, device firmware stored in the Device Firmware Database (built from the method discussed in Section 2.5). Third, if neither of the first two methods applies, we search through online reports including vendor manuals and websites, bug reporting forums, IoT hacking communities and so on. Fourth, we work with the vendor and request their help in validating the results. We primarily used the second and third method, as the first method is very expensive and the fourth method is often a black hole (i.e., no responses from vendor). Upon confirming our findings, we also try to estimate the impact of the finding by searching the online presence of the device on *Shodan* [4].

**Ethics.** Testing vulnerabilities and scanning real-world devices often bring up serious ethical concerns. In our study, we pay special attention to not cross legal and ethical boundaries. For both real and simulated devices, we evaluate the device in a local network that only allows outbound connections. The device is brought offline immediately after the experiment to avoid being exploited and used as a bot. To evaluate the impact of a particular security issue, we collect data from existing results of *Shodan*, instead of scanning vulnerable

Figure 6: Smart home IoT devices for vulnerability validation

devices directly. In this way, we don't introduce extra network scans. Most importantly, we release our findings to all affected vendors, and refrain from including the real name of any device that is still un-patched or under investigation.

### 3.3 Results Overview

We present our findings from the perspective of threats, by showing how many smart home IoT devices are potentially impacted by a given vulnerability or security weakness. However, it is also possible to look at the findings from a device's perspective, i.e., for a specific device, what kind of vulnerability or security weakness it may suffer from. The results are encouraging: we identified 324 device models from 73 vendors that are potentially vulnerable to a number of security issues. For the devices that we can confirm or disapprove, about 91% are confirmed to be vulnerable. The total number of users of these devices is estimated to be over 11.1 million.

#### 3.3.1 Vulnerable Software

To demonstrate how software vulnerabilities propagate across devices, we applied our analysis to five high profile vulnerabilities (shown in Table 3) that were reported in GoAhead web server which many smart home IoT devices utilize to provide a web-based interface. These vulnerabilities range from authentication bypass to backdoor account to remote code execution. We started from mobile companion app *object.liouzx.client* of *NEO Coolcam* IP Camera, which was known to be vulnerable to these vulnerabilities, and utilized the cross-app analysis to identify devices that might be similar in their software. Since these are relatively old vulnerabilities (reported in 2017), we expected fewer results. However, in total we still identified 72 device models belonging to 16 distinct vendors that share similar software as the vulnerable device. To validate the results, we utilized the methodology discussed in Section 3.2. We were able to confirm through online reports that 45 device models from four vendors are

indeed vulnerable. Since these results are already publicly disclosed, we included them in Table 3. Additionally, we confirmed through manual firmware analysis that six device models from three IP camera vendors, *Vendor A*, *Vendor B* and *Vendor C*, are also impacted by these vulnerabilities. We have informed those vendors about the vulnerabilities but no patch is released yet. Furthermore, we confirmed through real device that one baby monitor device from *Vendor D* is also impacted by the vulnerabilities. Vendor D has asked us to refrain from including their names until further investigation is done on their side. In total, we confirmed the existence of the vulnerabilities on 52 device models from eight different device vendors, with *seven device models from four vendors newly discovered*.

While validating the results, we also encountered one case where our platform mistakenly flagged a device as vulnerable. The analysis results output by the platform show that three device models produced by *KGUARD* have very similar interfaces with other vulnerable devices. However, our manual validation on the real device as well as emulated firmware shows that the *KGUARD* devices are not vulnerable. We inspected the firmware, and found that the software configuration of *KGUARD* is indeed very similar to the vulnerable devices. Specifically, we found that 26 out of 31 CGI programs and web pages are in common. But the vulnerable code was removed. Our hypothesis is that since these devices are relatively new on market (i.e., after the vulnerability was reported), *KGUARD* may have customized the software configuration and patched the vulnerability before releasing the product to the market.

We also want to highlight two observations we made during the process of results validation. First, although the vulnerabilities are old, we are still seeing a large set of devices to be potentially vulnerable. A Shodan search shows that there are potentially 58,456 devices running in the wild still being vulnerable and the total number of app downloads is more than 282,000 times. This is the result of a dataset with merely ~2K apps. With a large-scale analysis covering more device models and vendors, the problem can be even worse. This demonstrates a common issue in the smart home IoT market: the market is highly fragmented and many smaller vendors never bother taking care of the device after selling the device.

Another observation to highlight is the difficulty to validate the results, or rather the general challenge of evaluating the security of an IoT device. We were *not* able to validate findings on 17 device models from seven out of the 16 vendors, despite that the cross-app analysis tells us they might also be vulnerable. The validation was not successful for a number of reasons: some devices are not targeting U.S. market therefore we could not easily acquire, some devices do not provide firmware download therefore we could not evaluate, for devices that we could download firmware the encryption and packing render analysis difficult. In addition, the collaboration with device vendors have been very difficult. Many times,

Table 3: IoT devices impacted by vulnerable software and device rebranding

CVE	Impacted Vendor	Device Models	Validation Method	Mobile App	App Downloads	Confirmation Status
CVE-2017-8221 CVE-2017-8222 CVE-2017-8223 CVE-2017-8224 CVE-2017-8225	IP Camera Vendor A	4	Firmware	App A	100,000+	Newly Discovered
	IP Camera Vendor B	1	Firmware	App B	5,000+	
	IP Camera Vendor C	1	Firmware	App C	100,000+	
	Baby Monitor Vendor D	1	Device	App D	10,000+	
	Instar	2	Reports	camviewer.mobi.for_instar	1,000+	Independently Reconfirmed
	VStarcam	35	Reports	vstc.GENIUS.client	1,000+	
	Sricam	6	Reports	object.shazx1.client.yi object.smartmom.client	55,000+	
	Conceptronic	2	Reports/Firmware	camviewer.p2pwificam.client	10,000+	
	KGUARD	3	Device	object.kguard.client	10,000+	
	7 Vendors	17	N/A	7 apps	146,000+	Pending Confirmation

our email request about potential security issues went into a black hole (i.e., no responses ever received from the vendor). We believe this is also an artifact of market fragmentation as smaller vendors tend to care less about the security of their products.

### 3.3.2 Device Rebranding

Investigation of a more recent vulnerability, *CVE-2018-11560*, leads to another interesting finding of device rebranding. This vulnerability was initially reported in Insteon IP Camera 2864-222 (firmware 1.4.1.9), where the embedded web server on the device had a missing bounds check when parsing CGI parameters, resulting in a stack buffer overflow. We used the companion app of Insteon IP camera as the input to our Cross-App Analysis Engine to detect if any other devices might be vulnerable to the same vulnerability. To our surprise, we found that almost identical device interfaces are provided by a major IP camera vendor, *Foscam*. We initially suspected that the same web server might be used by both vendors, but later through research we found that Insteon IP camera 2864-222 is actually a rebranded version of Foscam IP Camera FI8918W—it is based on the exact same hardware and software but with a different brand name. Not surprisingly, early versions of Foscam IP camera also suffer from the same vulnerability, but no one has reported that.

The interesting part, however, is that Foscam actually patched the vulnerability *before* the vulnerability was reported in Insteon IP camera. We examined the firmware history of Foscam IP camera and found that the vulnerable code was shipped in over eight Foscam firmware versions before Jul. 2017, impacting at least 15 Foscam models. In firmware updates (2.x.1.120) of Jul. 2017, the vulnerability was patched. However, this patch never made it to the Insteon IP camera until the vulnerability was reported in 2018. We contacted Foscam about this issue, but their response neither confirmed nor denied the finding. Instead, we were advised to update to the newest version of firmware. This highlights another interesting issue about smart home IoT devices. Due to the fragmented market, smaller IoT vendors sometimes do not develop their own products. Instead, they customize IoT devices from OEMs and resell with their own branding. This

complicates the security management of the product and puts customers in danger, as vulnerabilities in upstream vendors tend to propagate to a broader set of downstream vendors but security patches are not. Indeed, a Shodan search with the IP camera fingerprints (e.g., server type, time stamps) shows that although Foscam released patches as early as Jul. 2017, there are still 30.7% (10,210 out of 33,230) devices that are not patched to the secure version.

Additionally, our analysis shows that re-branding is indeed not uncommon. With a dataset of ~2K apps, we identified 27 other re-branded device families not including Foscam example. Examples of these devices include smart plugs from *Bayit* and *Orvibo*, Wi-Fi sockets from *CHITCO* and *EDUP* and so on. Further validation is needed to confirm if these devices inherit any vulnerabilities from upstream vendors.

### 3.3.3 Vulnerable Hardware

Different IoT device vendors may rely on a common hardware module (e.g., Wi-Fi, Bluetooth), which, if vulnerable, could impact multiple devices. The challenge, however, is that IoT device vendors often do not publicize the hardware components in use. As a result, it is often difficult to decide if a device is vulnerable due to a vulnerable hardware component without tearing apart the physical device or unpacking the firmware to examine the driver code.

Through cross-app analysis, we identified a total of 166 devices belonging to 35 different vendors that are potentially impacted by two recent security weaknesses found in hardware. In one example, a recent study [36] demonstrated that Hi-Flying Wi-Fi module (HF-LPB100, HF-LPT100, HF-LPB200) can be leveraged by an adversary to steal home network Wi-Fi credentials. The Hi-Flying Wi-Fi module is a self-contained 802.11b/g/n module used by a number of IoT devices to provide wireless interfaces. As an important feature, the module supports credential (e.g., SSID, password) provisioning from device companion app to IoT device via *SmartLink*. As reported by the study [36], the provisioning process may leak Wi-Fi credentials: an adversary could passively listen to the traffic and gather the home Wi-Fi network credentials without much effort. Through our cross-app analysis, we identified that 26 apps, covering 108 devices from 21

vendors are potentially impacted by this security weakness. These apps have been downloaded more than 158,000 times. In another example, ESP8622, a low-cost Wi-Fi microchip that appears in many cheap IoT devices (e.g., Wi-Fi controller, smart plug), was reported to have a similar vulnerability in its *ESP-Touch* provisioning protocol. In our analysis, we identified that 21 apps covering 58 devices from 14 distinct vendors are potentially impacted by the security weakness. In total, these apps have been downloaded more than 120,000 times.

Among the devices flagged by the platform, we were able to confirm that 67 devices from 16 vendors are indeed impacted by the security weaknesses (43 devices from eight vendors are confirmed through vendor response. 24 devices from eight vendors are confirmed through firmware emulation, real device or online reports.). Through vendor response, we were also able to identify that seven devices from two vendors were mistakenly flagged by the platform as vulnerable (i.e., ~9% false positive rate). We manually examined the two apps to analyze the reason for the false positive. For one case, 14 devices supported by the *Revogi* app were flagged by the platform as potentially vulnerable. However, four of them (Power Plug SOW324, Power Strip SOW321 and SOW323, and Smart Light LTW311) were not actually using the vulnerable hardware. The issue was due to the imprecision of the static analysis performed by the platform. Since the app supports multiple devices from the same vendor, the code modules that control individual devices are not clearly distinguishable (i.e., some modules are shared across devices but others are independent). As a result, the platform was not able to attribute the network interfaces that correspond to the vulnerable hardware to a specific device. Instead, the platform outputs all the devices supported by the app as potentially vulnerable. For another case, three devices supported by the *smanos* app were flagged by the platform by mistake. The devices were found not to be using the vulnerable hardware, but the code module and the corresponding network interfaces that control the hardware was included in the app. This may be due to that the app developer built the app upon some open source templates that contain the hardware module, or maybe the device vendor changed their hardware configuration during the device development process, but the app code was never cleaned up. Nevertheless, the IPE method used by the platform is guided by static analysis to construct network interfaces as long as a code snippet is reachable from an Android *activity*, even though that activity may never be actually triggered by the real device.

### 3.3.4 Vulnerable Protocol

Similar to hardware components, IoT device vendors often do not publicize the protocols that a device speaks. These protocols range from more open and standard ones such as UPnP, mDNS and SSDP to proprietary ones such as TDDP<sup>5</sup>

<sup>5</sup>TDDP stands for TP-Link Device Debug Protocol.

used for debugging, penetrating private networks and various other purposes. Not knowing which protocol a device can speak creates a great security challenge of managing the device, especially when the protocols are found to be vulnerable or can be leveraged by an adversary to launch attacks.

Through cross-app analysis, we can identify devices that speak the same protocol, thus may suffer from similar security problems. For example, previous research [37] showed that SSDP protocol can be abused by adversaries in order to launch DDoS attacks. SSDP queries such as "ssdp:all" and "upnp:rootdevice" may result in a response size orders of magnitude larger, thus if openly accessible to the Internet may serve as a reflector to amplify requests sent by the attacker. Through cross-app analysis, we identified 39 devices from 11 different vendors that speak SSDP, despite that few of them clearly documented the protocol that their devices speak. As a result, once these devices are activated in the environment where a firewall is not configured to block incoming queries, they may act as reflectors for DDoS attacks. It's difficult to tell the exact number of devices that are exposed and vulnerable, but the total app downloads (over 10.2 million) indicate that a massive number of devices could possibly be harnessed by attackers.

We validated the results output by the platform. In total, we were able to confirm that 18 devices from six vendors are indeed speaking the SSDP protocol. One device, *Bixi* gesture controller, was mistakenly flagged by the platform. The case with *Bixi* gesture controller is interesting: the device itself does not speak SSDP, but its companion app does, therefore causing false positive for the platform. The reason is that the gesture controller is a device that allows users to control other devices via gesture. It does not speak SSDP but relies on its companion app to use SSDP to discover subsidiary devices for it to control. In this case, the network interface of the app is not an exact mirror of the device interface, causing false positives in the platform.

### 3.3.5 Vulnerable Backend Service

IoT devices may rely on the same IoT cloud backend service to relay command and control (e.g., to penetrate private home networks). When the backend service contains a security weakness, multiple IoT devices using the same service are impacted at the same time. However, without detailed knowledge of the registered customers of the cloud service, many of these impacted devices are left vulnerable until the problems are independently discovered.

Our cross-app analysis can help address this issue. In a particular case, the security weakness was initially reported on DeepSec 2017 [38], where an IoT cloud backend service is found to be using very short device IDs (i.e., only six digits) to register IoT devices. Consequently, any IoT device that is using the service to relay commands and control is vulnerable to device ID and password enumeration attacks. A successful

attack may enable attackers to authenticate to the device and abuse the device as a bot. We used the vulnerable device reported in DeepSec, *Yoosee*, as the seed for cross-app analysis and found 32 devices from 10 different vendors also rely on the same vulnerable backend to relay command and control. While it is hard to estimate the actual number of devices in the wild that are vulnerable, the total amount of downloads of these apps is over 226,000 times.

Among the 32 devices flagged by the platform, we were able to confirm that 12 devices from seven vendors are indeed sending requests to the specific backend server, and the device IDs are indeed enumerable (i.e., 6-digits). We also found that four devices from one vendor, namely *secrui*, were mistakenly flagged by the platform. The reason is similar to the "dead code" issue we encountered while validating results for devices with vulnerable hardware: we found that *secrui* app embedded a self-contained app *com/jwkj* that talks to the problematic backend server and thus the app interfaces exhibit similarity with those that are vulnerable. However, the embedded app was never actually executed nor did the devices supported by *secrui* app actually talk to the problematic backend server.

### 3.4 Accuracy of Results

In total, the platform flagged 324 devices from 73 vendors as potentially vulnerable, and we were able to confirm that 164 devices from 38 vendors are indeed vulnerable. This accounts for roughly 50.6% of all the devices flagged by the platform. During the process of validation, we were also able to identify that 15 devices from 5 vendors were mistakenly flagged by the platform as vulnerable. This accounts for 8.4% of all the devices that we could either confirm or disapprove (i.e., false positives). Table 4 enumerates the reasons for the false positives and the number of instances of each reason. The first reason for the false positive is the existence of the patch. After vulnerabilities were disclosed, vendors may patch the device. In this case, the app-device interface may stay largely the same, but the device is no longer vulnerable. This is a fundamental limitation of the approach, as the platform is designed to only extract information from the app, not the device. Thus, if the patch does not have any impact on the app, the approach cannot differentiate a vulnerable device from a patched one. The second reason for false positive is the "dead code" inside of the apps. Sometimes the apps may contain code that was *not* actually being used by the device (legacy code, code adopted from elsewhere without cleaning and etc.). Statically, it is difficult to decide if the code will ever be triggered and executed at runtime. Our platform currently may mistakenly include analysis results from such "dead code" if the "dead code" exhibit similarities with other vulnerable devices, thus causing false positives. The third reason for the false positive is the imprecision of the static analysis. Currently, the static analysis techniques used by the platform are

not precise enough to attribute network interfaces to individual devices if a single app supports multiple devices and these devices share much common control logic inside of the app. This issue, as well as the "dead code" issue listed above, are not a fundamental problem with the approach. Rather, they are an artifact of the static analysis techniques we used to analyze the apps in the platform. We are currently working on improvements to the techniques to improve the accuracy and precision of the static analysis. Finally, we encountered an exception case to our approach where the app interface is not an exact reflection of the device interface (i.e., the *Bixi* gesture controller). However, due to the nature of the device (i.e., a device that controls other devices), it is uncommon among the IoT devices. We are exploring the Google Play store to identify if there are any more devices of the similar kind.

Table 4: Reasons for the false positives

Reason	# of Devices	# of Vendors
Existence of the patch	3	1
Dead code inside of the apps	7	2
Fail to attribute interfaces to individual devices	4	1
Difference in device and app interface	1	1

## 4 Discussion

### 4.1 Miscellaneous Findings

During the process of analyzing the interfaces between apps and devices, we have some interesting observations, which are presented here.

**Confusing Trust Model.** We observed that IoT device developers sometimes have a confusing, if not conflicting, trust assumption regarding the local environment that their devices will run in. On one hand, they seem to assume that the local environment (i.e., consumer's home network) is not trustworthy. They apply encryption and authentication to protect the communication between the app and the device. On the other hand, they place an excessive amount of trust on the app, e.g. they would embed the encryption keys and authentication credentials into the app. In such a scenario, an adversary within the local environment can easily bypass the protections that the device developer built, as long as the adversary has access to the Google Play Store and has a basic knowledge of reverse engineering an app. As an example, TP-Link Smart Plug (HS110) accepts commands from its mobile companion app (and potentially anywhere else from within the LAN) without authentication. The vendor seems to be concerned about local threats to this design and, therefore, encrypts the communication. However, the encryption key in use (i.e., integer 171 XOR message) is simple and static, and most importantly built into the app. Anyone with access to the app can thus forge the

communication easily. This problem is also reported by [50]. Another example is the D-Link water sensor. D-Link water sensor requires authentication from its mobile companion app. However, the credentials used to authenticate the app is fixed (i.e., not configurable by user) and built into the app. These examples highlight the confusing mindset of many IoT device developers and the lack of general understanding of security. While in this paper we do not intend to give solutions to the problem, we believe a more standard architecture developed with security in mind can help limit the freedom offered to developers thus improving the security.

**“Convenient” Provisioning.** Smart home IoT devices are often headless—they do not provide direct user interfaces (e.g., touch screen, keyboard). As a result, they often rely on mobile companion apps to provision the credentials of home Wi-Fi network, in order for them to join the network. Our observation through studying the device interfaces is that the provisioning method is evolving from more user interactive approaches (e.g., AP Mode, WPS and out-of-band channels such as Bluetooth) to a more automated and hands-off approach where users do not need to do anything except providing the credentials. This presumably provides convenience, but many times at the cost of security. These newer methods such as *Smart Config* [30] and *Sound Wave*<sup>6</sup> often artificially create a side channel between the app and the device, and rely on these channels to transfer Wi-Fi credentials. Unfortunately, these side channels are publicly observable therefore allowing the credentials to be leaked. In addition, even without considering the openness of side channels, securing a side channel can often be much more difficult than normal means of communication. This highlights the long-lasting problem of balancing usability with security.

## 4.2 Limitations and Future Work

The major limitation of the approach discussed in this paper is the accuracy of the analysis results. As we based our analysis solely on mobile companion apps, we are inherently limited to the information we can obtain from the app, and sometimes the information we can obtain may not be an accurate reflection of the device. For example, a device may have patched a vulnerability and the patch did not change the device interfaces at all. In this case, our analysis will still output the device as potentially vulnerable since our platform would have no clue about the existence of the patch by just inspecting the app. This, however, is a trade-off we have to make in order to study IoT device security at scale. We believe a multi-stage solution can help address this limitation where the first stage (i.e., our platform) narrows down the scope of analysis by identifying the potentially vulnerable devices, and the second stage automates the vulnerability confirmation

<sup>6</sup>Wi-Fi credentials are encoded in the sound wave and sent out directly by the phone. This method is being used by devices such as 360 and *Securenet* IP Cameras.

with more targeted but rigorous analysis, e.g., dynamic/static analysis of firmware, device fuzzing.

Another limitation of the approach is that the network interface analysis can be rendered less effective in scenarios where IoT backend servers or cloud significantly decouple device interfaces from app interfaces. An example is the Google and Amazon devices where much of the management is done through the cloud. In this case, our approach can glean less information about the device software. However, information such as the Wi-Fi credential provisioning module and the backend services in-use are still available in the app, which allows the platform to predict security issues of these components.

This work could also benefit greatly from an automatic vulnerability collection system. Currently, this is a manual process: we manually collect the vulnerabilities and impacted devices that were reported publicly. We then propagate the vulnerability information to more devices through our platform. An automatic vulnerability collection system can help label the initial seed devices as well as evaluating security from a device’s perspective (i.e., to find the set of security issues that a given device may have).

Another aspect to improve on is the dimension and granularity of the similarity analysis, as mentioned in Section 2.4. Further improvements to the App Analysis Engine may allow the platform to detect similarities in finer components of a device software stack (e.g., web server, PHP interpreter, web application, OS, driver) as well as other dimensions (e.g., similar developer, similar development toolchain). This would enable us to track vulnerability propagation more comprehensively and accurately. We leave the refinement of the App Analysis Engine for future work.

The general methodology, i.e., utilizing companion app analysis to study the device, also enables a number of interesting applications that we plan to explore for the future work. For example, from app analysis, we could potentially tell what types of sensors are on a device and what types of network traffic a device may produce. This would allow a home security gateway, which is shipped as a default component of many Wi-Fi routers on the market, to enforce an accurate protection profile and detect anomalous behaviors of IoT devices in real time. As another example, instead of similarities, the Cross-App Analysis Engine in our platform can detect differences between devices. Such differences may enable a more accurate fingerprinting method of the device.

## 5 Related Work

**IoT device vulnerabilities.** IoT devices are affecting increasing number of users in every aspect of their life. Meanwhile, various studies revealed that firmware of many devices is filled with vulnerabilities. For instance, Paleari [44, 45] reported that D-Link DIR-645 routers expose critical web pages to unauthenticated remote attackers, allowing them to extract

root credentials and take full control of the device; also multiple web interfaces are affected by stack-buffer overflow that leads to remote code execution. Cui et al. [18] found that attackers may inject malicious firmware modifications to a device while it's updated. With the vulnerabilities and the huge amount of insecure devices [31], there arise a series of large-scale attacks, such as Mirai [35], BASHLITE [1], etc. To better understand the events, researchers have conducted comprehensive study on both features of the known vulnerabilities (and malware) [15] and their propagation [6, 39].

Various analysis approaches have been proposed to identify vulnerable IoT devices. For instance, with a network scanner (i.e., *nmap*), Cui et al. [19] found that over 13% devices are publicly accessible by default credentials. Similarly, using an Internet-wide scanning, Heninger et al. [27] showed that a large amount of TLS and SSH servers on embedded devices are affected by weak certificates and keys. Online services, *Shodan* [4] for example, allow security researchers to identify vulnerable online web services and devices. Such works are effective to find devices with known vulnerabilities and evaluate their impacts, but in many cases fail to catch problems that also appear in other devices.

Further, researchers are utilizing different techniques [16, 20, 24, 25, 47, 49, 55] to statically identify vulnerabilities in the device firmware. A majority of the approaches fall into the broader category of *vulnerability search*: derive *signatures* from known vulnerabilities, and then use them to search in other firmware images. To name a few, Costin et al. [16] conducted a large-scale study by scanning 32k firmware images with simple signatures (e.g., certificates, unique keyword), which is difficult to cover vulnerabilities that are not bound to specific strings. To address the problem, following works that collect robust features from such as I/O behavior of the image binary [47] and control flow graphs [24, 25] were proposed. Instead of extracting signatures from firmware image, Xiao et al. [55] presented an approach that discovers unknown vulnerabilities based on the study of existing security patches. In addition, Davidson et al. [20] built a symbolic execution framework on top of KLEE [9] for detecting vulnerabilities in MSP430 microcontroller family, which is difficult to scale as it needs to customize for specific architectural features of an IoT device. Similarly, Shoshitaishvili et al. [49] showed how symbolic execution and other techniques (e.g., program slicing) work to find authentication bypass vulnerabilities in a firmware image. Corteggiani et al. [14] improved symbolic execution of firmware by incorporating source code semantics, etc. While these approaches are effective, they rely on the static analysis of the firmware images, and therefore are limited in cases where the images are not publicly available or cannot be unpacked. In contrast, our work focuses on finding potential vulnerabilities using analysis of the IoT companion apps, which turns to be scalable, especially for IoT devices of smaller companies.

Another effective approach is dynamic firmware analy-

sis [10, 17, 42, 58]. Zaddach et al. [58] performed dynamic analysis by forwarding I/O access from an emulator to the actual hardware, and further, Muench et al. [42] presented how to orchestrate execution between multiple testing environments. Koscher et al. [34] used an FPGA bridge to allow the emulator full and real-time access to the hardware. While these approaches are accurate, they are not applicable to large-scale analysis because of the lack of budget to obtain the device, and the required effort to figure out the hardware interfaces. To address the problem, Costin et al. [17] built a QEMU-based emulation framework to discover vulnerabilities in web interfaces of an IoT device; Chen et al. [10] presented a full system emulation tool, FIRMADYNE, for Linux-based firmware in order to identify vulnerabilities. These works, however, also rely on feasibility of the firmware, and tend to be affected by the heterogeneous architectures of the firmware. Given the difficulty of fuzzing IoT devices directly [43], Chen et al. [11] proposed a testing method to detect memory corruptions in the device with the assistance from app analysis. Similarly, it requires presence of the physical device, and also fuzzing each individual device is time-consuming. Again, our work is more scalable since it is only based on static analysis of the companion apps, and leverages cross-app similarities as an indicator to find other potentially vulnerable devices.

**Mobile app analysis.** Dozens of static and dynamic techniques have been presented to analyze mobile apps. Among them, most related to our work are those [12, 32, 48, 60] proposed to collect runtime values in an Android app. These techniques may serve different purposes, e.g., collecting developer credentials [60], harvesting obfuscated/encrypted values for malware detection [48], extracting application imprints from network request [12] and reconstructing format of a protocol [32]. However, they have a basic idea in common: extracting parts of the application code (i.e., slices) that are related to the target (e.g., APIs, variables), and generating target value by only executing the slices. In this study, we designed the request construction with a similar *Instantiated Partial Execution* (IPE) as in [12]. Another related work is *Autoprobe* [56], which collects request probes from the malware, and then using the probes to fingerprint a remote malware server. *Autoprobe* is not applicable in our settings for several unique challenges. For instance, requests of an IoT device would not be triggered automatically because of the absence of the device; mobile companion apps often serve multiple devices, and thus it's difficult to pair the request and response and collect telemetry for each individual device. In our work, the interface analysis engine leverages several techniques that not only triggered the request, but also conducted a modularity analysis after locating the request/response pair.

## 6 Conclusion

In this paper, we present a platform to accelerate vulnerable device discovery in smart home IoT device market. Different

from previous approaches that examine real IoT devices or firmware images, our platform analyzes mobile companion apps of devices to indirectly detect device similarity and vulnerability propagation across devices, thus making it practical for large-scale analyses. By analyzing 2,081 mobile companion apps, our platform was able to discover 324 devices from 73 vendors that are potentially vulnerable to a number of security issues, out of which 164 devices from 38 vendors are confirmed to be indeed vulnerable.

## Acknowledgments

We are grateful to the anonymous reviewers for their insightful comments that greatly helped us improve the paper. In particular, we want to thank our shepherd, Adwait Nadkarni, for his guidance and constructive feedback about this paper. This work is supported in part by NSF CNS-1527141, 1618493, 1801432, 1838083 and ARO W911NF1610127.

## Abstract

In this paper, we provide the first large-scale empirical analysis of IoT devices in real-world homes by leveraging data collected from user-initiated network scans of 83M devices in 16M households. We find that IoT adoption is widespread: on several continents, more than half of households already have at least one IoT device. Device types and manufacturer popularity vary dramatically across regions. For example, while nearly half of North American homes have an Internet-connected television or streaming device, less than three percent do in South Asia where the majority of devices are surveillance cameras. We investigate the security posture of devices, detailing their open services, weak default credentials, and vulnerability to known attacks. Device security similarly varies geographically, even for specific manufacturers. For example, while less than 17% of TP-Link home routers in North America have guessable passwords, nearly half do in Eastern Europe and Central Asia. We argue that IoT devices are here, but for most homes, the types of devices adopted are not the ones actively discussed. We hope that by shedding light on this complex ecosystem, we help the security community develop solutions that are applicable to today's homes.

## 1 Introduction

The weak security posture of many popular IoT devices has enabled attackers to launch record-breaking DDoS attacks [4], compromise local networks [43, 57], and break into homes [22, 41]. However, despite much attention to IoT in the security community [22, 23, 29, 33, 55], there has been little investigation into what devices consumers are adopting and how they are configured in practice. In this work, we provide a large-scale empirical analysis of 83M IoT devices in 16M real-world homes. We partner with Avast Software, a popular antivirus company, whose consumer security software lets customers scan their local network for IoT devices that support weak authentication or have remotely exploitable

vulnerabilities. Leveraging data collected from user-initiated network scans in 16M households that have agreed to share data for research and development purposes, we describe the current landscape of IoT devices and their security posture.

IoT devices are widespread. More than half of households have at least one IoT device in three global regions and in North America more than 70% of homes have a network-connected device. Media devices like smart televisions are most common in seven of eleven global regions, but there is significant variance otherwise. For example, surveillance cameras are most popular in South and Southeast Asia, while work appliances prevail in East Asia and Sub-Saharan Africa. Home assistants are present in more than 10% of homes in North America but have yet to see significant adoption in other markets. There is a long tail of 14K total manufacturers, but surprisingly we find that 90% of devices worldwide are produced by only 100 vendors. A handful of companies like Apple, HP, and Samsung dominate globally, but there also exist a set of smaller vendors with significant regional adoption. For example, Vestel, a Turkish manufacturer, is the third largest media vendor in North Africa and the Middle East, but has negligible broader adoption.

A surprising number of devices still support FTP and Telnet with weak credentials. In Sub-Saharan Africa, North Africa, the Middle East, and Southeast Asia, around half of devices support FTP and in Central Asia, nearly 40% of home routers use Telnet. Similar to the regional differences in device type and manufacturer popularity, there are dramatic differences in the use of weak credentials. For example, while less than 15% of devices with FTP allow weak authentication in Europe and Oceania, more than half do in Southeast Asia and Sub-Saharan Africa. Interestingly, this is not entirely due to manufacturer preference. While less than 20% of TP-Link home routers allow access to their administration interface with a weak password in North America, nearly half do in Eastern Europe, Central Asia, and Southeast Asia. About 3% of homes in our dataset are externally visible and more than half of those have a known vulnerability or weak password.

Our results indicate that IoT is not a security concern of the

Figure 1: **WiFi Inspector**—WiFi Inspector allows users to scan their local network for insecure IoT devices. Data sharing back to Avast for research purposes is an explicit part of the installation process, and presented to the user in plain English. For ease of reading, we duplicate the text shown in panel (a) in Appendix A.

future, but rather one of today. We argue that there already exists a complex ecosystem of Internet-connected embedded devices in homes worldwide, but that these devices are of different than the ones considered by most recent work. We hope that by shedding light on the types of devices consumers are purchasing, we enable the security community to develop solutions that are applicable to today’s homes.

## 2 Methodology and Dataset

Our study leverages several network vantage points, including data collected from Avast, a passive network telescope, and active Internet-wide scans. In this section, we discuss these datasets and the role they play in our analysis.

### 2.1 WiFi Inspector

Avast Software is a security software company that provides a suite of popular antivirus and consumer security software products like *Avast Free Antivirus*. Avast software is sold on a freemium model: the company provides a free basic version of their product and charges for more advanced versions. Avast estimates that their software runs on 160 M Windows and 3 M Mac OS computers, and makes up approximately 12% of the antivirus market share [45].

As of 2015, all antivirus products from Avast include a tool called *WiFi Inspector* that helps users secure IoT devices and other computers on their home networks. WiFi Inspector runs locally on the user’s personal computer and performs network scans of the local subnet to check for devices that accept weak credentials or have remotely exploitable vulnerabilities. Scans can also be manually initiated by the end user. WiFi Inspector alerts users to security problems it finds during these scans and additionally provides an inventory of labeled IoT devices and vulnerabilities in the product’s main interface (Figure 1). We next describe how WiFi Inspector operates:

**Network Scanning** To inventory the local network, WiFi Inspector first generates a list of scan candidates from entries in the local ARP table as well through active ARP, SSDP, and mDNS scans. It then probes targets in increasing IP order over ICMP and common TCP/UDP ports to detect listening services.<sup>1</sup> Scans terminate after the local network has been scanned or a timeout occurs. After the discovery process completes, the scanner attempts to gather application layer data (e.g., HTTP root page, UPnP root device description, and Telnet banner) from listening services.

**Detecting Device Types** To provide users with a human-readable list of hosts on their network, WiFi Inspector runs a classification algorithm against the application-and transport-layer data collected in the scan. This algorithm buckets devices into one of fourteen categories:

1. Computer
2. Network Node (e.g., home router)
3. Mobile Device (e.g., iPhone or Android)
4. Wearable (e.g., Fitbit, Apple Watch)
5. Game Console (e.g., Xbox)
6. Home Automation (e.g., Nest Thermostat)
7. Storage (e.g., home NAS)
8. Surveillance (e.g., IP camera)
9. Work Appliance (e.g., printer or scanner)
10. Home Voice Assistant (e.g., Alexa)
11. Vehicle (e.g., Tesla)
12. Media/TV (e.g., Roku)
13. Home Appliance (e.g., smart fridge)
14. Generic IoT (e.g., toothbrush)

<sup>1</sup>WiFi Inspector scans several groups of TCP/UDP ports: common TCP ports (e.g., 80, 443, 139, 445); TCP ports associated with security problems (e.g., 111, 135, 161); common UDP ports (e.g., 53, 67, 69); and ports associated with services that provide data for device labeling (e.g., 20, 21, 22). When hosts are timely in responding, the scanner will additionally probe a second set of less common ports (e.g., 81–85, 9971). In total, the scanner will target up to 200 ports depending on host performance. The scanner will identify devices so long as they are connected to the network.

Protocol	Field	Search Pattern	Device Type Label	Confidence
DHCP	Class ID	(?i)SAMSUNG[- :_]Network[- :_]Printer	Printer	0.90
UPnP	Device Type	.*hub2.*	IoT Hub	0.90
HTTP	Title	(?i)Polycom - (? :SoundPoint IP )?(? :SoundStation IP )?	IP Phone	0.85
mDNS	Name	(?i)_nanoleaf(?:api ms)?\._tcp\.local\.	Lighting	0.90

Table 1: **Example Device Classification Rules**—Our device labeling algorithm combines a collection of 1,000 expert rules and a supervised classifier, both of which utilize network and application layer data. Here, we show a few examples of these expert rules, which provide 60% coverage of devices in a random sample of 1,000 devices.

We consider devices in the latter eleven categories to be IoT devices for the remainder of this work. Because the classifier greatly affects the results of this work, we describe the algorithm in detail in Section 2.2.

**Manufacturer Labeling** To generate a full device label, WiFi Inspector combines device type with the device’s manufacturer (e.g., Nintendo Game Console). Avast determines manufacturer by looking up the first 24 bits of each device’s MAC address in the public IEEE Organizationally Unique Identifier (OUI) registry [32]. We note that at times, the vendor associated with a MAC address is the manufacturer of the network interface rather than the device. For example, MAC addresses associated with some Sony Playstations belong to either FoxConn or AzureWave, two major electronic component manufacturers, rather than Sony. In this work, we manually resolve and document any cases that required grouping manufacturers together.

**Checking Weak Credentials** WiFi Inspector checks for devices that allow authentication using weak credentials by performing a dictionary-based attack against FTP and Telnet services as well as web interfaces that use HTTP basic authentication. When possible, WiFi Inspector will also try to log into HTTP-based administration interfaces that it recognizes. The scanner attempts to log in with around 200 credentials composed of known defaults (e.g., admin/admin) and commonly used strings (e.g., user, 1234, love) from password popularity lists, leaks, vendor and ISP default lists, and passwords checked by IoT malware. WiFi Inspector immediately notifies users about devices with guessable logins.

**Checking Common Vulnerabilities** In addition to checking for weak credentials, WiFi Inspector checks devices for vulnerability to around 50 recent exploits that can be verified without harming target devices (e.g., CVE-2018-10561, CVE-2017-14413, EDB-ID-40500, ZSL-2014-5208, and NON-2015-0211). Because there is bias towards more popular manufacturers in these scans, we do not provide ecosystem-level comparisons between different vulnerabilities.

## 2.2 Device Identification Algorithm

A significant portion of our work is based on identifying the manufacturers and types of IoT devices in homes. We de-

scribe the algorithm that Avast has developed in this section:

**Classifier** WiFi Inspector labels device type (e.g., computer, phone, game console) through a set of expert rules and a supervised classification algorithm, both of which run against network and application layer data. Classification is typically possible because manufacturers often include model information in web administration interfaces as well as in FTP and Telnet banners [4]. Additionally, devices broadcast device details over UPnP and mDNS [14]. WiFi Inspector uses expert rules—regular expressions that parse out simple fields (e.g., telnet banner or HTML title)—to label hosts that follow informal standard practices for announcing their manufacturer and model. This approach, while not comprehensive, reliably identifies common devices [4, 21]. WiFi Inspector contains approximately 1,000 expert rules that are able to identify devices from around 200 manufacturers. We show a sample of these rules in Table 1. However, these rules only identify 60% of devices from a random sample of 1,000 manually-labeled devices. To categorize the remaining devices, WiFi Inspector leverages an ensemble of four supervised learning classifiers that individually classify devices using network layer-data, UPnP responses, mDNS responses, and HTTP data. Therefore, when identifying a device, WiFi Inspector first tries the expert rules, and in the case of no match, next applies the ensemble of four supervised classifiers.

The network classifier is built using a random forest, which aggregates the following network features of a device:

1. MAC address
2. Local IP address
3. Listening services (i.e., port and protocol)
4. Application-layer responses on each port
5. DHCP class\_id and hostname

The UPnP, mDNS and HTTP classifiers leverage raw text responses. The classifier treats each response as a bag-of-words representation, and uses TF-IDF to weight words across all responses. This representation is fed as input to a Naïve Bayes classifier.

**Training and Evaluation** To train the supervised algorithm, Avast collected data on approximately 500K random devices from real-world scans. 200K of these were manually classified through an iterative clustering/labeling process, where experts clustered devices based on network properties

Classifier	Coverage	Accuracy	Macro F1
Supervised Ensemble	0.91	0.95	0.78
Network	0.89	0.96	0.79
UPnP	0.27	0.91	0.37
mDNS	0.05	0.94	0.25
HTTP	0.14	0.98	0.23
Final Classifier	0.92	0.96	0.80

Table 2: **Device Classifier Performance**—Our final classifier combines the supervised classifier and expert rules, and achieves 92% coverage and 96% accuracy against a manually labeled set of 1,000 devices.

Region	Homes		Devices	
North America	1.24 M	(8.0%)	9.2 M	(11.1%)
South America	3.2 M	(20.9%)	18 M	(21.6%)
Eastern Europe	4.2 M	(27.2%)	18.8 M	(22.6%)
Western Europe	2.9 M	(19.1%)	15 M	(18.0%)
East Asia	543 K	(3.5%)	3 M	(3.7%)
Central Asia	107 K	(0.7%)	500 K	(0.6%)
Southeast Asia	813 K	(5.3%)	3.6 M	(4.3%)
South Asia	824 K	(5.3%)	6.6 M	(7.7%)
N. Africa, Middle East	1.2 M	(7.5%)	6.1 M	(7.3%)
Oceania	124 K	(0.8%)	680 K	(0.8%)
Sub-Saharan Africa	266 K	(1.7%)	1.8 M	(2.2%)

Table 3: **Regional Distribution of Homes**—The 15.5M homes and 83M devices in our dataset are from geographically diverse regions. Because this breakdown is representative of Avast market share rather than organic density of homes and devices, we limit our analysis to within individual regions.

and labeled large clusters, winnowing and re-clustering until all devices were labeled. The remaining 300K devices were labeled using the expert rules. To tune model parameters, we performed five-fold cross-validation across the original training set. However, because the initial clustering was used to help identify devices in the clustering/labeling step, the dataset is not used for validation. Instead, Avast curated a validation set of 1,000 manually labeled devices, whose labels were never used for training. The final classifier achieves 96% accuracy and 92% coverage with a 0.80 macro average F1 score (Table 2). We mark devices we cannot classify as “unknown”.

### 2.3 Avast Dataset

Avast collects aggregate data about devices, vulnerabilities, and weak credentials from WiFi Inspector installations of consenting users for research and development purposes. Users are informed about this data collection in simple English when they install the product (Figure 1) and can opt out at any

time. We worked with Avast to analyze *aggregate data* about the types of devices in each region. No individual records or personally identifiable information was shared with our team. Although WiFi Inspector supports automatic vulnerability scans, we only use data from user-initiated scans in this paper so that we can guarantee that users knowingly scanned their networks. In addition, we exclude scans of public networks by only analyzing networks that were marked as home networks in Windows during network setup. We detail the ethical considerations and our safeguards in Section 2.6.

We specifically analyze data about devices found in scans run between December 1–31, 2018 on Windows installations. This dataset consists of data about 83 M devices from 15.5 M homes spanning 241 countries and territories, and 14.3 K unique manufacturers. For installations with multiple scans during this time period, we use the latest scan that found the maximum number of devices. We aggregate each country into 11 regions, defined by ISO 3166-2 [56]. As shown in Table 3, WiFi Inspector is more popular in Europe and South America than in North America. Because of this market share, as well as significant regional differences in IoT deployment, we discuss regions separately.

**Threats to Validity** While WiFi Inspector is installed in a significant number of homes, the dataset is likely colored by several biases. First, the data is predicated on users installing antivirus software on their computers. There is little work that indicates whether users with antivirus software have more or less secure practices. Second, we only analyzed data from installations on Windows machines due to differences between Mac and Windows versions of the software. This may skew the households we study to different socioeconomic groups or introduce other biases. Third, WiFi Inspector *actively notifies* users about problems it finds. As a result, users may have patched vulnerable hosts, changed default passwords, or returned devices to their place of purchase. This may skew our results to indicate that homes included in this study are more secure than in practice.

### 2.4 Network Telescope

While WiFi Inspector scans can identify the types of devices present in home networks, the data does not provide any insight into whether devices have been compromised. To understand whether devices are infected and scanning to compromise other devices (e.g., as was seen for Mirai [4]), we consider the IP addresses scanning in a large network telescope composed of approximately 4.7 million IP addresses. We specifically analyze the traffic for a 24 hour period on January 1, 2019 for scan activity using the methodology discussed by Durumeric et al. [17]: we consider an IP address to be scanning if it contacts at least 25 unique addresses in our telescope on the same port within a 480 second window. In total, we observe 1.7 M scans from a total of 529 K unique IP addresses from 1.4 billion packets during our measurement

period. Of the 500,716 homes scanned by WiFi Inspector on this day, 1,865 (0.37%) were found scanning on the network telescope.

## 2.5 Internet-Wide Scanning

We further augment the WiFi Inspector data with data collected from Internet-wide scans performed by Censys [16] to understand whether the vulnerabilities present on gateways (i.e., home routers) could be remotely exploitable. Similarly to our network telescope data, we investigate the intersection between Censys and Avast data for a 24-hour period on January 30, 2019 to control for potential DHCP churn. We also check whether devices that accept weak credentials for authentication present login interfaces on public IP addresses. We discuss the results in Section 4.

## 2.6 Ethical Considerations

WiFi Inspector collects data from inside users’ homes. To ensure that this data is collected in line with user expectations, we only collect statistics about homes where the user explicitly agreed to share data for research purposes. This data sharing agreement is not hidden in a EULA, but outlined in simple English. We show the dialogue where users acknowledge this in Figure 1. We note that this is an explicit *opt-out* process. The data sharing agreement is the last message shown to the user before the main menu, meaning users do not need to wait and remember to turn off data collection at a later time.

In order to keep up to date information on the devices in a home, WiFi Inspector runs periodic, automated scans of the local network. Automated scans do not perform any vulnerability testing or password weakness checks; they only identify devices through banners and MAC addresses. We limit our analysis to homes where a user explicitly *manually initiated* a network scan.

To protect user privacy and minimize risk to users, Avast only shared aggregate data with our team. This data was aggregated by device manufacturer, region, and device type. The smallest region contained over 100,000 homes. We never had access to data about individual homes or users; no personally identifiable information was ever shared with us. Avast did not collect any additional data for this work, nor did they change the retention period of any raw data. No data beyond the aggregates in this paper will be stored long term.

Internally, Avast adheres to a strict privacy policy: all data is anonymized and no personally identifiable information is ever shared with external researchers. All handling of WiFi Inspector data satisfies personal data protection laws, such as GDPR, and extends to data beyond its territorial scope (i.e., outside of the European Union). Specific identifiers like IP addresses are deleted in accordance with GDPR and only

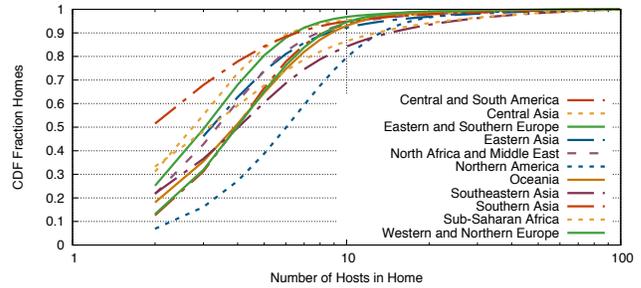

Figure 2: **Devices per Region**—There is significant variance in device usage across regions. The largest presence is in North America, where homes have a median seven hosts. Conversely, homes in South Asia have a median two hosts. The number of devices per home starts at two as all homes require at least one computer and one router to be included.

collected when explicitly necessary for the security function of the product.

## 3 IoT in Homes

It is vital that the security community understands the types of IoT devices that consumers install and their respective regional distributions given their increasing security and privacy implications. In this section, we provide one of first large-scale analyses of these devices based on scans from 15.5 M homes.

The presence of IoT devices varies by region. For example, while more than 70% of homes in North America have an IoT device, fewer than 10% of homes in South Asia do (Figure 2). Media devices (i.e., smart TVs and streaming devices) are the most common type of device in seven of the eleven regions, in terms of both presence in homes (2.5%–42.8%) and total number of devices (16.6%–59.0%). Four regions differ: surveillance devices are most common in South and Southeast Asia, while work appliances are most common in East Asia and Sub-Saharan Africa. We show the most popular devices in each region in Table 4.

Despite differences in IoT popularity across regions, there are strong correlations between regions for the *types* of devices that are popular.<sup>2</sup> In other words, the most popular types of devices are similar across regions. Still, certain pairs of regions differ. For example, homes in all Asian regions are least similar to homes in North America. On the other hand, homes in geographically similar regions (e.g., South Asia and Southeastern Asia) are highly correlated, even when they differ from the global distribution. The fact that distinct regions

<sup>2</sup>To quantify the preference for difference types of devices across regions, we leverage a Spearman’s rank correlation test across each pairwise region, taking the rank ordered list of device types for each region as input (Table 5). Per Cohen’s guidelines, we find all regions rank ordered distributions are strongly correlated (>0.7 coefficient) with p-values < 0.05 [11], indicating little change in the rank order of device type distributions across regions.

Region	IoT		Media/TV		Work Appl		Gaming		Voice Asst.		Surveil.		Storage		Automat.		Wearable		Other IoT	
	Homes	Devices	H	D	H	D	H	D	H	D	H	D	H	D	H	D	H	D	H	D
North America	71%	42.8	44.9	32.7	28.0	16.0	12.0	9.5	7.5	3.9	3.7	2.7	1.7	2.3	1.9	0.2	0.1	0.4	0.2	
South America	34.4%	20.5	51.7	7.5	24.0	4.3	9.8	0.1	0.3	4.6	13.3	0.3	0.6	0.0	0.1	0.0	0.1	0.1	0.2

East Asia	30.8%	12.2	25.8	14.9	44.5	6.3	12.1	0.9	1.6	2.2	9.1	3.1	6.5	0.1	0.2	0.1	0.2	0.0	0.1	
Central Asia	17.3%	13.5	54.2	1.6	12.0	0.6	2.4	0.0	0.2	2.4	30.3	0.2	0.8	0.0	0.0	0.0	0.1	0.0	0.0	
Southeast Asia	21.7%	9.0	25.4	7.5	31.2	1.0	2.7	0.2	0.5	7.8	37.0	0.9	2.7	0.1	0.2	0.1	0.3	0.0	0.0	
South Asia	8.7%	2.5	16.6	2.7	24.2	0.4	2.4	0.1	0.8	4.1	54.5	0.2	1.1	0.0	0.2	0.0	0.2	0.0	0.0	
N. Africa, M. East	19.1%	9.4	35.7	5.1	26.2	1.8	6.4	0.1	0.3	5.2	28.5	0.7	2.4	0.0	0.2	0.0	0.2	0.0	0.1	
Oceania	49.2%	30.7	46.6	19.8	25.9	10.1	12.7	3.2	4.2	3.0	5.3	3.5	4.3	0.7	0.9	0.1	0.2	0.0	0.0	
Sub-Saharan Africa	19.7%	6.9	21.7	10.9	49.9	2.5	7.1	0.1	0.4	2.8	18.0	0.8	2.3	0.1	0.3	0.1	0.3	0.0	0.1	

Table 4: **IoT in Homes**—We show the percent of households that have one or more of each type of IoT device and the percent of devices (in gray) in each region that are of a certain type. For example, 42.8% of homes in North America have at least one media device and 44.9% of North American IoT devices are media devices. For the presence of any IoT device, we only report the percent of homes with an IoT device.

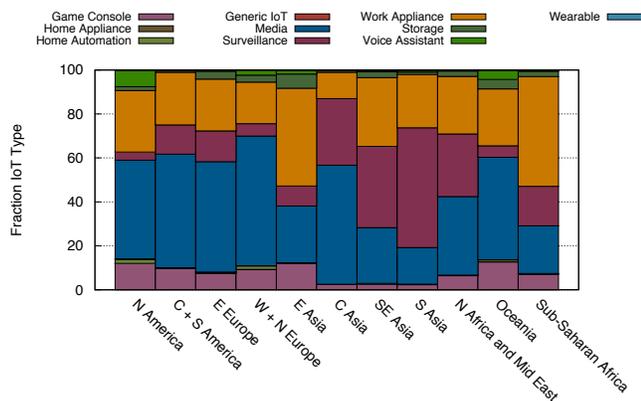

Figure 3: **IoT Device Distribution by Region**—IoT device type distributions vary between different geographic regions. For example, Surveillance devices are most prevalent in Asia, whereas Home Automation devices only appear in North America and Europe.

have unique preferences for device types points to deeper differences between regions, making it harder to reason about IoT in aggregate and more challenging to generalize findings from one region to others.

We also considered the relative popularity of types of devices within each region. Even in areas with similar rank order popularity, the proportion of device types in those regions varies (Figure 3). We compute a pairwise proportion test across each region to quantify the differences between regions and find that nearly all regions have varying proportions of IoT device types, except when a device type accounts for fewer than 1% of devices. We discuss each region below.

	N. America	S. America	E. Europe	W. Europe	East Asia	Central Asia	SE Asia	South Asia	N. Africa, ME	Oceania	S-S Africa
North America	–	81	88	92	88	76	77	81	87	93	86
South America	81	–	87	85	90	85	88	87	90	90	92
E. Europe	88	87	–	95	95	93	93	94	98	98	96
W. Europe	92	85	95	–	90	88	83	87	92	95	89
East Asia	88	90	95	90	–	90	93	92	93	98	99
Central Asia	76	85	93	88	90	–	93	90	94	90	93
Southeast Asia	77	88	93	83	93	93	–	99	95	96	95
South Asia	81	87	94	87	92	90	99	–	97	92	95
N. Africa, Middle East	87	90	98	92	93	94	95	97	–	96	95
Oceania	93	90	98	95	98	90	96	92	96	–	96
Sub-Saharan Africa	86	92	96	89	99	93	95	95	95	96	–

Table 5: **Regional Similarities**—We calculate the similarity between regions by computing the Spearman’s rank correlation test over each region’s rank order list of most popular types of devices. We show the most similar region (green) and least similar region (red) by row. Correlation coefficients presented are out of 100. In all cases, p-values were < 0.05.

### 3.1 North America

North America has the highest density of IoT devices of any region: 71.8% of homes have an IoT device compared to the global median of 40.2%. Similar to other regions, media devices (e.g., TVs and streaming boxes) and work appliances account for the most devices in North American homes. Nearly half of homes have one media device and one third have a work appliance (Table 4). Media devices are also the most prolific, accounting for 44.9% of IoT devices in North America. In contrast, work appliances only account for 28% of devices (Table 4). There is a long tail of manufacturers that produce media devices in the U.S., and the most popular vendor, Roku, only accounts for 17.4% of media devices (Table 11). Second most popular is Amazon (10.2%). In

contrast, there are only a handful of popular work appliance vendors—HP is the most common and accounts for 38.7% of work appliances in North America.

Though popular in every region, a considerably higher number of homes in North America contain a game console. This is one of the reasons that a smaller fraction of IoT devices are media-related than in Western and Northern Europe. There are three major vendors of game consoles: Microsoft (39%), Sony (30%),<sup>3</sup> and Nintendo (20%).

North America is the only region to see significant deployment of home voice assistants like Amazon Echo [3] and Google Home [25]. Nearly 10% of homes now have a voice assistant and the device class accounts for 7.5% of IoT devices in the region. Two thirds of home assistants are Amazon produced, the remaining one third are Google devices. North America is also one of the only region to see automation devices, which are present in 2.5% of homes. There are four major manufacturers in this space, Nest<sup>4</sup> (44.2%), Belkin (15.1%), Philips (14.4%), and Ecobee (9.8%). These vendors sell products such as the Nest Thermostat [42], Wemo smart plug [5], Philips Hue Smart Lights [46], and the Ecobee Smart Thermostat [19].

The relative ranking of IoT device type popularity generally does not change as more IoT devices are added to North American homes. To quantify this, we calculate the Spearman rank correlation for each pairwise set of homes based on the number of devices and observe only slight deviations from the overall regional distribution. As more devices are added to the network, the correlation coefficients for North America hover between 0.98–1.0, indicating minimal change. Despite minimal change in the relative ranking of IoT device types, we note that the fraction of each device type does vary as more IoT devices are added to the home. For example, for homes with one IoT device, voice assistants make up only 3.9% of all devices, down from 7.3% across all homes. Game consoles are also more popular in homes with only one IoT device, up from 13.9% to 16.5%.

## 3.2 Central and South America

South American homes are the least similar to North America of any region (Table 5). While the most common types of IoT devices in both regions are media devices (51.7% vs 44.9%) and work appliances (24% vs 28%), significantly fewer South American homes have an IoT device (34% vs 71%) and there are significantly more surveillance devices: 13.3% vs 3.7% of devices (Table 4). Prior research uncovered that there is an increased reliance on surveillance devices in Brazil and surrounding regions to deter violence [27, 34],

<sup>3</sup>Sony PlayStation devices are split across three vendors in this distribution primarily due to their network cards being manufactured by two third party vendors, Azurewave (11.6%) and Foxconn (9%).

<sup>4</sup>A classification error misclassifies Nest products as mobile devices. We manually correct this in our analysis since Nest does not sell mobile devices.

which may offer one explanation. The only other device type we commonly see are game consoles (9.8% of devices). No other class appears in more than a fraction of a percent of homes.

The vendor distribution of media devices in Central and South America differs from the global distribution. Two vendors appear in the top 5 for this region that do not appear in any other region. First is Arcadyan, a Taiwanese company that primarily manufactures cable boxes in this category, and is often found in LG Smart TVs. The second is Intelbras, a Brazilian company that manufactures DVRs and smart video players. Intelbras accounts for 11% of the surveillance cameras in the region, though they are third to Hikvision and Dahua.

## 3.3 Europe

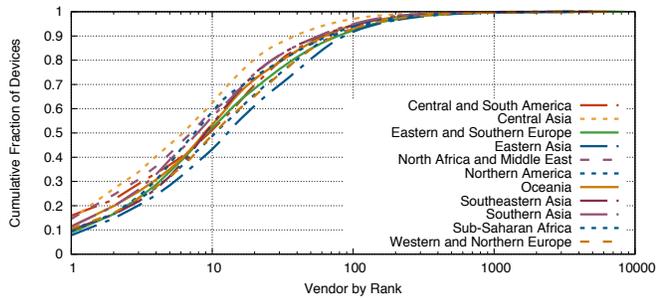

Eastern and Western Europe are both most similar to Oceania, primarily due to the three regions sharing a similar fraction of storage devices (Table 4). Still, the regions vary in terms of their IoT usage: 57.2% of Western European homes have at least one IoT device, compared to 25.7% in Eastern European homes.

Manufacturers in Western Europe are similar to the global distribution with a handful of exceptions. Sagemcom and Free, two French companies that sell media boxes and IP cameras, are the first and third largest media vendors in Western Europe, accounting for 15.7% and 9.3% of all devices compared to 5.7% and 3.2% globally. The markets of both companies are highly localized, as 99% of their devices in our dataset are located in Western and Northern Europe. In other device categories, such as work appliances, game consoles, and home automation, there is limited variance from the global distribution. Outside of North America and Oceania, Western Europe is the only other region where more than 1% of homes have a home automation device.

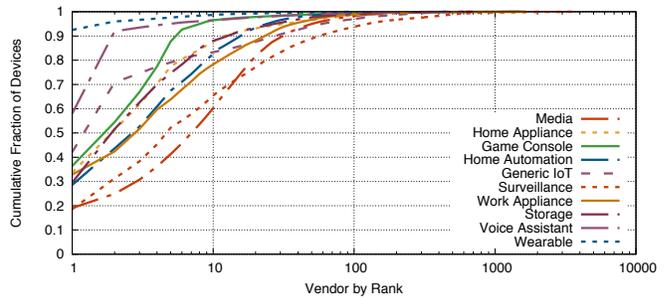

There are significantly more surveillance devices in Eastern Europe than Western Europe (14% versus 5.6% of devices). Eastern Europe is also unlike most other regions in that its rank ordered device type distribution changes as more IoT devices are added over time. For homes with one IoT device, surveillance devices only make up 5.3% of all IoT devices, but this changes drastically for homes with 3 IoT devices, where the number of surveillance devices shoots up to 13.8%. The fraction of surveillance devices continually increases as more IoT devices are added to Eastern European homes. In homes with 10 IoT devices, surveillance devices are the most popular device, accounting for 42.7% of all devices.

## 3.4 Asia

We analyze the four regions (East, Central, South, and South-east) of Asia separately as they have different IoT profiles. For example, surveillance devices make up 54.5%, 37%, and

(a) Vendors per Region

(b) Vendors per Device Type

**Figure 4: IoT Vendors per Region and Device Type**—There is a long tail of IoT manufacturers worldwide. However, in all regions, 100 vendors account for more than 90% of devices and 400 vendors account for 99%. In contrast, some device types are almost entirely dominated by one or two vendors. For example, Amazon and Google produce 91.9% of voice assistants and Hikvision produces 18.6% of surveillance devices.

30.3% of devices in South, Southeast, and Central Asia (Figure 3), whereas only 9.1% of devices are surveillance related in East Asia. This is not due to a large number of homes with cameras, but rather that other types of IoT devices are sparse. For example, only 9% of S.E. Asian Homes and 2.5% of South Asian homes contain a media device whereas more than 40% homes in North America and Western Europe do. Similar to other regions, Hikvision is the most prevalent vendor of surveillance devices in S.E. Asia and South Asia, making up 25.8% and 34.7% of surveillance devices in each region respectively. Unlike other regions, a private<sup>5</sup> vendor accounts for 15.5% of all surveillance devices in Southern Asia.

East and Central Asia are more similar to Eastern Europe and Africa than they are to South and Southeast Asia. East Asia, for example, is most similar to Sub-Saharan Africa because its largest device type is work appliances, which make up 44.5% of the devices in the region. Central Asia more closely follows Eastern Europe with media devices accounting for 54.2% of devices. All Asian regions do have one thing in common: they are all the least similar to North American homes, indicating fundamental differences in IoT device usage between the Asian countries and North America.

### 3.5 Africa and Middle East

The North Africa, Middle East (combined) region is most similar to Eastern Europe. Media devices are the most prevalent, appearing in 9.4% of homes and accounting for 35.7% of devices. Again, we observe a local media vendor with a large presence: Vestel, a Turkish TV manufacturer, is the third largest media vendor after Samsung and LG. Surveillance devices make up 28.5% of their overall devices, and appear in 5.2% of homes. Sub-Saharan Africa is distinct in

<sup>5</sup>Private vendors are ones that have paid an additional fee to IEEE to keep their MAC address mapping off of the public OUI list.

that work appliances are most popular (50% of devices). 11% homes in the region have at least one work appliance. The most popular vendor is HP (33.6%), followed by a long tail of other manufacturers.

### 3.6 Oceania

Oceania ranks third to North America and Western Europe in terms of fraction of homes that contain an IoT device (49.2% of homes). Similar to other regions, the most popular device type in the region are media devices, which are found in 30.7% of homes. This is followed by work appliances (19.8% of homes) and gaming consoles (10.1% of homes). Oceania is one of the only regions that contains home automation devices, appearing in 0.7% of homes in our dataset. Similar to North America and Western Europe, Oceania has a moderate number of voice assistant devices, which appear in 3.2% of homes and account for 4.2% of all devices. Unlike North America and Western Europe, homes in Oceania contain many networked storage devices. They account for 4.3% of all devices, which is most similar to homes in Eastern Europe and East Asia.

### 3.7 IoT Device Vendors

While we find devices from 14.3K unique vendors, 90% of all devices globally are manufactured by 100 vendors (Figure 4a). Globally, there are 4,157 vendors (29%) that only appear in one home. Unlike device type distributions, which are consistent across region, vendor distributions vary heavily across device type (Figure 4b). Some device types are dominated by a small handful of vendors. For example, Amazon and Google account for over 90% of voice assistant devices globally. Other device types like media devices and surveillance devices are split across many vendors. Media devices are the most heterogeneous by vendor: the top 10 vendors only account for 60% of devices.

Device Type	Mean Correlation	Top-10 Mean Correlation
Game Console	<b>0.43</b>	<b>0.49</b>
Voice Assistant	<b>0.23</b>	<b>0.26</b>
Home Automation	<b>0.98</b>	<b>0.98</b>
Surveillance	0.07	<b>0.28</b>
Work Appliance	0.04	<b>0.22</b>
Storage	0.05	-0.03
Media	0.04	0.09
Router	0.01	0.02
Mobile Device	0.01	0.03

Table 6: **Vendor Correlation by Device Type**—We show the mean correlation in rank ordered vendor distributions per device type across every pair of regions across all vendors as well as the top 10 vendors in each category. The correlations in bold are statistically significant, and indicate consistency in vendors for these device types across all regions in our dataset.

Regional differences in vendor preferences may cause the observed variance in vendor distributions across device types. To measure this, we compute the pairwise Spearman’s correlation for each vendor distribution across every pair of regions (e.g. vendor distribution for voice assistants in North America vs. East Asia). We then aggregate<sup>6</sup> over device type by taking the average correlation across each pair of regions (Table 6).

We observe that device types dominated by a handful of vendors globally (Figure 4b) show moderate to strong correlations across all regions, indicating stability in popular vendors across geographic areas. For example, game consoles are dominated by three major players (Microsoft, Sony, Nintendo) in almost every region across the world. In contrast, there are a number of device types, such as media and storage devices, for which there are no correlations across region, even when looking only at the top 10 vendors. This indicates that for these device types, regions have differing vendor preferences. This result aligns with our investigation of individual regions, where we observed many regions prefer local media vendors that are less prevalent in the global distribution.

## 4 Home Security

Beyond understanding the landscape of IoT devices, we investigate the security profile of devices in homes, including devices that allow weak authentication, the security profile of

<sup>6</sup>We note that correlation coefficients are not additive, so to aggregate we convert the respective correlation r-values to z-values using a Fisher’s Z transform [13], take the average of the Z values, and convert back to an r-value. In addition, we could only compare rank order for vendors who appeared in all 11 regions in the dataset. There were three device categories (wearables, home appliances, generic IoT) for which no vendors appeared in all regions; we could not compute correlations in these cases.

Port	Service	Devices	Port	Service	Devices
1900	UPnP	46.2%	139	SMB	10.6%
80	HTTP	45.7%	8443	HTTPS Alt.	9.5%
5353	mDNS	39.2%	8009	HTTP Alt.	9.3%
8080	HTTP Alt.	26.9%	445	SMB	8.7%
443	HTTPS	21.1%	7676	Custom	8.2%
9100	JetDirect	19.5%	49152	–	7.9%
515	LPR	16.5%	21	FTP	7.8%
631	IPP	11.8%	5000	UPnP	7.8%
554	RTSP	11.8%	23	Telnet	7.1%
8008	HTTP Alt.	11.1%			

Table 7: **Popular IoT Services**—We show the common open ports in IoT devices in our dataset. The most popular protocols are related to device discovery (UPnP, mDNS) and device administration (HTTP, HTTPS).

Credential	%	Credential	%
admin/admin	88.3%	admin/admin	35.6%
admin/	5.9%	root/xc3511	16.0%
Administrator/	1.4%	vodafone/vodafone	10.4%
sysadm/sysadm	0.9%	guest/guest	7.8%
root/	0.7%	admin/1234	7.5%
root/root	0.4%	root/hslwificam	3.9%
user/	0.4%	root/vizxv	3.7%
meo/meo	0.3%	root/oelinux123	2.2%
admin/password	0.3%	admin/4321	1.8%
admin/ttnet	0.3%		1.6%
other	1.0%	other	9.5%

(a) Weak FTP Credentials

(b) Weak Telnet Credentials

Table 8: **Most Popular Weak FTP and Telnet Credentials**—admin/admin accounts for the 88.3% and 35.6% of the weak FTP and Telnet credentials.

home routers, and the presence of homes that exhibit scanning behavior on a large darknet.

Many IoT devices act as embedded servers: 67.5% of devices provide at least one TCP- or UDP-based service. Many of these services are not surprising—network printers necessarily run services like IPP. However, we also note that devices commonly support older protocols like Telnet (7.1% of IoT devices) and FTP (7.8%). The most common protocol is Universal Plug and Play (UPnP), which is prevalent on 46.2% of devices. We also observe HTTP and mDNS on nearly half of devices. We show the top protocols in Table 7.

### 4.1 Weak Device Credentials

WiFi Inspector identifies devices that allow authentication with weak default credentials by attempting to log in to FTP and Telnet services with a small dictionary of common default credentials (Section 2). We find that 7.1% of IoT devices and 14.6% of home routers support one of these two protocols.

Region	FTP										Telnet						HTTP
	All IoT		Work Appl.		Surveillance		Router		Storage		All IoT		Surveillance		Router		TP-Link
	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln	Sup	Vuln

Sub-Saharan Africa	55.3	15.4	61.5	27.2	10.8	5.1	23.6	12.5	10.1	35.4	1.1	12.0	5.2	14.1	1.6	20.9	25.4

**Table 9: Weak Default Credentials by Region and Device Type**—We show the weak FTP and Telnet device population by region and device type, highlighting both the fraction of devices that support (Sup) each protocol as well as the fraction that are vulnerable with weak default credentials (Vuln). Some regions have a higher fraction of devices with weak credentials—in the largest case, 50% of FTP devices in Southeast Asia and 4.9% of all Telnet devices in Central Asia are weak. We further observe that the likelihood of having weak FTP credentials is correlated to weak Telnet credentials, indicating that the presence of weak credentials may be linked to weaker security posture in the region overall.

Of those, 17.4% exhibit weak FTP passwords and 2.1% have weak Telnet passwords. In both cases, `admin/admin` is most common and accounts for 88% of weak FTP and 36% of weak Telnet credentials (Table 8). The credential is used by FTP devices from 571 vendors and from 160 Telnet vendors.

Regions vary in terms of vulnerable IoT device populations. In the smallest case, 14.7% of FTP devices in Western Europe support weak default credentials while more than 55% of FTP devices in Sub-Saharan Africa that are weak. A similar, though not as drastic range exists for Telnet. North America has the smallest vulnerable population of Telnet devices (0.5%), Central Asia and South America share the largest vulnerable Telnet population (4.9% of all IoT Telnet devices), primarily because of their reliance on surveillance devices, which have the weakest Telnet profile of all IoT devices.

Nearly all of the IoT devices that support FTP are work appliances (76%), storage (9.1%), media (7.6%), and surveillance devices (5.1%). Media and surveillance devices appear in the list due to their global popularity—unlike storage and work appliances where 29% and 23% of devices support FTP respectively, only 1% of media devices and 4% of surveillance devices support FTP. This aligns with the business need for work and storage devices to facilitate user file transfer, and also explains why there is little variance in the types of devices that support FTP across regions.

Storage devices are the device type most likely to support FTP, though only a small fraction of them use weak credentials. There are two regional exceptions—East Asia and Sub-Saharan Africa (Table 9), which exhibit 12.2% and 10.1% of storage devices with weak credentials respectively. We observe this is primarily due to one vendor, ICP Electronics, which has a large market presence in the two regions: 12.1% and 10.1% of storage devices in East Asia and Sub-Saharan

Africa respectively. 74% of ICP storage devices exhibit weak default credentials.

A surprising number of home routers also support FTP (10.2%). TP-Link is responsible for the most routers with weak FTP credentials (Table 10)—regions that rely on TP-Link routers thus have a higher rate of devices with weak FTP credentials. Of all TP-Link devices across all regions, 9.3% offer an open FTP port, and 62.8% of those devices are protected by weak credentials.

Unlike FTP, there is little reason for any IoT devices to support Telnet in 2019. Yet, we find both that surveillance devices and routers consistently support the protocol. Surveillance devices have the weakest Telnet profile, with 10.7% of surveillance devices that support Telnet exhibiting weak credentials. This aligns with anecdotal evidence that suggests that these kinds of devices are easy to hack [4].

## 4.2 Home Routers

Nearly every home in our dataset has a home router. Similar to most types of IoT devices, there are regional differences and a long tail of vendors globally (Table 9). In total, we see home routers from 4.8K vendors. TP-Link is the most popular manufacturer globally (15% of routers) and is the top provider in five regions: South America, Central Asia, Eastern Europe, South Asia, and Southeast Asia. Arris is the most popular router vendor in North America (16.4%)—likely because popular ISPs like Comcast supply Arris routers to customers. Huawei is the most popular vendor in Sub-Saharan and North Africa, accounting for 19.8% and 25.6% of all routers respectively.

Vendor	% Open	% Weak	% of Weak	Vendor	% Open	% Weak	% of Weak	Vendor	% Open	% Weak	% of Weak
Ricoh	92.1%	71.2%	29.8%	TP-Link	9.3%	62.8%	55.9%	D-Link	38.9%	6.1%	33.0%
Kyocera	91.7%	97.1%	26%	Technicolor	22.9%	20.4%	9.6%	Huawei	13.6%	4.8%	18.7%
HP	7.3%	92.4%	24.5%	ZTE	9.9%	37.5%	9.5%	TP-Link	15.0%	1.4%	12.6%
Sharp	89.4%	94.2%	6.4%	MicroTik	46.9%	13.0%	5.3%	Zyxel	53.5%	2.9%	12.1%
Canon	2.7%	79.3%	2.1%	D-Link	16.2%	10.9%	3.9%	Intelbras	12.7%	26.4%	7.1%

(a) Work Appliance (FTP)

(b) Router (FTP)

(c) Router (Telnet)

**Table 10: Weak Vendors by Device Type**—We show the vendors that exhibit weak default credentials across each device type in our dataset sorted by the fraction of weak devices they contribute to their respective device types. For example, 71.2% of Ricoh printers that support FTP also support weak default credentials, and these make up 29.8% of all weak work appliances.

**Weak FTP/Telnet Credentials** More than 93% of routers have HTTP administration interfaces on port 80. We also find that many routers support DNS over UDP (66.5%), UPnP (63.4%), DNS over TCP (42.1%), HTTPS (42.2%), SSH (19.7%), FTP (10.8%), and Telnet (14.6%). Of the devices that support FTP and/or Telnet, 12% have weak FTP and 1.6% have weak Telnet credentials. 1.2% of *all* routers exhibit a weak FTP credential and 0.2% exhibit of all routers have a weak Telnet credential. For FTP, TP-Link routers had the weakest profile: 55.3% of their routers with an open FTP port exhibited a weak credential. For Telnet, D-Link routers were the weakest—6% of all open routers had a weak credential, and 35.3% of all D-Link routers had an open Telnet port. We show a breakdown by region in Table 10.

**Weak HTTP Administration Credentials** WiFi Inspector attempts to login to the HTTP interfaces for devices from a small number of common vendors, including TP-Link—the most common router manufacturer. In our dataset, there are 3.8M TP-Link home routers, of which 82% have an HTTP port open to the local network. WiFi Inspector was able to check for weak default credentials on 2.5 M (66%) of the devices with HTTP. Overall, 1.2 M (30%) of TP-Link routers exhibit weak HTTP credentials. Nearly all (99.6%) use `admin/admin`. The number of TP-Link routers with guessable passwords varies greatly across regions (Table 9). For example, only 6% of TP-Link routers in North America have weak passwords while around 45% do in South and Central Asia, and East and South Europe.

**External Exposure** To understand whether routers with weak default credentials are also exposed on the public Internet, we joined the WiFi Inspector dataset with Internet-wide scan data from Censys [16] for devices on a single day—January 30, 2019.<sup>7</sup> A small number of home routers host publicly accessible services: 3.4% expose HTTP, 0.8% FTP, 0.7% Telnet, and 0.8% SSH. Open gateways are primarily located in three regions—Central America (29.3%), Eastern Europe (20.6%), and Southeast Asia (17.2%). Of routers that are externally exposed, we find that 51.2% of them are

exposed with a vulnerability—far higher than the fraction non-externally available routers in our dataset with a weakness or vulnerability (25.8%). The most popular router vendor in these regions is TP-Link, which is also the vendor responsible for the most externally exposed routers (19.7%). We note this is not simply because TP-Link is the largest vendor—a proportion test across regions shows that TP-Link routers appear in the set of externally exposed routers at a higher rate than that of non-externally exposed routers.

### 4.3 Scanning Homes

While scan data can provide insight into the vulnerability of hosts, it typically does not indicate whether hosts have been compromised. We analyzed the homes from WiFi Inspector that were seen performing vulnerability scans in a large network telescope (Section 2) on January 1, 2019 to better understand infected devices. Of the 500.7 K homes that WiFi Inspector collected data from that day, 1,865 (0.37%) homes were found to be scanning for vulnerabilities. Scans most frequently target TCP/445 (SMB, 26.7% homes) followed by TCP/23 (Telnet, 11.3%), TCP/80 (HTTP, 10.7%), and TCP/8080 (HTTP, 9.4%). In addition to checking credentials, WiFi Inspector also checks devices for a handful of recent, known vulnerabilities (CVEs, EDBs, and others). 1,156 (62%) of scanning homes contained at least one known vulnerability—conversely, 7.2 M (46.8%) non scanning homes in our dataset contain at least one known vulnerability. To test the differences between these populations, we used a proportions t-test at a confidence interval of 95%. We observe that the two sets are statistically significantly different (p-value:  $2.31 \times 10^{-39}$ ), indicating that scanning homes have a higher vulnerability profile than homes globally. This trend also holds for the number of vulnerable devices in scanning homes (9.7%) compared to homes globally (5.7%). Unfortunately, we were unable to determine why homes without known vulnerabilities were seen scanning. This is likely due to devices being compromised through means outside of our measurement vantage point, for example, vulnerabilities that we do not test for.

Although the overall vulnerability profile of devices in scanning homes is higher, this is not true of all specific vul-

<sup>7</sup>We perform this analysis for January because of GDPR restrictions on Avast data.

nerabilities. Of the 25 vulnerabilities observed in scanning homes, 17 appeared at a ratio that was not statistically significantly different than devices globally. The remaining eight vulnerabilities were statistically significantly different, though six appear at a *smaller* rate in scanning homes than globally. The two vulnerabilities that appeared at a higher rate in scanning homes were both related to EternalBlue—a leaked NSA exploit targeting SMB on Windows that was primarily responsible for the WannaCry outbreak that impacted millions of Windows devices in 2017 [44]. Specifically, we identify 5.2% of devices within scanning homes that are vulnerable to EternalBlue, and further, 1.3% of devices in scanning homes are *already compromised*, and communicating through a backdoor. This additionally explains some fraction of the SMB scanning we observed on the darknet, as machines compromised via EternalBlue often scan for other hosts running vulnerable SMB servers. We note that although these homes contain vulnerable devices, we cannot claim that they are scanning as a result of these devices—for one, we do not have full vulnerability coverage, and two, it is an outstanding challenge to attribute device behavior from our vantage point. Still, the presence of any scanning homes in general indicates a threat landscape larger than simply publicly accessible devices, and one that should be considered by the security community.

## 5 Discussion

Recent security research has focused on new home IoT devices, such as smart locks and home automation. Our results suggest that while these devices are growing in importance in western regions, they are far from the most common IoT devices around the world. Instead, home IoT is better characterized by smart TVs, printers, game consoles, and surveillance devices—devices that have been connected to our home networks for more than a decade. Furthermore, these are the kinds of devices that still support weak credentials for old protocols: work appliances are the device type with the highest fraction of weak FTP credentials; surveillance devices are the worst for telnet credentials. Improving the security posture of these devices remains just as important as ensuring that new technologies are secure—our home networks are only as secure as their weakest link.

There are some immediate next steps. As outlined in Section 4, much of the devices that support weak credentials are manufactured by a handful of popular vendors across all regions (Table 10). The security community can start addressing these challenges by encouraging the largest offending vendors to adopt better security practices. On the policy end, law enforcement and legal entities have started to provide legal disincentives for weak security practices. In light of the Mirai attacks, the U.S. Federal Trade Commission has prompted legal action against D-Link [12] for putting U.S. consumers at risk.

A larger question remains on how to address the long tail of vendors. As described in Section 3, regions often have vastly different preferences for vendors across device types. As a result, working to improve the security of devices based solely on the global distribution may inadvertently leave smaller regions with divergent preferences less secure.

Finally, it is not immediately clear how to measure the impact of compromise on home security. In our work, we measured the prevalence of scanning, though this is just one indication of compromise. Furthermore, we only observed 0.37% of homes scanning; amounting to only 1.8 K homes on a single day. In spite of all the data collected within homes in this paper, we could not effectively identify why certain homes were compromised. Researchers have proposed systems to enable auditing of home IoT setups [55, 58], but there is still more work to be done.

## 6 Related Work

Our work build on research from a number of areas, primarily in home network measurement and IoT security.

**Home Network Measurement** Early research in home network measurement primarily focused on debugging networks—projects like Netalyzer [35] were conceived to enable users to debug their home Internet connectivity [9, 15, 49]. A number of follow on papers leveraged Netalyzer-like scans to investigate the state of devices in homes [1, 9, 14], as well to try and understand the implications of a connected home on user behavior [10].

Most similar to our work is presented by Grover et al. who installed home routers with custom firmware in 100 homes across 21 countries to measure the availability, infrastructure, and usage of home networks [26, 53]. Their work focuses on the network properties of home networks on aggregate, and also is able to measure networks continuously based on their position in the network. Our work instead focuses on the *devices* behind the NAT in their ubiquity and their security properties, with particular attention spent on IoT devices.

Recent work has built off of network scanning to enable rich device identification. Feng et al. built a system that leverages application layer responses to perform device identification without machine learning, similar to our hand curated expert rules [21]. This work has built off a number of papers that leverage banners and other host information to characterize hosts [6, 20, 39, 50, 51]. Other rule based engines have been used in other work on active, public scan data based on probing for application banners [4, 16].

**Home IoT Security** Home IoT security has been of recent interest to researchers in light of its growing security and privacy implications, from the systems level up through the application layer. Ma et al. investigated the rise of the Mirai botnet [4], which was largely composed of IoT devices compromised due to weak credentials and used to launch

massive DDoS attacks. This is not isolated to only attackers—researchers have been breaking the home IoT devices since their conception [8, 31, 38, 47, 59]. Notably, Fernandes et al. outlined a number of challenges in Samsung SmartThings devices, from their access control policy to their third-party developer integration [22]. In response, researchers have built systems to enable security properties in home IoT, such as information flow tracking and sandboxing [23, 33], improving device authentication [54], and enabling auditing information [55, 58]. Most recently, Alrawi et al. synthesized the security of home IoT devices into a SoK, where they present a systematization of attacks and defense on home IoT and outline how to reason about home IoT risk [2].

**Internet-Wide IoT Scanning** There has been a wealth of recent work that has used Internet-wide scanning for security analysis, including analyzing embedded systems on the public Internet (e.g., [4, 7, 18, 24, 28, 30, 36, 37, 40, 48, 52, 60]). In contrast to these works, we focus on devices inside of homes that are not visible through Internet-wide scanning.

## 7 Conclusion

In this paper, we conducted the first large-scale empirical analysis of IoT devices on real-world home networks. Leveraging internal network scans of 83M IoT devices in 16M homes worldwide, we find that IoT devices are widespread. In several regions, the majority of homes now have at least one networked IoT device. We analyzed the types and vendors of commonly purchased devices and provided a landscape of the global IoT ecosystem. We further analyzed the security profile of these devices and networks and showed that a significant fraction of devices use weak passwords on FTP and Telnet, are vulnerable to known attacks, and use default HTTP administration passwords that are left unchanged by users. We hope our analysis will help the security community develop solutions that are applicable to IoT devices already in today's homes.
