## A Data Sharing Policy

The first panel in Figure 1 presents users with a text blurb about WiFi Inspector's data sharing policy. For ease of reading, we have copied that text below here:

Nearly every software product you use collects information about you. Search engines, games, everything. We do the same. This allows us to provide better products and services for you. But we promise to respect your privacy. We also promise that we will never publish or share any of your personal information outside Avast, nor allow anyone else to use it to contact you for marketing purposes without your consent.

We do use the information that we collect to help us understand new and interesting trends. We may share this information with third parties outside Avast. However, before we do that, we will remove anything that identifies you personally. For more information, read our Privacy Policy.

If after installing this product, you'd prefer not to participate in data sharing with Avast and third parties, you can opt-out at any time by unchecking the "participate in data-sharing" box in the settings.

**Table 11: Most Popular Vendor per Region per Device Type**—We show the five most popular vendors per device type across the eleven regions in our dataset. We excluded two device types, wearable and home appliances, as they were barely present in our dataset and splitting up their vendor distribution by region provided only a handful of devices in each region.

## Abstract

Automatic exploit generation is a challenging problem. A challenging part of the task is to connect an identified exploitable state (exploit primitive) to triggering execution of code-reuse (e.g., ROP) payload. A control-flow hijacking primitive is one of the most common capabilities for exploitation. However, due to the challenges of widely deployed exploit mitigations, pitfalls along an exploit path, and ill-suited primitives, it is difficult to even manually craft an exploit with a control-flow hijacking primitive for an off-the-shelf modern Linux kernel. We propose KEPLER to facilitate exploit generation by automatically generating a “single-shot” exploitation chain. KEPLER accepts as input a control-flow hijacking primitive and bootstraps any kernel ROP payload by symbolically stitching an exploitation chain taking advantage of prevalent kernel coding style and corresponding gadgets. Comparisons with previous automatic exploit generation techniques and previous kernel exploit techniques show KEPLER effectively facilitates evaluation of control-flow hijacking primitives in the Linux kernel.

## 1 Introduction

Software bugs may have extremely serious consequences, especially for the OS kernel, where they could be fatal to the reliability and security of the entire OS because of the higher privilege that the kernel resides in and the abundance of hardware resources that the kernel has direct control of. Kernel bugs can lead to data leakage, privilege escalation and even persistent attacks [33]. One straightforward solution to minimize consequences of kernel bugs is to immediately patch all of the kernel bugs reported via mail lists and kernel fuzzers [72] [58] [52] [37]. In practice, considering the lack of manpower to patch all bugs timely, vendors typically prioritize their efforts to patch the bugs with more severe security

implications after assessing their exploitability. With the deployment of various kernel mitigations, the exploitability of bugs has been obviously weakened but still hard to decide. Despite the undecidability of the general exploitability problem, sometimes a carefully crafted exploit could serve as a constructive proof of exploitability.

Capable of proving exploitability by generating working exploits from a vulnerability Proof-of-Concepts (PoC), automatic exploit generation is a preferred choice for exploitability assessment because its soundness and efficiency [7] [3] [9] [64] [5] [55] [30] [75]. More importantly, automatically generating concrete exploits could not only help exploitability evaluation, but also let a user to gain advantages in adversarial settings (e.g. Capture-The-Flag competitions) by scoring fast. Last but not least, these generated exploits could potentially help defender-side to evaluate the effectiveness of proposals of new kernel mitigation.

The common workflow of automatic exploit generation systems are similar. In general we can divide them into the following two steps: ① *exploit primitive identification* and ② *exploit primitive evaluation*. In the first step, they search for pre-defined exploit primitive (“exploitable” states) based on the crashing path triggered by a PoC input. In the second step, after pinpointing an exploit primitive, they add exploit constraints and perform *constraint solving* to generate a concrete input to exercise a predefined exploit technique (e.g., `ret2libc` attack).

However, in order to generate working exploit for a control-flow hijacking primitive, there remains to be the following three challenges in the process of *exploit primitive evaluation* which limits the capability of automatic exploit generation techniques to target a complex real-world system such as the Linux kernel.

*Challenge 1, exploit mitigation.* Exploit mitigations are designed and introduced to reduce attack surface and raise the bar of exploitation. For a modern Linux kernel, many new hardware features [38] [11], compiler-assisted instrumentation [22] [40], sensitive data objects protection [12] [65] [21] [13] and virtualization-based hypervisor [49] [51] have

\*The main part of the work was done while studying at Pennsylvania State University.

<sup>†</sup>Key Laboratory of Network Assessment Technology, CAS

<sup>‡</sup>Beijing Key Laboratory of Network Security and Protection Technology

been introduced as exploit mitigations. As a consequence, many kernel exploit techniques are no longer effective [36] [61] [41] [39] [77], despite the fact that heavier enforcement such as control-flow integrity (CFI) [2] [16] [79] [78] is still *not* widely-adopted by major Linux releases perhaps due to performance concerns.

*Challenge 2, exploit path pitfall.* Side effects of exploit primitives could terminate exploitation in middle. Memory corruption, occurred along with an exploit primitive, can frustrate the attempt to trigger the primitive the second time, because an *exploit path* could unavoidably contain instructions triggering an unexpected termination of exploitation. Such termination can be a kernel panic of invalid memory access or an infinite loop in a kernel thread.

*Challenge 3, ill-suited exploit primitive.* Lack of stack pivoting gadget [54] which is a vital step to perform ROP attack and insufficient control over general registers can make an exploit primitive ill-suited. Although some strong primitives have been proven exploitable and even Turing complete [35], there is still a gap between ill-suited exploit primitive and the requirement of mounting a certain exploit technique.

Considering the three challenges, it could be quite difficult to even manually craft an exploit with a control flow hijack primitive. To address the above challenges, we propose KEPLER, an exploit primitive evaluation framework for real-world Linux kernel vulnerabilities. KEPLER employs a novel exploit technique designed for Linux kernel which reduces exploitation of a control-flow hijacking primitive to constructing a classical overflow in kernel stack. The exploit technique exposes less constraints over the quality of an exploit primitive and availability of stack pivoting gadget than previous exploit techniques and could still bypass currently widely deployed kernel mitigations while previous approaches could not. Starting from a possibly ill-suited *control-flow hijacking primitive* (CFHP), KEPLER overcomes the lack of stack pivoting gadget and manages to build a "single-shot" exploitation chain to bootstrap existing *Turing complete* exploit techniques such as return oriented programming (ROP) [56], with the ability to bypass mainstream kernel mitigations as well as detouring exploit path pitfalls.

To achieve this, KEPLER leverages a carefully designed code-reuse template for control-flow hijacking primitives to bypass widely-deployed mitigations in Linux kernel. KEPLER first enhances an exploit primitive to satisfy a minimal requirement of controlling dual registers (*e.g.*, `rip` and `rdi` for `x86-64`) at the same time. Starting from the primitive, KEPLER generates an exploit which sequentially executes a chain of five gadgets. The design of the code-reuse template involves several insights about Linux kernel coding style. Specifically, KEPLER reuses those stack-based invocations of kernel I/O channel functions to leak and smash kernel stack of current process and execute arbitrary user-supplied ROP payload. KEPLER leverages *blooming gadget* to enhance control over necessary registers for a control-flow hijacking primitive.

KEPLER uses a *bridging gadget* to combine the practice of leaking kernel stack canary and smashing kernel stack into a single shot and thus prevent unexpected kernel panic.

To generate exploits for each CFHP against arbitrary kernel binary, KEPLER operates in the following two phase: first, KEPLER statically analyzes the kernel binary for five categories of candidate gadgets. Then KEPLER starts kernel symbolic execution from the CFHP, and performs a *Depth First Search* (DFS) based gadget stitching algorithm over candidate gadgets.

Our evaluation of KEPLER shows that it is powerful for exploit primitive evaluation. To highlight the effectiveness of KEPLER, we compare KEPLER with existing exploit hardening/generation tools (*e.g.*, Q [60], fuze [75]) and KEPLER outperforms all of them in terms of generating effective kernel exploits under modern mitigation settings in Linux kernel.

This research work makes the following contribution:

- **Kernel single-shot exploitation.** We present a code-reuse exploit technique which converts a single ill-suited control-flow hijacking primitive into arbitrary ROP payload execution under various constraints posed by modern Linux kernel mitigations and the primitive itself. The proposed technique exploits prevalent kernel coding style and corresponding gadgets and thus is hard to defeat. Our approach to calculate exploitation chain is automatable because the gadget stitching problem could be cast as a search problem over a search space of reasonable size. In addition, the "single-shot"<sup>1</sup> nature of this technique makes it suitable for the vulnerabilities prone to unexpected termination because it avoids stressing a control-flow hijacking primitive for multiple times.
- **Semi-automatic exploit generator for Linux kernel.** We implement KEPLER using a set of tools including IDA SDK, QEMU/KVM and angr. Starting from a user-supplied control flow hijack primitive, KEPLER analyzes the Linux kernel binary, tracks down useful kernel gadgets, and automatically generates many gadget chains for launching "single-shot" exploitation and bypassing kernel mitigations. It requires no kernel source code and can be applied to stripped kernel images. KEPLER applies to modern Linux kernels; our evaluation uses version 4.15.0 which was the latest as of the time of our evaluation.
- **Practical impacts.** We systematically evaluate the effectiveness and efficiency of KEPLER using 16 real-world kernel vulnerabilities and 3 recently-released CTF challenges. Given a kernel control-flow hijacking primitive, we show that KEPLER generally could generate tens of

---

<sup>1</sup>The proposed exploit technique requires a lot of analysis effort, but with respect to the precondition for launching the attack, it requires only a single control-flow hijacking primitive.

thousands of distinct exploitation chains with the ability to bypass kernel mitigations and perform successful exploitation. We show that KEPLER can output the first working exploit for a kernel vulnerability in less than about 50 wall-clock minutes.

## 2 Background and Related Work

Exploit primitives [6] [47] [55] are machine states that violate security policies at various level and indicate an attacker could get extra capabilities beyond the normal functionality provided by the original program. A control-flow hijacking primitive (CFHP) is a machine state that potentially deviates from the legal control-flow graph. In the context of symbolic analysis, a control-flow hijacking primitive is usually identified by applying a heuristic which queries the backend constraint solver to check whether the number of possible control flow jump target is beyond a threshold when the control flow jump target contains symbolic bytes. An arbitrary memory write primitive is a machine state that an attacker could modify arbitrary kernel memory on his will. Similarly, an arbitrary memory leak primitive is a machine state which allows an attacker to dump data content at arbitrary kernel address. Sometimes the primitive does not allow an attacker to modify/leak data at arbitrary kernel address (*e.g.*, a stack info leak which only dump several bytes on kernel stack [68]), they are referred as restricted memory write/leak primitive.

As is described above, this research work mainly focuses on two aspects – ❶ facilitating exploit primitive evaluation for even ill-suited exploit primitives and bypassing widely-deployed kernel mitigation mechanisms by designing a new exploit technique. ❷ developing a tool to automate the newly proposed kernel exploitation approach. As a result, the works most relevant to ours include those pertaining to exploit primitive identification, exploit primitive evaluation and kernel exploit techniques/mitigations. In the following, we describe the existing works in these three directions and discuss their difference from ours.

### 2.1 Exploit Primitive Identification

To assist the process of finding a useful exploit primitive (*e.g.*, control-flow hijacking primitive and memory write/leak primitive), there is a rich collection of research works. For example, using preconditioned symbolic execution and concolic execution techniques, Brumley *et al.* develop AEG as well as mayhem to identify control-flow hijacking primitives for further exploitation. [3] [9] [7]. Shoshitaishvili *et al.* develop a cyber reasoning system Mechanical Phish [62]. It is built on angr [64] [69] [63] and performs fuzzing and symbolic tracing for the PoC to identify exploit primitives. To efficiently explore state space for exploit primitives in Linux kernel, Wu *et al.* propose an automatic technique that utilizes under-context fuzzing along with partial symbolic execution to ex-

plore CFHP and memory write primitive for UAF bugs [75]. To construct better exploit primitives with the capability of out-of-bound access, Heelan *et al.* utilize regression tests to obtain the knowledge of how to perform heap layout manipulation [30]. To obtain better exploit primitives for stack Use-Before-Initialization vulnerabilities, Lu *et al.* propose a deterministic stack spraying approach as well as an exhaustive memory spraying technique [46].

In this work, we do not focus on facilitating primitive identification. Rather, we assume an exploit primitive is already identified and our research endeavor centers around subsequent primitive evaluation phase.

### 2.2 Exploit Primitive Evaluation

In the primitive evaluation phase, a security analyst or an automatic exploit generation system tries suitable exploit techniques for the seemingly exploitable states identified before.

Initially, without considering Data Execution Prevention, such systems use straightforward techniques such as ret2stack-shellcode and ret2libc with a CFHP [3] [9] [62]. Taking  $W \oplus X$  into account, Schwartz *et al.* propose Q [60] to facilitate exploitation with a CFHP by automatically constructing a ROP chain. Our work addresses the problem of ROP bootstrapping without stack pivoting gadget and is orthogonal to automatic ROP chaining techniques [33] [60] [66] [24] [57] because we do not tackle the problem of ROP payload construction.

With the facilitation of forward and backward taint analysis, Mothe *et al.* devise a technical approach to craft working exploits for simple vulnerabilities in user-mode applications [48]. Utilizing symbolic execution, Repel *et al.* craft exploits with single memory write primitive (*e.g.*, unsafe unlink and lookaside list corruption) for those heap overflow vulnerabilities residing in the userland applications [55]. To facilitate primitive evaluation of kernel Use-After-Free exploitation, Xu *et al.* propose two memory collision mechanisms [77] to unleash CFHPs.

Recently, some research works take CFI into consideration for primitive evaluation [29] [8] [59] [23] [31] [32] [35]. For example, Ispoglou *et al.* propose block oriented programming (BOP) [35] to facilitate evaluation of repeatable arbitrary memory write primitives by proving the Turing completeness under CFI along with common userspace mitigations. BOP assumes the existence of a dispatcher gadget. BOP also automates exploit generation. As a repeatable arbitrary memory write primitive is almost "god-mode" of kernel exploitation, our work facilitates primitive evaluation for those weaker exploit primitives (*e.g.*, non-repeatable and ill-suited CFHP) in real-world .

In this work, we also develop a tool for facilitating primitive evaluation. However, this research work is fundamentally different from the aforementioned works in at least one of the following aspects. First, without assuming a perfect ex-

exploit primitive (e.g., unlimited number of invocations of an arbitrary memory write primitive), we can facilitate exploit primitive evaluation for those usually ignored exploit primitive (e.g., ill-suited primitives and primitive that can only be triggered once). Second, rather than dealing with applications in the user space, our tool targets the Linux kernel where exploitation typically involves complicated operations and sophisticated security mitigation mechanisms are generally enabled. Third, rather than generating one single exploit for a target vulnerability, our tool automatically explores many possible exploitation chains and output various working exploits.

### 2.3 Kernel Exploit Techniques/mitigations

Initially, a CFHP in the kernel can directly execute shellcode in user-space because there is no isolation between user and kernel space (e.g., `ret2usr`). Supervisor Mode Execution Prevention (SMEP) [38] prevents kernel from executing userspace code. An attacker can use code-reuse attack. To set stack pointer to controlled payload, she uses the prevalent "pivot-to-userspace" gadget to pivot stack to userspace [44]. With adoption of Supervisor Mode Access Prevention (SMAP [11]), an attacker can no longer rely on a fake stack in userspace because userspace memory access is forbidden except during I/O channel functions. Because there is usually none intra-kernel stack pivoting gadget for a Linux kernel, an attacker usually chooses to disable SMAP by flipping corresponding bits in the `cr4` register [41]. However, the "cr4-flipping" attack typically rely on double CFHPs [41] and not suitable for a *none re-triggerable* CFHP. In addition, a virtualization-based hypervisor can detect `cr4` register modification by inspecting a `vmexit` and thus mitigate such exploitation [49] [51]. `Ret2dir` [39] attack sprays the `physmap` region by calling `syscall mmap`, as the direct mapped physical memory is marked as executable previously, diverting a CFHP to land on `physmap` led to arbitrary shellcode execution. However, with a kernel patch applied, these `physmap` pages are no longer executable.

To enforce CFI policy for the kernel, several kernel CFI solutions [16] [70] [26] have been proposed, however, these mitigations are not broadly adopted by major Linux release version such as CentOS, Ubuntu and Debian.

Data-only kernel exploit techniques directly use a memory write primitive to modify sensitive kernel data objects such as process credentials, page tables and virtual dynamic shared object (vdso) [36]. However, mitigations have been proposed [17] [67] and deployed [40] to prevent these low-hanging fruits.

Note some memory write primitive can be transformed to a control-flow hijacking primitive by overwriting and invoking a code pointer in kernel's data section or in the heap [19].

Kernel address space layout randomization (KASLR) is widely deployed in order to present the attacker an unpredictable attack surface. However, due to its lack of timely

re-randomization and coarse-grained nature (only randomizing section base address), an attacker does not even need an arbitrary read primitive [45] [71] to bypass KASLR. With a hardware side channel [34] [28], he can infer the coarse memory layout without leaking any kernel memory content. Despite kernel Page Table Isolation (KPTI [13]) removes some side channels with extra overhead, he can also uses a restricted memory leak primitive to infer the coarse memory layout [68]. In the default setting of Linux kernel, knowing coarse memory layout is enough for various exploit techniques. (Kernel) Code diversification/randomization [14] [15] [27] [74] [42] [53] could significantly raise the bar of code-reuse exploitation by thwarting an attacker from locating useful gadget.

## 3 Assumptions and Threat Model

Our threat model consists of a modern Linux kernel protected by widely-deployed mitigations with a known vulnerability.

**Mitigation setting.** Similar to recent major Linux release versions, we make the following assumptions of kernel mitigations. A kernel has enabled SMEP and SMAP [11] protection to prevent direct userspace access in kernel execution. A kernel has enabled stack canary to protect return address over stack for all functions containing local variable [22]. A kernel has enabled protection to prevent direct modification of sensitive kernel data objects including process credential [40] and page table [17]. A kernel has enabled KASLR. A kernel has enabled KPTI [13] protection. A kernel has been protected by virtualization-based hypervisor which prevents unauthorized modification of `cr4` register [49]. A kernel has set `physmap` pages as non-executable. A kernel has enabled `STATIC_USERMODEHELPER`. The option routes all `call_usermodehelper()` calls through a guard binary that can properly filter the requested userland programs to be run by the kernel [43]. However, A kernel does not enable a CFI enforcement such as RAP [70] because of performance concerns. **Available Exploit Primitives.** We assume there is a PoC which triggers the vulnerability and leads to a control-flow hijacking primitive (CFHP). We assume the CFHP is already identified with the PoC through either manual analysis or dynamic analysis such as symbolic tracing, thus finding exploit primitives is orthogonal to our work and we can focus on evaluating the CFHP. We assume a restricted memory leak primitive to help infer coarse kernel memory layout (e.g., getting the base address of code section `.text` and `physmap` region). We do not assume the existence of an arbitrary memory write primitive which could write to arbitrary kernel memory address. We do *not* assume the existence of an arbitrary memory leak primitive that can dump arbitrary kernel memory content. Under the threat model, the content in arbitrary memory address such as the stack canary value of arbitrary kernel thread usually remains secret because the coarse kernel memory layout information does not reveal the stack canary value of a kernel stack. We also assume the location of current kernel stack

remains secret although a restricted memory leak primitive might help leak a pointer to current stack under some specific vulnerability context.

## 4 Motivating Example

```

1 | struct ip_mc_socklist {
2 |     struct ip_mc_socklist *next_rcu;
3 |     struct ip_mreqn multi;
4 |     unsigned int sfmode;
5 |     struct ip_sf_socklist *sflist;
6 |     struct rcu_head rcu;
7 | };

```

(a) Definition of struct `ip_mc_socklist`. Its first member `next_rcu` is unmanageable because the PoC uses a heap spray technique which does not allow us to control first QWORD of struct `ip_mc_socklist`.

```

1 | void ip_mc_drop_socket(struct sock *sk){
2 |     struct inet_sock *inet = inet_sk(sk);
3 |     struct ip_mc_socklist *iml;
4 |     // inet->mc_list is a dangling pointer
5 |     while ((iml = inet->mc_list) != NULL) {
6 |         // iml is alias of the dangling pointer
7 |         inet->mc_list = iml->next_rcu;
8 |         // queuing a rcu_head for execution in
9 |         // the future
10 |         kfree_rcu(iml, rcu);
11 |     }
12 | }
13 | void rcu_reclaim(struct rcu_head *head){
14 |     head->func(head); // control-flow hijack
15 | }
16 | void rcu_do_batch(...){
17 |     struct rcu_head *next, *list;
18 |     while (list) {
19 |         next = list->next; // next rcu is
20 |         // unmanageable
21 |         rcu_reclaim(list);
22 |         list = next;
23 |     }
24 | }

```

(b) Tailored source code pertaining to the CFHP. function `ip_mc_drop_socket` repeat invoking `kfree_rcu()` which queues a rcu task for asynchronous execution until `inet->mc_list` is NULL. The site pertaining to the CFHP is in function `rcu_reclaim`.

Table 1: A control-flow hijacking primitive in kernel UAF vulnerability CVE-2017-8890.

We illustrate the challenges in evaluating a CFHP on x86-64 with CVE-2017-8890 [50], a recent vulnerability in the Linux kernel.

### 4.1 Vulnerability and Exploit Primitive

The root cause of the bug is an Use-After-Free over an object `ip_mc_socklist` defined in Table 1a. As is shown in Table 1b, the UAF bug results in a dangling pointer `inet->mc_list` and

`*iml` become an alias of the dangling pointer in line 5. In line 7, there is an UAF access by dereferencing `iml->next_rcu`. In line 9, `kfree_rcu(iml)` queues a callback denoted by `iml->rcu`. Function `rcu_do_batch` handles the previously queued callback when the CPU gets a chance to process the rcu callback list, thus triggers another UAF access to the `ip_mc_socklist` object in `rcu_reclaim()`. The loop from line 5 to line 10 will continue and add another callback if `iml->next_rcu` is not NULL.

The CFHP is due to an asynchronous `kfree_rcu` call over the dangling pointer `*iml`. To be specific, by manipulating the value in `iml->rcu_head` through a proper heap spray, a security analyst can get a CFHP later in `rcu_reclaim()` because function `kfree_rcu()` (line 9) is designed to queue a rcu callback denoted by `iml->rcu_head`. Function `rcu_do_batch` will be executed in the future, it will iterate over a list of `rcu_head` added by `kfree_rcu()`. The statement pertaining to the CFHP (line 13) allows the attacker to control `rip(head->func)` through heap spraying. At the time of the control-flow hijacking, register `rdi(head)` points to a controllable memory region.

## 4.2 Challenges of Crafting Working Exploit

However, developing an exploit with the aforementioned CFHP is quite difficult because of the following challenges.

### 4.2.1 Challenge 1: Exploit Mitigations

Widely deployed kernel mitigations frustrate a large amount of straight forward exploit techniques. With the presence of SMEP/SMAP protection, it is impossible to directly launch a traditional `ret2user/pivot2usr` attack. The `ret2dir` attack [39] is also not suitable because the `physmap` region is no longer executable [10]. With the write-protection over sensitive data such as process credential and page table, it is not possible to direct overwrite these data to escalate privilege by converting the CFHP into a memory write primitive.

A security analyst may think of the "cr4-flipping" attack which usually requires two CFHPs: one for flipping the `cr4` register and the other to launch `ret2user/pivot2usr`. However, this is often infeasible because virtualization based hypervisor could easily detect the behavior of flipping `cr4` register by inspecting a `vmexit` [49] [51]. Even if there is not protection over `cr4` register, leveraging the "cr4-flipping" attack or a similar exploit technique relying multiple CFHP with this CFHP still faces the following challenge.

### 4.2.2 Challenge 2: Exploit Path Pitfall

Attempting to leverage the "cr4-flipping" exploit technique, a security analyst would expect two CFHPs to disable SMEP/SMAP and pivoting to userspace respectively. However, such a exploit technique could be infeasible because of the exploit path pitfall after the first CFHP.

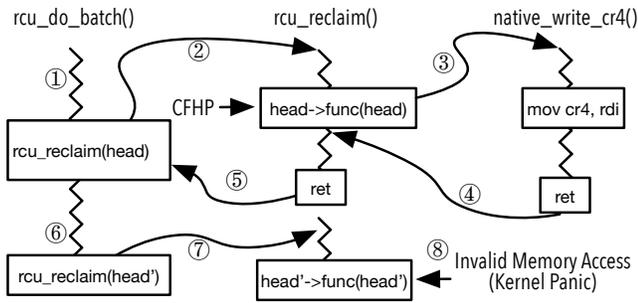

Figure 1: Demonstration of an exploit path pitfall in the motivating example. After applying the first CFHP to overwrite `cr4` register with `native_write_cr4()`, `rcu_reclaim(head')` is invoked but `head'` is unmanageable and panics the kernel.

As is shown in Figure 1, after using the CFHP in `rcu_reclaim` to disable SMAP protection by invoking the function `native_write_cr4()` to zero the corresponding bits in `cr4` register, an attacker encounters an unexpected termination: in previous execution, the loop from line 5 to line 10 in Table 1b queues another `rcu` callback denoted by `head'` (`iml->next_rcu->rcu`) which is not under our control and causes a kernel panic.

This kernel panic attributes to an invalid memory access. The heap spray technique used by the PoC does not allow an attacker to control first `QWORD` of `iml` (an `ip_mc_socklist` object) because the first `QWORD` of a freed chunk becomes heap-metadata, thus `iml->next_rcu` becomes unmanageable.

A straight-forward solution to tackle the invalid memory access is adding extra constraints to ensure all related memory accesses are valid. However, constraint solving for complex program usually incurs high cost (both `cpu` time and memory) [4] and could fail because of constraint conflicts [5]. Instead of devoting extra resource to handle these pitfalls, an ideal exploit path should effectively detour them. As a result of lacking control of `iml->next_rcu`, the exploit path pitfall can not be simply prevented by techniques like adding constraints over the sprayed data and thus unavoidably panic the kernel. Although it is possible to tackle the problem by further tuning the PoC [55] [75] and obtain a better exploit primitive, the showcased exploit path pitfall already hinders the evaluation of the CFHP.

In addition, an exploit path pitfall could also be attributed to un-successful heap spray. Due to the undeterminacy of kernel execution, there is not any heap spray technique with 100% success ratio. To get multiple CFHPs for a UAF vulnerability, an attacker may need to do multiple rounds of heap spraying and trigger a vulnerability multiple times, which could dramatically decrease the success ratio of the entire exploitation.

Even if two control-flow hijack primitive is available to the attacker, it could still be very difficult for him to bypass the

mitigation combination of SMAP as well as virtualization-based hypervisor, because the attempt to modify `cr4` register (in order to turn off SMAP and pivot kernel stack to userspace) could be easily prevented.

### 4.2.3 Challenge 3: Ill-suited Exploit Primitive

Facing the infeasibility of popular kernel exploit techniques, it is nature for a security analyst to use generic code-reuse technique such as ROP [56] as a second resort.

*Stack pivoting* is a vital step [54] for a ROP attack especially when an attacker does not control the contents on the stack (e.g., the CFHP does not result from a stack overflow). In userspace, many heap exploits relying on a stack pivoting gadget (e.g., function `swapcontext()` and `setcontext()` in `libc`) to bootstrap a ROP attack.

It is however difficult in the target kernel to pivot stack pointer to a memory region under our control with this CFHP. The reason behind is two-fold. First, as is mentioned before, we can not simply pivot to a userspace with a traditional gadget such as `xchg eax,esp; ret` because of SMAP. Second, there is not a suitable stack pivoting gadget in a Linux kernel binary for this CFHP. Considering register `rdi` points to controllable area with this primitive, it would be great to have a gadget to overwrite `rsp` with a controllable memory address, such as gadget with form `xchg r**,rsp; ret, mov rsp,[r**]; jmp rxx` and `mov rsp,r**; ret` for consecutive payload [39]. Unfortunately, similar traditional stack-pivoting gadget does not exist or contains unavoidable exploit path pitfall (e.g., gadget `xchg rsp, r14; jmp rsp` could successfully pivot the stack pointer but inevitably panics the kernel) in our investigation across various modern linux kernel images.

Although previous works have demonstrated the power of code-reuse attack, mounting a traditional ROP attack for the CFHP seems surprisingly difficult because of the lack of stack pivoting gadget.

Without the capability of performing ROP attack, one may think of reusing other kernel functions. Unfortunately, there is also a problem of insufficient control over general registers because only `rdi` points to a memory region under control and other registers are not in control initially. We need to enhance this CFHP by controlling more general registers and perform subsequent exploitation.

## 5 Overview

To tackle the three challenges exposed by the motivating example, a security analyst needs to design a new exploit technique to turn a CFHP into a more exploit-friendly machine state based on the vulnerability context and his prior experience. Due to the lack of a ready-to-use exploit technique, he could expect a lot of debugging and manual efforts to explore possible exploit paths and improve his prototype exploit during the exploit development process and such practice could

be extremely time-consuming and even fruitless.

In the following, we discuss the considerations that go into the design of KEPLER as well as the high level design of this framework to facilitate CFHP evaluation.

## 5.1 Requirements for Design

To support evaluation of a CFHP with working exploits, KEPLER should receive as input a state representing a CFHP and it should be able to find an exploit path towards privilege escalation and output corresponding exploit. To achieve the above ultimate goal, KEPLER should adopt an exploit technique which satisfies the following requirements.

*First*, an exploit technique is able to bypass all the widely-deployed mitigations enabled in the threat model. *Second*, taking potential exploit path pitfalls into consideration, an exploit technique should depend on only one control-flow hijacking primitive and detour these pitfalls to prevent an unexpected termination and make exploitation more reliable. The form of an exploit technique would be ideally similar to a “magic gadget<sup>2</sup>” which is previously mentioned in user-space exploitation [18], especially in the context of adversarial scenarios like Capture-The-Flag cyber competition. *Third*, an exploit technique should benefit from time-tested exploit technique such as ROP by efficiently bootstrapping traditional code-reuse attack in absence of stack pivoting gadget with an ill-suited CFHP. *Last but not least*, an exploit technique should be suitable for the automation framework. On one hand, it should be hard-to-defeat and not depend on any special code or feature which could be easily eliminated. On the other hand, the exploit generation phase should be easily automated - it should be a well-defined search problem over a search space of reasonable size.

## 5.2 High Level Design

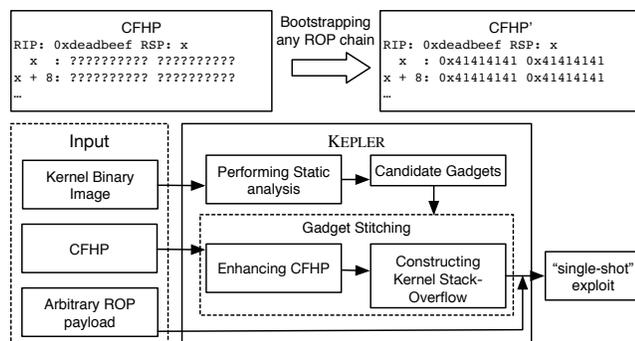

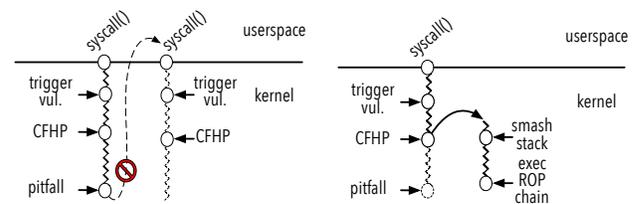

Figure 2: Overall of KEPLER’s design.

<sup>2</sup>The term “magic gadget” means given a CFHP, one can instantly succeed in exploitation (e.g., getting a shell) by diverting control-flow to such gadget, thus boost exploit development and gain advantages in a game.

To satisfy the requirements mentioned above, we design KEPLER to facilitate exploit primitive evaluation. KEPLER automatically generates an exploitation chain to bootstrap any kernel ROP chain with a single CFHP through “single-shot” exploitation.

Figure 2 shows how KEPLER automates the analysis task necessary to leverage a CFHP to produce an exploit in the presence of aforementioned challenges. Given a kernel state snapshot representing the CFHP, KEPLER enhances its power to construct a kernel stack-overflow by symbolically stitching several types of candidate gadget identified by static analysis on the kernel binary image.

As is mentioned before, our basic idea is to bootstrap a traditional ROP attack with a CFHP in Linux kernel. At the high level, we achieve this by a “single-shot” exploitation chain which transforms a function pointer corruption based primitive (CFHP) into a stack-overflow based primitive (CFHP’) as is shown in Figure 2.

(a) Exploitation by invoking a control-flow hijacking primitive twice. (b) Exploitation with a single control flow hijack primitive.

Figure 3: A comparison of two exploitation approaches; a known approach triggers a vulnerability twice but blocked by an exploit path pitfall and the other triggers the vulnerability only once.

Although there is not any gadget in Linux kernel which allows an attacker to directly escalate privilege, The proposed “single-shot” exploitation is similar to “magic gadget” mentioned above in a sense that it only requires a single CFHP and could reliably achieve the goal of arbitrary code execution in kernel context. To be specific, as is shown in Figure 3b, the “single-shot” exploitation chain could finish exploitation with a single CFHP and thus is able to circumvent an exploit path pitfall after the return of CFHP which could cause an unexpected termination otherwise. We can benefit from a stack-overflow based CFHP because it allows us to place arbitrary ROP payload on current kernel stack without any stack pivoting gadget. Given the scarcity (or non-existence) of intra-kernel stack pivoting gadget, we argue that constructing a kernel stack overflow is the most generic approach to perform a kernel ROP attack.

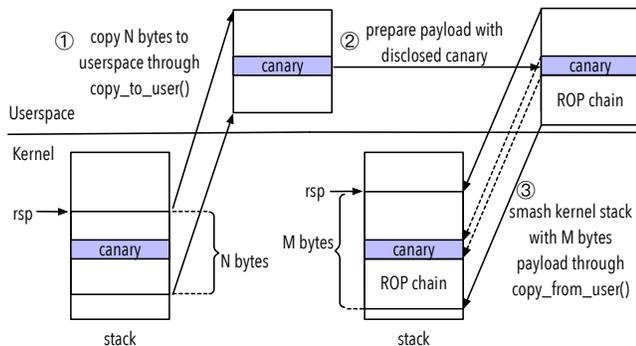

Figure 4: An overview of “single-shot” exploitation which discloses kernel stack canary and then smashes the kernel stack with arbitrary user-supplied ROP payload.

## 6 Design

In this section, we describe the exploit technique adopted by KEPLER and the insights behind the exploit technique. As is mentioned before, KEPLER uses a CFHP to construct a stack overflow and bootstraps arbitrary ROP payload.

Our “single-shot” exploitation technique builds on two key ideas of *breaking isolation with I/O functions* and *improving exploit success ratio with a single CFHP*.

First, we can break isolation between kernel-space and user-space by abusing kernel I/O functions. The insight behind is such data channels are born to bypass SMAP which prohibits user-space access because SMAP is explicitly and temporarily disabled during execution of these functions. Figure 4 illustrates a practice of reusing I/O functions to construct kernel stack overflow by first leaking kernel stack canary with `copy_to_user` and then smashing kernel stack with `copy_from_user`.

Second, “single-shot” exploitation can be achieved through stitching various kernel function gadgets. We can enhance register control for a CFHP with *blooming gadget* - a prevalent family of function gadgets in Linux kernel. We can detour exploit path pitfalls with a *bridging gadget*.

### 6.1 Constructing Stack Overflow

There is a family of prevalent stack smashing gadgets inside Linux kernel, we observe they could greatly aid constructing stack-overflow via taking intrinsic *short return path* triggered by a page fault. However, such gadgets can not be directly used because initial CFHP does not have enough register control and the presence of a stack canary. We address the two problem in Section 6.2 and 6.3.

#### 6.1.1 Looking into Stack-Smashing Gadget

We present stack-smashing gadgets which relies on functions that serve as data channel between user-space and kernel-

```

1 | static long bsg_ioctl(struct file *file, unsigned
  |     int cmd, unsigned long arg){
2 |     struct sg_io_v4 hdr;
3 |     ...
4 |     if (copy_from_user(&hdr, uarg, sizeof(hdr)))
5 |         return -EFAULT; // short return
6 |     ...
7 | }

```

(a) Source code.

```

1 | ...
2 |     mov rdi, rsp
3 |     call <_copy_from_user>
4 |     test rax, rax
5 |     je 0xffffffff813d6ce4
6 |     mov rax, 0xffffffffffffffff2
7 |     jmp <epilogue>
8 | ...
9 | <epilogue>:
10 |     mov rcx, QWORD PTR [rsp+0xa0]
11 |     xor rcx, QWORD PTR gs:0x28
12 |     jne <__stack_chk_fail>
13 |     add rsp, 0xa8
14 |     pop rbx
15 |     ret

```

(b) Assembly code.

Table 2: The kernel code fragment of an stack-smashing gadget that could smash kernel stack with carefully crafted payload.

space. The gadget could aid exploitation by transporting payload of arbitrary length from user-space to kernel stack, without assuming the stack location is already known.

As is named after, `copy_from_user(void* dst, void* src, unsigned long length)`<sup>3</sup> is a heavily used I/O kernel function which migrates data from the user to kernel space. Recall that SMAP prevents kernel code from accessing user-space address, and to temporarily bypass the restriction, `copy_from_user` uses a special instruction `STAC` to set `AC` flag in `EFLAGS` register before accessing user-space memory, thus allows the subsequent instructions to explicitly access user-space memory. Once the copy is finished, instruction `CLAC` is executed to re-enable SMAP.

As is specified in Linux kernel implementation, the function `copy_from_user()` takes as input three arguments - `dst`, `src` and `length` - which indicate the destination, source and length of the data that need to be copied from the user to kernel space.

From the perspective of an attacker, a kernel stack overflow could be caused if he lets the CFHP jump to the site right before the invocation of `copy_from_user` (line 2 in Table 2b) and the machine state satisfies the following three requirements:

<sup>3</sup>The security of `copy_from_user` has been improved by adding extra checks during the development of Linux Kernel. For example, upon failure during copy, set the `dst` memory region after the successfully copied bytes to zero to prevent uninitialized use.

❶ parameter `dst` (e.g., `rdi`) points to current kernel stack, ❷ parameter `src` (e.g., `rsi`) points to any user-space address so that its content is controllable by an attacker, ❸ parameter `length` (e.g., `rdx`) is greater than the size of current stack frame to cause a kernel stack overflow.

An interesting observation is that most (91% in Linux 4.15) invocations of this function set destination `dst` to address of a variable on kernel stack and thus will copy user data into a kernel stack. If control-flow is hijacked to a invoking site of this function (e.g., line 2 in Table 2b), an attacker could abuse such coding style to satisfy the requirement ❶ above because the code snippet help set `rdi` to current stack frame. However requirements ❷ and ❸ are still waiting to be satisfied given the initial CFHP does not imply any control over register `rdi` and register `rsi`. We will address this issue with blooming gadget in Section 6.3.

### 6.1.2 Choosing Short Return Path

The prevalent error handling code which is introduced to make kernel code more robust also provides a short return path for an attacker. An attacker could benefit from such a short return path after overflowing current stack frame.

As is depicted in line 4-5 in Table 2a, function `bsg_ioctl` will directly return if return value of `copy_from_user` is *not* zero. Our statistic indicates the function `copy_from_user()` has been invoked at 671 sites in Linux 4.15. Among all these invocation sites, more than 99% contain the fault handling implementation.

The insight of prioritizing short return path after stack smash is to prevent un-expected kernel panic as well as avoid the complexity of resolving extra data dependency in an error-prone and long normal return path of the function containing tens of basic blocks.

To take a short return path, `copy_from_user` must return a non-zero value as is shown in Table 2a. Reviewing the source code of kernel function `copy_from_user`, we have identified 3 different situations which will force the function to return a non-zero value, 1) incurring an integer overflow when calculating `src+length`, 2) neither `src+length` nor `src` residing in user-space, 3) encountering an unresolvable page fault during copy. For the first two situations, the function `copy_from_user()` performs sanity check and returns a non-zero value without actually copying data to the kernel. For the last situation, the function migrates data to the kernel and pads with zeros the bytes failing to be copied.

### 6.1.3 Triggering Page Fault during `copy_from_user`

To force `copy_from_user` returning a non-zero value as well as successfully copying the ROP payload from user-space to kernel stack, we trigger page fault after copying enough payload according to the last condition described above.

We illustrate a representative example in Figure 5. We map two adjacent pages (`p1` and `p2`) in the user-space and

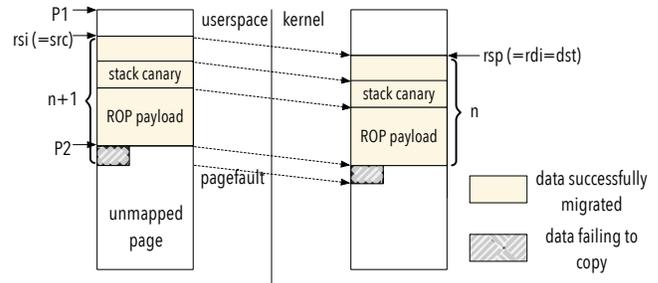

Figure 5: An example where `copy_from_user` triggers a page fault when copying user data to kernel stack.

then unmap the second one. We fill the end of the page `p1` with the actual payload including a stack canary and a ROP chain. We will discuss how to leak stack canary in Section 6.2. Through the technical approaches mentioned in Section 6.3, assume we have already obtained the control over registers `rsi` and `rdx` pertaining to the second and third parameters of `copy_from_user` respectively. Leveraging the control over registers, we manipulate the values in these registers. More specifically, we set `rsi` and `rdx` to `p1 + PAGE_SIZE - n` and `n + 1` respectively, with `n` representing the length of payload actual copied. When the function attempts to copy the last byte, it fails to access the content at `p2` and triggers a page fault because the page `p2` is not mapped into the memory. Eventually `copy_from_user` returns a positive number 1 because one byte is not successfully copied.

## 6.2 Bypassing Stack Canary

As is mentioned earlier, to prepare a working payload for stack smash, an attacker has to know the value of kernel stack canary which remains secret in our threat model. We consider the presence of a strong kernel stack canary setting where stack canary is enabled for all functions containing a local variable.

We will first introduce two kinds of prevalent gadgets, then we discuss how to pair them to dump kernel stack memory.

### 6.2.1 Exposing Stack-disclosure Gadget and Auxiliary Function

To leak stack canaries, an intuitive way is to construct an info leak of its value to user-space through an official data channel such that SMAP is not violated. In the following we introduce stack-disclosure gadget which is twin gadget of stack-smash gadget as well as auxiliary function prologue gadget.

**Stack-disclosure gadget.** Function `copy_to_user()` is widely used in the Linux kernel codebase to copy kernel memory into user-space. In Linux kernel 4.15, our statistic indicates this function has been invoked at 594 sites. Of all these invocations, 82% are used for copying data from kernel

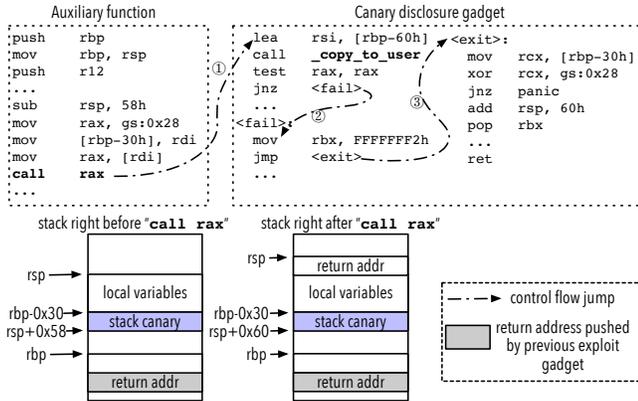

Figure 6: An example of canary disclosure gadget and its corresponding auxiliary gadget.

stack to user-space. Since this naturally establish a channel to migrate data from kernel stack to user-space, we could exploit the characteristic of this kernel function to disclose the canary on kernel stack.

**Auxiliary function.** To successfully return from a stack-disclosure gadget and continue exploitation, we use auxiliary function to create a similar stack frame as the stack-disclosure gadget and transfer the control-flow to stack-disclosure gadget with an indirect call after the function prologue.

Auxiliary function should have stack canary protection and contain a controllable indirect call after its own function prologue which establishes a stack frame. Its layout of stack frame could be paired with a stack-disclosure gadget to form a “complete” stack frame and pass the stack canary check by putting a valid stack canary on the stack.

### 6.2.2 Disclosing Canary on Kernel Stack

By diverting the control-flow to a call site of `copy_to_user()`, we are closer to successfully disclose stack contents by satisfying the following four requirements. ❶, the registers should be set properly as parameters for `copy_to_user`, ❷, the kernel should not panic during the path caller function returns, ❸, the caller function of `copy_to_user` checks stack canary before return, ❹, the return address on stack must be set properly to continue the rest of the exploitation.

To tackle the first requirement, we leverage *blooming gadget* described in Section 6.3. For the second requirement, we could *trigger a page fault* and take a *short return path* similar to the technique described in Section 6.1.2. For the last two requirements, we pair stack-disclosure gadget with auxiliary function to generate a valid stack frame.

The key insight behind using auxiliary function to pair with stack-disclosure gadget is reusing the canary generated by the prologue of auxiliary function. A pair of them should have the same number of saved registers, the same canary location and stack size of 8 bytes difference.

```

1 | static void aliasing_gtt_unbind_vma(struct
    |     i915_vma *vma) {
2 |     ...
3 |     vma->vm->clear_range(vma->vm, vma->node.start,
    |         vma->size);
4 |     ...
5 | }

```

Table 3: The kernel code fragment (a blooming gadget) that could enhance the control over multiple general registers.

To elucidate the rationale behind the pairing, we take for example the routine of canary disclosure in Figure 6. We re-direct a CFHP to auxiliary function, After the prologue of auxiliary function which saves registers and establishes a stack frame, the target of indirect call `call rax` is set to the stack disclosure gadget in ❶. Then content of current stack frame is copied to user-space by `copy_to_user`, a page fault is triggered to force non-zero return value of `copy_to_user`, as result *short return path* is taken in ❷. Before the function returns, stack canary sanity check is performed ❸, because the auxiliary function put a valid stack canary in current stack frame, the canary check is successfully passed and return to the caller of auxiliary function.

## 6.3 Putting them together: "Single-shot" Exploitation

It remains challenging to use an ill-suited CFHP to first disclose stack canary and then smashing kernel stack. The reason behind is a CFHP in practice may have limitations in the following two aspects. First, difficulty in combining aforementioned two building blocks with a single CFHP, second, lack of register control. "Single-shot" exploitation uses a *blooming gadget* to amplify control over other registers and a *bridging gadget* to combine the two actions sequentially.

### 6.3.1 Augmenting CFHP with Blooming Gadget

To enhance a CFHP with the ability to control more registers, we introduce a family of *blooming gadgets*. The use of blooming gadget is inspired by COOP [59] which exploits a series of type confusions C++ program. Although Linux is written in C, its code heavily exhibits feature of object-oriented programming. The “self” object is usually passed as the first argument of function through `rdi`. And oftentimes the function contains “indirect call using function pointer that resides in the object passed as parameter. We could let the CFHP to land at these functions to abuse type confusion.

We illustrate one such blooming gadget in Table 3. Kernel function `aliasing_gtt_unbind_vma()` contains an indirect call with three parameters calculated by dereferencing the function’s first parameter `*vma`. Assume we have a CFHP with

```

1 void regcache_mark_dirty(struct regmap *map) {
2     map->lock(map->lock_arg); // the 1st
3     control-flow hijack
4     map->cache_dirty = true;
5     map->no_sync_defaults = true;
6     map->unlock(map->lock_arg); // the 2nd
7     control-flow hijack
8 }

```

Table 4: The source code of a bridging gadget – the kernel code fragment that could spawn multiple CFHPs.

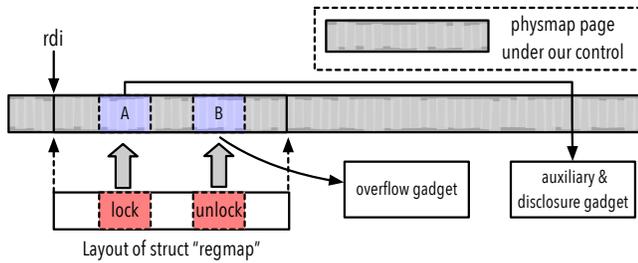

Figure 7: Memory layout after using physmap spray [39] to allocate physmap pages with data under our control.

control over `rdi`, we can get an augmented CFHP which controls `rdi`, `rsi`, and `rdx` at the same time at line 3 in Table 3.

Note a blooming gadget works only if `rdi` is controllable at beginning. We found this requirement is easy to fulfill in practice. Our insight is that a CFHP usually has one register potentially controllable - either the register is fully controllable or the register points to a heap area under control. Such primitive can be turned into a CFHP with `rdi` control easily through a single gadget which ends with an indirect call. A worst case happens where a CFHP implies none of potentially controllable registers. Fortunately, we are still able to leverage uninitialized or controllable data on kernel stack as well as a common ROP gadget. For example, we could use the gadget `add rsp, 0x68; pop rdi; ret` to gain control over `rdi` if `rsp+0x68` and `rsp+0x70` is under our control.

### 6.3.2 Spawning Multiple CFHPs with Bridging Gadget

As is demonstrated in the motivating example in Section 4, an exploitation practice depending on re-triggerable CFHP is not reliable because of exploit path pitfalls. We use bridging gadget - a family of kernel functions with multiple controllable indirect calls - to spawns two CFHPs and combine canary leak and stack smash into a single shot.

For example, function `regcache_mark_dirty` shown in Table 4 is such a bridging gadget which contains two indirect calls, `map->lock` in line 2 and `map->unlock` in line 5.

As we can observe from the kernel gadget shown in Table 4, the function pointers tied to these two indirect calls are enclosed in a data object referred by the first argument

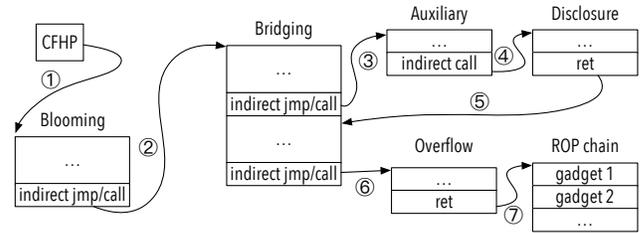

Figure 8: An illustration of how KEPLER stitches various kernel gadgets for ultimate exploitation.

of the function `regcache_mark_dirty()`. Recall that the first argument of a function is specified by the general register `rdi`, and we can usually obtain the control over that register using technique described in Section 6.3.1. As a result, in order to obtain control over both function pointers, we could first employ `ret2dir` [39] to allocate physmap pages and carefully crafted a data object accordingly. Then, we could refer the register `rdi` to a proper spot and set `rip` to the entry site of the gadget shown in Table 4. As is shown in Figure 7, assume the data carefully crafted in the spots of A and B represent the address of the auxiliary gadget together with a disclosure gadget responsible for leaking stack canary as well as the entry address of the gadget pertaining to stack smashing respectively. Then, by executing the bridging gadget shown in Table 4, we could first leak canary using the first indirect call. After the return of the call to `copy_to_user()`, there is no operations between the consecutive indirect calls that impose additional constraint to the second function pointer. Therefore, we could perform the stack smashing using the second function pointer without involving unexpected termination.

## 7 Implementation

Using IDA Pro SDK [20] and angr [64], we implemented KEPLER with about 8,000 lines of Python code. KEPLER is an automated tool that tracks down the aforementioned exploitation gadgets and chains them for exploitability assessment. Figure 8 depicts how these gadgets are concatenated. While previous sections have discussed the basic building blocks to perform an "single-shot" exploitation, the exploitation chain could not be determined once and for all with static analysis because uniqueness of each CFHP and different gadget combinations bring about the variation of the exploitation context. For example, the consecutive exploitation gadgets might no longer obtain the control over related registers with a different initial CFHP.

To address this problem, we developed our tool to assess each of the gadget chains potentially useful for kernel exploitation. More specifically, we follow the guidance of the exploitation chain construction shown in Figure 8, and design our tool to perform a depth-first exhaustive search which explores all the possible combinations of exploitation gad-

gets. When performing the depth-first search: starting from the `rip` hijack site, KEPLER symbolically executes the gadget chain that the search algorithm explores. To determine whether a gadget chain is useful for exploitation, our tool checks the memory access and deems a gadget chain useless if that exploitation chain attempts to access the user space or an unmapped kernel memory region. In addition, KEPLER examines the control over the registers at two critical sites – one at the entry of the disclosure gadget and the other at the entry of the overflow gadget. We implemented KEPLER to deem a gadget chain useless and terminate symbolic execution earlier if it has no control over the registers `rdi` and `rdx` at the first checking site or has no control over `rsi` and `rdx` at the second checking site. The reason behind this implementation is that, after executing bridging and auxiliary gadgets, we might lose the control over the registers needed for disclosure and overflow gadgets. With the check right before symbolically executing the two gadgets, we can quickly determine the usefulness of the gadget chain in exploitation, terminate unnecessary symbolic execution and thus save the computation resources.

In the process of the assessment of the exploitation chain, KEPLER symbolically executes each exploitation gadget. For some of them, they might carry a large number of basic blocks and even infinite loops. This could significantly influence the efficiency our tool and even incur the state explosion problem. To avoid these issues, for each path in an exploitation gadget, we set KEPLER to explore at most 20 basic blocks. In addition, we developed KEPLER to concretize each symbolic address. To be more specific, we set up a kernel page under our control in the `physmap` region and then concretize each symbolic address with a non-overlapping address of that memory page. In this work, we implemented this concretization mechanism by simply extending `ControlledData` – one of the symbolic address concretization strategies of `angr`.

For each gadget chain that passes the assessment, KEPLER further performs constraint solving to generate payload accordingly. Technically, this can be easily done by using `angr`. However, the `Z3` solver used in `angr` consumes memory exhaustively and generally does not release the memory used for constraint solving even after the completion of computation. To address this problem, KEPLER partitions symbolic execution and constraint solving into two different processes. In this way, KEPLER could terminate the memory-intensive process every time the constraint solving is completed and thus free the memory for consecutive computation.

As is described in Section 6.1, the payload smashed to the stack contains the stack canary disclosed as well as a sequence of addresses indicating an ROP chain that performs actual exploitation. With respect to the stack canary, we employ a separated thread in the user-space to rapidly retrieve the canary – whenever it is disclosed to the user-space – and then make it ready for stack smashing. Regarding the ROP chain used in this work, we simply choose the ROP payload com-

monly used for privilege escalation. In Appendix, we specify the ROP payload used in this work. It invokes kernel functions `commit_creds()` and `prepare_kernel_cred()` to obtain the root privilege. Note that the construction of an ROP payload is out of scope of this paper. There are many commonly-adopted ROP payloads, which can be naturally hooked with our new kernel exploitation technique.

## 8 Case Study and Evaluation

In this section, we demonstrate our new exploit technique and evaluate our automated tool KEPLER using real-world kernel vulnerabilities and some recently-released CTF challenges. To be specific, we compare KEPLER with various kernel exploitation techniques to show it is an effective exploit technique, we also compare KEPLER with automatic exploit generation systems to highlight its power in evaluating exploitability with a CFHP. In addition, we show the efficacy and efficiency of KEPLER in facilitating exploitation chain construction.

### 8.1 Setup

We first randomly selected 3 recently released CTF challenges as well as 16 real-world kernel vulnerabilities archived between 2016 and 2017. Then, we successfully assembled these vulnerabilities in a mainline Linux kernel 4.15.0 by inserting them into the kernel code or reverting their patch accordingly. In this work, we evaluate our tool KEPLER by using this single Linux kernel, and demonstrate the effectiveness of “single-shot” exploitation by launching exploitations against the inserted vulnerabilities.

As is summarized in Table 5, the vulnerabilities inserted cover various types such as Use-After-Free and Out-Of-Bound (OOB) read/write etc. It should be noted that the CVEs selected are a little bit unbalanced – with more in 2017 and less in 2016. On the one hand, this is because there are more than  $2\times$  of kernel vulnerabilities reported in 2017 than those in 2016 [1]. On the other hand, this is because some components in Linux kernel experience significant overhaul since 2016 and we have difficulty of re-enabling the corresponding vulnerabilities in a new kernel image.

In order to run and evaluate KEPLER, we also assembled and configured a testbed which has a 32-core Intel(R) Xeon(R) Platinum 8124M CPU and 256GB of memory. For each vulnerability, we then used this testbed to run 28 concurrent workers which symbolically explore the kernel code space and track down useful exploitation chains in parallel.

### 8.2 Effectiveness of “single-shot” exploitation

By searching the Internet, we gathered 10 exploits pertaining to the vulnerabilities inserted. As is shown in Table 5, these

ID	Vulnerability type	Public exploit	Q	FUZE	KEPLER	G1	G2	G3	G4	First chain (min)	Total time (hour)	Total # of exploitation chains
CVE-2017-16995	OOB readwrite	✓ †	✗	✗	✓	41	114	27	201	45	37	29788

Table 5: The comparison of exploitability as well as performance of KEPLER. G1, G2, G3 and G4 represent the blooming gadget, bridging gadget, auxiliary and disclosure gadget pair, and stack-smash gadget. The “first chain” column indicates the time spent on pinpointing the first exploitation chain. The “total time” column specifies the total amount of time spent on finding all useful exploitation chains. † symbol represents the cases where the exploits could only bypass major mitigations (e.g., SMAP and SMEP) and fail to bypass others under our threat model. ✓ and ✗ symbols indicate the existence and non-existence of a working exploit.

publicly available exploits perform exploitation through various approaches and therefore demonstrate different capability in bypassing kernel mitigations. Among these exploits, we found there are only 5 of them demonstrating the ability to perform exploitation under our aforementioned threat model. In comparison with the working exploits generated by KEPLER, publicly available exploits demonstrate much weaker exploitability (with 5 vs 17 cases). To some extent, this implies existing exploitation approaches highly rely upon the quality of the target vulnerability and corresponding CFHP, whereas our approach KEPLER could utilize prevalent kernel function and gadgets to explore exploitable machine states and thus escalate the exploitability for a CFHP. However, previous exploit technique Q [60] could not generate working exploit because Q rely on a stack pivoting gadget while its gadget discovery phase return none of working pivoting gadget<sup>4</sup>. FUZE could only generate exploit for 3 cases because it evaluate exploitability of a CFHP simply with two straight forward exploit technique: pivot-2-usr and “cr4-flipping”. The former does not bypass SMAP and the latter only works when at least two CHFPs is available.

Even for the vulnerabilities against which both public exploits and ours demonstrate the same capabilities in bypassing mitigations, we argue that our approach still exhibits stronger exploitability. This is because the public exploits circumvent mitigations by manipulating control registers with two CFHPs,

<sup>4</sup>The result related to Q in our evaluation is based on inference of its design instead of running its tool because we were not able to get the source code of Q.

as is discussed in Section 2.3, this practice can be easily restricted by virtualization extension. For the two vulnerabilities CVE-2017-17053 and CVE-2016-9793 for which our approach fails to derive working exploits, we manually examine their execution traces leading to the kernel panic. We find that the failure results from the following fact. In order to take the control over rip prior to exploitation, both of these vulnerabilities require an exploit to access the data in the user space. This violates the protection of SMAP. KEPLER restricts any operations that violate our threat model and output a failure if none of the exploitation chains could avoid such violation.

### 8.3 Effectiveness and Efficiency of Our Tool

Our experiment utilizes KEPLER to explore the aforementioned kernel image with the vulnerabilities inserted. In this process, we exhaustively search gadget chains useful for exploitation and mitigation circumvention. In Table 5, we show the total number of useful exploitation chains identified as well as the total amount of time spent on finding these gadget chains. As we can observe, KEPLER could automatically pinpoint tens of thousands of unique kernel gadget chains to perform exploitation without triggering kernel protections. Since we implement KEPLER to perform gadget chain exploration in parallel, we also discover that these gadget chains could typically be identified within 50 hours. These observations together imply that KEPLER could diversify the ways of performing kernel exploitation in an efficient fashion. Given that some commercial security products pinpoint kernel exploita-

tion by using the patterns of exploits, the ability to diversify exploitation has the potential to assist an adversary to bypass the detection of commercial security products.

From Table 5, we also observe that, for different vulnerabilities, KEPLER generates different number of gadget chains useful for exploitation. This can be attributed to the following fact. In the process of gadget chain identification and assessment, KEPLER starts gadget assessment from different machine states and contexts. For some vulnerabilities, the machine states and contexts do not provide us with sufficient control over some registers and memory regions. Under this circumstance, the availability of useful kernel gadgets would vary and thus influence the total number of generated exploits.

In Table 5, we also depict the time spent on finding the first kernel gadget chain useful for exploitation. As we can observe, KEPLER could quickly output an useful exploitation chain in less than about 50 wall-clock minutes (and the corresponding CPU-core time is roughly 1400 minutes given the prototype system uses 28 concurrent workers). This implies KEPLER has the potential to be used as a tool to quickly derive a working exploit without too many human efforts. Last but not least, Table 5 also shows the total number kernel gadgets in different categories. As we can observe, there are typically tens of gadgets in each categories. This means that one cannot simply block our exploitation approach by eliminating a small number of kernel gadgets. In Section 9, we will further discuss the defense of our exploitation approach.

## 9 Discussion and Future Research

In this section, we discuss some plausible defence mechanisms against our “single-shot” exploitation chain. Also, we elaborate why they are not effective nor suitable for preventing the proposed attack. Following our discussion and analysis, we then provide some suggestions for the future research.

**Plausible Defense Mechanisms.** To defend against the exploit chain mentioned above, one straightforward reaction is to eliminate the gadgets that must be used in kernel exploitation. However, as we have already demonstrated and discussed in Section 8, the tool we develop could enrich the choices of the gadgets needed for exploitation. This means that, following this potential solution, Linux developers would inevitably introduce significant amount of kernel code changes and it is difficult to guarantee these changes would not bring about negative influence upon Linux kernel execution. Other security mitigation could also be used as potential defense mechanisms. For example, there have already been a rich collection of research works on control and data flow integrity protection (e.g. [2] [78] [79] [25] [16] [26]). In addition, randomizing stack canary per-function call [73] could ideally prevent our exploit technique because it discourage the effort to fake stack frame and leak stack canary with `copy_to_user`. Integrating and enabling them in Linux kernel, they could easily fail the attack mentioned above. Unfortunately, these techniques usually in-

cur unacceptable overhead (e.g., [16] has an average overhead of 13%) or sometimes rely upon hardware features to reduce their overhead (e.g., [25]). As a result, they are barely used as a practical, general defense solution in popular release version of Linux kernel.

**Possible Future Research.** Looking ahead, we suggest the future research could be conducted from two aspects. From the perspective of automatic exploit primitive evaluation, we believe there is an emerging need to invent technique to systematically evaluate various exploit primitives, especially for those weak exploit primitives. In practice, theory and techniques should be proposed to facilitate deriving better exploit primitive with a initially weak exploit primitive. From the perspective of defense, on one hand, we believe there remains the need to design lightweight control-flow enforcements for Linux kernel. On the other hand, instead of manually overhauling kernel code, one could augment GCC with the ability to eliminate the exploitation gadgets at compilation time.

## 10 Conclusion

We show it is generally challenging to generate exploits with a control-flow hijacking primitive in the Linux kernel under a realistic threat model, while there are a lot of research efforts in identifying exploit primitives and facilitating exploit generation with various exploit primitives. We propose KEPLER, a framework to facilitate evaluation of control-flow hijacking primitives which leverages a novel “single-shot” exploitation to convert a control-flow hijacking primitive into a classic stack overflow and thus bootstrap traditional code-reuse attack against modern Linux kernel. In comparison with previous automatic exploit generation and exploit hardening techniques, we show that KEPLER outperforms other exploit techniques and is able to generate thousands of exploit chains for a control-flow hijacking primitive in Linux kernel despite the challenges of widely-deployed security mitigations, exploit path pitfalls and ill-suited exploit primitives. Following the experimental results, we safely conclude that KEPLER can significantly facilitate evaluating control-flow hijacking primitive in the Linux kernel.

## 11 Availability

We release the source code of KEPLER, a kernel embeded with vulnerabilities and generated gadget chains for research and education purposes [76].

## Appendix

As is discussed in Section 6, we utilize a series of kernel gadgets to bypass kernel mitigations. After that, we redirect the control flow of the Linux kernel to a universal ROP payload. By using that payload,

```

1 // copy more payloads to the kernel stack
2 // prepare arguments for copy_from_user()
3 p[i++]=POP_RAX; // pop rax ; ret
4 p[i++]=POP_RSI; // pop rsi ; ret
5 p[i++]=0xffffffff81254a99; // mov rdi, rsp ;
   call rax
6 p[i++]=POP_RAX;
7 p[i++]=0x1000;
8 p[i++]=0xffffffff81a04201; // sub rdi, rax ;
   mov rax, rdi ; ret
9 p[i++]=POP_RSI;
10 p[i++]=STAGE_TWO_ROP_PAYLOAD;
11 p[i++]=POP_RDX; // pop rdx ; ret
12 p[i++]=0x1040;
13 p[i++]=COPY_FROM_USER; // copy_from_user()
14
15 // subtract rsp to the first gadget
16 p[i++]=POP_RAX;
17 p[i++]=0x1040;
18 p[i++]=0xffffffff81a04201; // sub rdi, rax ;
   mov rax, rdi ; ret
19 p[i++]=POP_R12; // pop r12 ; ret
20 p[i++]=0xffffffff810001cc; // ret
21 p[i++]=0xffffffff81c01688; // mov rsp, rax ;
   push r12 ; ret

```

Table 7: The kernel ROP payload that copies an ROP payload to the current stack frame and then subtracts the stack pointer to execute the ROP payload.

we demonstrate the exploitability of a kernel vulnerability. In Table 6, we show an ROP payload used in this work. As is specified, it first performs privilege escalation. Then, it sets the Linux kernel to fall into asleep for a long time by using the kernel function `msleep()`.

Considering Linux kernel might perform inline permission checks and we need to execute an ROP payload with an arbitrary length, we further utilize the ROP payload like the one shown in Table 7 to address this payload length issue.

# PeX: A Permission Check Analysis Framework for Linux Kernel

## Abstract

Permission checks play an essential role in operating system security by providing access control to privileged functionalities. However, it is particularly challenging for kernel developers to correctly apply new permission checks and to scalably verify the soundness of existing checks due to the large code base and complexity of the kernel. In fact, Linux kernel contains millions of lines of code with hundreds of permission checks, and even worse its complexity is fast-growing.

This paper presents PeX, a static Permission check error detector for Linux, which takes as input a kernel source code and reports any missing, inconsistent, and redundant permission checks. PeX uses KIRIN (Kernel InteRface based Indirect call aNalysis), a novel, precise, and scalable indirect call analysis technique, leveraging the common programming paradigm used in kernel abstraction interfaces. Over the interprocedural control flow graph built by KIRIN, PeX automatically identifies all permission checks and infers the mappings between permission checks and privileged functions. For each privileged function, PeX examines all possible paths to the function to check if necessary permission checks are correctly enforced before it is called.

We evaluated PeX on the latest stable Linux kernel v4.18.5 for three types of permission checks: Discretionary Access Controls (DAC), Capabilities, and Linux Security Modules (LSM). PeX reported 36 new permission check errors, 14 of which have been confirmed by the kernel developers.

## 1 Introduction

Access control [38] is an essential security enforcement scheme in operating systems. They assign users (or processes) different access rights, called permissions, and enforce that only those who have appropriate permissions can access critical resources (e.g., files, sockets). In the kernel, access control

is often implemented in the form of *permission checks* before the use of *privileged functions* accessing the critical resources.

Over the course of its evolution, Linux kernel has employed three different access control models: Discretionary Access Controls (DAC), Capabilities, and Linux Security Modules (LSM). DAC distinguishes privileged users (a.k.a., root) from unprivileged ones. The unprivileged users are subject to various permission checks, while the root bypasses them all [4]. Linux kernel v2.2 divided the root privilege into small units and introduced *Capabilities* to allow more fine-grained access control. From kernel v2.6, Linux adopted LSM in which various security hooks are defined and placed on critical paths of privileged operations. These security hooks can be instantiated with custom checks, facilitating different security model implementations as in SELinux [41] and AppArmor [3].

Unfortunately, for a new feature or vulnerability found, these access controls have been applied to the Linux kernel code in an ad-hoc manner, leading to *missing*, *inconsistent*, or *redundant* permission checks. Given the ever-growing complexity of the kernel code, it is becoming harder to manually reason about the mapping between permission checks and privileged functions. In reality, kernel developers rely on their own judgment to decide which checks to use, often leading to over-approximation issues. For instance, *Capabilities* were originally introduced to solve the “super” root problem, but it turns out that more than 38% of *Capabilities* indeed check CAP\_SYS\_ADMIN, rendering it yet another root [5].

Even worse, *there is no systematic, sound, and scalable way to examine whether all privileged functions (via all possible paths) are indeed protected by correct permission checks*. The lack of tools for checking the soundness of existing or new permission checks can jeopardize the kernel security putting the privileged functions at risk. For example, DAC, CAP and LSM introduce hundreds of security checks scattered over millions of lines of the kernel code, and it is an open problem to verify if all code paths to a privileged function encounter its corresponding permission check before reaching the function. Given the distributed nature of kernel development and the significant amount of daily updates, chances are that some

\*This work was started when Tong Zhang interned at Samsung Research America, mentored by Wenbo Shen and Ahmed M. Azab.

†Corresponding author.

‡Now at Google.

parts of the code may miss checks on some paths or introduce the inconsistency between checks, weakening the operating system security.

This paper presents PeX, a static permission check analysis framework for Linux kernel. PeX makes it possible to soundly and scalably detect any missing, inconsistent and redundant permission checks in the kernel code. At a high level, PeX statically explores all possible program paths from user-entry points (e.g., system calls) to privileged functions and detects permission check errors therein. Suppose PeX finds a path in which a privileged function, say  $PF$ , is protected (preceded) by a check, say  $Chk$  in one code. If it is found that any other paths to  $PF$  bypass  $Chk$ , then it is a strong indication of a missing check. Similarly, PeX can detect inconsistent and redundant permission checks. While conceptually simple, it is very challenging to realize a sound and precise permission check error detection at the scale of Linux kernel.

In particular, there are two daunting challenges that PeX should address. First, Linux kernel uses indirect calls very frequently, yet its static call graph analysis is notoriously difficult. The latest Linux kernel (v4.18.5) contains 15.8M LOC, 247K functions, and 115K indirect callsites, rendering existing precise solutions (e.g., SVF [43]) unscalable. Only workaround available to date is either to apply the solutions unsoundly (e.g., only on a small code partition as with K-Miner [22]) or to rely on naive imprecise solutions (e.g., type-based analysis). Either way leads to undesirable results, i.e., false negatives (K-Miner) or positives (type-based one).

For a precise and scalable indirect call analysis, we introduce a novel solution called *KIRIN* (Kernel InteRface based Indirect call aNalysis), which leverages kernel abstraction interfaces to enable precise yet scalable indirect call analysis. Our experiment with Linux v4.18.5 shows that KIRIN allows PeX to detect many previously unknown permission check bugs, while other existing solutions either miss many of them or introduce too many false warnings.

Second, unlike Android which has been designed with the permission-based security model in mind [2], Linux kernel does not document the mapping between a permission check and a privileged function. More importantly, the huge Linux kernel code base makes it practically impossible to review them all manually for the permission check verification.

To tackle this problem, PeX presents a new technique which takes as input a small set of known permission checks and automatically identifies all other permission checks including their wrappers. Moreover, PeX’s dominator analysis [31] automates the process of identifying mappings between permission checks and their potentially privileged functions as well. Our experiment with Linux kernel v4.18.5 shows that starting from a small set of well-known 3 DAC, 3 Capabilities, and 190 LSM checks, PeX automatically (1) identifies 19, 16, and 53 additional checks, respectively, and (2) derives 9243 pairs of permission checks and privileged functions.

The contributions of this paper are summarized as follows:

Table 1: Commonly used permission checks in Linux.

Type	Total #	Permission Checks
DAC	3	generic_permission, sb_permission, inode_permission
Capabilities	3	capable, ns_capable, avc_has_perm_noaudit
LSM	190	security_inode_readlinkat, security_file_ioctl, etc..

- **New Techniques:** We proposed and implemented PeX, a static permission check analysis framework for Linux kernel. We also developed new techniques that can perform scalable indirect call analysis and automate the process of identifying permission checks and privileged functions.
- **Practical Impacts:** We analyzed DAC, Capabilities, and LSM permission checks in the latest Linux kernel v4.18.5 using PeX, and discovered 36 new permission check bugs, 14 of which have been confirmed by kernel developers.
- **Community Contributions:** We will release PeX as an open source project, along with the identified mapping between permission checks and privileged functions. This will allow kernel developers to validate their codes with PeX, and to contribute to PeX by refining the mappings with their own domain knowledge.

## 2 Background: Permission Checks in Linux

This section introduces DAC, Capabilities, and LSM in Linux kernel. Table 1 lists practically-known permission checks in Linux. Unfortunately, the full set is not well-documented.

### 2.1 Discretionary Access Control (DAC)

DAC restricts the accesses to critical resources based on the identity of subjects or the group to which they belong [36, 46]. In Linux, each user is assigned a user identifier (uid) and a group identifier (gid). Correspondingly, each file has properties including the owner, the group, the  $rwX$  (read, write, and execute) permission bits for the owner, the group, and all other users. When a process wants to access a file, DAC grants the access permissions based on the process’s uid, gid as well as the file’s permission bits. For example in Linux, `inode_permission` (as listed in Table 1) is often used to check the permissions of the current process on a given inode. More precisely speaking, however, it is a wrapper of `posix_acl_permission`, which performs the actual check.

In a sense, DAC is a coarse-grained access control model. Under the Linux DAC design, the “root” bypasses all permission checks. This motivates fine-grained access control scheme—such as Capabilities—to reduce the attack surface.

### 2.2 Capabilities

Capabilities, since Linux kernel v2.2 (1999), enable a fine-grained access control by dividing the root privilege into small sets. As an example, for users with the `CAP_NET_ADMIN` capability, kernel allows them to use `ping`, without the need to grant the full root privilege. Currently, Linux kernel v4.18.5 supports 38 Capabilities including `CAP_NET_ADMIN`,

CAP\_SYS\_ADMIN, and so on. Functions `capable` and `ns_capable` are the most commonly used permission checks for Capabilities (as listed in Table 1). Both determine whether a process has a particular capability or not, while `ns_capable` performs an additional check against a given user namespace. They internally use `security_capable` as the basic permission check.

Capabilities are supposed to be fine-grained and distinct [4]. However, due to the lack of clear scope definitions, the choice of specific Capability for protecting a privileged function has been made based on kernel developers’ own understanding in practice. Unfortunately, this leads to frequent use of CAP\_SYS\_ADMIN (451 out of 1167, more than 38%), and it is just treated as yet another root [5]; grsecurity points out that 19 Capabilities are indeed equivalent to the full root [1].

### 2.3 Linux Security Module (LSM)

LSM [51], introduced in kernel v2.6 (2003), provides a set of fine-grained pluggable hooks that are placed at various security-critical points across the kernel. System administrators can register customized permission checking callbacks to the LSM hooks so as to enforce diverse security policies. The latest Linux kernel v4.18.5 defines 190 LSM hooks. One common use of LSM is to implement Mandatory Access Control (MAC) [8] in Linux (e.g., SELinux [40, 41], AppArmor [3]). MAC enforces more strict and non-overridable access control policies, controlled by system administrators. For example, when a process tries to read the file path of a symbolic link, `security_inode_readlink` is invoked to check whether the process has `read` permission to the symlink file. The SELinux callback of this hook checks if a policy rule can grant this permission (e.g., `allow domain_a type_b:lnk_file read`). It is worth noting that the effectiveness of LSM and its MAC mechanisms highly depend on whether the hooks are placed *correctly* and *soundly* at all security-critical points. If a hook is missing at any critical point, there is no way for MAC to enforce a permission check.

## 3 Examples of Permission Check Errors

This section illustrates different kinds of permission check errors, found by PeX and confirmed by the Linux kernel developers. We refer to those functions, that validate whether a process (a user or a group) has proper permission to do certain operations, as *permission checks*. Similarly, we define *privileged functions* to be those functions which only a privileged process can access and thus require permission checks.

### 3.1 Capability Permission Check Errors

Figure 1 shows real code snippets of Capability permission check errors in Linux kernel v4.18.5. Figure 1a shows the kernel function `scsi_ioctl`, in which `sg_scsi_ioctl` (Line 7) is safeguarded by two Capability checks, CAP\_SYS\_ADMIN and CAP\_SYS\_RAWIO (Line 5). To the contrary, `scsi_cmd_ioctl` in Figure 1b calls the same function `sg_scsi_ioctl` (Line

```

1 int scsi_ioctl(struct scsi_device *sdev, int cmd,
2               ↪ void __user *arg)
3 {
4     ...
5     case SCSI_IOCTL_SEND_COMMAND:
6         if (!capable(CAP_SYS_ADMIN) ||
7             ↪ !capable(CAP_SYS_RAWIO))
8             return -EACCESS;
9         return sg_scsi_ioctl(sdev->request_queue, NULL,
10                             ↪ 0, arg);
11     ...
12 }

```

(a) `sg_scsi_ioctl` (Line 7) is called **with** CAP\_SYS\_ADMIN and CAP\_SYS\_RAWIO capability checks (Line 5). `arg` is user space controllable.

```

1 int scsi_cmd_ioctl(struct request_queue *q, ...,
2                  ↪ void __user *arg)
3 {
4     ...
5     case SCSI_IOCTL_SEND_COMMAND:
6         if (!arg)
7             break;
8         err = sg_scsi_ioctl(q, bd_disk, mode, arg);
9         break;
10        ...
11        return err;
12    }

```

(b) `sg_scsi_ioctl` (Line 8) is called **without** capability checks. `arg` is user space controllable.

```

1 int sg_scsi_ioctl(struct request_queue *q, struct
2                  ↪ gendisk *disk, fmode_t mode, struct
3                  ↪ scsi_ioctl_command __user *sic)
4 {
5     ...
6     err = blk_verify_command(req->cmd, mode);
7     ...
8     return err;
9 }
10 int blk_verify_command(unsigned char *cmd, fmode_t
11                       ↪ mode)
12 {
13     ...
14     if (capable(CAP_SYS_RAWIO))
15         return 0;
16     ...
17     return -EPERM;
18 }

```

(c) `sg_scsi_ioctl` calls `blk_verify_command`, which checks CAP\_SYS\_RAWIO capability.

Figure 1: Capability check errors discovered by PeX.

8) without any Capability check. These two functions share three similarities. First, both of them are reachable from the userspace by `ioctl` system call. Second, both call `sg_scsi_ioctl` with a userspace parameter, `void __user *arg`. Last, there is no preceding Capability check on all possible paths to them (though `scsi_ioctl` performs two checks).

The kernel is supposed to sanitize userspace inputs and check permissions to ensure that only users with appropriate permissions can conduct certain privileged operations. As SCSI (Small Computer System Interface) functions manipulate the hardware, they should be protected by Capabilities. At first glance, `scsi_ioctl` seems to be correctly protected (while `scsi_cmd_ioctl` misses two Capability checks).

However, delving into `sg_scsi_ioctl` ends up with a different conclusion. As shown in Figure 1c, `sg_scsi_ioctl` calls `blk_verify_command`, which in turn checks CAP\_SYS\_RAWIO. Considering all together, `scsi_ioctl` checks CAP\_SYS\_ADMIN once but CAP\_SYS\_RAWIO “twice”, leading to a *redundant* permission check. On the other hand, `scsi_cmd_ioctl` checks

```

1 static int do_readlinkat(int dfd, const char __user
  ↳ *pathname, char __user *buf, int bufsiz)
2 {
3     ...
4     error = security_inode_readlink(path.dentry);
5     if (!error) {
6         touch_atime(&path);
7         error = vfs_readlink(path.dentry, buf, bufsiz);
8     }
9     ...
10 }

```

(a) Kernel LSM usage in system call `readlinkat`. `vfs_readlink` (Line 7) is protected by `security_inode_readlink` (Line 4). Both `pathname` and `buf` (Line 1 and Line 7) are user controllable.

```

1 int ksys_ioctl(unsigned int fd, unsigned int cmd,
  ↳ unsigned long arg)
2 {
3     ...
4     error = security_file_ioctl(f.file, cmd, arg);
5     if (!error)
6         error = do_vfs_ioctl(f.file, fd, cmd, arg);
7     ...
8 }
9
10 int xfs_readlink_by_handle(struct file *parfilp,
  ↳ xfs_fsop_handlerreq_t *hreq)
11 {
12     ...
13     error = vfs_readlink(dentry, hreq->ohandle, olen);
14     ...
15 }

```

(b) Kernel LSM usage in system call `ioctl`. It calls `security_file_ioctl` (Line 4) to protect `do_vfs_ioctl` (Line 6). `hreq->ohandle` and `olen` are also user controllable.

Figure 2: LSM check errors discovered by PeX.

only `CAP_SYS_RAWIO`, resulting in a *missing* permission check for `CAP_SYS_ADMIN`. In particular, PeX detects this bug as an *inconsistent* permission check because the two paths disagree with each other, and further investigation shows that one is redundant and the other is missing.

### 3.2 LSM Permission Check Errors

The example of LSM permission check errors is related to how LSM hooks are instrumented for two different system calls `readlinkat` and `ioctl`.

Figure 2a shows the LSM usage in the `readlinkat` system call. On its call path, `vfs_readlink` (Line 7) is protected by the LSM hook `security_inode_readlink` (Line 4) so that a LSM-based MAC mechanism, such as SELinux or AppArmor, can be realized to allow or deny the `vfs_readlink` operation.

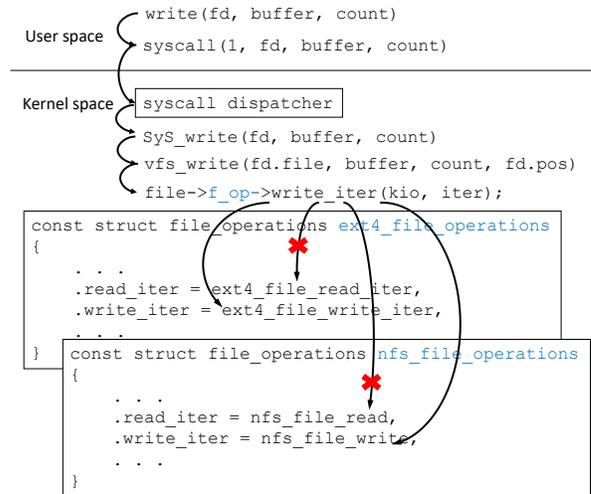

Figure 2b presents two sub-functions for the system call `ioctl`. Similar to the above case, `ioctl` calls `ksys_ioctl`, which includes its own LSM hook `security_file_ioctl` (Line 4) before `do_vfs_ioctl` (Line 6). This is proper design, and there is no problem so far. However, it turns out that there is a path from `do_vfs_ioctl` to `xfs_readlink_by_handle` (Line 10), which eventually calls the same privileged function `vfs_readlink` (see Line 7 in Figure 2a and Line 13 in Figure 2b). While this function is protected by the `security_inode_readlink` LSM hook in `readlinkat`, that is not the case for the path to the function going through `xfs_readlink_by_handle`. The problem is that SELinux maintains separate ‘allow’ rules for `read` and `ioctl`. With the *missing* LSM `security_inode_readlink` check, a user only with

```

1 struct file_operations {
2     ...
3     ssize_t (*read_iter) (struct kiocb *, struct
  ↳ iov_iter *);
4     ssize_t (*write_iter) (struct kiocb *, struct
  ↳ iov_iter *);
5     ...
6 }

```

(a) The Virtual File System (VFS) kernel interface.

(b) VFS indirect calls in Linux kernel.

Figure 3: Indirect call examples via the VFS kernel interface.

the ‘`ioctl` allow rule’ may exploit the `ioctl` system call to trigger the `vfs_readlink` operation, which should only be permitted by the different ‘`read` allow rule’.

The above two Capability and LSM examples show how challenging it is to ensure correct permission checks. There are no tools available for kernel developers to rely on to figure out whether a particular function should be protected by a permission check; and, (if so) which permission checks should be used.

## 4 Challenges

This section discusses two critical challenges in designing static analysis for detecting permission errors in Linux kernel.

### 4.1 Indirect Call Analysis in Kernel

The first challenge lies in the frequent use of indirect calls in Linux kernel and the difficulties in statically analyzing them in a scalable and precise manner. To achieve a modular design, the kernel proposes a diverse set of abstraction layers that specify the common *interfaces* to different concrete implementations. For example, Virtual File System (VFS) [12] abstracts a file system, thereby providing a unified and transparent way to access local (e.g., `ext4`) and network (e.g., `nfs`) storage devices. Under this kernel programming paradigm, an abstraction layer defines an interface as a set of indirect function pointers while a concrete module initializes these pointers with its own implementations. For example, as shown in Figure 3a, VFS abstracts all file system operations in a *ker-*

*nel interface* struct `file_operations` that contains a set of function pointers for different file operations. When a file system is initialized, it initializes the VFS interface with the concrete function addresses of its own. For instance, Figure 3b shows that `ext4` file system sets the `write_iter` function pointer to `ext4_file_write_iter`, while `nfs` sets the pointer to `nfs_file_write`.

However, kernel’s large code base challenges the resolution of these numerous function pointers within kernel interfaces. For example, the kernel used in our evaluation (v4.18.5) includes 15.8M LOC, 247K functions, and 115K indirect call-sites. This huge code base makes existing precise pointer analysis techniques [23–25, 35, 43] unscalable. In fact, Static Value Flow (SVF) [43], i.e., the state-of-the-art analysis that uses flow- and context-sensitive value flow for high precision, failed to scale to the huge Linux kernel. That is because SVF is essentially a whole program analysis, and its indirect call resolution thus requires tracking all objects such as functions, variables, and so on, making the value flow analysis unscalable to the large-size Linux kernel. In our experiment of running SVF for the kernel on a machine with 256GB memory, SVF was crashed due to an out of memory error<sup>1</sup>.

Alternatively, one may opt for a simple “type-based” function pointer analysis, which would scale to Linux kernel. However, the type-based indirect call analysis would suffer from serious imprecision with too many *false* targets, because function pointers in the kernel often share the same type. For example, in Figure 3a, two function pointers `read_iter` and `write_iter` share the same function type. Type based pointer analysis will even link `write_iter` to `ext4_file_read_iter` falsely, which may lead to false permission check warnings.

PeX addresses this problem with a new kernel-interface aware indirect call analysis technique, detailed in §5.

## 4.2 The Lack of Full Permission Checks, Privileged Functions, and Their Mappings

The second challenge lies in soundly enumerating a set of permission checks and inferring correct mappings between permission checks and privileged functions in Linux kernel.

Though some commonly used permission checks for DAC, Capabilities, and LSM are known (Table 1), kernel developers often devise custom permission checks (wrappers) that internally use basic permission checks. Unfortunately, the complete list of such permission checks has never been documented. For example, `ns_capable` is a commonly used permission check for Capabilities, but it calls `ns_capable_common` and `security_capable` in sequence. It is the last `security_capable` that performs the actual capability check. In other words, all the others are “wrappers” of the “basic” permission check `security_capable`. This example

<sup>1</sup>SVF internally uses LLVM SparseVectors to save memory overhead by only storing the set bits. However, it still blows up both the memory and the computation time due to the expensive insert, expand and merge operations.

shows how hard it is for a permission check analysis tool to keep up with all permission checks.

To make matters worse, Linux kernel has no explicit documentation that specifies which privileged function should be protected by which permission checks. This is different from Android [2], which has been designed with the permission-based security model in mind from the beginning. Take the Android `LocationManager` class as an example; for the `getLastKnownLocation` method, the API document states explicitly that permission `ACCESS_COARSE_LOCATION` or `ACCESS_FINE_LOCATION` is required [7].

Unfortunately, existing *static* permission error checking techniques are not readily applicable in order to address these problems. Automated LSM hook verification [44] works only with clearly defined LSM hooks, which would miss many wrappers in the kernel setting. Many other tools require heavy manual efforts such as user-provided security rules [20, 56], authorization constraints [33], annotation on sensitive objects [21]. These manual processes are particularly error-prone when applied to huge Linux code base. Alternatively, some works such as [18, 32] rely on *dynamic* analysis. However, such run-time approaches may significantly limit the code coverage being analyzed, thereby missing real bugs.

Moreover, all of above existing works cannot detect permission checks soundly. Their inability to recognize permission checks or wrappers leads to missing privileged functions or false warnings for those that are indeed protected by wrappers. Since the huge Linux kernel code base makes it practically impossible to review them all manually, reasoning about the mapping is considered to be a daunting challenge.

In light of this, PeX presents a novel static analysis technique that takes as input a small set of known permission checks to identify their basic permission checks and leverages them as a basis for finding other permission check wrappers (§6.2). In addition, PeX proposes a dominator analysis based solution to automatically infer the mappings between permission checks and privileged functions (§6.3).

## 5 KIRIN Indirect Call Analysis

PeX proposes a precise and scalable indirect call analysis technique, called KIRIN (Kernel InteRface based Indirect call aNalysis), on top of the LLVM [27] framework. KIRIN is inspired by two key observations: (1) almost all (95%) indirect calls in the Linux kernel are originated from kernel interfaces (§4.1) and (2) the type of a kernel interface is preserved both at its initialization site (where a function pointer is defined) and at the indirect callsite (where a function pointer is used) in LLVM IR. For example in Figure 3b, the kernel interface object `ext4_file_operations` of the type `struct file_operations` is statically initialized where `ext4_file_write_iter` is assigned to the field of `write_iter`. For the indirect call site `file→f_op→write_iter`, one can identify that `f_op` is of the type `struct file_operations` and

```

1 @ext4_file_operations = dso_local local_unnamed_addr
  ↳ constant %struct.file_operations {
2   %struct.module* null,
3   i64 (%struct.file*, i64, i32)* @ext4_llseek,
4   i64 (%struct.file*, i8*, i64, i64*)* null,
5   i64 (%struct.file*, i8*, i64, i64*)* null,
6   i64 (%struct.kiocb*, %struct.iov_iter*)*
  ↳ @ext4_file_read_iter,
7   i64 (%struct.kiocb*, %struct.iov_iter*)*
  ↳ @ext4_file_write_iter,

```

(a) LLVM IR of ext4\_file\_operations initialization.

```

1 %25 = load %struct.file_operations*,
  ↳ %struct.file_operations** %f_op, align 8
2 %write_iter.i.i = getelementptr inbounds
  ↳ %struct.file_operations,
  ↳ %struct.file_operations* %25, i64 0, i32 5
3 %26 = load i64 (%struct.kiocb*, %struct.iov_iter*)*,
  ↳ i64 (%struct.kiocb*, %struct.iov_iter**)
  ↳ %write_iter.i.i, align 8
4 %call.i.i = call i64 @26(%struct.kiocb* nonnull
  ↳ %kiocb.i, %struct.iov_iter* nonnull %iter.i) #10

```

(b) LLVM IR of callsite file→f\_op→write\_iter in vfs\_write.

Figure 4: Indirect callsite resolution for vfs\_write.

infer that ext4\_file\_write\_iter is one of potential call targets. Based on this observation, PeX first collects indirect call targets at kernel interface initialization sites (§5.1) and then resolves them at indirect callsites (§5.2).

## 5.1 Indirect Call Target Collection

In Linux kernel, a kernel interface is often defined in a C struct comprised of function pointers (§4.1): e.g., struct file\_operations in Figure 3a. Many kernel interfaces (C structs) are *statically* allocated and initialized as with ext4\_file\_operations and nfs\_file\_operations in Figure 3b. Some interfaces may be *dynamically* allocated and initialized at run time for reconfiguration.

For the former, KIRIN scans all Linux kernel code linearly to find all statically allocated and initialized struct objects with function pointer fields. Then, for each struct object, KIRIN keep tracks of which function address is assigned to which function pointers field using an offset as a key for the field. For instance, Figure 4a shows the LLVM IR of statically initialized ext4\_file\_operations. KIRIN finds that the kernel interface type is struct file\_operations (Line 1), and ext4\_file\_write\_iter is assigned to the 5th field write\_iter (Line 7). Therefore, KIRIN figures out that write\_iter may point to ext4\_file\_write\_iter, not ext4\_file\_read\_iter (even though they have the same function type).

For the rest dynamically initialized kernel interfaces, KIRIN performs a data flow analysis to collect any assignment of a function address to the function pointer inside a kernel interface. KIRIN’s field-sensitive analysis allows the collected targets to be associated with the individual field of a kernel interface.

```

1 struct usb_driver* driver =
  ↳ container_of(intf->dev.driver, struct
  ↳ usb_driver, drvwrap.driver);
2 retval = driver->unlocked_ioctl(intf,
  ↳ ctl->ioctl_code, buf);

```

(a) C code of a container\_of usage, followed by an indirect call.

```

1 #define container_of(ptr, type, member) ({
2   void *__mptr = (void *) (ptr);
3   ((type *) (__mptr - offsetof(type, member))); })
4 %unlocked_ioctl = getelementptr inbounds i8*, i8**
  ↳ %add.ptr76, i64 3

```

(b) Original container\_of and the LLVM IR for the callsite.

```

1 #define container_of(ptr, type, member) ({
2   type* __res;
3   void *__mptr = ((void *) ((void *) (ptr) -
  ↳ offsetof(type, member)));
4   memcpy(&__res, &__mptr, sizeof(void*));
5   (__res); })
6 %unlocked_ioctl = getelementptr inbounds
  ↳ %struct.usb_driver, %struct.usb_driver* %20, i64
  ↳ 0, i32 3

```

(c) Modified container\_of and the LLVM IR for the callsite.

Figure 5: Fixing container\_of missing struct type problem.

## 5.2 Indirect Callsite Resolution

KIRIN stores the result of the above first pass in a key-value map data structure in which the key is a pair of kernel interface type and an offset (a field), and the value is a set of call targets. At each indirect callsite, KIRIN retrieves the type of a kernel interface and the offset from LLVM IR, looks up the map using them as a key, and figures out the matched call targets. For example, Figure 4b shows the LLVM IR snippet in which an indirect call file→f\_op→write\_iter is made inside of vfs\_write. When an indirect call is made (Line 4), KIRIN finds that the kernel interface type is struct file\_operations (Line 1) and the offset is 5 (Line 2). In this way, KIRIN reports that ext4\_file\_write\_iter (assigned at Line 7 in Figure 4a) is one of potential call targets that are indirectly called by dereferencing write\_iter.

When applying KIRIN to Linux kernel, we found in certain callsites, the kernel interface type is not presented in the LLVM IR, making their resolution impossible. For example, the macro container\_of is commonly used in order to get the starting address of a struct object by using a pointer to its own member field. Figure 5a shows an example of using container\_of (Line 1). It calculates the starting address of usb\_driver through its own member drvwrap.driver. Based on the address, the code at Line 2 makes an indirect call by using a function pointer unlocked\_ioctl that is another member of the struct usb\_driver object.

Figure 5b shows the original macro container\_of (Lines 1-3) and resulting LLVM IR (Line 4). The problem of this macro is that it involves a pointer manipulation, the LLVM IR of which voids the struct type information, i.e., the second argument of the macro. To solve this problem, KIRIN redefines container\_of in a way that the struct type is preserved in the LLVM IR (on which KIRIN works), as in Figure 5c (Lines 1-5). This adds back the kernel interface type

`struct.usb_driver` in the LLVM IR (Line 6), thereby enabling KIRIN to infer the correct type of `driver` and resolve the targets for `unlocked_ioctl`.

Our experiment (§7.2) shows that KIRIN resolves 92% of total indirect callsites for `allyesconfig`. PeX constructs a more sound (less missing edges) and precise (less false edges) call graph than other existing workarounds (e.g., [22]).

## 6 Design of PeX

Figure 6 shows the architecture of PeX. It takes as input kernel source code (in the LLVM bitcode format) and common permission checks (Table 1), analyzes and reports all detected permission check errors, including missing, inconsistent, and redundant permission checks. In addition, PeX produces the mapping of permission checks and privileged functions, which has not been formally documented.

At a high-level, PeX first resolves indirect calls with our new technique called KIRIN (§5). Next, PeX builds an augmented call graph—in which indirect callsites are connected to possible targets—and cuts out only the portion reachable from user space (§6.1). Based on the partitioned call graph, PeX then generates the interprocedural control flow graph (ICFG) where each callsite is connected to the entry and the exit of the callee [17]. Then, starting from a small set of (user-provided) permission checks, PeX automatically detects their wrappers (§6.2). After that, for a given permission check, PeX identifies its potentially privileged functions on top of the ICFG (§6.3), followed by a heuristic-based filter to prune obviously non-privileged functions (§6.4). Finally, for each privileged function, PeX examines all user space reachable paths to it to detect any permission checks error on the paths (§6.5). The following section describes these steps in detail.

### 6.1 Call Graph Generation and Partition

PeX generates the call graph leveraging the result of KIRIN (§5), and then partitions it into two groups.

**User Space Reachable Functions:** Starting from functions with the common prefix `sys_` (indicating system call entry points), PeX traverses the call graph, marks all visited functions, and treats them as user space reachable functions. The user reachable functions in this partition are investigated for possible permission check errors.

**Kernel Initialization Functions:** Functions that are used only during booting are collected to detect redundant checks. The Linux kernel boots from the `start_kernel` function, and calls a list of functions with the common prefix `__init`. PeX performs multiple call graph traversals starting from `start_kernel` and each of the `__init` functions to collect them.

Other functions such as IRQ handlers and kernel thread functions are not used in later analysis since they cannot be directly called from user space. The partitioned call graph serves as a basis for building an interprocedural control flow

graph (ICFG) [31] used in the inference of the mapping between permission checks and privileged functions (§6.3).

### 6.2 Permission Check Wrapper Detection

Sound and precise detection of permission check errors requires a complete list of permission checks, but they are not readily available (§4.2). One may name some commonly used permission checks, as in Table 1. However, they are often the wrapper of basic permission checks, which actually perform the low-level access control, and even worse there could be other wrappers of the wrapper.

PeX solves this by automating the process of identifying all permission checks including wrappers. PeX takes an incomplete list of user-provided permission checks as input. Starting from them, PeX detects basic permission checks, by performing the *forward call graph slicing* [26, 37, 45] over the augmented call graph. For a given permission check function, PeX searches all call instructions inside the function for the one that passes an argument of the function to the callee. In other words, PeX identifies the callees of the permission check function which take its *actual* parameter as their own *formal* parameter. Similarly, PeX then conducts *backward call graph slicing* [26, 37, 45] from these basic permission checks to detect the list of their wrappers. PeX refers to only those callers that pass permission parameters as wrappers, excluding other callers just using the permission checks.

Figure 7 shows an example of the permission check wrapper detection. Given a known permission check `ns_capable` (Lines 10-13), PeX first finds `security_capable` (Line 4) as a basic permission check, and then based on it, PeX detects another permission check wrapper `has_ns_capability` (Lines 14-20). Note that the parameter `cap` is passed from both the parents `ns_capable_common` and `has_ns_capability` to the child `security_capable`; and the result of `security_capable` is returned to them. Our evaluation (§7.3) shows that based on 196 permission checks in Table 1, PeX detects 88 wrappers.

### 6.3 Privileged Function Detection

It is important to understand the mappings between permission checks and privileged functions for effective detection of any permission check errors therein. However, the lack of clear mapping in Linux kernel complicates the detection of permission check errors (§4.2).

To address this problem, PeX leverages an interprocedural *dominator* analysis [31] that can automatically identify the privileged functions protected by a given permission check. PeX conservatively treats all targets (callees) of those call instructions, that are dominated by each permission check (§6.2) on top of the ICFG (§6.1), as its *potential* privileged functions. The rationale behind the dominator analysis is based on the following observation: since there is no single path that allows the dominated call instruction to be reached without visiting the dominator (i.e., the permission check),

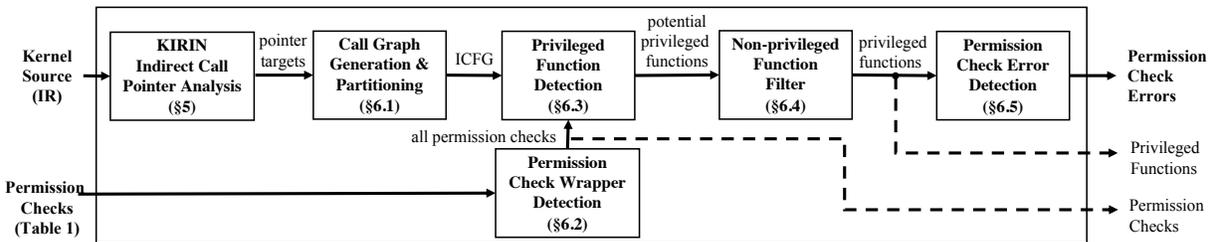

Figure 6: PeX static analysis architecture. PeX takes as input kernel source code and permission checks, and reports as output permission check errors. PeX also produces mappings between identified permission checks and privileged functions as output.

```

1  static bool ns_capable_common(struct user_namespace
2  ↪ *ns, int cap, bool audit)
3  {
4  ...
5  capable = audit ?
6  ↪ security_capable(current_cred(), ns, cap) :
7  ↪ security_capable_noaudit(current_cred(), ns,
8  ↪ cap);
9  if (capable == 0)
10 return true;
11 return false;
12 }
13 bool ns_capable(struct user_namespace *ns, int cap)
14 {
15 return ns_capable_common(ns, cap, true);
16 }
17 bool has_ns_capability(struct task_struct *t,
18 ↪ struct user_namespace *ns, int cap)
19 {
20 ...
21 ret = security_capable(__task_cred(t), ns, cap);
22 ...
23 }

```

Figure 7: Permission check wrapper examples.

### Algorithm 1 Privileged Function Detection

**INPUT:**  
*pcfuns* - all permission checking functions

**OUTPUT:**  
*pvfuns* - privileged functions

```

1: procedure PRIVILEGED FUNCTION DETECTION
2:   for  $f \leftarrow pcfuns$  do
3:     for  $u \leftarrow User(f)$  do
4:        $CallInst \leftarrow CallInstDominatedBy(u)$  ▷ Inter-procedural analysis, for
         full program path
5:        $callee \leftarrow getCallee(CallInst)$ 
6:        $pvfuns.insert(callee)$ 
7:     end for
8:   end for
9:   return  $pvfuns$ 
10: end procedure

```

the callee is likely to be the one that should be protected by the check on all paths<sup>2</sup>.

Algorithm 1 shows how PeX uses the dominator analysis to find potential privileged functions *pvfuns* for a given list of permission check functions *pcfuns*. For each permission check function  $f$  (Line 2), PeX finds all users of  $f$ , i.e., the callsite invoking  $f$  (Line 3). For each user (callsite)  $u$ , PeX performs interprocedural dominator analysis over the ICFG to find all dominated call instructions (Line 4). All their callees are then added to *pvfuns* (Lines 5-6).

Note that the call graph generated by KIRIN (§5) has resolved most of the indirect calls, which allows PeX to

<sup>2</sup>This does not necessarily mean that the permission check dominates all call instructions of ICFG which invoke the resulting privileged function. As long as some call instructions are dominated by the check, their callees are treated as privileged functions.

perform—on top of the resulting ICFG—more sound privileged function detection. For example, our experiment (§7.3) shows that KIRIN can identify `ecryptfs_setxattr` (reachable via indirect calls over the ICFG) as a privileged function and detect its missing permission check bug (Table 6, LSM-17). Note that if some other unsound workaround such as [22] had been used, this bug could not have been detected.

### 6.4 Non-privileged Function Filter

The conservative approach in §6.3 may lead to too many potential privileged functions. In this step, PeX applies heuristic-based filters to prune out false privileged functions. In the current prototype, the filter contains a set of kernel library functions which are not privileged functions, e.g., `kmalloc`, `strcmp`, `kstrtoint`. Though PeX is currently designed to avoid false negatives (and thus leverages a small set of library filters only), one can add more aggressive filters to purge more false privileged functions. With releasing PeX, we expect a good opportunity for the kernel development community to contribute to the design of non-privileged function filters where domain knowledge is helpful.

### 6.5 Permission Check Error Detection

This last step is validating the use of privileged functions to detect any potential permission check errors. For a given mapping between a permission check and a privileged function, PeX performs a backward traversal of the ICFG, starting from the privileged functions with the corresponding permission check in mind. Note that PeX validates every possible path to each privileged function of interest.

Algorithm 2 shows PeX’s permission check error detection algorithm. Recall that PeX treats user reachable kernel functions and kernel initialization functions separately and detects different forms of errors (§6.1). Lines 2-12 shows how PeX detects missing, redundant, and inconsistent checks in user reachable kernel functions. For each privileged function  $f$  (Line 5) in a mapping, PeX finds all possible paths *allpath* from user entry points to that privileged function  $f$  over the ICFG (Line 6). Line 7-18 checks each path  $p$  for the preceding permission check function, the lack of which should be reported as a bug. If the call to the privileged function (*pvcall*) is not preceded by the corresponding permission check func-

## Algorithm 2 Permission Check Error Detection

```
INPUT:
pc - pv - permission check function to privileged function mapping
pcfuncs - all permission check functions
kinitfuncs - kernel init functions
1: procedure PERMISSION CHECK ERROR DETECTION
2:   for pair ← pc - pv do
3:     pvfuncs ← pair.pv           ▷ privileged functions
4:     pcfunc ← pair.pc           ▷ permission check functions
5:     for f ← pvfuncs do
6:       allpath ← getAllPathUseFunc(f) ▷ get all user reachable paths that
call the privileged function f
7:       for p ← allpath do
8:         pvcall ← PrivilegeFunctionCallInPath(p)
9:         if pvcall not Preceded by pcfunc then
10:          if pvcall not Preceded by any pcfuncs then
11:            report(p)           ▷ Report missing checks
12:          else
13:            report(p)           ▷ Report inconsistent check
14:          end if
15:        else if pvcall Preceded by multiple same pcfunc then
16:          report(p)           ▷ Report redundant checks
17:        end if
18:      end for
19:    end for
20:  end for
21:  for f ← kinitfuncs do
22:    if f uses any pcfuncs then
23:      report(f)               ▷ Report unnecessary checks during kernel boot
24:    end if
25:  end for
26: end procedure
```

tion (`pcfunc`) and any other check functions (those in `pcfuncs`) over a given path `p`, then PeX reports a missing check (Lines 6-7). And if `pvcall` is preceded not by the corresponding check (`pcfunc`) but other check in `pcfuncs`, PeX reports an inconsistent check. Finally, if PeX discovers that `pvcall` is indeed preceded by `pcfunc` checks but multiple times, then it reports a redundant check (Lines 15-17). Besides, Lines 21-25 shows how PeX detects redundant checks in kernel initialization functions. As `kinitfuncs` includes a conservative list of functions that can only be executed during booting (thus obviating the need of any checks), all detected permission checks are marked as redundant (Lines 22-24).

## 7 Implementation and Evaluation

PeX was implemented using LLVM [27]/Clang-6.0. It contains about 7K lines of C/C++ code. Clang was modified to preserve the kernel interface type at allocation/initialization sites by using an *identified struct* type instead of using unnamed *literal struct* type. We also automated the generation of the single-file whole vmlinux LLVM bitcode `vmlinux.bc` using `wllvm` [13]. This avoids building each kernel module separately or changing kernel build infrastructures, as observed in prior kernel static analysis works [22, 49]. We evaluated PeX on the latest stable Linux kernel v4.18.5. In summary, KIRIN resolves 86%–92% of indirect callsites depending on its compilation configurations. PeX reported 36 permission check errors warnings to the Linux community, 14 of which have been confirmed as real bugs.

Table 2: Input Statistics for Kernel v4.18.5.

	defconfig	allyesconfig
# of yes(=y) config	1284	9939
# of compiled LOC	2,414,772	15,881,692
vmlinux size	481 MB	3.8 GB
vmlinux.bc size	387 MB	3.3 GB
# of total functions	42,264	247,465
# of syscall entries	857	1,027
# of init functions	1,570	9,301
# of indirect callsites (ICS)	20,338	115,537

Table 3: Indirect Call Pointer Analysis.

	defconfig			allyesconfig		
	KIRIN	TYPE	KM	KIRIN	TYPE	KM
% of ICS resolved	86	100	1	92	100	na
# of avg target	3.6	10K	3.6	6.2	81K	na
analysis time (min)	1	1	9,869	6.6	1	na

### 7.1 Evaluation Methodology

We evaluated PeX with two different kernel configurations: (1) `defconfig`, the (commonly-used) default configuration, and (2) `allyesconfig` with all non-conflict configuration options enabled. The use of `allyesconfig` not only stress-tests PeX (including KIRIN) with a larger code base than `defconfig`, but also covers the majority of kernel code, allowing PeX to detect more bugs. In addition, we used 3 DAC, 3 Capabilities, and 190 LSM permission checks (Table 1) as input permission checks, from which PeX finds other wrappers. For the non-privileged function filter, we collected 1827 library functions from `lib` directory in the kernel source code. All experiments were carried out on a machine running Ubuntu 16.04 with two Intel Xeon E5-2650 2.20GHz CPU and 256GB DRAM.

### 7.2 Evaluation of KIRIN

We compared the effectiveness and efficiency of KIRIN with type-based approach and SVF-based K-Miner approach.

K-Miner [22] works around the scalability problem in SVF by analyzing the kernel on a per system call basis, rather than taking the entire kernel code for analysis. K-Miner generates a (small-size) partition of kernel code which can be reached from a given system call, and (unsoundly) applies SVF for that partition. For comparison, we took K-Miner’s implementation from the github [6] and added the logic to count the number of resolved indirect callsites and the average number of targets per callsite. As K-Miner was originally built on LLVM/Clang-3.8.1, we recompiled the same kernel v4.18.5 using `wllvm` with the same kernel configurations.

Table 3 summaries evaluation results of KIRIN, comparing it to the type-based approach and K-Miner approach in terms of the percentage of indirect callsite (ICS) resolved, the average number of targets per ICS, and the total analysis time.

#### 7.2.1 Resolution Rate

For K-Miner, we observe somewhat surprising results: it resolves only 1% of all indirect callsites. After further inves-

tigation, we noticed that SVF runs on each partition whose code base is smaller than the whole kernel, its analysis scope is significantly limited and unable to resolve function pointers in other partitions, leading to the poor resolution rate.

Besides, we found out that K-Miner does not work for `allyesconfig` which contains a much larger code base than `defconfig`. Note that K-Miner evaluated its approach only for `defconfig` in the original paper [22]. The K-Miner approach turns out to be not scalable to handle `allyesconfig` which ends up encountering out of memory error even for analyzing a single system call.

### 7.2.2 Resolved Average Targets

For KIRIN, the number of average indirect call targets per resolved indirect callsite is much smaller than that of the type-based approach as shown in the second row of Table 3. The reason is that the type-based approach classifies all functions (not only address-taken functions) into different sets based on the function type. This implies that all functions in the set are regarded as possible call targets of that function pointer. For example, as shown in Figure 3a, two functions `ext4_file_read_iter` and `ext4_file_write_iter` share the same type. As a result, the type-based approach incorrectly identifies both functions as possible call targets of the function pointer `f_ops→write_iter`.

### 7.2.3 Analysis Time

The total analysis times of each ICS resolution approach are shown in the last row of Table 3. As expected, the type-based approach is the fastest, finishing analysis in 1 minute for both configurations. KIRIN runs slower than the type-based approach. However, the analysis time of KIRIN ( $\approx 1$  minute) is comparable to that of the type-based approach for `defconfig`, while KIRIN takes 6.6 minutes for `allyesconfig`.

For a fair comparison with K-Miner, care must be taken when we collect its indirect call analysis time. For a given system call, we measured K-Miner’s running time from the beginning until it produces the SVF point-to result, which does not include the later bug detection time. To obtain the total analysis time of K-Miner, we summed up the running times of all system calls. The result shows that SVF based K-Miner takes about 9,869 minutes to finish analyzing all system calls of `defconfig`, which is much slower than KIRIN’s.

## 7.3 PeX Result

Table 4 summarizes PeX’s intermediate program analyses. As `allyesconfig` subsumes `defconfig` in static analysis, we focus on discussing `allyesconfig` results here. Overall, PeX finishes all analyses within a few hours and reports about two thousand groups of warnings, which are classified by privileged functions. One may implement a multi-threaded version of PeX to further reduce the analysis time.

Given the small number of input DAC, CAP, and LSM permission checks (3, 3, and 190 each), PeX’s permission check

Table 4: PeX Results.

	defconfig			allyesconfig		
	DAC	CAP	LSM	DAC	CAP	LSM
# of input checks	3	3	190	3	3	190
# of detected wrappers	11	13	34	19	16	53
# of priv func detected	174	869	2030	631	3770	10915
# of priv func after filter	116	582	1635	537	3245	10260
# of warnings grouped by priv func	72	210	853	221	850	1017
total time (min)	6	8	11	83	247	169

Table 5: Comparison of PeX warnings when used with different indirect call analyses.

	defconfig				allyesconfig			
	DAC	CAP	LSM	Bugs	DAC	CAP	LSM	Bugs
KIRIN	72	210	853	21	221	850	1017	36
TYPE	218	348	1319	21	164	964	4364	19 (PeX Timeout)
KM	54	196	241	6	na	na	na	na (SVF Timeout)

detection (§6.2) was able to identify 19, 16 and 53 permission check wrappers. For example, PeX detects wrappers such as `nfs_permission` and `may_open` for DAC; `sk_net_capable` and `netlink_capable` for Capabilities; and `key_task_permission` and `__ptrace_may_access` for LSM.

Table 4 also shows the number of potentially privileged functions detected by PeX (§6.3) and the number of remaining privileged functions after kernel library filtering (§6.4). We found that there are typically 1-to-1 or 2-to-1 mapping between permission checks and privileged functions. Overall, PeX reports 221, 850, and 1017 warnings (grouped by privileged functions) for DAC, CAP, and LSM, respectively.

Table 6 shows the list of 36 bugs we reported, 14 of which have been confirmed by Linux kernel developers. Kernel developers ignored some bugs and decided not to make changes because they believe that the bugs are not exploitable. We discuss them in detail in §7.5.

**Comparison.** To highlight the effectiveness of KIRIN, we repeated the end-to-end PeX analysis using type-based (PeX+TYPE) and K-Miner-style (PeX+KM) indirect call analyses. Table 5 shows the resulting number of warnings and detected bugs when the 36 bugs— shown in Table 6—are used as an oracle for false negative comparison.

For `allyesconfig`, PeX+TYPE and PeX+KM could not complete the analysis within the 12-hour experiment limit. PeX+TYPE generated too many (false) edges in ICFG and suffered from path explosion during the last phase of PeX analysis; only 19 bugs were reported before the timeout. In the mean time, PeX+KM timed out on an earlier pointer analysis phase, thereby failing to report any bug.

When `defconfig` is used for comparison, PeX+TYPE and PeX+KM were able to complete the analysis. In this setting, PeX+KIRIN (original) and PeX+TYPE both report 21 bugs (a subset of 36 bugs detected with `allyesconfig`). Though PeX+TYPE can capture them all (as type-based analysis is

sound yet imprecise), it generates up to 3x more warnings, placing a high burden on the users side for their manual review. On the other hand, as an unsound solution, PeX+KM produces a limited number of warnings, resulting in the detection of only 6 bugs missing the rest.

## 7.4 Manual Review of Warnings

The manual review process of reported warnings is to determine whether a privileged function identified by PeX (§6.3) is a *true* privileged function or not. As long as one can confirm that a function is indeed privileged, reported warnings regarding its missing, inconsistent, and redundant permission checks should be *true positives* from PeX’s point of view.

Though kernel developers with domain knowledge may be able to discern them with no complication, we (as a third-party) try to understand whether a given function can be used to access critical resources (e.g., device, file system, etc.). As a result, we conservatively reported 36 bug warnings to the community; we suspect that there could be more true warnings missed due to our lack of domain knowledge. We plan to release PeX and the list of potential privileged functions, hoping kernel developers will contribute to identify privileged functions and fix more true permission errors.

Certain static paths reported by PeX may not be feasible dynamically during program execution, resulting in false positives. One may devise a solution solving path constraints as in symbolic execution engines [16] to address this problem, PeX currently does not do so.

## 7.5 Discussion of Security Bug Findings

### 7.5.1 Missing Check

Figure 2b is one of the confirmed missing LSM checks (LSM-21). We discuss two more confirmed cases.

The CAP-4 missing check in kernel `random` device driver is particularly critical and triggered active discussion in the kernel developer community (including Torvalds). Random number generator serves as the foundation of many cryptography libraries including OpenSSL, and thus the quality of the random number is very critical. This security bug allows attackers to manipulate entropy pool, which can potentially corrupt many applications using cryptography libraries. Specifically, a problematic path starts from `evdev_write` and reaches the privileged function `credit_entropy_bits`, which can control the entropy in the entropy pool, while bypassing the required `CAP_SYS_ADMIN` permission check.

The LSM-21 missing check in `xfs_file_ioctl` led to another interesting discussion among kernel developers [9]. With this interface, a userspace program may perform low-level file system operations, but `security_inode_read_link` LSM hook was missing. An adversary could exploit this interface and gain access to the whole file system that is not allowed by LSM policy. Interestingly, however, the privileged function performed `CAP_SYS_ADMIN` Capability permis-

sion check. This created disagreement between kernel developers: one group argues that the LSM hook is necessary, while another thinks that `CAP_SYS_ADMIN` is sufficient. We agree with the former because LSM is designed to limit the damage of a compromised process to the system, even the ones of root user [40]. We believe that LSM permission checks should still be enforced as always for better security even when the current user is root.

Kernel developers decided not to fix 9 of our reports because they believe these bugs are not exploitable. As discussed earlier, PeX in the current form neither validates if a suspicious static path is dynamically reachable, nor generates a concrete exploit to demonstrate the security issue; we believe both are good future works. Nonetheless, we have one complaint to share.

For the LSM-19 and LSM-20 cases, PeX found that the LSM hooks `security_kernel_read_file` and `security_kernel_post_read_file` were used to protect the privileged functions `kernel_read_file` and `kernel_post_read_file` in some program paths. We reported missing LSM hooks in `load_elf_binary` and `load_elf_library` for these privileged functions. However, the kernel developers responded that those hooks are used to monitor loading firmware/kernel modules only (not other files), and thus no patch is required. Here, the implication we found is three-fold. First, the permission check names are ambiguous and misleading. Second, we were not able to find any documentation of such LSM specification regarding the protection of firmware/kernel modules. Last, PeX actually found a counter-example in `IMA` where the same checks are indeed used for loading other files (neither firmware nor kernel modules). Consequently, we suggest changing the function name and documenting the clear intention to avoid any confusion and to prevent system administrators from creating an LSM policy that does not work.

### 7.5.2 Inconsistent Check

The CAP-13 inconsistent check has been discussed in Figure 1. One program path in Figures 1a and 1c has two `CAP_SYS_RAWIO` checks and one `CAP_SYS_ADMIN` check, while another path in Figures 1b and 1c has only one `CAP_SYS_ADMIN` check. PeX detects this bug as an inconsistent check, but from the viewpoint of correction, which requires adding `CAP_SYS_RAWIO`, this may also be viewed as a missing check. There is a separate redundant check error in `CAP_SYS_RAWIO`.

Upon further investigation, we were interested in learning the practices in using multiple capabilities together. `scsi_ioctl` in Figure 1a checks both `CAP_SYS_ADMIN` and `CAP_SYS_RAWIO`. However, in a different network subsystem (not shown), we found that `too_many_unix_fds` performs a *weaker* permission check with the `CAP_SYS_ADMIN` or `CAP_SYS_RAWIO` condition. We believe this OR-based weaker check is not a good practice because this in effect makes `CAP_SYS_ADMIN` too powerful (like root), diminishing the ben-

Table 6: Bugs Reported By PeX. Confirmed or Ignored.

LSM-36	fs/ocfs2/cluster/tcp.c	o2net_open_listening_sock()	redundant security_socket_create	C

efit of fine-grained capability-based access control.

The CAP-14 and CAP-15 inconsistent error reports were acknowledged but ignored by the kernel developers for the following reason. For the same privileged function `prctl_set_mm_exe_file`, which is used to set an executable file, PeX discovered one case requiring `CAP_SYS_RESOURCE` in user namespace, and another case checking `CAP_SYS_ADMIN` in init namespace. Kernel developers responded that each case is fine by design for that specific context. PeX does not consider the precise context in which `prctl_set_mm_exe_file` is used (similar to aforementioned `security_kernel_read_file` used for loading kernel modules), leading to an imprecise report, but we believe that both CAP-14 and CAP-15 are worthwhile for further investigation.

### 7.5.3 Redundant Check

A redundant check occurs in two forms. **First**, for user-reachable functions, it happens when a privileged function is covered by the same permission checks multiple times. We reported three cases. The CAP-16 case was discussed in Figures 1a and 1c with two `CAP_SYS_RAWIO` checks, which was ignored by kernel developers. On the other hand, for the LSM-35 and LSM-36 cases found in the `ocfs2` file system, the other kernel developer group confirmed and promised to fix the bugs. **Second**, any permission check in kernel-initialization

functions is marked as redundant because the boot thread is executed under root. PeX detected tens of such cases, but we did not report them as they are less critical.

## 8 Related Work

### 8.1 Hook Verification and Placement

There is a series of studies on checking kernel LSM hooks. Automated LSM hook verification work [56] verifies the complete mediation of LSM hooks relying manually specified security rules. While [20] automates LSM hook placements utilizing manually written specification of security sensitive operations. However, required manual processes are error-prone when applied to huge Linux code base. Edwards et al. [18] proposed to use dynamic analysis to detect LSM hook inconsistencies. While PeX is using static analysis, can achieve better code coverage.

**AutoISES** [44] is the most closely related work to PeX. AutoISES regards data structures, such as the structure fields and global variables, as privileged, applies static analysis to extract security check usage patterns, and validates the protections to these data structures. The difference between AutoISES and PeX is three-fold. First, PeX is privileged function oriented while AutoISES is more like data structure oriented.

Second, AutoISES is designed for LSM only, whose permission checks (hooks) are clearly defined, and therefore it is not applicable to DAC and Capabilities due to their various permission check wrappers. In contrast, PeX works for all three types of permission checks. Third, AutoISES uses type-based pointer analysis to resolve indirect calls, while PeX uses KIRIN to resolve indirect calls in a more precise manner.

There are also works [21, 32, 33] that extend authorization hook analysis to user space programs, including X server and postgresql. However, their approaches cannot be applied to the huge kernel scale. Moreover, all of above works either do not analyze indirect calls at all, or apply over approximate indirect call analysis techniques, such as type-based approach or field insensitive approach. To the contrary, PeX uses KIRIN, a precise and scalable indirect call analysis technique, which can also benefit these works by finding more accurate indirect call targets.

## 8.2 Kernel Static Analysis Tools

**Coccinelle** [34] is a tool that detects a bug of pre-defined pattern based on text pattern matching on the symbolic representation of bug cases. This is basically intra-procedural analysis. Building upon Coccinelle, Wang et al. proposed another pattern matching based static tool which detects potential double-fetch vulnerabilities in the Linux kernel [48].

**Sparse** [11] is designed to detect the problematic use of pointers belonging to different address space (kernel space or userspace). Later, Sparse was used to build a static analysis framework called **Smatch** [10] for detecting different sorts of kernel bugs. However, Smatch is also based on intra-procedural analysis, thus it can only find shallow bugs.

**Double-Fetch** [52], **Check-it-again** [49] focus on detecting time of check to time of use (TOCTTOU) bugs. **Dr. Checker** [29] is designed for analyzing Linux kernel drivers. It adopts the modular design, allowing new bug detectors to be plug-in easily. **KINT** [50] applies taint analysis to detect integer errors in Linux kernel while **UniSan** [28] leverages the same analysis to detect uninitialized kernel memory leakages to the userspace. **Chucky** [53] also uses a taint analysis to analyze missing checks in different sources in userspace programs and Linux kernel. However, Chucky can handle only kernel file system code due to the lack of pointer analysis. Note that to resolve indirect call targets, all these works leverage a type-based approach, which is not as accurate as KIRIN, thus suffering from false positives.

**MECA** [54] is an annotation based static analysis framework, and it can detect security rule violations in Linux. **APISan** [55] aims at finding API misuse. It figures out the right API usage through the analysis of existing code base and performs intra-procedural analysis to find bugs. To achieve the former, APISan relies on relaxed symbolic execution which is complementary to the techniques used in PeX.

## 8.3 Permission Check Analysis Tools

Engler et al. propose to use programmer beliefs to automatically extract checking information from the source code. They apply the checking information to detect missing checks [19]. **RoleCast** [42] leverages software engineering patterns to detect missing security checks in web applications. **TESLA** [14] implements temporal assertions based on LLVM instrument, in which the FreeBSD hooks are checked by inserted assertions dynamically. Different from TESLA, PeX uses KIRIN to analyze jump targets of all kernel function pointers statically, achieving better resolution rate and code coverage. **JIGSAW** [47] is a system that can automatically derive programmer expectations on resources access and enforce it on the deployment. It is designed for analyzing userspace programs, cannot be applied to kernel directly.

**JUXTA** [30] is a tool designed for detecting semantic bugs in filesystem while **PScout** [15] is a static analysis tool for validating Android permission checking mechanisms. **Kratos** [39] is a static security check framework designed for the Android framework. It builds a call graph using LLVM and tries to discover inconsistent check paths in the framework. However, Android has well-documented permission check specifications [2], i.e., privileged functions and the permission required for them are both clearly defined. In contrast, the Linux kernel has no such documentation, which makes it impossible to apply PScout and Kratos to Linux kernel permission checks.

## 9 Conclusion

This paper presents PeX, a static permission check analysis framework for Linux kernel, which can automatically infer mappings between permission checks and privileged functions as well as detect missing, inconsistent, and redundant permission checks for any privileged functions. PeX relies on KIRIN, our novel call graph analysis based on kernel interfaces, to resolve indirect calls precisely and efficiently.

We evaluated both KIRIN and PeX for the latest stable Linux kernel v4.18.5. The experiments show that KIRIN can resolve 86%-92% of all indirect callsites in the kernel within 7 minutes. In particular, PeX reported 36 permission check bugs of DAC, Capabilities, and LSM, 14 of which have already been confirmed by the kernel developers. PeX source code is available at <https://github.com/lzto/pex>, along with the identified mapping between permission checks and privileged functions. We believe that such a mapping allows kernel developers to validate their code with PeX and encourages them to contribute to PeX by refining the mapping with their domain knowledge.

## Abstract

Isolating sensitive state and data can increase the security and robustness of many applications. Examples include protecting cryptographic keys against exploits like OpenSSL’s Heartbleed bug or protecting a language runtime from native libraries written in unsafe languages. When runtime references across isolation boundaries occur relatively infrequently, then conventional page-based hardware isolation can be used, because the cost of kernel- or hypervisor-mediated domain switching is tolerable. However, some applications, such as the isolation of cryptographic session keys in network-facing services, require very frequent domain switching. In such applications, the overhead of kernel- or hypervisor-mediated domain switching is prohibitive.

In this paper, we present ERIM, a novel technique that provides hardware-enforced isolation with low overhead on x86 CPUs, even at high switching rates (ERIM’s measured overhead is less than 1% for 100,000 switches per second). The key idea is to combine protection keys (MPKs), a feature recently added to x86 that allows protection domain switches in userspace, with binary inspection to prevent circumvention. We show that ERIM can be applied with little effort to new and existing applications, doesn’t require compiler changes, can run on a stock Linux kernel, and has low runtime overhead even at high domain switching rates.

## 1 Introduction

It is good software security practice to partition sensitive data and code into isolated components, thereby limiting the effects of bugs and vulnerabilities in a component to the confidentiality and integrity of that component’s data. For instance, isolating cryptographic keys in a network-facing service can thwart vulnerabilities like the OpenSSL Heartbleed bug [37]; isolating a managed language’s runtime can protect its security invariants from bugs and vulnerabilities in co-linked native libraries; and, isolating jump tables can prevent attacks on an application’s control flow.

Isolation prevents an untrusted component from directly accessing the private memory of other components. Broadly speaking, isolation can be enforced using one of two approaches. First, in software fault isolation (SFI) [47], one instruments the code of untrusted components with bounds checks on indirect memory accesses, to prevent access to other components’ memory. The bounds checks can be added by the compiler or through binary rewriting. Bounds checks impose overhead on the execution of all untrusted components; additional overhead is required to

prevent control-flow hijacks [30], which could circumvent the bounds checks. On x86-64, pointer masking-based SFI techniques like Native Client [42] incur overheads of up to 42% on the execution of untrusted code [30]. Even with hardware-supported bounds checks, like those supported by the Intel MPX ISA extension [26], the overhead is up to 30%, as shown in by Koning *et al.* [30] and later in Section 6.5.

Another approach is to use hardware page protection for memory isolation [9, 10, 13, 32, 33, 34]. Here, access checks are performed in hardware as part of the address translation with no additional overhead on execution *within* a component. However, transferring control *between* components requires a switch to kernel or hypervisor mode in order to change the (extended) page table base. Recent work such as Wedge, Shreds, SeCage, SMVs, and light-weight contexts (lwCs) [10, 13, 24, 33, 34] have reduced the overhead of such switching, but the cost is still substantial. For instance, Litton *et al.* [33] report a switching cost of about 1us per switch for lwCs, which use kernel-managed page tables for in-process isolation. This amounts to an overhead of nearly 10% for an application that switches 100,000 times a second and, in our experiments, an overhead of up to 65% on the throughput of the web server NGINX when lwCs are used to isolate session keys (Section 6.5). Techniques based on Intel VT-x extended page tables with VMFUNC [34] have less overhead, but the overhead is still high—up to 14.4% on NGINX’s throughput in our experiments (Section 6.5).

In this paper, we present ERIM, the first isolation technique for x86 that combines near-zero overhead on in-component execution with very low cost switching among components. ERIM relies on a recent x86 ISA extension called protection keys (MPK) [28]. With MPK, each virtual page can be tagged with a 4-bit domain id, thus partitioning a process’s address space into up to 16 disjoint domains. A special register, PKRU, that is local to each logical core determines which domains the core can read or write. Switching domain permissions requires writing the PKRU register in userspace, which takes only 11–260 cycles on current Intel CPUs, corresponding to an overhead of 0.07% to 1.0% per 100,000 switches/s on a 2.6 GHz CPU. This amounts to an overhead of at most 4.8% on the throughput of NGINX when isolating all session keys, which is up to 6.3x, 13.5x and 3x lower than the overhead of similar protection using SFI (with Intel MPX), lwCs and Intel VT-x, respectively.

However, MPK by itself does not provide strong security because a compromised or malicious component can sim-

ply write to the PKRU register and grant itself permission to access any component. ERIM relies on *binary inspection* to ensure that all occurrences of instructions that update the PKRU in the binary are *safe*, i.e., they cannot be exploited to gain unauthorized access. With this, ERIM provides isolation without requiring control-flow integrity in untrusted code, and therefore avoids the runtime overhead of ensuring control-flow integrity in unsafe languages.

While ERIM's binary inspection enforces the safety of its MPK-based isolation, it creates a potential usability issue: What to do if a binary has *unintentional* occurrences of PKRU-updating instructions? Since x86 does not require instruction alignment, such occurrences could arise within a longer instruction, or spanning the bytes of two or more adjacent instructions. Any such sequence could be exploited by a control-flow hijack attack and must be rejected by the binary inspection mechanism. To handle such cases, we describe a novel procedure to *rewrite* any instruction sequence containing an unaligned PKRU-updating instruction to a functionally equivalent sequence without the instruction. This rewriting procedure can be integrated with a compiler or our binary inspection.

ERIM is the first technique that enables efficient isolation in applications that require very high domain switching rates ( $\sim 10^5/s$  or more) and also spend significant time executing inside untrusted components. We evaluate our ERIM prototype on three such applications: 1) Isolating the frequently accessed session keys in a web server (NGINX), 2) isolating a managed language runtime from native libraries written in unsafe languages, and 3) efficiently isolating the safe region in code-pointer integrity [31]. In all cases, we observe switching rates of order  $10^5$  or more per second per core. ERIM provides strong, hardware-based isolation in all these cases, with overheads that are considerably lower than those of existing techniques. Moreover, ERIM does not require compiler support and can run on stock Linux.

In summary, this paper makes the following contributions. 1) We present ERIM, an efficient memory isolation technique that relies on a combination of Intel's MPK ISA extension and binary inspection, but does not require or assume control-flow integrity. 2) We describe a complete rewriting procedure to ensure binaries cannot be exploited to circumvent ERIM. 3) We show that ERIM can protect applications with high inter-component switching rates with low overhead, unlike techniques based on hardware (extended) page tables and SFI (even with hardware support).

## 2 Background and related work

In this section, we survey background and related work. Enforcing relevant security or correctness invariants while trusting only a small portion of an application's code generally requires *data encapsulation*. Encapsulation itself requires *isolating* sensitive data so it cannot be accessed by untrusted code, and facilitating *switches* to trusted code that has access

to the isolated state. We survey techniques for isolation and switching provided by operating systems, hypervisors, compilers, language runtimes, and binary rewriting, as well as other work that uses MPK for memory isolation.

**OS-based techniques** Isolation can be easily achieved by placing application components in separate OS processes. However, this method has high overhead even with a moderate rate of cross-component invocation. Novel kernel abstractions like light-weight contexts (lwCs) [33], secure memory views (SMVs) [24] and nested kernels [14], combined with additional compiler support as in Shreds [13] or runtime analysis tools as in Wedge [10], have reduced the cost of such data encapsulation to the point where isolating *long-term* signing keys in a web server is feasible with little overhead [33]. Settings that require more frequent switches like isolating *session keys* or the safe region in CPI [31], however, remain beyond the reach of OS-based techniques.

Mimosa [20] relies on the Intel TSX hardware transactional memory support to protect private cryptographic keys from software vulnerabilities and cold-boot attacks. Mimosa restricts cleartext keys to exist only within uncommitted transactions, and TSX ensures that an uncommitted transaction's data is never written to the DRAM or other cores. Unlike ERIM, which is a general-purpose isolation technique, Mimosa specifically targets cryptographic keys, and is constrained by hardware capacity limits of TSX.

**Virtualization-based techniques** In-process data encapsulation can be provided by a hypervisor. Dune [9] enables user-level processes to implement isolated compartments by leveraging the Intel VT-x x86 virtualization ISA extensions [28]. Koning et al. [30] sketch how to use the VT-x VMFUNC instruction to switch extended page tables in order to achieve in-process data isolation. SeCage [34] similarly relies on VMFUNC to switch between isolated compartments. SeCage also provides static and dynamic program analysis based techniques to automatically partition monolithic software into compartments, which is orthogonal to our work. TrustVisor [36] uses a thin hypervisor and nested page tables to support isolation and additionally supports code attestation. SIM [44] relies on VT-x to isolate a security monitor within an untrusted guest VM, where it can access guest memory with native speed. In addition to the overhead of the VMFUNC calls during switching, these techniques incur overheads on TLB misses and syscalls due to the use of extended page tables and hypercalls, respectively. Overall, the overheads of virtualization-based encapsulation are much higher than those of ERIM.

Nexen [45] decomposes the Xen hypervisor into isolated components and a security monitor, using page-based protection within the hypervisor's privilege ring 0. Control of the MMU is restricted to the monitor; compartments are de-privileged by scanning and removing exploitable MMU-modifying instructions. The goal of Nexen is quite different

from ERIM's: Nexen aims to isolate co-hosted VMs and the hypervisor's components from each other, while ERIM isolates components of a user process. Like ERIM Nexen scans for and removes exploitable instructions.

**Language and runtime techniques** Memory isolation can be provided as part of a memory-safe programming language. This encapsulation is efficient if most of the checks can be done statically. However, such isolation is language-specific, relies on the compiler and runtime, and can be undermined by co-linked libraries written in unsafe languages.

Software fault isolation (SFI) [47] provides memory isolation in unsafe languages using runtime memory access checks inserted by the compiler or by rewriting binaries. SFI imposes a continuous overhead on the execution of untrusted code. Additionally, SFI by itself does not protect against attacks that hijack control flow (to possibly bypass the memory access checks). To get strong security, SFI must be coupled with an additional technique for control-flow integrity (CFI) [6]. However, existing CFI solutions have nontrivial overhead. For example, code-pointer integrity (CPI), one of the cheapest reasonably strong CFI defenses, has a runtime overhead of at least 15% on the throughput of a moderately performant web server (Apache) [31, Section 5.3]. In contrast, ERIM does not rely on CFI for data encapsulation and has much lower overhead. Concretely, we show in Section 6 that ERIM's overhead on the throughput of a much more performant web server (NGINX) is no more than 5%.

The Intel MPX ISA extension [28] provides architectural support for bounds checking needed by SFI. A compiler can use up to four bounds registers, and each register can store a pair of 64-bit starting and ending addresses. Specialized instructions check a given address and raise an exception if the bounds are violated. However, even with MPX support, the overhead of bounds checks is of the order of tens of percent points in many applications (Section 6.5 and [12, 30, 40]).

**Hardware-based trusted execution environments** Intel's SGX [27] and ARM's TrustZone [8] ISA extensions allow (components of) applications to execute with hardware-enforced isolation. JITGuard [17], for instance, uses SGX to protect the internal data structures of a just-in-time compiler from untrusted code, thus preventing code-injection attacks. While SGX and TrustZone can isolate data even from the operating system, switching overheads are similar to other hardware-based isolation mechanisms [30].

IMIX [18] and MicroStach [38] propose minimal extensions to the x86 ISA, adding load and store instructions to access secrets in a safe region. The extended ISA can provide data encapsulation. Both systems provide compilers that automatically partition secrets. However, for data encapsulation in the face of control-flow hijack attacks, both systems require CFI. As mentioned, CFI techniques have nontrivial overhead. ERIM, on the other hand, provides strong isolation without relying on CFI and has lower overhead.

**ASLR** Address space layout randomization (ASLR) is widely used to mitigate code-reuse exploits such as those based on buffer overflow attacks [43, 23]. ASLR has also been used for data encapsulation by randomizing data layout. For example, as one of the isolation techniques used in CPI [31, 46], a region of sensitive data is allocated at a random address within the 48-bit x86-64 address space and its base address is stored in a segment descriptor. All pointers stored in memory are offsets into the region and do not reveal its actual address. However, all forms of ASLR are vulnerable to attacks like thread spraying [43, 25, 16, 19, 39]. Consequently, ASLR is not viable for strong memory isolation, despite proposals such as [35] to harden it.

**ARM memory domains** ARM memory domains [7] are similar to Intel MPK, the x86 feature that ERIM relies on. However, unlike in MPK, changing domains is a kernel operation in ARM. Therefore, unlike MPK, ARM's memory domains do not support low-cost user-mode switching.

**MPK-based techniques** Koning et al. [30] present MemSentry, a general framework for data encapsulation, implemented as a pass in the LLVM compiler toolchain. They instantiate the framework with several different memory isolation techniques, including many described above and one based on MPK domains. However, MemSentry's MPK instance is secure only with a separate defense against control-flow hijack/code-reuse attacks to prevent adversarial misuse of PKRU-updating instructions in the binary. Such defenses have significant overhead of their own. As a result, the overall overhead of MemSentry's MPK instance is significantly higher than that of ERIM, which does not rely on a defense against control-flow hijacks.

In concurrent work [22], Hedayati *et al.* describe how to isolate userspace libraries using VMFUNC or Intel MPK. The MPK-based method is similar to ERIM, but does not address the challenge of ensuring that there are no exploitable occurrences of PKRU-modifying instructions. Rewriting binaries in this manner is a key contribution of our work (Section 4). Finally, Hedayati *et al.* rely on kernel changes while ERIM can run safely on a stock Linux kernel.

libmpk [41] virtualizes MPK memory domains beyond the 16 supported in hardware. It also addresses potential security issues in the API of Linux's MPK support. libmpk addresses concerns orthogonal to ERIM because neither limitation is relevant to ERIM's use of MPK. libmpk could be combined with ERIM in applications that require more than 16 components, but the integration remains as future work.

In recent work, Burow *et al.* [11] survey implementation techniques for shadow stacks. In particular, they examine the use of MPK for protecting the integrity of shadow stacks. Burow *et al.*'s measurements of MPK overheads (Fig. 10 in [11]) are consistent with ours. Their use of MPK could be a specific use-case for ERIM, which is a more general framework for memory isolation.

### 3 Design

**Goals** ERIM enables efficient data isolation within a user-space process. Like prior work, it enables a (trusted) application component to isolate its sensitive data from untrusted components. Unlike prior work, ERIM supports such isolation with *low overhead* even at *high switching rates* between components *without requiring control-flow integrity*. In the following, we focus on the case of two components that are isolated from each other within a single-threaded process. Later, we describe generalizations to multi-threaded processes, more than two components per process, and read-only sharing among components.

We use the letter T to denote a trusted component and U to denote the remaining, untrusted application component. ERIM's key primitive is memory isolation: it reserves a region of the address space and makes it accessible exclusively from the trusted component T. This reserved region is denoted  $M_T$  and can be used by T to store sensitive data. The rest of the address space, denoted  $M_U$ , holds the application's regular heap and stack and is accessible from both U and T. ERIM enforces the following invariants:

- (1) While control is in U, access to  $M_T$  remains disabled.
- (2) Access to  $M_T$  is enabled atomically with a control transfer to a designated entry point in T and disabled when T transfers control back to U.

The first invariant provides isolation of  $M_T$  from U, while the second invariant prevents U from confusing T into accessing  $M_T$  improperly by jumping into the middle of  $M_T$ 's code.

**Background: Intel MPK** To realize its goals, ERIM uses the recent MPK extension to the x86 ISA [28]. With MPK, each virtual page of a process can be associated with one of 16 protection keys, thus partitioning the address space into up to 16 *domains*. A new register, PKRU, that is local to each logical core, determines the current access permissions (read, write, neither or both) on each domain for the code running on that core. Access checks against the PKRU are implemented in hardware and impose no overhead on program execution.

Changing access privileges requires writing new permissions to the PKRU register with a *user-mode* instruction, WRPKRU. This instruction is relatively fast (11–260 cycles on current Intel CPUs), does not require a syscall, changes to page tables, a TLB flush, or inter-core synchronization.

The PKRU register can also be modified by the XRSTOR instruction by setting a specific bit in the eax register prior to the instruction (XRSTOR is used to restore the CPU's previously-saved extended state during a context switch).

For strong security, ERIM must ensure that untrusted code cannot exploit WRPKRU or XRSTOR instructions in executable pages to elevate privileges. To this end, ERIM combines MPK with binary inspection to ensure that all executable occurrences of WRPKRU or XRSTOR are *safe*, i.e., they cannot be exploited to improperly elevate privilege.

**Background: Linux support for MPK** As of version 4.6, the mainstream Linux kernel supports MPK. Page-table entries are tagged with MPK domains, there are additional syscall options to associate pages with specific domains, and the PKRU register is saved and restored during context switches. Since hardware PKRU checks are disabled in kernel mode, the kernel checks PKRU permissions explicitly before dereferencing any userspace pointer. To avoid executing a signal handler with inappropriate privileges, the kernel updates the PKRU register to its initial set of privileges (access only to domain 0) before delivering a signal to a process.

#### 3.1 High-level design overview

ERIM can be configured to provide either complete isolation of  $M_T$  from U (confidentiality and integrity), or only write protection (only integrity). We describe the design for complete isolation first. Section 3.7 explains a slight design re-configuration that provides only write protection.

ERIM's isolation mechanism is conceptually simple: It maps T's reserved memory,  $M_T$ , and the application's general memory,  $M_U$ , to two different MPK domains. It manages MPK permissions (the PKRU registers) to ensure that  $M_U$  is always accessible, while only  $M_T$  is accessible when control is in U. It allows U to securely transfer control to T and back via *call gates*. A call gate enables access to  $M_T$  using the WRPKRU instruction and immediately transfers control to a specified entry point of T, which may be an explicit or inlined function. When T is done executing, the call gate disables access to  $M_T$  and returns control to U. This enforces ERIM's two invariants (1) and (2) from Section 3. Call gates operate entirely in user-mode (they don't use syscalls) and are described in Section 3.3.

**Preventing exploitation** A key difficulty in ERIM's design is preventing the untrusted U from exploiting occurrences of the WRPKRU or XRSTOR instruction sequence on executable pages to elevate its privileges. For instance, if the sequence appeared at any byte address on an executable page, it could be exploited using control-flow hijack attacks. To prevent such exploits, ERIM relies on *binary inspection* to enforce the invariant that only *safe* WRPKRU and XRSTOR occurrences appear on executable pages.

A WRPKRU occurrence is safe if it is immediately followed by one of the following: (A) a pre-designated entry point of T, or (B) a specific sequence of instructions that checks that the permissions set by WRPKRU do not include access to  $M_T$  and terminates the program otherwise. A safe WRPKRU occurrence cannot be exploited to access  $M_T$  inappropriately. If the occurrence satisfies (A), then it does not give control to U at all; instead, it enters T at a designated entry point. If the occurrence satisfies (B), then it would terminate the program immediately when exploited to enable access to  $M_T$ .

A XRSTOR is safe if it is immediately followed by a specific sequence of instructions to check that the eax bit that

causes XRSTOR to load the PKRU register is not set. Such a XRSTOR cannot be used to change privilege and continue execution.<sup>1</sup>

ERIM's call gates use only safe WRPKRU occurrences (and do not use XRSTOR at all). So, they pass the binary inspection. Section 3.4 describes ERIM's binary inspection.

**Creating safe binaries** An important question is how to construct binaries that do not have unsafe WRPKRUs and XRSTORs. On x86, these instructions may arise inadvertently spanning the bytes of adjacent instructions or as a sub-sequence in a longer instruction. To eliminate such inadvertent occurrences, we describe a binary rewriting mechanism that rewrites any sequence of instructions containing a WRPKRU or XRSTOR to a functionally equivalent sequence without any WRPKRUs and XRSTORs. The mechanism can be deployed as a compiler pass or integrated with our binary inspection, as explained in Section 4.

### 3.2 Threat model

ERIM makes no assumptions about the untrusted component (U) of an application. U may behave arbitrarily and may contain memory corruption and control-flow hijack vulnerabilities that may be exploited during its execution.

However, ERIM assumes that the trusted component T's binary does not have such vulnerabilities and does not compromise sensitive data through explicit information leaks, by calling back into U while access to  $M_T$  is enabled, or by mapping executable pages with unsafe/exploitable occurrences of the WRPKRU or XRSTOR instruction.

The hardware, the OS kernel, and a small library added by ERIM to each process that uses ERIM are trusted to be secure. We also assume that the kernel enforces standard DEP—an executable page must not be simultaneously mapped with write permissions. ERIM relies on a list of legitimate entry points into T provided either by the programmer or the compiler, and this list is assumed to be correct (see Section 3.4). The OS's dynamic program loader/linker is trusted to invoke ERIM's initialization function before any other code in a new process.

Side-channel and rowhammer attacks, and microarchitectural leaks, although important, are beyond the scope of this work. However, ERIM is compatible with existing defenses. Our current *prototype* of ERIM is incompatible with applications that simultaneously use MPK for other purposes, but this is not fundamental to ERIM's design. Such incompatibilities can be resolved as long as the application does not re-use the MPK domain that ERIM reserves for T.

### 3.3 Call gates

A call gate transfers control from U to T by enabling access to  $M_T$  and executing from a designated entry point of T, and

<sup>1</sup>We know of only one user-mode Linux application – the dynamic linker, `ld`, that legitimately uses XRSTOR. However, `ld` categorically does not restore PKRU through XRSTOR, so this safe check can be added to it.

```
-----  
xor ecx, ecx                                1  
xor edx, edx                                2  
mov PKRU_ALLOW_TRUSTED, eax                3  
WRPKRU // copies eax to PKRU              4  
  
// Execute trusted component's code      6  
  
xor ecx, ecx                                8  
xor edx, edx                                9  
mov PKRU_DISALLOW_TRUSTED, eax           10  
WRPKRU // copies eax to PKRU            11  
cmp PKRU_DISALLOW_TRUSTED, eax          12  
je continue                               13  
syscall exit // terminate program        14  
continue:                                 15  
// control returns to the untrusted      16  
application here  
-----
```

Listing 1: Call gate in assembly. The code of the trusted component's entry point may be inlined by the compiler on line 6, or there may be an explicit direct call to it.

later returns control to U after disabling access to  $M_T$ . This requires two WRPKRUs. The primary challenge in designing the call gate is ensuring that both these WRPKRUs are safe in the sense explained in Section 3.1.

Listing 1 shows the assembly code of a call gate. WRPKRU expects the new PKRU value in the `eax` register and requires `ecx` and `edx` to be 0. The call gate works as follows. First, it sets PKRU to enable access to  $M_T$  (lines 1–4). The macro `PKRU_ALLOW_TRUSTED` is a constant that allows access to  $M_T$  and  $M_U$ .<sup>2</sup> Next, the call gate transfers control to the designated entry point of T (line 6). T's code may be invoked either by a direct call, or it may be inlined.

After T has finished, the call gate sets PKRU to disable access to  $M_T$  (lines 8–11). The macro `PKRU_DISALLOW_TRUSTED` is a constant that allows access to  $M_U$  but not  $M_T$ . Next, the call gate checks that the PKRU was actually loaded with `PKRU_DISALLOW_TRUSTED` (line 12). If this is not the case, it terminates the program (line 14), else it returns control to U (lines 15–16). The check on line 12 may seem redundant since `eax` is set to `PKRU_DISALLOW_TRUSTED` on line 10. However, the check prevents *exploitation* of the WRPKRU on line 11 by a control-flow hijack attack (explained next).

**Safety** Both occurrences of WRPKRU in the call gate are safe. Neither can be exploited by a control flow hijack to get unauthorized access to  $M_T$ . The first occurrence of WRPKRU (line 4) is immediately followed by (a direct control transfer to) a designated entry point of T. This instance can-

<sup>2</sup>To grant read (resp. write) access to domain  $i$ , bit  $2i$  (resp.  $2i + 1$ ) must be set in the PKRU. `PKRU_ALLOW_TRUSTED` sets the 4 least significant bits to grant read and write access to domains 0 ( $M_U$ ) and 1 ( $M_T$ ).

not be exploited to transfer control to anywhere else. The second occurrence of WRPKRU (line 11) is followed by a check that terminates the program if the new permissions include access to  $M_T$ . If, as part of an attack, the execution jumped directly to line 11 with any value other than `PKRU_DISALLOW_TRUSTED` in `eax`, the program would be terminated on line 14.

**Efficiency** A call gate's overhead on a roundtrip from U to T is two WRPKRUs, a few very fast, standard register operations and one conditional branch instruction. This overhead is very low compared to other hardware isolation techniques that rely on pages tables and syscalls or hypervisor trampolines to change privileges (see also Section 6.5).

**Use considerations** ERIM's call gate omits features that readers may expect. These features have been omitted to avoid having to pay their overhead when they are not needed. First, the call gate does not include support to pass parameters from U to T or to pass a result from T to U. These can be passed via a designated shared buffer in  $M_U$  (both U and T have access to  $M_U$ ). Second, the call gate does not scrub registers when switching from T to U. So, if T uses confidential data, it should scrub any secrets from registers before returning to U. Further, because T and U share the call stack, T must also scrub secrets from the stack prior to returning. Alternatively, T can allocate a private stack for itself in  $M_T$ , and T's entry point can switch to that stack immediately upon entry. This prevents T's secrets from being written to U's stack in the first place. (A private stack is also necessary for multi-threaded applications; see Section 3.7).

### 3.4 Binary inspection

Next, we describe ERIM's binary inspection. The inspection prevents U from mapping any executable pages with unsafe WRPKRU and XRSTOR occurrences and consists of two parts: (i) an inspection function that verifies that a sequence of pages does not contain unsafe occurrences; and, (ii) an interception mechanism that prevents U from mapping executable pages without inspection.

**Inspection function** The inspection function *scans* a sequence of pages for instances of WRPKRU and XRSTOR. It also inspects any adjacent executable pages in the address space for instances that cross a page boundary.

For every WRPKRU, it checks that the WRPKRU is safe, i.e., either condition (A) or (B) from Section 3.1 holds. To check for condition (A), ERIM needs a list of designated entry points of T. The source of this list depends on the nature of T and is trusted. If T consists of library functions, then the programmer marks these functions, e.g., by including a unique character sequence in their names. If the functions are not inlined by the compiler, their names will appear in the symbol table. If T's functions are subject to inlining or if they are generated by a compiler pass, then the compiler must be directed to add their entry locations to the symbol

table with the unique character sequence. In all cases, ERIM can identify designated entry points by looking at the symbol table and make them available to the inspection function.

Condition (B) is checked easily by verifying that the WRPKRU is immediately followed by *exactly* the instructions on lines 12–15 of Listing 1. These instructions ensure that the WRPKRU cannot be used to enable access to  $M_T$  and continue execution.

For every XRSTOR, the inspection function checks that the XRSTOR is followed immediately by the following instructions, which check that the `eax` bit that causes XRSTOR to load PKRU (bit 9) is not set: `bt eax, 0x9; jnc .safe; EXIT; .safe:...` Here, `EXIT` is a macro that exits the program. Trivially, such a XRSTOR cannot be used to enable access to  $M_T$  and continue execution.

**Interception** On recent ( $\geq 4.6$ ) versions of Linux, interception can be implemented *without kernel changes*. We install a `seccomp-bpf` filter [29] that catches `mmap`, `mprotect`, and `pkey_mprotect` syscalls which attempt to map a region of memory as executable (mode argument `PROT_EXEC`). Since the `bpf` filtering language currently has no provisions for reading the PKRU register, we rely on `seccomp-bpf`'s `SECCOMP_RET_TRACE` option to notify a `ptrace()`-based tracer process. The tracer inspects the tracee and allows the syscall if it was invoked from T and denies it otherwise. The tracer process is configured so that it traces any child of the tracee process as well. While `ptrace()` interception is expensive, note that it is required only when a program maps pages as executable, which is normally an infrequent operation.

If programs map executable pages frequently, a more efficient interception can be implemented with a simple Linux Security Module (LSM) [50], which allows `mmap`, `mprotect` and `pkey_mprotect` system calls only from T. (Whether such a call is made by U or T is easily determined by examining the PKRU register value at the time of the syscall.) Our prototype uses this implementation of interception. Another approach is to implement a small (8 LoC) change to `seccomp-bpf` in the Linux kernel, which allows a `bpf` filter to inspect the value of the PKRU register. With this change in place, we can install a `bpf` filter that allows certain syscalls only from T, similar to the LSM module.

With either interception approach in place, U must go through T to map executable pages. T maps the pages only after they have passed the inspection function. Regardless of the interception method, pages can be inspected upfront when T attempts to map them as executable, or on demand when they are executed for the first time.

On-demand inspection is preferable when a program maps a large executable segment but eventually executes only a small number of pages. With on-demand inspection, when the process maps a region as executable, T instead maps the region read-only but records that the pages are pending inspection. When control transfers to such a page, a fault occurs. The fault traps to a dedicated signal handler, which

ERIM installs when it initializes (the LSM or the tracer prevents U from overriding this signal handler). This signal handler calls a T function that checks whether the faulting page is pending inspection and, if so, inspects the page. If the inspection passes, then the handler remaps the page with the execute permission and resumes execution of the faulting instruction, which will now succeed. If not, the program is terminated.

The interception and binary inspection has very low overhead in practice because it scans an executable page at most once. It is also fully transparent to U's code if all WRPKRUs and XRSTORs in the binary are already safe.

**Security** We briefly summarize how ERIM attains security. The binary inspection mechanism prevents U from mapping any executable page with an unsafe WRPKRU or XRSTOR. T does not contain any executable unsafe WRPKRU or XRSTOR by assumption. Consequently, only safe WRPKRUs and XRSTORs are executable in the entire address space at any point. Safe WRPKRUs and XRSTORs preserve ERIM's two security invariants (1) and (2) by design. Thus  $M_T$  is accessible only while T executes starting from legitimate T entry points.

### 3.5 Lifecycle of an ERIM process

As part of a process's initialization, before control is transferred to `main()`, ERIM creates a second MPK memory domain for  $M_T$  in addition to the process's default MPK domain, which is used for  $M_U$ . ERIM maps a memory pool for a dynamic memory allocator to be used in  $M_T$  and hooks dynamic memory allocation functions so that invocations are transparently redirected to the appropriate pool based on the value of the PKRU register. This redirection provides programmer convenience but is not required for security. If U were to call T's allocator, it would be unable to access  $M_T$ 's memory pool and generate a page fault. Next, ERIM scans  $M_U$ 's executable memory for unsafe WRPKRUs and XRSTORs, and installs one of the interception mechanisms described in Section 3.4. Finally, depending on whether `main()` is in U or T, ERIM initializes the PKRU register appropriately and transfers control to `main()`. After `main()` has control, the program executes as usual. It can map, unmap and access data memory in  $M_U$  freely. However, to access  $M_T$ , it must invoke a call gate.

### 3.6 Developing ERIM applications

We describe here three methods of developing applications or modifying existing applications to use ERIM.

The *binary-only* approach requires that either U or T consist of a set of functions in a dynamic link library. In this case, the library and the remaining program can be used in unmodified binary form. An additional ERIM dynamic wrapper library is added using `LD_PRELOAD`, which wraps the entry points with stub functions that implement the call gates and have names that indicate to the ERIM runtime the

---

```

typedef struct secret {
    int number; } secret;
secret* initSecret() {
    ERIM_SWITCH_T;
    secret * s = malloc(sizeof(secret));
    s->number = random();
    ERIM_SWITCH_U;
    return s;
}
int compute(secret* s, int m) {
    int ret = 0;
    ERIM_SWITCH_T;
    ret = f(s->number, m);
    ERIM_SWITCH_U;
    return ret;
}

```

---

Listing 2: C component isolated with ERIM

valid entry points. We have used this approach to isolate SQLite within the Node.js runtime (Section 5).

The *source* approach requires that either U or T consist of a set of functions that are not necessarily in a separate compilation unit or library. In this case, the source code is modified to wrap these functions with stubs that implement the call gates, and choose names that indicate valid entry points. We used this approach to isolate the crypto functions and session keys in OpenSSL (Section 5).

The *compiler* approach requires modifications to the compiler to insert call gates at appropriate points in the executable and generate appropriate symbols that indicate valid entry points. This approach is the most flexible because it allows arbitrary inlining of U and T code. We used this approach to isolate the metadata in CPI (Section 5).

Next, we give a simple example describing the process of developing a new C application using the *source* approach. ERIM provides a C library and header files to insert call gates, initialize ERIM, and support dynamic memory allocation. Listing 2 demonstrates an example C program that isolates a data structure called `secret` (lines 1–2). The structure contains an integer value. Two functions, `initSecret` and `compute`, access secrets and bracket their respective accesses with call gates using the macros `ERIM_SWITCH_T` and `ERIM_SWITCH_U`. ERIM isolates `secret` such that only code that appears between `ERIM_SWITCH_T` and `ERIM_SWITCH_U`, i.e., code in T, may access `secret`. `initSecret` allocates an instance of `secret` while executing inside T by first allocating memory in  $M_T$  and then initializing the `secret` value. `compute` computes a function `f` of the `secret` inside T.

### 3.7 Extensions

Next, we discuss extensions to ERIM's basic design.

**Multi-threaded processes** ERIM’s basic design works as-is with multi-threaded applications. Threads are created as usual, e.g. using `libpthread`. The PKRU register is saved and restored by the kernel during context switches. However, multi-threading imposes an additional requirement on T (not on ERIM): In a multi-threaded application, it is essential that T allocate a private stack in  $M_T$  (not  $M_U$ ) for each thread and execute its code on these stacks. This is easy to implement by switching stacks at T’s entry points. Not doing so and executing T on standard stacks in  $M_U$  runs the risk that, while a thread is executing in T, another thread executing in U may corrupt or read the first thread’s stack frames. This can potentially destroy T’s integrity, leak its secrets and hijack control while access to  $M_T$  is enabled. By executing T’s code on stacks in  $M_T$ , such attacks are prevented.

**More than two components per process** Our description of ERIM so far has been limited to two components (T and U) per process. However, ERIM generalizes easily to support as many components as the number of domains Linux’s MPK support can provide (this could be less than 16 because the kernel may reserve a few domains for specific purposes). Components can have arbitrary pairwise trust relations with each other, as long as the trust relations are transitive. A simple setting could have a default domain that trusts all other domains (analogous to U) and any number of additional domains that do not trust any others. ERIM’s initialization code creates a private heap for each component, and ERIM’s custom allocator allocates from the heap of the currently executing component. Each component can also (in its own code) allocate a per-thread stack, to protect stack-allocated sensitive data when calling into other untrusted domains. Stacks can be mandatorily switched by ERIM’s call gates.

**ERIM for integrity only** Some applications care only about the integrity of protected data, but not its confidentiality. Examples include CPI, which needs to protect only the integrity of code pointers. In such applications, efficiency can be improved by allowing U to *read*  $M_T$  directly, thus avoiding the need to invoke a call gate for reading  $M_T$ . The ERIM design we have described so far can be easily modified to support this case. Only the definition of the constant `PKRU_DISALLOW_TRUSTED` in Listing 1 has to change to also allow read-only access to  $M_T$ . With this change, read access to  $M_T$  is always enabled.

**Just-in-time (jit) compilers with ERIM** ERIM works with jit compilers that follow standard DEP and do not allow code pages that are writable and executable at the same time. Such jit compilers write new executable code into newly allocated, non-executable pages and change these pages’ permissions to non-writable and executable once the compilation finishes. ERIM’s `mprotect` interception defers enabling execute permissions until after a binary inspection, as described in Section 3.4. When a newly compiled page is executed for the first time, ERIM handles the page exe-

ecute permission fault, scans the new page for unsafe WRPKRUs/XRSTORs and enables the execute permission if no unsafe occurrences exist. This mechanism is safe, but may lead to program crashes if the jit compiler accidentally emits an unsafe WRPKRU or XRSTOR. ERIM-aware jit compilers can emit WRPKRU- and XRSTOR-free binary code by relying on the rewrite strategy described in Section 4, and inserting call gates when necessary.

**OS privilege separation** The design described so far provides memory isolation. Some applications, however, require privilege separation between T and U with respect to OS resources. For instance, an application might need to restrict the filesystem name space accessible to U or restrict the system calls available to U.

ERIM can be easily extended to support privilege separation with respect to OS resources, using one of the techniques described in Section 3.4 for intercepting systems calls that map executable pages. In fact, intercepting and disallowing these system calls when invoked from U is just a special case of privilege separation. During process initialization, ERIM can instruct the kernel to restrict U’s access rights. After this, the kernel refuses to grant access to restricted resources whenever the value of the PKRU is not `PKRU_ALLOW_TRUSTED`, indicating that the syscall does not originate from T. To access restricted resources, U must invoke T, which can filter syscalls.

## 4 Rewriting program binaries

The binary inspection described in Section 3.4 guarantees that executable pages do not contain unsafe instances of the WRPKRU and XRSTOR instructions. This is *sufficient* for ERIM’s safety. In this section, we show how to generate or modify program binaries to not contain unsafe WRPKRUs and XRSTORs, so that they pass the binary inspection.

Intentional occurrences of WRPKRU that are not immediately followed by a transfer to T and all occurrences of XRSTOR, whether they are generated by a compiler or written manually in assembly, can be made safe by inserting the checks described in Section 3.4 after the instances. Inadvertent occurrences—those that arise unintentionally as part of a longer x86 instruction and operand, or spanning two consecutive x86 instructions/operands—are more interesting. We describe a rewrite strategy to eliminate such occurrences and how the strategy can be applied by a compiler or a binary rewriting tool. The strategy can rewrite any sequence of x86 instructions and operands containing an inadvertent WRPKRU or XRSTOR to a functionally equivalent sequence without either. In the following we describe the strategy, briefly argue why it is complete, and summarize an empirical evaluation of its effectiveness.

**Rewrite strategy** WRPKRU is a 3 byte instruction, `0x0F01EF`. XRSTOR is also always a 3-byte instruction, but it has more variants, fully described by the regular expres-

Overlap with	Cases	Rewrite strategy	ID	Example
Opcode	Opcode = WRPKRU/ XRSTOR	Insert safety check after instruction	1	
Mod R/M	Mod R/M = 0x0F	Change to unused register + move command	2	add ecx, [ebx + 0x01EF0000] → mov eax, ebx; add ecx, [eax + 0x01EF0000];
		Push/Pop used register + move command	3	add ecx, [ebx + 0x01EF0000] → push eax; mov eax, ebx; add ecx, [eax + 0x01EF0000]; pop eax;
Displacement	Full/Partial sequence	Change mode to use register	4	add eax, 0x0F01EF00 → (push ebx;) mov ebx, 0x0F010000; add ebx, 0x0000EA00; add eax, ebx; (pop ebx;)
	Jump-like instruction	Move code segment to alter constant used in address	5	call [rip + 0x0F01EF00] → call [rip + 0x0FA0EEFF]
Immediate	Full/Partial sequence	Change mode to use register	6	add eax, 0x0F01EF → (push ebx;) mov ebx, 0x0F01EE00; add ebx, 0x00000100; add eax, ebx; (pop ebx;)
	Associative opcode	Apply instruction twice with different immediates to get equivalent effect	7	add ebx, 0x0F01EF00 → add ebx, 0x0E01EF00; add ebx, 0x01000000

Table 1: Rewrite strategy for intra-instruction occurrences of WRPKRU and XRSTOR

sion 0x0FAE[2|6|A][8-F]. There are two cases to consider. First, a WRPKRU or XRSTOR sequence can span two or more x86 instructions. Such sequences can be “broken” by inserting a 1-byte nop like 0x90 between the two consecutive instructions. 0x90 does not coincide with any individual byte of WRPKRU or XRSTOR, so this insertion cannot generate a new occurrence.

Second, a WRPKRU or XRSTOR may appear entirely within a longer instruction including any immediate operand. Such cases can be rewritten by replacing them with a semantically equivalent instruction or sequence of instructions. Doing so systematically requires an understanding of x86 instruction coding. An x86 instruction contains: (i) an opcode field possibly with prefix, (ii) a MOD R/M field that determines the addressing mode and includes a register operand, (iii) an optional SIB field that specifies registers for indirect memory addressing, and (iv) optional displacement and/or immediate fields that specify constant offsets for memory operations and other constant operands.

The strategy for rewriting an instruction depends on the fields with which the WRPKRU or XRSTOR subsequence overlaps. Table 1 shows the complete strategy.

An opcode field is at most 3-bytes long. If the WRPKRU (XRSTOR) starts at the first byte, the instruction *is* WRPKRU (XRSTOR). In this case, we make the instruction safe by inserting the corresponding check from Section 3.4 after it. If the WRPKRU or XRSTOR starts after the first byte of the opcode, it must also overlap with a later field. In this case, we rewrite according to the rule for that field below.

If the sequence overlaps with the MOD R/M field, we change the register in the MOD R/M field. This requires a free register. If one does not exist, we rewrite to push an existing register to the stack, use it in the instruction, and pop

it back. (See lines 2 and 3 in Table 1.)

If the sequence overlaps with the displacement or the immediate field, we change the mode of the instruction to use a register instead of a constant. The constant is computed in the register before the instruction (lines 4 and 6). If a free register is unavailable, we push and pop one. Two instruction-specific optimizations are possible. First, for jump-like instructions, the jump target can be relocated in the binary; this changes the displacement in the instruction, obviating the need a free register (line 5). Second, associative operations like addition can be performed in two increments without an extra register (line 7). Rewriting the SIB field is never required because any WRPKRU or XRSTOR must overlap with at least one non-SIB field (the SIB field is 1 byte long while these instructions are 3 bytes long).

Compilers and well-written assembly programs normally do not mix data like constants, jump tables, etc. with the instruction stream and instead place such data in a non-executable data segment. If so, WRPKRU or XRSTOR sequences that occur in such data can be ignored.

**Compiler support** For binaries that can be recompiled from source, rewriting can be added to the codegen phase of the compiler, which converts the intermediate representation (IR) to machine instructions. Whenever codegen outputs an inadvertent WRPKRU or XRSTOR, the surrounding instructions in the IR can be replaced with equivalent instructions as described above, and codegen can be run again.

**Runtime binary rewriting** For binaries that cannot be recompiled, binary rewriting can be integrated with the interception and inspection mechanism (Section 3.4). When the inspection discovers an unsafe WRPKRU or XRSTOR on an executable page during its scan, it overwrites the page with

1-byte traps, makes it executable, and stores the original page in reserve without enabling it for execution. Later, if there is a jump into the executable page, a trap occurs and the trap handler discovers an entry point into the page.

The rewriter then disassembles the *reserved page* from that entry point on, rewriting any discovered WRPKRU or XRSTOR occurrences, and copies the rewritten instruction sequences back to the executable page. To prevent other threads from executing partially overwritten instruction sequences, we actually rewrite a fresh copy of the executable page with the new sequences, and then swap this rewritten copy for the executable page. This technique is transparent to the application, has an overhead proportional to the number of entry points in offending pages (it disassembles from every entry point only once) and maintains the invariant that only safe pages are executable.

A rewritten instruction sequence is typically longer than the original sequence and therefore cannot be rewritten in-place. In this case, binary rewriting tools place the rewritten sequence on a new page, replace the first instruction in the original sequence with a direct jump to the rewritten sequence, and insert a direct jump back to the instruction following the original sequence after the rewritten sequence. Both pages are then enabled for execution.

**Implementation and testing** The rewrite strategy is arguably complete. We have implemented the strategy as a library, which can be used either with the inspection mechanism as explained above or with a *static* binary rewrite tool, as described here. To gain confidence in our implementation, we examined all binaries of five large Linux distributions (a total of 204,370 binaries). Across all binaries, we found a total of 1213 WRPKRU/XRSTOR occurrences in code segments. We then used a standard tool, Dyninst [15], to try to disassemble and rewrite these occurrences. Dyninst was able to disassemble 1023 occurrences and, as expected, our rewriter rewrote all instances successfully. Next, we wanted to run these 1023 rewritten instances. However, this was infeasible since we did not know what inputs to the binaries would cause control to reach the rewritten instances. Hence, we constructed two hand-crafted binaries with WRPKRUs/XRSTORs similar to the 1023 occurrences, rewrote those WRPKRUs/XRSTORs with Dyninst and checked that those rewritten instances ran correctly. Based on these experiments, we are confident that our implementation of WRPKRU/XRSTOR rewriting is robust.

## 5 Use Cases

ERIM goes beyond prior work by providing efficient isolation with very high component switch rates of the order of  $10^5$  or  $10^6$  times a second. We describe three such use cases here, and report ERIM's overhead on them in Section 6.

**Isolating cryptographic keys in web servers** Isolating *long-term* SSL keys to protect from web server vulnerabil-

ities such as the Heartbleed bug [37] is well-studied [33, 34]. However, long-term keys are accessed relatively infrequently, typically only a few times per user session. *Session keys*, on the other hand, are accessed far more frequently—over  $10^6$  times a second per core in a high throughput web server like NGINX. Isolating session keys is relevant because these keys protect the confidentiality of individual users. With its low-cost switching, ERIM can be used to isolate session keys efficiently. To verify this, we partitioned OpenSSL's low-level crypto library (libcrypto) to isolate the session keys and basic crypto routines, which run as T, from the rest of the web server, which runs as U.

**Native libraries in managed runtimes** Managed runtimes such as a Java or JavaScript VM often rely on third-party native libraries written in unsafe languages for performance. ERIM can isolate the runtime from bugs and vulnerabilities in a native library by mapping the managed runtime to T and the native libraries to U. This use case leverages the “integrity only” version of ERIM (Section 3.7). We isolated Node.js from a native SQLite plugin. Node.js is a state-of-the-art managed runtime for JavaScript and SQLite is a state-of-the-art database library written in C [1, 2]. The approach generalizes to isolating several mutually distrusting libraries from each other by leveraging ERIM's multi-component extension from Section 3.7.

**CPI/CPS** Code-pointer integrity (CPI) [31] prevents control-flow hijacks by isolating sensitive objects—code pointers and objects that can lead to code pointers—in a *safe region* that cannot be written without bounds checks. CPS is a lighter, less-secure variant of CPI that isolates only code pointers. A key challenge is to isolate the safe region efficiently, as CPI can require switching rates on the order of  $10^6$  or more switches/s on standard benchmarks. We show that ERIM can provide strong isolation for the safe region at low cost. To do this, we override the CPI/CPS-enabled compiler's intrinsic function for writing the sensitive region to use a call gate around an inlined sequence of T code that performs a bounds check before the write. (MemSentry [30] also proposes using MPK for isolating the safe region, but does not actually implement it.)

## 6 Evaluation

We have implemented two versions of an ERIM prototype for Linux.<sup>3</sup> One version relies on a 77 line Linux Security Module (LSM) that intercepts all mmap and mprotect calls to prevent U from mapping pages in executable mode, and prevents U from overriding the binary inspection handler. We additionally added 26 LoC for kernel hooks to Linux v4.9.110, which were needed by the LSM. We also implemented ERIM on an *unmodified* Linux kernel using the ptrace-based technique described in Section 3.4. In the

<sup>3</sup>Available online at <https://gitlab.mpi-sws.org/vahldiek/erim>.

following, we show results obtained with the modified kernel. The performance of ERIM on the stock Linux kernel is similar, except that the costs of `mmap`, `mprotect`, and `pkey_mprotect` syscalls that enable execute permissions are about 10x higher. Since the evaluated applications use these operations infrequently, the impact on their overall performance is negligible.

Our implementation also includes the ERIM runtime library, which provides a memory allocator over `M_T`, call gates, the ERIM initialization code, and binary inspection. These comprise 569 LoC. Separately, we have implemented the rewriting logic to eliminate inadvertent WRPKRU occurrences (about 2250 LoC). While we have not yet integrated the logic into either a compiler or our inspection handler, the binaries used in our performance evaluation experiments do not have any unsafe WRPKRU occurrences and do not load any libraries at runtime. However, the binaries did have two legitimate occurrences of `XRSTOR` (in the dynamic linker library `ld.so`), which we made safe as described in Section 3.4. Two other inadvertent `XRSTOR` occurred in data-only pages of executable segments in `libm`, which is used by the SPEC benchmarks. We made these safe by re-mapping the pages read-only. Hence, the results we report are on completely safe binaries.

We evaluate the ERIM prototype on microbenchmarks and on the three applications mentioned in Section 5. Unless otherwise mentioned, we perform our experiments on Dell PowerEdge R640 machines with 16-core MPK-enabled Intel Xeon Gold 6142 2.6GHz CPUs (with the latest firmware; Turbo Boost and SpeedStep were disabled), 384GB memory, 10Gbps Ethernet links, running Debian 8, Linux kernel v4.9.60. For the OpenSSL/webserver experiments in Sections 6.2 and 6.5, we use NGINX v1.12.1, OpenSSL v1.1.1 and the ECDHE-RSA-AES128-GCM-SHA256 cipher. For the managed language runtime experiment (Section 6.3), we use Node.js v9.11.1 and SQLite v3.22.0. For the CPI experiment (Section 6.4), we use the Levee prototype v0.2 available from <http://dslab.epfl.ch/proj/cpi/> and Clang v3.3.1 including its CPI compile pass, runtime library extensions and link-time optimization.

## 6.1 Microbenchmarks

**Switch cost** We performed a microbenchmark to measure the overhead of invoking a function with and without a switch to a trusted component. The function adds a constant to an integer argument and returns the result. Table 2 shows the cost of invoking the function, in cycles, as an inlined function (I), as a directly called function (DC), and as a function called via a function pointer (FP). For reference, the table also includes the cost of a simple syscall (`getpid`), the cost of a switch on `lwc`s, a recent isolation mechanism based on kernel page table protections [33], and the cost of a VMFUNC (Intel VT-x)-based extended page table switch.

In our microbenchmark, calls with an ERIM switch are be-

Call type	Cost (cycles)
Inlined call (no switch)	5
Direct call (no switch)	8
Indirect call (no switch)	19
Inlined call + switch	60
Direct call + switch	69
Indirect call + switch	99
<code>getpid</code> system call	152
Call + VMFUNC EPT switch	332
<code>lwc</code> switch [33] (Skylake CPU)	6050

Table 2: Cycle counts for basic call and return

tween 55 and 80 cycles more expensive than their no-switch counterparts. The most expensive indirect call costs less than the simplest system call (`getpid`). ERIM switches are up to 3-5x faster than VMFUNC switches and up to 100x faster than `lwc` switches.

Because the CPU must not reorder loads and stores with respect to a WRPKRU instruction, the overhead of an ERIM switch depends on the CPU pipeline state at the time the WRPKRUs are executed. In experiments described later in this section, we observed average overheads ranging from 11 to 260 cycles per switch. At a clock rate of 2.6GHz, this corresponds to overheads between 0.04% and 1.0% for 100,000 switches per second, which is significantly lower than the overhead of any kernel- or hypervisor-based isolation.

**Binary inspection** To determine the cost of ERIM’s binary inspection, we measured the cost of scanning the binaries of all 18 applications in the CINT/FLOAT SPEC 2006 CPU benchmark. These range in size from 9 to 3918 4KB pages, contain between 35 and 63765 intentional WRPKRU instructions when compiled with CPI (see Section 6.4), no unintended WRPKRU and no `XRSTOR` instructions. The overhead is largely independent of the number of WRPKRU instructions and ranges between 3.5 and 6.2 microseconds per page. Even for the largest binary, the scan takes only 17.7ms, a tiny fraction of a typical process’ runtime.

## 6.2 Protecting session keys in NGINX

Next, we use ERIM to isolate SSL session keys in a high performance web server, NGINX. We configured NGINX to use only the ECDHE-RSA-AES128-GCM-SHA256 cipher and AES encryption for sessions. We modified OpenSSL’s `libcrypto` to isolate all session keys and the functions for AES key allocation and encryption/decryption into ERIM’s T, and use ERIM call gates to invoke these functions.

To measure ERIM’s overhead on the peak throughput, we configure a single NGINX worker pinned to a CPU core, and connect to it remotely over HTTPS with keep-alive from 4 concurrent ApacheBench (`ab`) [3] instances each simulating 75 concurrent clients. The clients all request the same file, whose size we vary from 0 to 128KB across experi-

File size (KB)	1 worker		3 workers		5 workers		10 workers	
	Native (req/s)	ERIM rel. (%)						
0	95,761	95.8	276,736	96.1	466,419	95.7	823,471	96.4
1	87,022	95.2	250,565	94.5	421,656	96.1	746,278	95.5
2	82,137	95.4	235,820	95.1	388,926	96.6	497,778	100.0
4	76,562	95.3	217,602	94.9	263,719	100.0		
8	67,855	96.0	142,680	100.0				

Table 3: Nginx throughput with multiple workers. The standard deviation is below 1.5% in all cases.

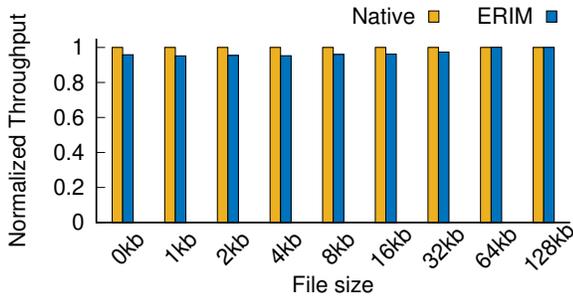

Figure 1: Throughput of NGINX with one worker, normalized to native (no protection), with varying request sizes. Standard deviations were all below 1.1%.

File size (KB)	Throughput		Switches/s	CPU load native (%)
	Native (req/s)	ERIM rel. (%)		
0	95,761	95.8	1,342,605	100.0
1	87,022	95.2	1,220,266	100.0
2	82,137	95.4	1,151,877	100.0
4	76,562	95.3	1,073,843	100.0
8	67,855	96.0	974,780	100.0
16	45,483	97.1	820,534	100.0
32	32,381	97.3	779,141	100.0
64	17,827	100.0	679,371	96.7
128	8,937	100.0	556,152	86.4

Table 4: Nginx throughput with a single worker. The standard deviation is below 1.1% in all cases.

ments.<sup>4</sup> Figure 1 shows the average throughput of 10 runs of an ERIM-protected NGINX relative to native NGINX without any protection for different file sizes, measured after an initial warm-up period.

ERIM-protected NGINX provides a throughput within 95.18% of the unprotected server for all request sizes. To explain the overhead further, we list the number of ERIM switches per second in the NGINX worker and the worker’s CPU utilization in Table 4 for request sizes up to 128KB. The overhead shows a general trend up to requests of size 32

<sup>4</sup>Since NGINX only serves static files in this experiment, its support for Lua and JavaScript is not used. As a result, this experiment does not rely on any support for Jit, which we have not yet implemented.

KB: The worker’s core remains saturated but as the request size increases, the number of ERIM switches per second decrease, and so does ERIM’s relative overhead. The observations are consistent with an overhead of about 0.31%–0.44% for 100,000 switches per second. For request sizes 64KB and higher, the 10Gbps network saturates and the worker does not utilize its CPU core completely in the baseline. The free CPU cycles absorb ERIM’s CPU overhead, so ERIM’s throughput matches that of the baseline.

Note that this is an extreme test case, as the web server does almost nothing and serves the same cached file repeatedly. To get a more realistic assessment, we set up NGINX to serve from main memory static HTML pages from a 571 MB (15,520 pages) Wikipedia snapshot of 2006 [48]. File sizes vary from 417 bytes to 522 KB (average size 37.7 KB). 75 keep-alive clients request random pages (selected based on pageviews on Wikipedia [49]). The average throughput with a single NGINX worker was 22,415 requests/s in the baseline and 21,802 requests/s with ERIM (std. dev. below 0.6% in both cases). On average, there were 615,000 switches a second. This corresponds to a total overhead of 2.7%, or about 0.43% for 100,000 switches a second.

**Scaling with multiple workers** To verify that ERIM scales with core parallelism, we re-ran the first experiment above with 3, 5 and 10 NGINX workers pinned to separate cores, and sufficient numbers of concurrent clients to saturate all the workers. Table 3 shows the relative overheads with different number of workers. (For requests larger than those shown in the table, the network saturates, and the spare CPU cycles absorb ERIM’s overhead completely.) The overheads were independent of the number of workers (cores), indicating that ERIM adds no additional synchronization and scales perfectly with core parallelism. This result is expected as updates to the per-core PKRU do not affect other cores.

### 6.3 Isolating managed runtimes

Next, we use ERIM to isolate a managed language runtime from an untrusted native library. Specifically, we link the widely-used C database library, SQLite, to Node.js, a state-of-the-art JavaScript runtime and map Node.js’s runtime to T and SQLite to U. We modified SQLite’s entry points to invoke call gates. To isolate Node.js’s stack from SQLite, we run Node.js on a separate stack in  $M_T$ , and switch to the

Test #	Switches/s	ERIM overhead (%)
100	11,183,281	12.73%
110	8,329,914	12.18%
400	8,161,584	15.42%
120	7,190,766	13.81%
142	7,074,553	9.41%
500	6,419,008	12.13%
510	5,868,395	5.60%
410	5,091,212	3.64%
240	2,358,524	3.74%
280	2,303,516	3.22%
170	1,264,366	4.22%
310	1,133,364	2.92%
161	1,019,138	2.81%
160	1,014,829	2.73%
230	670,196	2.04%
270	560,257	2.28%

Table 5: Overhead relative to native execution for SQLite speedtest1 tests with more than 100,000 switches/s. Standard deviations were below 5.6%.

standard stack (in  $M_U$ ) prior to calling a SQLite function. Finally, SQLite uses the libc function `memmove`, which accesses libc constants that are in  $M_T$ , so we implemented a separate `memmove` for SQLite. In total, we added 437 LoC.

We measure overheads on the speedtest1 benchmark that comes with SQLite and emulates a typical database workload [4]. The benchmark performs 32 short tests that stress different database functions like selects, joins, inserts and deletes. We increased the iterations in each test by a factor of four to make the tests longer. Our baseline for comparison is native SQLite linked to Node.js without any protection. We configure the benchmark to store the database in memory and report averages of 20 runs.

The geometric mean of ERIM’s runtime overhead across all tests is 4.3%. The overhead is below 6.7% on all tests except those with more than  $10^6$  switches per second. This suggests that ERIM can be used for isolating native libraries from managed language runtimes with low overheads up to a switching cost of the order of  $10^6$  per second. Beyond that the overhead is noticeable. Table 5 shows the relative overheads for tests with switching rates of at least 100,000/s. The numbers are consistent with an average overhead between 0.07% and 0.41% for 100,000 switches/s. The actual switch cost measured from direct CPU cycle counts varies from 73 to 260 cycles across all tests. It exceeds 100 cycles only when the switch rate is less than 2,000 times/s. We verified that these are due to i-cache misses—at low switch rates, the call gate instructions are evicted between switches.

## 6.4 Protecting sensitive data in CPI/CPS

Next, we use ERIM to isolate the safe region of CPI and CPS [31] in a separate domain. We modified CPI/CPS’s

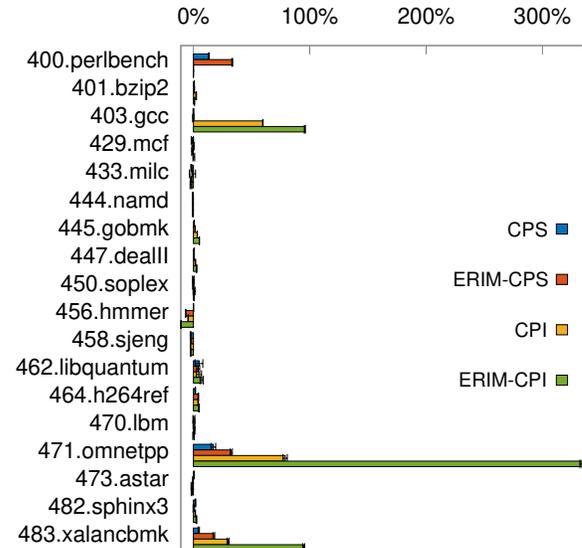

Figure 2: Percentage overhead relative to no protection.

LLVM compiler pass to emit additional ERIM switches, which bracket any code that modifies the safe region. The switch code, as well as the instructions modifying the safe region, are inlined with the application code. In addition, we implemented simple optimizations to safely reduce the frequency of ERIM domain switches. For instance, the original implementation sets sensitive code pointers to zero during initialization. Rather than generate a domain switch for each pointer initialization, we generate loops of pointer set operations that are bracketed by a single pair of ERIM domain switches. This is safe because the loop relies on direct jumps and the code to set a pointer is inlined in the loop’s body. In all, we modified 300 LoC in LLVM’s CPI/CPS pass.

Like the original CPI/CPS paper [31], we compare the overhead of the original and our ERIM-protected CPI/CPS system on the SPEC CPU 2006 CINT/FLOAT benchmarks, relative to a baseline compiled with Clang without any protection. The original CPI/CPS system is configured to use ASLR for isolation, the default technique used on x86-64 in the original paper. ASLR imposes almost no switching overhead, but also provides no security [43, 25, 16, 19, 39].

Figure 2 shows the average runtime overhead of 10 runs of the original CPI/CPS (lines “CPI/CPS”) and CPI/CPS over ERIM (lines “ERIM-CPI/CPS”). All overheads are normalized to the unprotected SPEC benchmark. We could not obtain results for 400.perlbench for CPI and 453.povray for both CPS and CPI. 400.perlbench does not halt when compiled with CPI and SPEC’s result verification for 453.povray fails due to unexpected output. These problems exist in the code generated by the Levee CPI/CPS prototype with CPI/CPS enabled (`-fcps/-fcpi`), not our modifications.

Benchmark	Switches/sec	ERIM-CPI overhead relative to orig. CPI in %
403.gcc	16,454,595	22.30%
445.gobmk	1,074,716	1.77%
447.deall	1,277,645	0.56%
450.soplex	410,649	0.60%
464.h264ref	1,705,131	1.22%
471.omnetpp	89,260,024	144.02%
482.sphinx3	1,158,495	0.84%
483.xalancbmk	32,650,497	52.22%

Table 6: Domain switch rates of selected SPEC CPU benchmarks and overheads for ERIM-CPI without binary inspection, *relative to the original CPI with ASLR*.

*CPI*: The geometric means of the overheads (relative to no protection) of the original CPI and ERIM-CPI across all benchmarks are 4.7% and 5.3%, respectively. The relative overheads of ERIM-CPI are low on all individual benchmarks except gcc, omnetpp, and xalancbmk.

To understand this better, we examined switching rates across benchmarks. Table 6 shows the switching rates for benchmarks that require more than 100,000 switches/s. From the table, we see that the high overheads on gcc, omnetpp and xalancbmk are due to extremely high switching rates on these three benchmarks (between  $1.6 \times 10^7$  and  $8.9 \times 10^7$  per second). Further profiling indicated that the reason for the high switch rate is tight loops with pointer updates (each pointer update incurs a switch). An optimization pass could hoist the domain switches out of the loops safely using only direct control flow instructions and enforcing store instructions to be bound to the application memory, but we have not implemented it yet.

Table 6 also shows the overhead of ERIM-CPI excluding binary inspection, relative to the original CPI over ASLR (not relative to an unprotected baseline as in Figure 2). This relative overhead is exactly the cost of ERIM’s switching. Depending on the benchmark, it varies from 0.03% to 0.16% for 100,000 switches per second or, equivalently, 7.8 to 41.6 cycles per switch. These results again indicate that ERIM can support inlined reference monitors with switching rates of up to  $10^6$  times a second with low overhead. Beyond this rate, the overhead becomes noticeable.

*CPS*: The results for CPS are similar to those for CPI, but the overheads are generally lower. Relative to the baseline without protection, the geometric means of the overheads of the original CPS and ERIM-CPS are 1.1% and 2.4%, respectively. ERIM-CPS’s overhead relative to the original CPS is within 2.5% on all benchmarks, except perlbench, omnetpp and xalancbmk, where it ranges up to 17.9%.

## 6.5 Comparison to existing techniques

In this section, we compare ERIM to isolation using SFI (with Intel MPX), extended page tables (with Intel VT-

x/VMFUNC), kernel page tables (with ITCs), and instrumentation of untrusted code for full memory safety (with WebAssembly). In each case, our primary goal is a *quantitative* comparison of the technique’s overhead to that of ERIM. As we show below, ERIM’s overheads are substantially lower than those of the other techniques. But before presenting these results, we provide a brief *qualitative* comparison of the techniques in terms of their threat models.

**Qualitative comparison of techniques** Isolation using standard kernel page tables affords a threat model similar to ERIM’s. In particular, like ERIM, the OS kernel must be trusted. In principle, isolation using a hypervisor’s extended page tables (VMFUNC) can afford a stronger threat model, in which the OS kernel need not be trusted [34].

Isolation using SFI, with or without Intel MPX, affords a threat model weaker than ERIM’s since one must additionally trust the transform that adds bounds checks to the untrusted code. For full protection, a control-flow integrity (CFI) mechanism is also needed to prevent circumvention of bounds checks. This further increases both the trusted computing base (TCB) and the overheads. In the experiments below, we omit the CFI defense, thus underestimating SFI overheads for protection comparable to ERIM’s.

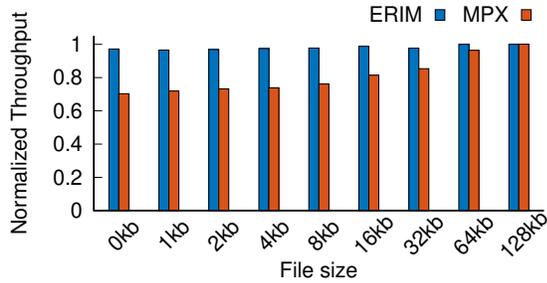

Instrumenting untrusted code for full memory safety, i.e., bounds-checking at the granularity of individual memory allocations, implicitly affords the protection that SFI provides. Additionally, such instrumentation also protects the untrusted code’s data from other outside threats, a use case that the other techniques here (including ERIM) do not handle. However, as for SFI, the mechanism used to instrument the untrusted code must be trusted. In our experiments below, we enforce memory safety by compiling untrusted code to WebAssembly, and this compiler must be trusted.

Next, we quantitatively compare the overheads of these techniques to those of ERIM.

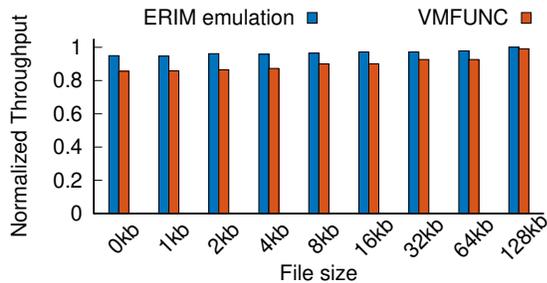

**SFI using MPX** We start by comparing the cost of ERIM’s isolation to that of isolation based on SFI using MPX. For this, we follow the NGINX experiment of Section 6.2. We place OpenSSL (trusted) in a designated memory region, and use MemSentry [30] to compile all of NGINX (untrusted) with MPX-based memory-bounds checks that prevent it from accessing the OpenSSL region directly.<sup>5</sup> To get comparable measurements on the (no protection) baseline and ERIM, we recompile NGINX with Clang version 3.8, which is the version that MemSentry supports. We then re-run the single worker experiments of Section 6.2.

Figure 3a shows the overheads of MPX and ERIM on NGINX’s throughput, relative to a no-protection baseline. The MPX-based instrumentation reduces the throughput of NGINX by 15-30% until the experiment is no longer CPU-

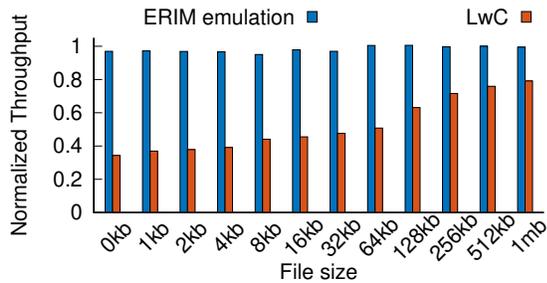

<sup>5</sup>This setup *reduces* the overheads of MPX as compared to the setup of Section 6.2, which isolates only small parts of OpenSSL. It is also less secure. Hence, the MPX overheads reported here are conservative.

(a) ERIM vs. SFI using MPX (averages of 3 runs, std. devs. below 1.9%)

(b) Emulated ERIM vs. VMFUNC (averages of 3 runs, std. devs. below 0.9%)

(c) Emulated ERIM vs. LwC (averages of 5 runs, std. devs. below 1.1%)

Figure 3: Comparison of NGINX throughput with ERIM and alternative isolation techniques

bound (file sizes  $\geq 64\text{kb}$ ). In contrast, ERIM reduces overheads by no more than 3.5%. Across all file sizes, MPX overheads are 4.2-8.5x those of ERIM.

MPX (more generally, SFI) and ERIM impose overhead in different ways. MPX imposes an overhead during the execution of NGINX (the untrusted component), while ERIM imposes an overhead on component switches. Consequently, one could argue that, as the switch rate increases, ERIM *must* eventually become more expensive than MPX. While this is theoretically true, in this experiment, we already observe extremely high switch rates of 1.2M/s (for file size 0kb) and, even then, MPX’s overhead is 8.4x that of ERIM’s overhead.

Further, as explained earlier, for strong security, SFI must be supported by control-flow integrity, which would induce

additional overheads that are not included here.

**Extended page tables (VMFUNC)** Next, we compare ERIM to isolation based on extended page tables (EPTs) using Intel VT-x and VMFUNC. To get access to EPTs, we use Dune [9] and a patch from MemSentry. We create two page tables—one maps the trusted region that contains session keys, and the other maps the untrusted region that contains all the remaining state of NGINX and OpenSSL. Access to the first table is efficiently switched on or off using the VMFUNC EPT switch call provided by the MemSentry patch. This call is faster than an OS process switch since it does not switch the process context or registers. Since we use Dune, the OS kernel runs in hypervisor mode. It has the switch overheads of hypervisor-based isolation using VMFUNC but includes the OS kernel in the TCB.

Unfortunately, MemSentry’s patch works only on old Linux kernels which do *not* have the page table support needed for MPKs and, hence, cannot support ERIM. Consequently, for this comparison, we rely on an emulation of ERIM’s switch overhead using standard x86 instructions. This emulation is described later in this section, and we validate that it is accurate to within 2% of ERIM’s actual overheads on a variety of programs. So we believe that the comparative results presented here are quite accurate.

Figure 3b shows the throughput of NGINX protected with VMFUNC and emulated ERIM, relative to a baseline with no protection for different file sizes (we use Linux kernel v3.16). Briefly, VMFUNC induces an overhead of 7-15%, while the corresponding overhead of emulated ERIM is 2.1-5.3%. Because both VMFUNC and ERIM incur overhead on switches, overheads of both reduce as the switching rate reduces, which happens as the file size increases. (The use of Dune and extended page tables also induces an overhead on all syscalls and page walks in the VMFUNC isolation.)

To directly compare VMFUNC’s overheads to *actual* ERIM’s, we calculated VMFUNC’s overhead as a function of switch rate. Across different file sizes, this varies from 1.4%-1.87% for 100,000 switches/s. In contrast, actual ERIM’s overhead in the similar experiment of Section 6.2 never exceeds 0.44% for 100,000 switches/s. This difference is consistent with the microbenchmark results in Table 2.

**Kernel page tables (lwCs)** Next, we compare ERIM’s overhead to that of lwCs [33], a recent system for in-process isolation based on kernel page-table protections. LwCs map each isolated component to a separate address space in the same process. A switch between components requires kernel mediation to change page tables, but does not require a process context switch. To measure lwC overheads, we re-run the NGINX experiment of Section 6.2, using two lwC contexts, one for the session keys and encryption/decryption functions and the other for NGINX and the rest of OpenSSL. Unfortunately, lwCs were prototyped in FreeBSD, which does not support MPK, so we again use our emulation of

ERIM's switch overhead to compare. All experiments reported here were run on Dell OptiPlex 7040 machines with 4-core Intel Skylake i5-6500 CPUs clocked at 3.2 GHz, 16 GB memory, 10 Gbps Ethernet cards, and FreeBSD 11.

Figure 3c shows the throughput of NGINX running with lwCs and emulated ERIM, relative to a baseline without any protection. With lwCs, the throughput is never above 80% of the baseline, and for small files, where the switch rate is high, the throughput is below 50%. In contrast, the throughput with emulated ERIM is within 95% of the baseline for all file sizes. In terms of switch rates, lwCs incur a cost of 10.5-18.3% for 100,000 switches/s across different file sizes. *Actual* ERIM's switch overhead during the similar experiment of Section 6.2 is no more than 0.44% across all file sizes, which is two orders of magnitude lower than that of lwCs.

**Memory safety (WebAssembly)** Finally, we compare ERIM's overheads to those of full memory safety on untrusted code. Specifically, we compare to compilation of untrusted code through WebAssembly [21], a memory-safe, low-level language that is now supported natively by all major web browsers and expected to replace existing SFI techniques like Native Client in the Chrome web browser. We compare to ERIM using the experiment of Section 6.3. We re-compile the (untrusted) SQLite library to WebAssembly via emscripten v1.37.37's WebAssembly backend [5], and run the WebAssembly within Node.js, which supports the language. Across tests of Table 5, the overhead of using WebAssembly varies from 81% to 193%, which is one to two orders of magnitude higher than ERIM's overhead.

**Emulating ERIM's switch cost** We describe how we emulate ERIM's switch cost when comparing to VMFUNC and lwCs above. Specifically, we need to emulate the cost of a WRPKRU instruction, which isn't natively supported in the environments of those experiments. We do this using xor instructions to consume the appropriate number of CPU cycles, followed by RDTSCP, which causes a pipeline stall and prevents instruction re-ordering. Specifically, we execute a loop five times, with `xor eax,ecx; xor ecx,eax; xor eax,ecx`, followed by a single RDTSCP after the loop.

To validate the emulation we re-ran the SPEC CPU 2006 benchmark with CPI/CPS (Section 6.4) after swapping actual WRPKRU instructions with the emulation sequence shown above and compared the resulting overheads. In each *individual* test, the difference in overhead between actual ERIM and the emulation is below 2%. We note that a perfectly precise emulation is impossible since emulation cannot exactly reproduce the effects of WRPKRU on the execution pipeline. (WRPKRU must prevent the reordering of loads and stores with respect to itself.) Depending on the specific benchmark, our emulation slightly over- or underestimates the actual performance impact of WRPKRU. We also observed that emulations of WRPKRU using LFENCE or MFENCE (the latter was suggested by [30]) in place of

RDTSCP incur too little or too much overhead, respectively.

## 7 Conclusion

Relying on the recent Intel MPK ISA extension and simple binary inspection, ERIM provides hardware-enforced isolation with an overhead of less than 1% for every 100,000 switches/s between components on current Intel CPUs, and almost no overhead on execution within a component. ERIM's switch cost is up to two orders of magnitude lower than that of kernel page-table based isolation, and up to 3-5x lower than that of VMFUNC-based isolation. For VMFUNC, virtualization can cause additional overhead on syscalls and page table walks. ERIM's overall overhead is lower than that of isolation based on memory-bounds checks (with Intel MPX), even at switch rates of the order of  $10^6/s$ . Additionally, such techniques require control-flow integrity to provide strong security, which has its own overhead. ERIM's comparative advantage prominently stands out on applications that switch very rapidly and spend a non-trivial fraction of time in untrusted code.

## Abstract

Information hiding (IH) is an important building block for many defenses against code reuse attacks, such as code-pointer integrity (CPI), control-flow integrity (CFI) and fine-grained code (re-)randomization, because of its effectiveness and performance. It employs randomization to probabilistically “hide” sensitive memory areas, called safe areas, from attackers and ensures their addresses are not leaked by any pointers directly. These defenses used safe areas to protect their critical data, such as jump targets and randomization secrets. However, recent works have shown that IH is vulnerable to various attacks.

In this paper, we propose a new IH technique called SafeHidden. It continuously re-randomizes the locations of safe areas and thus prevents the attackers from probing and inferring the memory layout to find its location. A new thread-private memory mechanism is proposed to isolate the thread-local safe areas and prevent adversaries from reducing the randomization entropy. It also randomizes the safe areas after the TLB misses to prevent attackers from inferring the address of safe areas using cache side-channels. Existing IH-based defenses can utilize SafeHidden directly without any change. Our experiments show that SafeHidden not only prevents existing attacks effectively but also incurs low performance overhead.

## 1 Introduction

*Information hiding* (IH) is a software-based security technique, which hides a memory block (called “safe area”) by randomly placing it into a very large virtual address space, so that memory hijacking attacks relying on the data inside the safe area cannot be performed. As all memory pointers pointing to this area are ensured to be concealed, attackers could not reuse existing pointers to access the safe area. Moreover, because the virtual address space is huge

and mostly inaccessible by attackers, the high randomization entropy makes brute-force probing attacks [45, 47] very difficult to succeed without crashing the program. Due to its effectiveness and efficiency, IH technique has become an important building block for many defenses against code reuse attacks. Many prominent defense methods, such as code-pointer integrity (CPI), control-flow integrity (CFI) and fine-grained code (re-)randomization, rely on IH to protect their critical data. For example, O-CFI [40] uses IH to protect all targets of indirect control transfer instructions; CPI [30] uses IH to protect all sensitive pointers; RERANZ [57], Shuffler [59], Oxymoron [4], Isomeron [15] and ALSR-Guard [36] use IH to protect the randomization secrets.

For a long time, IH was considered very effective. However, recent advances of software attacks [20, 35, 19, 43, 22] have made it vulnerable again. Some of these attacks use special system features to avoid system crashes when scanning the memory space [19, 35]; some propose new techniques to gauge the unmapped regions and infer the location of a safe area [43]; some exploit the thread-local implementation of safe areas, and propose to duplicate safe areas by using a thread spraying technique to increase the probability of successful probes [20]; others suggest that cache-based side-channel attacks can be used to infer the location of safe areas [22]. These attacks have fundamentally questioned the security promises offered by IH, and severely threatened the security defenses that rely on IH techniques.

To counter these attacks, this paper proposes a new information hiding technique, which we call SafeHidden. Our key observation is as follows: The security of IH techniques relies on (1) a high entropy of the location of the safe areas, and (2) the assumption that no attacks can reduce the entropy without being detected. Prior IH techniques have failed because they solely rely on the program crashes to detect attacks, but recent attacks have devised novel methods to reduce entropy without crashing the programs.

SafeHidden avoids these design pitfalls. It mediates all types of probes that may leak the locations of the safe areas, triggers a re-randomization of the safe areas upon detecting

\*To whom correspondence should be addressed.

legal but suspicious probes, isolates the *thread-local* safe areas to maintain the high entropy, and raises security alarms when illegal probes are detected. To differentiate accidental accesses to unmapped memory areas and illegal probing of safe areas, SafeHidden converts safe areas into *trap areas* after each re-randomization, creating a number of trap areas after a sequence of re-randomization operations. Accesses to any of these trap areas are captured and flagged by SafeHidden. SafeHidden is secure because it guarantees that *any attempt to reduce the entropy of the safe areas' locations either lead to a re-randomization (restoring the randomness) or a security alarm (detecting the attack)*.

SafeHidden is designed as a loadable kernel module, which is self-contained and can be transparently integrated with existing software defense methods (e.g., CPI and CFI). The design and implementation of SafeHidden entail several unconventional techniques: First, to mediate all system events that may potentially lead to the disclosure of safe area locations, SafeHidden needs to intercept all system call interfaces, memory access instructions, and TLB miss events that may be exploited by attackers to learn the virtual addresses of the safe areas. Particularly interesting is how SafeHidden traps TLB miss events: It sets the reserved bits of the page table entries (PTE) of the safe area so that all relevant TLB miss events are trapped into the page fault handler. However, because randomizing safe areas also invalidates the corresponding TLB entries, subsequent benign safe area accesses will incur TLB misses, which may trigger another randomization. To address this challenge, after re-randomizing the safe areas, SafeHidden utilizes hardware transactional memory (i.e., Intel TSX [2]) to determine which TLB entries were loaded before re-randomization and preload these entries to avoid future TLB misses.

Detecting TLB misses is further complicated by a new kernel feature called kernel page table isolation (KPTI) [1]. Because KPTI separates kernel page tables from user-space page tables, TLB entries preloaded in the kernel cannot be used by the user-space code. To address this challenge, SafeHidden proposes a novel method to temporarily use user-mode PCIDs in the kernel mode. To prevent the Meltdown attack (the reason that KPTI is used), it also flushes all kernel mappings of newly introduced pages from TLBs.

Second, SafeHidden proposes to isolate the *thread-local* safe area (by placing it in the *thread-private* memory) to prevent the attackers from reducing its randomization entropy. Unlike conventional approaches to achieve *thread-private* memory, SafeHidden leverages hardware-assisted *extended page table* (EPT) [2]. It assigns an EPT to each thread; the physical pages in other threads' *thread-local* safe area are configured not accessible in current thread's EPT. Compared to existing methods, this method does not need any modification of kernel source code, thus facilitating adoption.

To summarize, this paper makes the following contributions to software security:

- It proposes the re-randomization based IH technique to protect the safe areas against all known attacks.
- It introduces the use of *thread-private* memory to isolate *thread-local* safe areas. The construction of *thread-private* memory using hardware-assisted *extended page tables* is also proposed for the first time.
- It devises a new technique to detect TLB misses, which is the key trait of cache side-channel attacks against the locations of the safe areas.
- It develops a novel technique to integrate SafeHidden with KPTI, which may be of independent interest to system researchers.
- It implements and evaluates a prototype of SafeHidden, and demonstrates its effectiveness and efficiency through extensive experiments.

The rest of the paper is organized as follows. Section 2 reviews information hiding techniques and existing attacks. Section 3 explains the threat model. Section 4 presents the core design of SafeHidden. Section 5 details the implementation of SafeHidden. Section 6 provides the security and the performance evaluation. Discussion, related work, and conclusion are provided in Section 7, 8 and 9.

## 2 Background and Motivation

### 2.1 Information Hiding

*Information hiding* (IH) technique is a simple and efficient isolation defense to protect the data stored in a safe area. It places the safe area at a random location in a very large virtual address space. It makes sure that no pointer pointing to the safe area exists in the regular memory space, hence, making it unlikely for attackers to find the locations of the safe areas through pointers. Instead, normal accesses to the safe area are all done through an offset from a dedicated register.

Table 1 lists some of the defenses using the IH technique. The column “TL” shows whether the safe area is used only by its own thread or by all threads. The column “AF” shows how frequent the code accesses the safe area. Because most accesses to the safe area are through indirect/direct control transfer instructions, their frequencies are usually quite high. The column “Content in protected objects” shows the critical data tried to protect in safe areas. The column “Reg” shows the designated register used to store the (original) base address of the safe area. Some of them use the x86 segmentation register *%fs/%gs*. Others use the stack pointer register on X86\_64, *%rsp*, that originally points to the top of the stack. They access a safe area via an offset from those registers. For the *%gs* register, they often use the following formats: *%gs:0x10*, *%gs:(%rax)*, *%gs:0x10(%rax)*, etc. For the *%rsp* register, they often use the following formats: *0x10(%rsp)*, *(%rsp, %rax, 0x8)*, *pushq %rax*<sup>1</sup>, etc.

<sup>1</sup>It still conforms to the access model. The designated register is *%rsp*,

Defense	Protected Objects	Reg	Content in Protected Objects	AF	TL
<b>O-CFI</b> [40]	Bounds Lookup Table	%gs	The address boundaries of basic blocks targeted by an indirect branch instruction.	High	No
<b>RERANZ</b> [57]	Real Return Address Table	%gs	The table that contains the return addresses pushed by call instructions.	High	Yes
<b>Isomeron</b> [15]	Execution diversifier data	%gs	The mapping from the randomized code to the original code.	High	No
<b>ASLR-Guard</b> [36]	AG-Stack	%rsp	Dynamic code locators stored on the stack, such as return addresses.	High	Yes
	Safe-stack	%gs	ELF section remapping information and the key of code locator encryption.	High	No
<b>Oxymoron</b> [4]	Randomization-agnostic translation table	%fs	The translation table that contains the assigned indexes that are used to replace all references to code and data.	High	No
<b>Shuffler</b> [59]	Code pointer table	%gs	The table that contains all indexes that are transformed from all function pointers at their initialization points.	High	No
<b>CFCI</b> [61]	Protected Memory	%gs	File name and descriptors, and the mapping between file names and file descriptors.	Low	No
<b>CPI</b> [30]	Safe Stack	%rsp	Return address, spilled register, and objects accessed within the function through the stack pointer register with a constant offset.	High	Yes
	Safe Pointer Store	%gs	Sensitive pointers and the bounds of target objects pointed by these pointers.	High	No

Table 1: The list of defenses using information hiding (IH) techniques. **AF** is short for *Access Frequency*. **TL** is short for *Thread Local*.

A safe area is usually designed to be very small. For example, the size of a safe area shown in Table 1 is usually limited to be within 8 MB in practice. On today’s mainstream X86.64 CPUs, the randomization entropy of an 8 MB safe area is  $2^{24}$ . Such a high randomization entropy makes brute force probing attacks [45, 47] hard to guess its location successfully. A failed guess will result in a crash and detected by administrators.

## 2.2 Attacks against Information Hiding

Recent researches have shown that the IH technique is vulnerable to attacks. To locate a safe area, attackers may either improve the memory scanning technique to avoid crashes, or trigger the defense’s legal access to the safe area and infer its virtual address using side-channels.

### 2.2.1 Memory Scanning

The attackers could avoid crashes during their brute-force probing. For example, some adversaries have discovered that some daemon web servers have such features. The daemon servers can fork worker processes that inherit the memory layout. If a worker process crashes, a new worker process will be forked. This enables the so-called *clone-probing* attacks where an adversary repeatedly probes different clones in order to scan the target memory regions [35]. CROP [19] chooses to use the exception handling mechanism to avoid crashes. During the probing, an access violation will occur when an inadmissible address is accessed. But, it can be captured by an exception handler instead of crashing the system.

Attackers could also use memory management APIs to infer the memory allocation information, and then locate the safe area. In [43], it leverages the *allocation oracles* to obtain the location of a safe area. In a user’s memory space, there are many unmapped areas that are separated by code and data areas. To gauge the size of the largest unmapped

and the offset is equal to 0. The only difference is that it will change the value of the designated register.

area, it uses a binary search method to find the exact size by allocating and freeing a memory region repeatedly. After getting the exact size, it will allocate the memory in this area through the *persistent allocation oracle*. It then uses the same method to gauge the second largest unmapped area. Because a safe area is mostly placed in an unmapped area, an attacker can probe its surrounding areas to find its location without causing exceptions or crashes.

All probing attacks need to use such covert techniques to probe the memory many times without causing crashes because the size of a user’s memory space is very large. In [20], it finds the safe area in many defenses is thread local (see Table 1). So, it proposes to leverage the thread “spraying” technique to “spray” a large number of safe areas to reduce the number of probings. After spraying, the attackers only need very few probes to locate the safe area.

### 2.2.2 Cache-based Side-Channel Attacks

To translate a virtual address to a physical address, the MMU initiates a page table (PT) walk that visits each level of the page table sequentially in the memory. To reduce the latency, most-recently accessed page table entries are stored in a special hardware cache, called *translation lookaside buffer* (TLB). Because of the large virtual address space in 64-bit architectures, a hierarchy of cache memories has been used to support different levels of page-table lookup. They are called the page table caches, or *paging-structure caches* by Intel [2]. In addition, the accessed PT entries are also fetched into the last level cache (LLC) during the page-table walk.

It has been demonstrated that cache-based side-channels can break coarse-grained address space layout randomization [22]. The location of the safe area can be determined through the following attack method: First, the attacker triggers the defense system’s access to the safe area. To ensure this memory access invokes a PT walk, the attacker cleanses the corresponding TLB entries for the safe area’s virtual address beforehand. Second, the attacker conducts a Prime+Probe or Evict+Time cache side-channel

attack [44] to monitor which cache sets are used during the PT walk. As only certain virtual addresses map to a specific cache set, the virtual address of the safe area can be inferred using cache side-channel analysis.

However, it is worth mentioning that *to successfully determine the virtual address of one memory area, hundreds of such Prime+Probe or Evict+Time tests are needed. It is also imperative that the addresses of the PTEs corresponding to this memory area are not changed during these tests. That is, the cache entries mapped by these PTEs are not changed.* Our defense effectively invalidates such assumptions.

### 3 Threat Model

We consider an IH-based defense that protects a vulnerable application against code reuse attacks. This application either stands as a server that accepts and handles remote requests (e.g., through a web interface), or executes a sandboxed scripting code such as JavaScript as done in a modern web browsers. Accordingly, we assume the attacker has the permission to send malicious remote requests to the web servers or lure the web browsers to visit attacker-controlled websites and download malicious JavaScript code.

This IH-based defense has a safe area hidden in the victim process’s memory space. We assume the *design* of the defense is not flawed: That is, before launching code reuse attacks, the attacker must circumvent the defense by revealing the locations of the safe areas (e.g., using one of many available techniques discussed in Section 2.2). We also assume the implementation of defense system itself is not vulnerable, and it uses IH correctly. We assume the underlying operating system is trusted and secured.

We assume the existence of some vulnerabilities in the application that allows the attacker to (a) read and write arbitrary memory locations; (b) allocate or free arbitrary memory areas (e.g., by interacting with the application’s web interface or executing script directly); (c) create any number of threads (e.g., as a JavaScript program). These capabilities already represent the strongest possible adversary given in the application scenarios. Given these capabilities, all known attacks against IH can be performed.

#### 3.1 Attack Vectors

Particularly, we consider the following attack vectors. All known attacks employ one of the four vectors listed below to disclose the locations of the safe areas.

- **Vector-1:** Gathering memory layout information to help to locate safe areas, by probing memory regions to infer if they are mapped (or allocated);
- **Vector-2:** Creating opportunities to probe safe areas without crashing the system, e.g., by leveraging resumable exceptions;

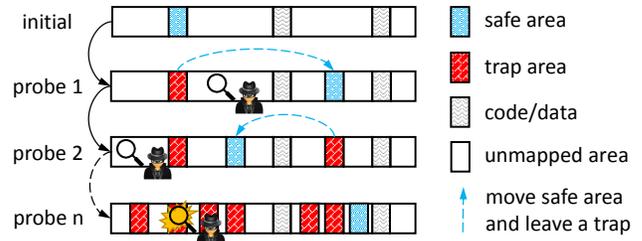

Figure 1: The high-level overview of the proposed re-randomization with the dispersed trap areas.

- **Vector-3:** Reducing the entropy of the randomized safe area locations to increase the success probability of probes, by decreasing the size of unmapped areas or increasing the size of safe areas;
- **Vector-4:** Monitoring page-table access patterns using cache side-channels to infer the addresses of safe areas, while triggering legal accesses to safe areas.

### 4 SafeHidden Design

We proposed SafeHidden, an IH technique that leverages re-randomization to prevent the attackers from locating the safe areas. It protects safe areas in both single-threaded programs and multi-threaded programs. It is designed primarily for Linux/X86\_64 platform, as most of the defenses leveraging IH are developed on this platform.

At runtime, SafeHidden detects all potential memory probes. To avoid overly frequent re-randomization, it migrates the safe area to a new randomized location only after the detection of a suspicious probing. It then leaves a trap area of the same size behind. Figure 1 illustrates the high-level overview of the re-randomization method. In the figure, the memory layout is changed as the location of the safe area is being moved continuously, and the unmapped memory space becomes more fragmented by trap areas. The ever-changing memory layout could block **Vector-1**.

As the attackers continue to probe, new trap areas will be created. Gradually, it becomes more likely for probes to stumble into trap areas. If the attacker touches a trap area through any type of accesses, SafeHidden will trigger a security alarm and capture the attack. The design of trap areas mitigates the attacks from **Vector-2**, and significantly limits the attackers’ ability to probe the memory persistently. While the attackers are still able to locate a safe area before accessing the trap areas, the probability is proven to be very small (see Section 4.4).

To block **Vector-3**, SafeHidden prevents unlimited shrink of unmapped areas and unrestricted growth of safe areas: (1) *Unmapped areas*. Because IH assumes that safe areas are hidden in a very large unmapped area, SafeHidden must prevent extremely large mapped areas. In our design, the

Events	Interception Points	Responses in SafeHidden			
		SA	UA	TA	OA
memory management syscalls	<i>mmap, munmap, mremap, mprotect, brk, ...</i>	Alarm	Rand	Alarm	–
syscalls that could return EFAULT	<i>read, write, access, send, ...</i>	Alarm	Rand	Alarm	–
cloning memory space	<i>clone, fork, vfork</i>	Rand	Rand	Rand	Rand
memory access instructions	<i>page fault exception</i>	–	Rand	Alarm	–

Table 2: Summary of potential stealthy probings and SafeHidden’s responses. “SA”: safe areas, “UA”: unmapped areas, “TA”: trap areas, “OA”: other areas. “Alarm”: triggering a security alarm. “Rand”: triggering re-randomization. “–”: do nothing.

maximum size of the mapped area allowed by SafeHidden is 64 TB, which is half of the entire virtual address space in the user space. Rarely do applications consume terabytes of memory; even big data applications only use gigabytes of virtual memory space; (2) *Safe areas*. Although safe areas in IH techniques are typically small and do not expand at runtime, attackers could create a large number of threads to increase the total size of the *thread-local* safe areas. To defeat such attacks, SafeHidden uses *thread-private* memory space to store *thread-local* safe areas. It maintains strict isolation among threads. When the *thread-local* safe area is protected using such a scheme, the entropy will not be reduced by thread spraying because any thread sprayed by an attacker can only access its own local safe area.

To mitigate **Vector-4**, SafeHidden also monitors legal accesses to the safe area that may be triggered by the attacker. Once such a legal access is detected, SafeHidden randomizes the location of the safe area. As the virtual address of the safe area is changed during re-randomization, the corresponding PTEs and their cache entries that are used by the attacker to make inferences no longer reflects the real virtual address of the safe area. Thus, **Vector-4** is blocked. It is worth noting that unlike the cases of detecting illegal accesses to the safe area, no trap area is created after the re-randomization.

In the following subsections, we will detail how SafeHidden recognizes and responds to the stealthy memory probes (see Section 4.1), how SafeHidden achieves the *thread-private* memory (see Section 4.2) and how SafeHidden defeats cache-based side-channel analysis (see Section 4.3).

## 4.1 Stealthy Memory Probes

In order to detect potential stealthy memory probes, we list all memory operations in the user space that can potentially be used as probings from the attackers (see Table 2).

The first row of Table 2 lists system calls that are related to memory management. The attackers could directly use them to gauge the layout of the memory space by allocating/deallocating/moving the memory or changing the permission to detect whether the target memory area is mapped or not. The second row lists the system calls that could return an EFAULT (bad address) error, such as “`ssize_t write(int fd, void * buf, size_t count)`”. These system calls have a parameter pointing to a memory address. If

the target memory is not mapped, the system call will fail without causing a crash, and the error code will be set to EFAULT. These system calls can be used to probe the memory layout without resulting in a crash. The third row lists the system calls that can clone a memory space. The attackers could use them to reason about the memory layout of the parent process from a child process. The fourth row lists memory access instructions that can trigger a *page fault exception* when the access permission is violated. The attackers could register or reuse the signal handler to avoid a crash when probing an invalid address.

Four types of memory regions are considered separately: safe areas, unmapped areas, trap areas, and other areas. Unmapped areas are areas in the address space that are not mapped; trap areas are areas that were once safe areas; other areas store process code and data. As shown in Table 2, SafeHidden intercepts different types of memory accesses to these areas and applies different security policy accordingly:

- If the event is an access to an unmapped area, SafeHidden will randomize the location of all safe areas. The original location of a safe area become a trap area.
- If the event is a memory cloning, it will perform randomization in the parent process after creating a child process, in order to make the locations of their safe areas different.
- If the event is an access to safe areas through memory management system calls or system calls with EFAULT return value, SafeHidden will trigger a security alarm.
- If the event is an access to trap areas through memory access instructions, memory management system calls, or system calls with EFAULT return value, it will trigger a security alarm.
- SafeHidden does not react to memory accesses to other areas. Since they do not have pointers pointing to the safe areas, probing other areas do not leak the locations.

To avoid excessive use of the virtual memory space, SafeHidden sets an upper limit on the total size of all trap areas (the default is 1 TB). Once the size of trap areas reaches the upper limit, SafeHidden will remove some randomly chosen trap area in each randomization round.

The design of such a security policy is worth further discussion here. Trap areas are previous locations of safe areas, which should be protected from illegal accesses in the same way as safe areas. As normal application behaviors never access safe areas and trap areas in an illegal way, accesses to them should raise alarms. For accesses to unmapped areas, an immediate alarm may cause false positives because the application may also issue memory management system calls, system calls with an EFAULT return value, or a memory access that touches unmapped memory areas. Therefore, accesses to unmapped areas only trigger re-randomization of the safe area to restore the randomness (that could invalidate the knowledge of previous probes), but no alarm will be raised. An alternative design would be counting the number of accesses to unmapped areas and raising a security alarm when the count exceeds a threshold. However, setting a proper threshold is very difficult because different probing algorithms could have different probing times. Therefore, monitoring critical subsets of the unmapped areas—the safe areas and trap areas—appears a better design choice.

## 4.2 Thread-private Memory

*Thread-private* memory technique was usually used in multi-threaded record-and-replay techniques [25, 7, 31]. We propose to use *thread-private* memory to protect safe areas. Conventional methods to implement *thread-private* memory is to make use of *thread-private* page tables in the OS kernel. As a separate page table is maintained for each thread, a reference page table for the entire process is required to keep track of the state of each page. The modification of the kernel is too complex, which cannot be implemented as a loadable kernel module: For example, to be compatible with *kswapd*, the reference page table must be synchronized with the private page tables of each thread, which requires tracking of CPU accesses of each PTE (especially the setting of the accessed and dirty bits<sup>2</sup> by CPU). The need for kernel source code modification and recompilation restricts the practical deployment of this approach.

To address this limitation, we propose a new approach to implement *thread-private* memory using the hardware virtualization support. Currently, a memory access in a guest VM needs to go through two levels of address translation: a *guest virtual address* is first translated into a *guest physical address* through the guest page table (GPT), which is then translated to its *host physical address* through a hypervisor maintained table, e.g., the *extended page table* (EPT) [38] in Intel processors, or the *nested page table* (NPT) [56] in AMD processors. Using Intel’s EPT as an example, multiple virtual CPUs (VCPU) within a guest VM will share the same EPT. For instance, when the two VCPUs of a guest VM run

<sup>2</sup>These flags are provided for use by memory-management software to manage the transfer of pages into and out of physical memory. CPU is responsible for setting these bits via the physical address directly.

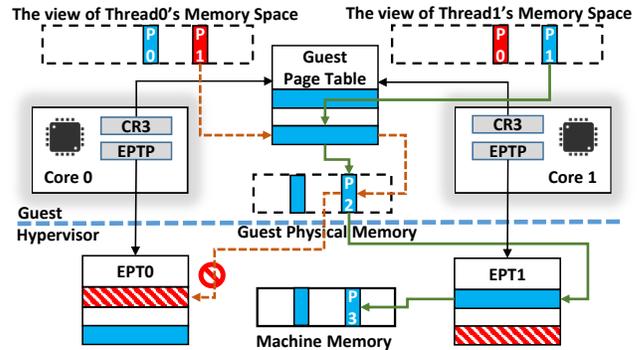

Figure 2: An example of the *thread-private* memory mechanism. P0 and P1 is *thread-private* memory page of Thread0 and Thread1, respectively.

two threads of the same program, both the virtual CR3 registers point to the page table of the program, and both EPT pointers (EPTPs) of VCPUs are pointing to a shared EPT.

To implement a *thread-private* memory, we can instead make each EPTP to point to a *separate* EPT to maintain its own *thread-private* memory. In such a scheme, each thread will have its own private EPT. The physical pages mapped in a thread’s private memory in other threads’ private EPTs will be made inaccessible. Figure 2 depicts an example of our *thread-private* memory scheme. When Thread1 tries to access its *thread-private* memory page P1, the hardware will walk both GPT and EPT1 to get the P3 successfully. But when Thread0 tries to access P1, it will trigger an EPT violation exception when the hardware walking EPT0 and be captured by the hypervisor.

In such a scheme, when a thread is scheduled on a VCPU, the hypervisor will set EPTP to point to its own EPT. In addition, SafeHidden synchronizes the EPTs by tracking the updates of the entries for the *thread-local* safe areas. For example, when mapping a guest physical page, SafeHidden needs to add the protection of all threads’ EPTs for this page.

The *thread-private* memory defeats **Vector-3** completely. When *thread-local* safe areas are stored in such *thread-private* memory, spraying *thread-local* safe areas is no longer useful for the attackers because it will spray many prohibited areas that are similar to trap areas, called *shielded areas* (e.g., P1 is Thread0’s shielded area in Figure 2), and be captured more easily.

## 4.3 Thwarting Cache Side-Channel Attacks

As discussed in Section 2.2.2, a key step in the cache side-channel attack by Gras et al. [22] is to force a PT walk when an access to the safe area is triggered. Therefore, a necessary condition for such an attack is to allow the attacker to induce TLB misses in a safe area. SafeHidden mitigates such attacks by intercepting TLB misses when accessing safe areas.

To only intercept the TLB miss occurred in safe areas,

SafeHidden leverages a reserved bit in a PTE on X86\_64 processors. When the reserved bit is set, a *page fault exception* with a specific error code will be triggered when the PTE is missing in TLB. Using this mechanism, a TLB miss can be intercepted and handled by the page fault handler. SafeHidden sets the reserved bit in all of the PTEs for the safe areas. Thus, when a TLB miss occurs, it is trapped into the page fault handler and triggers the following actions: (1) It performs one round of randomization for the safe area; (2) It clears the reserved bit in the PTE of the faulting page; (3) It loads the PTE (after re-randomization) of the faulting page into the TLB; (4) It then sets the reserved bit of the PTE again. It is worth noting that loading the TLB entry of the faulting page is a key step. Without this step, the program’s subsequent accesses to the safe area will cause TLB misses again, which will trigger another randomization.

The re-randomization upon TLB miss effectively defeats cache-based side-channel analysis. As mentioned in Section 2.2.2, a successful side-channel attack requires hundreds of Prime+Probe or Evict+Time tests. However, as each test triggers a TLB miss, the safe area is re-randomized after every test. The PTEs used to translate the safe areas in each PT levels are re-randomized. Thus, the cache entries mapped by these PTEs are also re-randomized that completely defeating cache-based side-channels [22].

Nevertheless, two issues may arise: First, the PTEs of a safe area could be updated by OS (e.g., during a page migration or a reclamation), and thus clearing the reserved bits. To avoid these unintended changes to the safe areas’ PTEs, SafeHidden traps all updates to the corresponding PTEs to maintain the correct values of the reserved bits. Second, as the location of a safe area is changed after a randomization, it will cause many TLB misses when the safe area is accessed at the new location, which may trigger many false alarms and re-randomizations. To address this problem, SafeHidden reloads the safe area’s PTEs that were already loaded in the TLB back to the TLB after re-randomization. This, however, requires SafeHidden to know which PTEs were loaded in the TLB before the re-randomization. To do so, SafeHidden exploits an additional feature in Intel transactional synchronization extensions (TSX), which is Intel’s implementation of hardware transactional memory [2]. During a re-randomization, SafeHidden touches each page in the safe area from inside of a TSX transaction. If there is a TLB miss, a *page fault exception* will occur because the reserved bit of its PTE is set. But this exception will be suppressed by a TSX transaction and handled by its abort handler. Therefore, SafeHidden can quickly find out all loaded PTEs before the re-randomization and reload them for the new location in the TLB without triggering any *page fault exception*.

Integrating SafeHidden with kernel page table isolation (KPTI) [1] introduces additional challenges. KPTI is a default feature used in the most recent Linux kernels. It separates the kernel page tables from user-space page tables,

which renders the pre-loaded TLB entries of the safe areas in kernel unusable by the user-space application. We will detail our solution in section 5.

## 4.4 Security Analysis

SafeHidden by design completely blocks attacks through **Vector-1**, **Vector-3**, and **Vector-4**. However, it only probabilistically prevents attacks through **Vector-2**. As such, in this section, we outline an analysis of SafeHidden’s security guarantee. Specifically, we consider a defense system with only one safe area hidden in the unmapped memory space. We abstract the attackers’ behavior as a sequence of memory probes, each of which triggers one re-randomization of the safe area and creates a new trap area.

$$P_{c,ith} = \begin{cases} (i \cdot P_t) \cdot \prod_{j=1}^{i-1} (1 - P_h - j \cdot P_t) & \text{if } i \leq M \\ (M \cdot P_t) \cdot \left( \prod_{j=1}^M (1 - P_h - j \cdot P_t) \right) \cdot (1 - P_h - M \cdot P_t)^{i-1-M} & \text{if } i > M \end{cases} \quad (1)$$

**The probability of detecting probes.** Let the probability of detecting the attacks within N probes be  $P_{c,n}$ . Then the cumulative probability  $P_{c,n} = \sum_{i=1}^n P_{c,ith}$ , where  $P_{c,ith}$  represents the probability that an attacker *escapes* all  $i - 1$  probes, but is captured in the  $i$ th probe when it hits a trap area. An *escape* means that the attacker’s probe is unsuccessful but remains undetected.  $P_{c,ith}$  is calculated in Equation (1), where  $i$  denotes the number of probes,  $j$  denotes the number of existing trap areas,  $P_h$  denotes the probability that the attacker hits the safe area in a probe,  $P_t$  represents the probability that the attacker hits one of the trap areas in a probe,  $M$  denotes the maximum number of trap areas. As an *escape* results in one re-randomization and the creation of a trap area, we approximate the number of existing trap areas with the number of escapes. But the number only increases up to  $M$ . So we consider if  $i$  reaches  $M$  separately. In the equation,  $(i \cdot P_t)$  or  $(M \cdot P_t)$  represents the probability that the probes are detected in the  $i$ th probe and  $(1 - P_h - j \cdot P_t)$  or  $(1 - P_h - M \cdot P_t)$  represents the probability of *escaping* the  $i$ th probe.

**The attacker’s success probability.** We denote the probability of the attacker’s successfully locating the safe area within N probes as  $P_{s,n}$ .  $P_{s,n} = \sum_{i=1}^n P_{s,ith}$ , where  $P_{s,ith}$  represents the probability that the attacker escapes in the first  $i - 1$  probes, but succeed in the  $i$ th probe.  $P_{s,ith}$  is provided in Equation (2).

$$P_{s,ith} = \begin{cases} P_h \cdot \prod_{j=1}^{i-1} (1 - P_h - j \cdot P_t) & \text{if } i \leq M \\ P_h \cdot \left( \prod_{j=1}^M (1 - P_h - j \cdot P_t) \right) \cdot (1 - P_h - M \cdot P_t)^{i-1-M} & \text{if } i > M \end{cases} \quad (2)$$

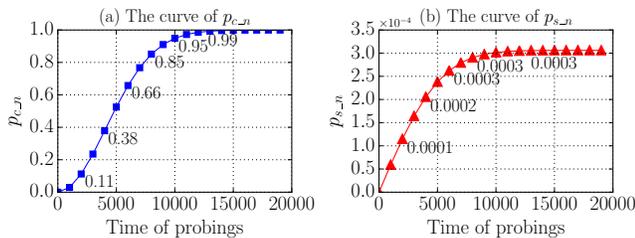

Figure 3: The probability of being captured by SafeHidden within  $N$  probes (a) and the probability of locating the safe areas within  $N$  probes successfully (b).

**Discussion.** When the size of the safe area is set to 8 MB, and the maximum size of all trap areas is set to 1 TB, as shown in Figure 3(a),  $P_{c,n}$  increases as the number of probes grows. When the number of probes reaches 15K, SafeHidden detects the attack with a probability of 99.9%;  $P_{c,n}$  approaches 100% as the number of probes reaches 20K. Figure 3(b) suggests the value of  $P_{s,n}$  increases as the number of probes increases, too. But even if the attacker can escape in 15K probes (which is very unlikely given Figure 3(a)), the probability of successfully locating the safe area is still only 0.03% (shown in Figure 3(b)), which is the maximum that could ever be achieved by the attacker. Notice that our abstract model favors the attackers, for example: (1) no *shielded areas* are considered in the analysis; (2) randomization triggered by applications’ normal activities and TLB misses is ignored in the analysis. Obviously, in the real world situation, the attacker’s success probability will be even lower, and the attack will be caught much sooner.

## 5 System Implementation

SafeHidden is designed as a loadable kernel module. Users could deploy SafeHidden by simply loading the kernel module, and specifying, by passing parameters to the module, which application needs to be protected and which registers point to the safe area. *No modification of the existing defenses or re-compiling the OS kernel is needed.*

### 5.1 Architecture Overview of SafeHidden

As described in Section 4.2, SafeHidden needs the hardware virtualization support. It can be implemented within a Virtual Machine Monitor (VMM), such as Xen or KVM. However, the need for virtualization does not preclude its application in non-virtualized systems. To demonstrate this, we integrated a thin hypervisor into the kernel module for a non-virtualized OS. The thin hypervisor virtualizes the running OS as the guest without rebooting the system. The other components inside the kernel module are collectively called GuestKM, which runs in the guest kernel.

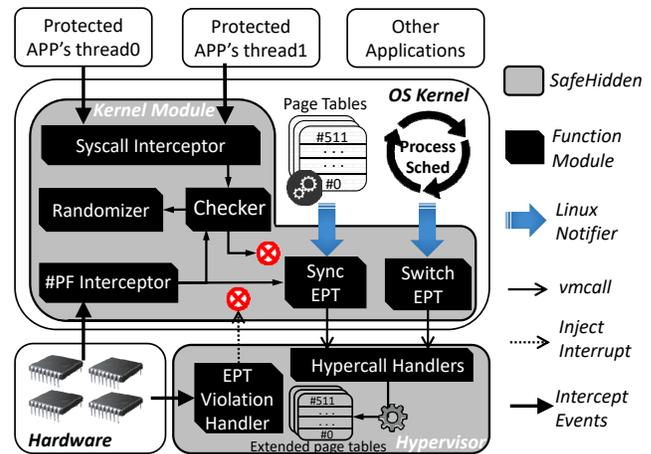

Figure 4: Architecture overview of SafeHidden.

After loading the SafeHidden module, it first starts the hypervisor and then triggers the initialization of GuestKM to install hooks during the *Initialization Phase*. Figure 4 shows an overview of SafeHidden’s architecture. We can see that SafeHidden is composed of two parts: the hypervisor and the GuestKM. In the initialization phase, GuestKM installs hooks to intercept three kinds of guest events: *context switching*, *page fault exceptions*, and certain *system calls*.

SafeHidden then starts to protect the safe areas by randomizing their locations and isolating the *thread-local* safe areas during the *Runtime Monitoring Phase*. In the GuestKM, the *Syscall Interceptor* and the *#PF Interceptor* modules are used to intercept *system calls* and *page fault exceptions*. When these two types of events are intercepted, they will request the *Checker* module to determine if SafeHidden needs to raise a security alarm, or if it needs to notify the *Randomizer* module to perform randomization. Meanwhile, SafeHidden needs to maintain the *thread-private* EPT to isolate the *thread-local* safe areas. The *sync EPT* module is used to synchronize the protected threads’ page tables with their EPTs. The *switch EPT* module will switch EPTs when a protected thread is scheduled. Because both modules need to operate EPTs, they are coordinated by the *Hypercall Handlers* module. The *EPT Violation Handler* module is used to monitor illegal accesses to the *thread-local* safe areas.

### 5.2 Initialization Phase

**Task-1: starting hypervisor.** When the kernel module is launched, the hypervisor starts immediately. It configures the EPT paging structures, enables virtualization mode, and places the execution of the non-virtualized OS into the virtualized guest mode (non-root VMX mode). At this time, it only needs to create a default EPT for guest. Because the guest is a mirror of the current running system, the default EPT stores a one-to-one mapping that maps each guest physical address to the same host physical address.

**Task-2: installing hooks in guest kernel.** When the guest starts to run, GuestKM will be triggered to install hooks to intercept three kinds of events: 1) To intercept the *system calls*, GuestKM modifies the `system_call_table`'s entries and installs an alternative handler for each of them; 2) To intercept the *page fault exception*, GuestKM uses the `ftrace` framework in Linux kernel to hook the `do_page_fault` function; 3) To intercept *context switches*, GuestKM uses the standard `preemption_notifier` in Linux, `preempt_notifier_register`, to install hooks. It can be notified through two callbacks, the `sched_in()` and the `sched_out()`, when a context switch occurs.

### 5.3 Runtime Monitoring Phase

**Recognizing safe areas.** GuestKM intercepts the `execve()` system call to monitor the startup of the protected process. Based on the user-specified dedicated register, GuestKM can monitor the event of setting this register to obtain the value. In Linux kernel, the memory layout of a process is stored in a list structure, called `vm_area_struct`. GuestKM can obtain the safe area by searching the link using this value. According to Table 1, there are two kinds of registers that store the pointer of a safe area: 1) The 64-bit Linux kernel only allows a user process to set the `%gs` or `%fs` segmentation registers through the `arch_prctl()` system call<sup>3</sup>. So, GuestKM intercepts this system call to obtain the values of these registers; 2) All existing methods listed in Table 1 use `%rsp` pointed safe area to protect the stack. So, GuestKM analyzes the execution result of the `execve()` and the `clone()` system calls to obtain the location of the safe area, i.e., the stack, of the created thread or process. Once a safe area is recognized, its PTEs will be set invalid by setting the reserved bits.

To determine whether a safe area is *thread-local* or not, GuestKM monitors the event of setting the dedicated register in child threads. If the register is set to point to a different memory area, it means that the child thread has created its *thread-local* safe area, and the original safe area belongs to the parent. Until the child thread modifies the register to point to a different memory area, it shares the same safe area with its parent.

**Randomizing safe areas.** As described in Section 4.1 and 4.3, when GuestKM needs to perform randomization, it invokes the customized implementation of `do_mremap()` function in the kernel with a randomly generated address (by masking the output of the `rdrand` instruction with `0x7fffffff000`) to change the locations of the safe areas. If the generated address has been taken, the process is repeated until a usable address is obtained. It is worth noting that GuestKM only changes the virtual address of

<sup>3</sup>Recent CPUs supporting the `WRGSBASE/WRFSSBASE` instructions allow setting the `%gs` and `%fs` base directly, but they are restricted by the Linux kernel to use in user mode.

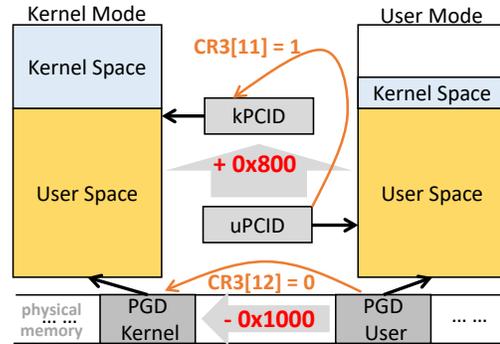

Figure 5: Overview of kernel page-table isolation.

the safe area, the physical pages are not changed. After migrating each safe area (not triggered by the TLB miss event), GuestKM will invoke `do_mmap()` with the protection flag `PROT_NONE` to set the original safe area to be a trap area. For multi-threaded programs, when the execution of a thread triggers a randomization (not triggered by the TLB miss event), the safe areas of all threads need to be randomized. To ensure the correctness, GuestKM needs to block all threads before randomizing all (or *thread-shared*) safe areas.

Although all safe areas used in existing defenses in Table 1 are *position-independent*, we do not rule out the possibility that future defenses may store some *position-dependent* data in the safe area. However, as any data related to an absolute address can be converted to the form of a base address with an offset, they can be made position independent. Therefore, after randomizing all safe areas, SafeHidden just needs to modify the values of the dedicated registers to point to the new locations of the safe areas.

**Loading TLB entries under KPTI.** The kernel page table isolation (KPTI) feature [1] was introduced into the mainstream Linux kernels to mitigate the Meltdown attack [32]. For each process, it splits the page table into a user-mode page table and a kernel-mode page table (as shown in Figure 5). The kernel-mode page table includes both kernel-space and user-space addresses, but it is only used when the system is running in the kernel mode. The user-mode page table used in the user mode contains all user-space address mappings and a minimal set of kernel-space mappings for serving system calls, handling interrupts and exceptions. Whenever entering or exiting the kernel mode, the kernel needs to switch between the two page tables by setting the CR3 register. To accelerate the page table switching, the roots of the page tables (i.e., PGD kernel and PGD user in Figure 5) are placed skillfully in the physical memory so that the kernel only needs to set or clear the bit 12 of CR3.

Moreover, to avoid flushing TLB entries when switching page tables, the kernel leverages the Process Context Identifier (PCID) feature [2]. When PCID is enabled, the first 12 bits (bit 0 to bit 11) of the CR3 register represents the PCID of the process which is used by the processor to identify the

owner of a TLB entry. The kernel assigns different PCIDs to the user and kernel modes (i.e., kPCID and uPCID in the figure). When entering or exiting the kernel mode, the kernel needs to switch between kPCID and uPCID. To accelerate this procedure, kPCID and uPCID of the same process only differ in one bit. Therefore, the kernel only needs to set or clear the bit 11 of CR3.

```

1 // .S file
2 .globl asm_load_pte_irqs_off
3 .align 0x1000
4 asm_load_pte_irqs_off:

20  btc 11, %r11 // clear uPCID bit
21  mov %r11, %cr3 //set CR3
22  retq //return uPCID
23 // .c file
24 void load_pte_into_TLB(unsigned long addr) {
25     unsigned long flags, uPCID;
26     // disable preemption and interrupts
27     get_cpu(); local_irq_save(flags);
28     uPCID = asm_load_pte_irqs_off(addr);
29     // flush the TLB entries for a given pcid and addr
30     invpcid_flush_one(uPCID, asm_load_pte_irqs_off);
31     // enable preemption and interrupts
32     local_irq_restore(flags); put_cpu();
33 }

```

Listing 1: The code snippet to load the TLB entries under KPTI.

As mentioned in Section 4.3, SafeHidden needs to load PTEs of the safe areas into the TLB every time it randomizes the safe areas. However, it is challenging to make SafeHidden compatible with KPTI. This is because SafeHidden only runs in the kernel mode—it uses the kernel-mode page table with kPCID, but the TLB entries of the safe areas must be loaded from the user-mode page table using uPCID.

An intuitive solution is to map SafeHidden into the kernel space portion of the user-mode page tables. Then the PTE loading is performed with uPCID. However, this method introduces more pages into the user-mode page tables and thus increases the attack surface of the Meltdown attack.

We propose the following alternative solution: SafeHidden still runs in the kernel mode using the kernel-mode page table. Before loading the TLB entries of the safe areas, it switches from kPCID to uPCID temporarily. Then without switching to the user-mode page table, it accesses the safe area pages to load the target PTEs into the TLB with uPCID.

There is no need to switch to the user-mode page table for two reasons: (1) TLB entries are only tagged with PCIDs and virtual addresses; (2) the user-space addresses are also mapped in the kernel-mode page table. After the PTE loading, SafeHidden switches back to kPCID and then flushes the TLBs of the instruction/data pages related to the loading operation. This is to avoid these TLB entries (tagged with uPCID) to be exploited by the Meltdown attack.

Listing 1 illustrates the details of how to load user PTEs into the TLB from the kernel mode code under KPTI. Line 24 shows the function definition of this loading operation. Line 27 disables interrupts and preemptions to avoid unintended context switches. Line 28 invokes the assembly code for the loading operation. Line 6 reads the current CR3 register which contains the root of the kernel-mode page table and the kPCID. Line 8-10 switch to use uPCID (but keeping the kernel-mode page table unchanged). Line 8 sets the *noflush* bit to avoid flushing the target PCID’s TLB entries when setting the CR3 register. Line 12 enables data access to user pages by disabling SMAP temporarily. Line 13-14 load the target PTE into TLB with uPCID by reading a byte from this page. Line 16-21 switch back to kPCID. Because line 12-21 code runs under the kernel-mode page table with uPCID, this code page mapping will be loaded into the TLB that can be accessed by user-mode code later. This page content could be leaked from the malicious process using the Meltdown attack. So line 30 flushes the mapping from the TLB.

**Reloading TLB entries after randomization.** SafeHidden uses Intel TSX to test which PTEs of the safe areas are loaded in the TLB. The implementation is very similar to the method of loading the user-mode TLB entries. The only difference is that SafeHidden encloses the code of line 13 (Listing 1) into a transaction (between *xbegin* and *xend* instructions). In fact, not all PTEs of the safe area need to be tested. SafeHidden only tests the PTEs that were reloaded in the last re-randomization.

**Tracking GPT updates.** The GPT entries of safe areas will be updated dynamically. In order to track such updates efficiently, we choose to integrate the Linux MMU notifier *mmu\_notifier\_register* in GuestKM. The MMU notifier provides a collection of callback functions to notify two kinds of page table updates: invalidation of a physical page and migration of a physical page. But it does not issue a callback when OS maps a physical page to a virtual page. To address this problem, we handle it in a lazy way by intercepting the *page fault exception* to track this update. Once GuestKM is notified about these updates, GuestKM makes the modified entry invalid or valid, and then issues a *hypercall* to notify the hypervisor to synchronize all EPTs.

**Creating and destructing thread-private EPT.** If a thread has no *thread-local* safe area, it shares its parent’s EPT. If it is the main thread, it will be configured to use the default EPT. If a thread has a *thread-local* safe area, GuestKM will

issue a *hypercall* to notify the hypervisor to initialize an EPT for this thread. When initializing an EPT, SafeHidden will configure the entries based on other threads' local safe areas by walking the GPT to find all physical pages in the safe areas. Meanwhile, SafeHidden will also modify the entries of other thread's EPT to make all *thread-local* safe areas isolated from each other. Whenever SafeHidden changes other thread's EPT, it will block the other threads first. GuestKM also intercepts the `exit()` system call to monitor a thread's destruction. Once a thread with a private EPT is killed, GuestKM notifies the hypervisor to recycle its EPT.

**Monitoring context switches.** When a thread is switched out, GuestKM will be notified through the `sched_out()` and it will switch to the default EPT assigned to the corresponding VCPU. When GuestKM knows a new thread is switched in through the `sched_in()`, it will check whether the thread has a private EPT or not, and switches to its EPT in if it does.

**Monitoring illegal accesses.** GuestKM intercepts all system calls in Table 2 and checks their access areas by analyzing their arguments. If there is an overlap between their access areas with any of the trap areas, the safe areas, or the shielded areas, GuestKM will trigger a security alarm. Because there is no physical memory allocated to the trap areas, any memory access to those areas will be captured by intercepting the *page fault exception*. With the isolation of the *thread-local* safe area, any memory access to the shielded areas will trigger an *EPT violation exception*, which will be captured by the hypervisor (that notifies GuestKM). GuestKM triggers a security alarm in cases of any of these events.

**Handling security alarms.** How these security alarms are handled depends on the applications. For example, when SafeHidden is applied in browsers to prevent exploitation using JS code, it could mark the website from which the JS code is downloaded as malicious and prevent the users from visiting the websites. When SafeHidden is used to protect web servers, alarms can be integrated with application firewalls to block the intrusion attempts.

## 6 Evaluation

We implemented SafeHidden on Ubuntu 18.04 (Kernel 4.20.3 with KPTI enabled by default) that runs on a 3.4GHZ Intel(R) Core(TM) i7-6700 CPU with 4 cores and 16GB RAM. To evaluate the security and performance of SafeHidden, we implemented by ourselves two defenses that use safe areas, *OCFI* and *SS*. *OCFI* is a prototype implementation of O-CFI [40], which uses *thread-shared* safe areas (Table 1). *OCFI* first randomizes the locations of all basic blocks and then instruments all indirect control transfer instructions that access the safe areas, i.e., indirect calls, indirect jumps, and returns. Each indirect control transfer instruction has an entry in the safe areas, which contains the boundaries of possible targets. For each instrumented instruction, *OCFI* obtains

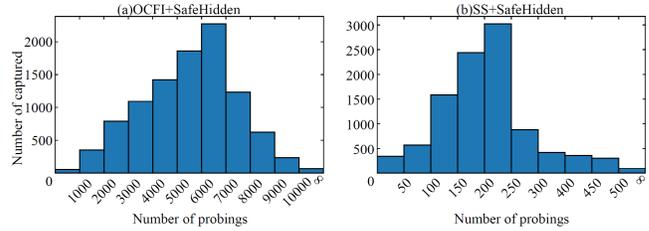

Figure 6: The distribution of probing times before being captured (10,000 probes launched).

its jump target and checks if it is within the legal range.

*SS* is our implementation of a shadow stack, which is an example of the *thread-local* safe areas (see Table 1). Shadow stacks are used in Safe Stack [30], ASLR-Guard [36], and RERANZ [57]. *SS* adopts a compact shadow stack scheme [41] (in contrast to a parallel shadow stack scheme). In our implementation, the pointer (i.e., offset) to the stack top is stored at the bottom of the shadow stack. To be compatible with uninstrumented libraries, *SS* instruments function prologues and epilogues to access the shadow stacks (i.e., the safe areas). Listing 2 shows the function prologue for operating shadow stacks. The epilogue is similar but in an inverse order. The epilogue additionally checks if the return address has been modified.

In both cases, the size of the safe area is set to be 8 MB. To use SafeHidden with *SS* and *OCFI*, one only needs to specify in SafeHidden that the `%gs` register points to the safe areas. No other changes are needed.

```

1 mov(%rsp), %rax //get the return address
2 mov %gs:0x0, %r10 //get the shadow stack (ss) pointer
3 mov %rax, %gs:(%r10) //push the return address into ss
4 mov %rsp, %gs:0x8(%r10) //push the stack frame into ss
5 add $0x10, %gs:0x0 //increment the shadow stack pointer

```

Listing 2: The shadow stack prologue.

## 6.1 Security Evaluation

We evaluated SafeHidden in four experiments. Each experiment evaluates its defense against one attack vector.

In the first experiment, we emulated an attack that uses the *allocation oracles* [43] to probe *Firefox* browsers under *OCFI*'s protection. The prerequisite of this attack is the ability to accurately gauge the size of the unmapped areas around the safe areas. To emulate this attack, we inserted a shared library into *Firefox* to gauge the size of the unmapped areas. When SafeHidden is not deployed, the attack can quickly locate the safe area with only 104 attempts. Then we performed 10,000 trials of this attack on *Firefox* protected by *OCFI* and SafeHidden. The result shows that all the 10,000 trials failed, but in two different scenarios: In the first scenario (9,217 out of 10,000 trials), the attacks failed to gauge the size of the unmapped areas even when the powerful binary search method is used. The prerequisite of a

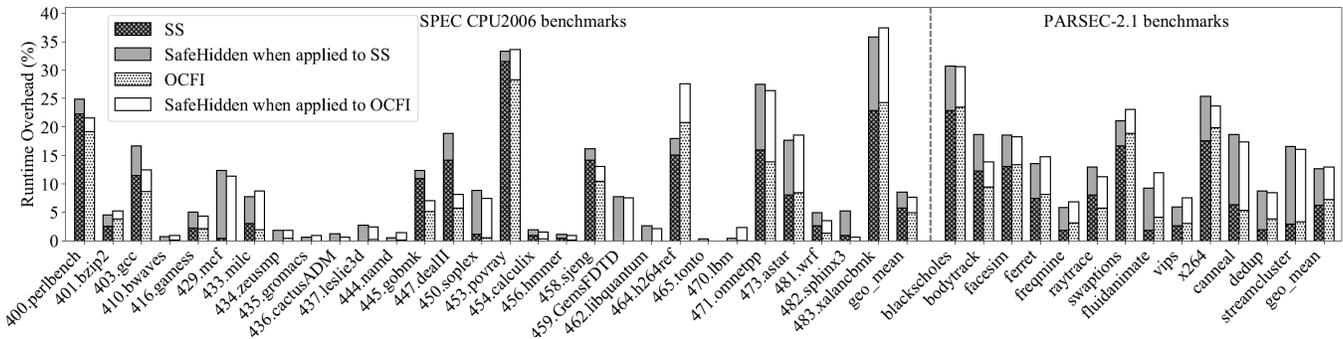

Figure 7: Performance overhead of SPEC and Parsec-2.1 benchmarks brought by SafeHidden when applied to the SS and OCFI defenses.

binary search is that the location of the target object does not change. However, SafeHidden’s re-randomization confuses the binary search because the safe area moves continuously. In the second scenario, even though the attacks can gauge the exact size of an unmapped area, they always stumble into one of the trap areas when accessing the surroundings of the unmapped area, which triggers security alarms.

In the second experiment, we launched 10,000 trials of CROP attacks [19] to probe a *Firefox* protected by *OCFI*. The result shows that the attacks always successfully identified the location of the safe area when SafeHidden is not deployed. The time required is less than 17 minutes with no more than 81,472,151 probes. However, the attacks always fail when SafeHidden is deployed. Figure 6 (a) shows the distribution of the number of probes before an attack is detected by hitting a trap area. We can see that the distribution is concentrated in the range between [2000, 9000]. This experiment shows that SafeHidden can prevent the continuous probing attacks effectively.

In the third experiment, we launched 10,000 trials of the CROP attack using thread spraying to probe *Firefox* protected by *SS*. We sprayed  $2^{14}$  (=16,384) threads with more than 16,384 *thread-local* safe areas, and then scanned the *Firefox* process with a CROP attack. The result shows that when SafeHidden is not deployed, the attacks can probe the locations of the safe areas successfully. The time taken is 0.16s, with only 2,310 probes. With SafeHidden deployed, all probes are captured before succeeding. Figure 6 (b) shows the distribution of the number of probes before being captured. The distribution is concentrated in the range between [50, 300], which is much lower than those in the second experiment. There are two reasons for that: 1) The other threads’ local safe areas become the current thread’s *shielded areas*, which increases the probability of the probes being captured; 2) All safe areas will be randomized after each probe, which increases the number of trap areas quickly.

In the fourth experiment, we emulated a cache side-channel attack against page tables using Revanc [54], which is a tool based on [46]. This tool allocates a memory buffer and then measures the access time of different pages in this buffer repeatedly. It could infer the base address of this

buffer. To utilize this attack method against IH, we kept this memory buffer in a safe area by modifying the source code to force any access to this memory buffer through an offset from the `%gs` register. When SafeHidden is not deployed, this attack can obtain the correct base address of this buffer. The attack fails when SafeHidden is deployed.

## 6.2 Performance Evaluation

We evaluated SafeHidden’s impact on the application’s performance in terms of CPU computation, network I/O, and disk I/O, respectively. For the experiment of CPU computation, we ran SPEC CPU2006 benchmarks with *ref* input and multi-threaded Parsec-2.1 benchmarks using *native* input with 8 threads; For the experiment of network I/O, we chose the Apache web server `httpd-2.4.38` and `Nginx-1.14.2` web server. Apache was configured to work in *mpm-worker* mode, running in one worker process with 8 threads. Nginx was configured to work with 4 worker processes; For the experiment of disk I/O, we chose benchmark tool `Bonnie++` (version 1.03e). For each benchmark, we prepared two versions of the benchmark: (1) protected by *SS*, and (2) protected by *OCFI*. We evaluated both the performance overhead of protecting these benchmarks using *SS* and *OCFI* defenses and the additional overhead of deploying SafeHidden to enhance the *SS* and *OCFI* defenses.

### 6.2.1 CPU Intensive Performance Evaluation

Figure 7 shows the performance overhead of the *OCFI* and *SS* defenses, and also the performance overhead of SafeHidden when applied to enhance the *OCFI* and *SS* defenses. For SPEC benchmarks, we can see that the geometric mean performance overhead incurred by *OCFI* and *SS* is 4.94% and 5.79%, respectively. For Parsec benchmarks, the geometric mean performance overhead incurred by *OCFI* and *SS* is 7.23% and 6.24%. The overhead of some applications (e.g., *perlbench*, *povray*, *Xalancbmk* and *blackscholes*) is higher because these applications frequently execute direct function calls and indirect control transfer instructions, which trigger accesses to safe areas. Note these overheads were caused by

Table 3: Statistical data of SafeHidden when applied to the SS and OCFI defenses to protect SPEC CPU2006 and Parsec-2.1 benchmarks.

the adoption of *OCFI* and *SS*, but not SafeHidden.

For SPEC benchmarks, we can see that the geometric mean performance overhead incurred by SafeHidden when protecting *OCFI* and *SS* is 2.75% and 2.76%, respectively. For Parsec benchmarks, the geometric mean performance overhead incurred by SafeHidden is 5.78% and 6.44%, respectively. It shows that SafeHidden is very efficient in protecting safe areas. Based on the experimental results, we can also see that SafeHidden is more efficient in protecting single-threaded applications. This is due to two reasons: (1) All threads need to be blocked when randomizing the *thread-shared* safe areas or the *thread-local* safe areas (when not triggered by a TLB miss); (2) When protecting the *thread-local* safe areas, SafeHidden needs to synchronize the *thread-private* EPTs with the guest page table, which could introduce VM-Exit events.

Table 3 details some statistical data of SafeHidden when applied to the *OCFI* and *SS* defenses to protect SPEC and Parsec benchmarks. The column “#randomization” shows the number of re-randomization to safe areas. On SPEC and Parsec benchmarks, there are three operations that can trigger a re-randomization: (1) Using `brk()` to move the top of the heap; (2) Using `mmap()` to allocate a memory chunk; (3) TLB misses occurred in safe areas. Because *OCFI* and *SS* did not introduce extra invocation of system calls, the numbers of `brk()` and `mmap()` are the same. Combined with Figure 7, we can see that for most of SPEC benchmarks (except *mcf*, *soplex*, *GemsFDTD* and *omnetpp*), the performance overhead is related to the total number of re-randomization. The reason why those four benchmarks had different performance overhead is the virtualization overhead incurred

by the hypervisor. For example, the hypervisor introduced 7.18% performance overhead for *GemsFDTD*. Except *x264* using *SS*, *canneal* and *streamcluster*, the overhead of most Parsec benchmarks is also related to the total number of re-randomization. For *canneal* and *streamcluster*, most of performance overhead is introduced by the virtualization. For *x264*, it spawns child threads more frequently than other benchmarks, which causes SafeHidden to frequently create and initialize *thread-private* EPTs.

## 6.2.2 Network I/O Performance Evaluation

Figure 8 shows the performance degradation of Apache and Nginx servers under the protection of *SS* and *OCFI* with and without SafeHidden. We use *ApacheBench* (*ab*) to simulate 100 concurrent clients constantly sending 10,000 requests, each request asks the server to transfer a file. We also varied the size of the requested file, i.e., {1K, 5K, 20K, 100K, 200K, 500K}, to represent different configurations. From the figure, we can see that *SS* only incurs 1.60% and 1.98% overhead on average when protecting Apache and Nginx. *OCFI* only incurs 1.45% and 2.13% overhead on average when protecting Apache and Nginx. We can also see that SafeHidden incurs 12.18% and 12.07% on average when applied to *SS* and *OCFI* to protect Apache. But SafeHidden incurs only 5.51% and 5.35% on average when applied to *SS* and *OCFI* to protect Nginx. So SafeHidden is more efficient in protecting Nginx than Apache. This is due to two reasons: (1) For each request to Nginx, Nginx will invoke several I/O system calls, such as `recvfrom()`, `write()`, `writew()`, etc., which only access the allocated memory space in the

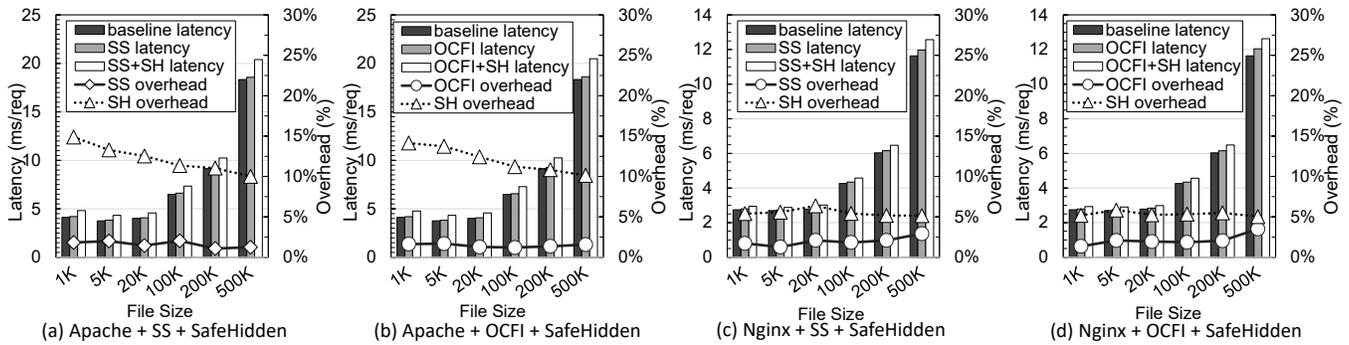

Figure 8: Network I/O Performance overhead brought by SafeHidden (short for SH) when applied to the SS and OCFI defenses.

Ngix process. The system calls in Ngix will not trigger randomization of the safe area. But for each request to Apache, Apache will invoke the `mmap()` system call to map the requested file into the virtual memory space which could trigger the extra randomization of all safe areas compared with Ngix; (2) Apache is a multi-threaded program. SafeHidden needs to block all threads when performing randomization of safe areas triggered by the `mmap()` system call.

### 6.2.3 Disk I/O Performance Evaluation

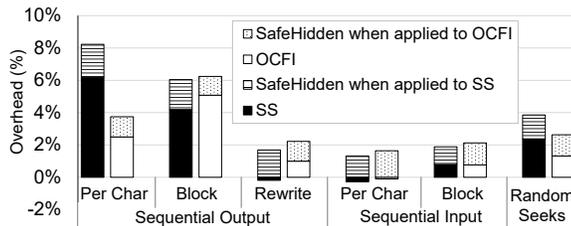

Figure 9: Disk I/O Performance overhead brought by SafeHidden when applied to the SS and OCFI defenses.

The Bonnie++ sequentially reads/writes data from/to a particular file in different ways. The read/write granularity varies from a character to a block (i.e., 8192 Bytes). Furthermore, we also test the time cost of the random seeking. Figure 9 shows the disk I/O measurement results: *SS* and *OCFI* defenses incur low performance overhead, i.e., 2.18% overhead on average for *SS* and 1.76% overhead on average for *OCFI*. SafeHidden brings only 1.58% overhead on average for *SS* and 3.08% overhead on average for *OCFI*. Compared with SPEC and Parsec benchmarks, this tool invokes the `write()` and `read()` system calls to write and read a very large file frequently. But these system calls only access the allocated memory space that does not trigger randomization of safe areas.

## 7 Discussion

**TLBleed attack.** TLBleed [21] exploits the shared TLBs between the hyper-threads on the same core to infer vic-

tim programs' memory access patterns. Potentially, it could be used to reduce the entropy of ASLR by triggering TLB misses and observing into which TLB set the target object is mapped. When TLBleed is used against SafeHidden, by triggering only L1 DTLB misses without L2 TLB misses, TLBleed may reduce the entropy of the safe area location by 4 bits (in the case of a 16-set L1 DTLB), which leads to roughly 20 bits entropy remaining for 8 MB safe area. However, attempts to further reduce the entropy will trigger re-randomization of safe areas with high probability. So, TLBleed is not able to defeat SafeHidden.

**Spectre attack.** The Spectre attack [28] leverages speculative execution and side-channels to read the restricted virtual memory space. As the memory protection related exceptions are suppressed in the speculatively executed code, SafeHidden could not detect Spectre attacks.

**Resilience to attacks.** SafeHidden is resilient to all known attacks against safe areas. Variants of existing attacks would also be prevented: (1) The attacker may try to fill up the address space quickly by using the *persistent allocation oracle* [43] to avoid SafeHidden from creating too many trap areas. But as SafeHidden sets an upper limit for the total mapped memory regions, such attacks are prevented; (2) The attacker could exploit the *paging-structure caches* to conduct the side-channel analysis. However such attacks will also trigger TLB misses, which will be detected by SafeHidden. Although it is difficult to prove SafeHidden has eliminated all potential threats, we believe it has considerably raised the cost of attacks in this arms race.

**The impact of NMI on the solution of integrating KPTI.** During the execution of the assembly code in listing 1, the interrupts are disabled to avoid unintended context switches. But the non-maskable interrupt (NMI) could break this protection. If a NMI occurs when the code is running, the NMI handler will run on the kernel-mode page table with the uPCID. So the memory pages accessed in the NMI handler could be leaked via the Meltdown attack. To avoid this, the entry of the NMI handler could be instrumented (by rewriting the NMI entry in IDT) to switch back to the kPCID.

## 8 Related Work

**Protecting safe areas.** MemSentry [29], IMIX [16], MicroStache [39], and ERIM [52] are the closest to our work. MemSentry adopts a *software-fault isolation* (SFI) approach to protecting frequently accessed safe areas by leveraging Intel’s memory protection extensions (MPX) technology. It restricts the addresses of all memory accesses that can not access the safe area. But it is still not practical because it significantly increases the performance overhead [16]. The main disadvantage of MemSentry is the SFI approach is not safe, i.e., un-instrumented instructions can still access the safe region [16]. By modifying the Intel’s simulation, IMIX extends the x86 ISA with a new memory-access permission to mark safe areas as security sensitive and allows accesses to safe areas only using a newly introduced instruction. Similarly, MicroStache achieves it by modifying the Gem5 simulator. However, IMIX and MicroStache are not yet supported by commodity hardware. ERIM protects safe areas by turning on access permission only when accesses are requested. To quickly switch the access permission on and off, it adopts the newly released Intel hardware feature memory protection keys (MPK) [2]. But it is still not suitable to protect the frequently accessed safe areas. For example, it incurs >1X performance overhead when protecting the shadow stack [29]. Different from SafeHidden, all these methods require modification of the source code of both the defense and the protected applications. Please note that most defenses listed in Table 1 (except two) work on COTS binaries. In particular, Shuffler [59] mentioned that defeats probing attacks by moving the location of its code pointer table (i.e., the safe area) continuously. But this method only blocks attacks from **Vector-1**. For example, using **Vector-2**, persistent attacks could always succeed. Different from Shuffler, SafeHidden blocks all existing attack vectors against IH.

**Protecting CFI metadata.** CFI is an important defense against code reuse attacks [3]. A CFI mechanism stores control-flow restrictions in its metadata. Like other types of safe areas, the metadata of CFI mechanisms needs to be protected. However, many CFI metadata only needs write protection without concerning about its secrecy. Therefore, these CFI mechanisms do not need IH. In contrast, some CFI metadata is writable, as it needs to be dynamically updated [8, 41, 42, 37], and others need to be kept as secrets [40, 61, 53, 60]. These CFI mechanisms must protect their metadata either by memory isolation [8, 53, 42, 41, 37] or IH [40, 60, 61]. SafeHidden can be applied to improve the security of IH for these CFI mechanisms.

**Intra-process isolation.** SFI is commonly used to restrict intra-process memory accesses [55]. However, both software-only and hardware-assisted SFIs incur high performance overhead [20, 43]. SeCage uses double-EPT to protect sensitive data, e.g., the session key and the private key

[34]. Shreds [11] utilizes the domain-based isolation support provided by the ARM platform to protect the thread-sensitive data. Intel software guard extension (SGX) [2] protects the sensitive data using a secure enclave inside the application which cannot be accessed by any code outside the enclave. However, none of the approaches mentioned above can be used to protect frequently accessed safe areas because of their high switching overhead.

**Tracking TLB misses.** Intel performance monitoring units (PMU) [2] can be used to profile the TLB miss, but it is not precise enough. In contrast, setting reserved bits in PTE can help to track the TLB miss precisely. Some works had used this feature for performance optimization [17, 6, 5]. SafeHidden extends this method to detect side-channel attacks against the safe areas, which is the first time to our best knowledge such a feature is used in security.

**Trap areas as security defenses.** Booby-traps [12] first proposes to defeat code reuse attacks by inserting the trap gadgets in applications. CodeArmor [10] inserts the trap gadgets into the virtual (original loaded) code space. To protect the secret table’s content against probing attacks, Readactor++ [14] inserts trap entries into the PLT and vtable, and Shuffler [59] inserts the trap entries into its code pointer table. To defeat the JIT-ROP [49] attacks, Heisenbyte [51] and NEAR [58] propose to trap the code after being read. Different from these works, SafeHidden uses the trap to capture the probing attacks against IH.

**TSX for Security.** The TSX is proposed to improve the performance of multi-threaded programs, but many studies have utilized TSX to improve system security. For example, Mimoso [23] uses TSX to protect private keys from memory disclosure attacks. TxIntro leverages the strong atomicity to ensure consistent and concurrent virtual machine introspection (VMI) [33]. In addition, TSX has been used to perform or detect the side-channel attacks against the Kernel ASLR [27] or the enclave in SGX [48, 9]. Different from these works, SafeHidden uses the TSX to identify TLB entries.

**EPT for Security.** The EPT has been used to isolate VMs [26], to protect processes from the malicious OS and/or other processes [18, 50, 24], and to protect sensitive code/data within a process [34]. The EPT also supports more restrict memory permission check (i.e., the execute-only permission), which has been used to prevent the JIT-ROP [49] attacks [51, 13, 58]. Different from prior works, SafeHidden uses the EPT to achieve the *thread-private* memory.

## 9 Conclusion

This paper presented a new IH technique, called SafeHidden, which is transparent to existing defenses. It re-randomizes the locations of safe areas at runtime to prevent attackers from persistently probing and inferring the memory layout to

locate the safe areas. A new *thread-private* memory mechanism is proposed to isolate the *thread-local* safe areas and prevent the adversaries from reducing the randomization entropy via thread spraying. It also randomizes the safe areas after the TLB miss event to prevent the cache-based side-channel attacks. The experimental results show that our prototype not only prevents all existing attacks successfully but also incurs low performance overhead.

## Acknowledgments

We are grateful to our shepherd Mathias Payer for guiding us in the final version of this paper. We would like to thank the anonymous reviewers for their insightful suggestions and comments. ## Abstract

AMD’s Secure Encrypted Virtualization (SEV) is an emerging technology to secure virtual machines (VM) even in the presence of malicious hypervisors. However, the lack of trust in the privileged software also introduces an assortment of new attack vectors to SEV-enabled VMs that were mostly unexplored in the literature. This paper studies the insecurity of SEV from the perspective of the unprotected I/O operations in the SEV-enabled VMs. The results are alerting: not only have we discovered attacks that breach the confidentiality and integrity of these I/O operations—which we find very difficult to mitigate by existing approaches—but more significantly we demonstrate the construction of two attack primitives against SEV’s memory encryption schemes, namely a memory decryption oracle and a memory encryption oracle, which enables an adversary to decrypt and encrypt arbitrary messages using the memory encryption keys of the VMs. We evaluate the proposed attacks and discuss potential solutions to the underlying problems.

## 1 Introduction

Secure Encrypted Virtualization (SEV) is an emerging processor feature available in recent AMD processors that encrypts the entire memory of virtual machines (VM) transparently. Memory encryption is performed by a hardware memory encryption engine (MEE) embedded in the memory controller that encrypts memory traffic on the fly, with a key unique to each of the VMs. As the encryption keys are generated from random sources at the time of VM launches and are securely protected inside the secure processor in their lifetime, privileged software, including the hypervisor, is not able to extract the keys and use them to decrypt the VMs’ memory content. Therefore, SEV enables a stronger threat model, where the hypervisor is removed from the trusted computing base (TCB). It is explicitly stated in AMD’s SEV whitepaper [20] that “SEV technology is built around a threat model where an attacker is assumed to have access to not only execute user level

privileged code on the target machine, but can potentially execute malware at the higher privileged hypervisor level as well.” Hence, SEV provides a trusted execution environment (TEE) for (mostly) unmodified VMs to perform confidential computation that is shielded from strong adversaries that control the entire privileged software stack.

The lack of trust in the hypervisor, unfortunately, increases considerably the attack surface that a VM has to guard against. As the hypervisor controls the VMs’ access to hardware resources including CPU, physical memory, I/O devices, the VM’s CPU scheduling, memory management, and I/O operations must be mediated by untrusted software. As a result, new attack vectors have emerged as researchers explore the security properties of this new hardware feature. For instance, Hetzelt and Buhren [17] demonstrated attacks against SEV-enabled VMs by exploiting unencrypted virtual machine control block (VMCB) at the time of `VMExit`. They show that a malicious hypervisor may learn the machine state of the guest VM by reading register values stored in the VMCB and alter these register values before returning to the VM. The lack of integrity of the encrypted memory has been identified by several prior studies [9, 12, 17, 25], which enables a malicious hypervisor to perform a variety of attacks.

This paper studies a previously unexplored problem under SEV’s trust model—the unprotected I/O operations of SEV-enabled VMs. While the entire memory of the VMs can be encrypted using keys that are not known to the hypervisor, direct memory access (DMA) from the virtualized I/O devices must operate on *unencrypted memory* or *memory shared with the hypervisor*. As a result, neither the confidentiality nor the integrity of the I/O operations can be guaranteed under SEV’s trust models.

More importantly, this paper goes beyond the investigation of I/O insecurity itself. In particular, we further demonstrate that these unprotected I/O operations can be leveraged by the adversary to construct (1) an encryption oracle to encrypt arbitrary memory blocks using the guest VM’s memory encryption key, and (2) a decryption oracle to decrypt any memory pages of the guest. We demonstrate in the paper that these

two powerful attack primitives can be constructed in a very stealthy manner—the oracles can be queried by the adversary repeatedly and frequently without crashing the attacked VMs.

In addition, as a by-product of the study, this paper also reveals a severe side-channel vulnerability of SEV: As the adversary is able to manipulate the nested page tables, it could alter the `present` bit or `reserve` bit of the nested page table entries to force guest VM's memory accesses to the corresponding pages to trigger page faults. While this page-fault side channel has been previously studied in the context of Intel SGX [36] and even used in previous attacks against SEV [17], it is also reported that page faults from SEV-enabled guest VMs leak the entire faulting addresses (and error code) to the hypervisor (unlike in SGX where the page offset is masked). This fine-grained page-fault attack enables fine-grained tracing of the encrypted VM's memory access patterns, and particularly in this paper is used to facilitate the construction of the memory decryption oracle.

**Contribution.** This paper contributes to the study of TEE security in the following aspects:

- The paper studies a previously unexplored security issue of AMD SEV—the unprotected I/O operations of SEV-enabled guest VMs. The root cause of the problem is the incompatibility between AMD-V's I/O virtualization with SEV's memory encryption scheme.
- The paper demonstrates that the unprotected I/O operations could also be exploited to construct powerful attack primitives, enabling the adversary to perform arbitrary memory encryption and decryption.
- The paper reports the lack of page-offset masking of the faulting addresses during SEV's page faults handling, which leads to fine-grained side-channel leakage. The paper also demonstrates the use of both fine-grained and coarse-grained side channels in its I/O attacks.
- The paper empirically evaluates the fidelity of the attacks and discusses both hardware and software approaches to mitigating the I/O security issues.

**Responsible disclosure.** We have reported our findings to AMD and disclosed the technical details with AMD researchers. While we were confirmed that the presented attacks work on current release of SEV processors, AMD researchers suggested future generations of SEV chipsets are likely to be immune from these attacks. Some of the technical feedback we obtained from AMD has been integrated into the paper.

**Roadmap.** Section 2 presents the overview of AMD's SEV and explains the root causes of the exploited I/O operations in this paper. Section 3 describes several attacks exploiting the unprotected I/Os. Section 4 presents an evaluation of the fidelity of the attacks. Section 5 discusses potential solutions to securing SEV's I/O operations. Section 6 summarizes related work and Section 7 concludes the paper.

## 2 Overview of AMD SEV

### 2.1 Overview

AMD Secure Encrypted Virtualization (SEV) is a security extension for AMD Virtualization (AMD-V) architecture [2]. AMD-V is designed as a virtualization substrate for cloud computing services, which allows one physical server to run multiple isolated guest virtual machines (VM) concurrently. AMD's SEV is designed atop its Secure Memory Encryption (SME) technology.

**Secure Memory Encryption.** SME [20] is AMD's technology for real-time memory encryption, which aims at providing strong protection against memory snooping and cold boot attacks. An Advanced Encryption Standard (AES) engine is embedded in the on-die memory controller that encrypts/decrypts memory traffic when it is transferred out of or into the processor. A single ephemeral encryption key is generated for the entire machine from a random source every time system resets. The key is managed by a 32-bit ARM Cortex-A5 Secure Processor (AMD-SP). When SME is enabled, physical address bit 47 (also called the *C-bit*) in the page table entry (PTE) is used to mark whether the memory page is encrypted, thus enabling page-granularity encryption. Transparent SME, or TSME, is a mode of operating of SME, which allows encryption of the entire memory regardless of the C-bit. Thus TSME allows unmodified operating system to use the memory encryption technology.

**Secure Encrypted Virtualization.** AMD's SEV combines the AMD-V architecture and the SME technology to support encrypted virtual machines [20]. SEV aims to protect the security of guest VMs even in the presence of a malicious hypervisor, by using two isolation techniques: First, the data of guest VMs inside the processor is protected by an access control mechanism using Address Space Identifier (ASID). Specifically, the data in the CPU cache is tagged with ASID of each VM; thus it is prevented from being accessed by other VMs or the hypervisor. Second, the guest VM's data outside the processor (*e.g.*, in the DRAM) is protected via memory encryption. Rather than using a single AES key for the whole machine as in the case of SME, SEV allows each VM to use a distinct ephemeral key, thus preventing the hypervisor from reading the encrypted memory of each VM. Because memory encryption keys are managed by the secure co-processor, privileged software layers are not allowed to access or manipulate these keys.

Beside confidentiality, authenticity of the platform and integrity of the guest VMs are also provided by SEV. An identification key embedded in the firmware is signed by both AMD and the owner of the machine to demonstrate that the platform is an authentic AMD platform with SEV capabilities, which is administered by the machine owner. The initial contents of memory, along with a set of metadata of the VM, can be signed by the firmware so that the users of the guest VMs

Table 1: Effects of C-bits in guest page tables (gPT) and nested page tables (nPT).  $M$  is the plaintext;  $E_k()$  is the encryption function under a memory encryption key  $k$ ;  $k_g$  and  $k_h$  represent the guest VM and the hypervisor’s memory encryption keys, respectively.

gPT	nPT	
	C-bit=0	C-bit=1
C-bit=0	$M$	$E_{k_h}(M)$
C-bit=1	$E_{k_g}(M)$	$E_{k_g}(M)$

may verify the identity and the initial states of the launched VMs through remote attestation.

## 2.2 Memory Encryption

**ASID and memory encryption.** The encryption keys used for memory encryption are generated from random sources when the VMs are launched. They are securely stored inside the secure processor for their entire life-cycle. Each VM has its own unique memory encryption key  $K_{vek}$ , which is indexed by the ASID of the VM. When the VM accesses a memory page that is mapped to its address space with its C-bit set, the memory will be first decrypted using the VM’s  $K_{vek}$  before loaded into the CPU caches. Data in the caches are stored in plaintext; each cache line, in addition to the regular cache tags, is also tagged by the ASID of the VM. As such, the same physical memory may have multiple copies cached in the hardware caches. AMD does not maintain the consistency of the cache copies with different ASID tags [20].

**Encryption with nested paging.** AMD-V utilizes nested paging structures [1] to facilitate memory isolation between guest VMs. When the virtual address used by the guest VM (gVA) is to be translated into physical address, it is first translated into a guest physical addressing (gPA) using the guest page table (gPT), and the gPA is then translated into the host physical address (hPA) using the nested page table (nPT). While gPT is located in guest VM’s address space, nPT is controlled directly by the host.

With AMD’s SME technology, bit 47 of a PTE is called the *C-bit*, which is used to indicate whether or not the corresponding page is encrypted. When the C-bit of a page is set (*i.e.*, 1), the page is encrypted. As both the gPT and the nPT has C-bits, the encryption state of a page is controlled by the combination of the two C-bits in its PTEs in the gPT and nPT. The effect of C-bits in the gPT and nPT is shown in Table 1. To summarize, whenever the C-bit of gPT is set to 1, the memory page is encrypted with the guest VM’s encryption key  $k_g$ ; when the C-bit of gPT is cleared, the C-bit of nPT determines the encryption state of the page: the page is encrypted under the hypervisor’s key  $k_h$  when C-bit is 1; otherwise the page is not encrypted.

To share memory pages between a guest VM and the hypervisor while preventing physical attacks, it is required to

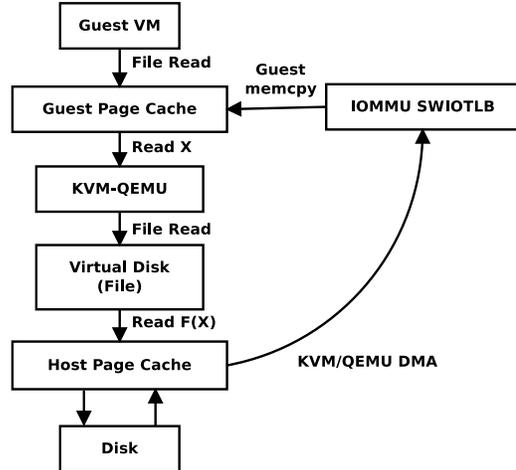

Figure 1: An example of a disk I/O operation by an SEV-enabled VM.

have the memory page’s C-bit set to 0 in its gPT and the C-bit set to 1 in its nPT, so that the page is encrypted under the hypervisor’s encryption key.

**Encryption modes of operation.** SEV uses AES as its encryption algorithm. The memory encryption engine encrypts data with a 128-bit key using the Electronic Codebook (ECB) mode of operation [12]. Therefore, each 16-byte aligned memory block is encrypted independently. A physical address-based tweak function  $T()$  is utilized to make the ciphertext dependent of not only the plaintext but also its physical address [20]. Specifically, the tweak function is defined as  $T(x) = \oplus_{x_i=1} t_i$ , where  $x_i$  is the  $i$ th bit of host physical address  $x$ ,  $\oplus$  is the bitwise exclusive-or (*i.e.*, XOR) and  $t_i$  ( $1 \leq i \leq 128$ ) is a 128-bit constant vector. The tweak function takes a physical address as an input and outputs a 128-bit value  $T(x)$ . Therefore, the ciphertext  $c$  of a plaintext  $m$  at address  $P_m$  is  $c = E_K(m \oplus T(P_m))$ . The tweak function prevents attacker from inferring plaintext by comparing the ciphertext of two 16-byte memory blocks. However, as the constant vectors  $t_i$ s remain the same for all VMs (and the hypervisor) on the machine, they can be easily reverse engineered by an adversary.

**Known issues with SME memory encryption.** One root problem exploited in prior studies on SEV’s insecurity is the lack of integrity of its encrypted memory [9, 12, 17, 25].

## 2.3 Virtualized I/O Operations

Similar to other virtualization technologies, SEV-enabled VMs interact with I/O devices through virtual hardware using Quick Emulator (QEMU). Common methods for VMs to perform I/O operations are programmed I/O, memory-mapped I/O, and direct memory access (DMA). Among these methods, DMA is most frequently used method for SEV-enabled VMs to do I/O accesses.

**Direct Memory Access in SEV.** With the assistance of DMA chips, programmable peripheral devices can transfer data to and from the main memory without involving the processor. With virtualization, a common way to support DMA is through IOMMU, which is a hardware memory management unit that maps the DMA-capable I/O buses to the main memory. However, unique to SEV is that the memory is encrypted. While the MMU supports memory encryption with multiple ASIDs, IOMMU only supports one ASID (*i.e.*, ASID=0). Therefore, in SEV-enabled VMs, DMA operations are performed on memory pages that are shared between the guest and the hypervisor (encrypted with the hypervisor’s  $K_h$ ). A bounce buffer, called Software I/O Translation Buffer (SWIOTLB), is allocated on these memory pages.

To illustrate the DMA operation from the guest, a disk I/O read is shown in Figure 1. When a guest application needs to read data from file, it first checks whether the file is already stored in its page cache. A miss in the guest page cache will trigger read from virtual disks, which is emulated by QEMU-KVM. The data is actually read from the physical disk by QEMU-KVM’s DMA operation into SWIOTLB and then copied to the disk device driver’s I/O buffer by the guest VM itself. The disk write operation is the inverse of this process, in which the data is first copied from the guest into SWIOTLB and then processed by QEMU.

### 3 Security Issues

In this section, we explore the security issues of the lack of protection for SEV’s I/O operations. We start of our exploration with the most straightforward consequence of vulnerability—the insecurity of I/O operations itself—and present an attack example that breaches the integrity of I/O operations. To comprehensively study the attack surface, we also enumerate the I/O operations from a guest VM that are vulnerable to such attacks and discuss the challenges of implementing effective countermeasures. Next, we show that I/O insecurity leads to a complete compromise of the memory encryption scheme of SEV, by constructing powerful attack primitives that leverage the unprotected I/O operations to enable the adversary to encrypt or decrypt arbitrary messages with the guest VM’s memory encryption key,  $k_{vek}$ .

#### 3.1 Threat Model

We consider a scenario in which the VMs’ memory are encrypted and protected by AMD SEV technology. The hypervisor run on a machine controlled by a third-party service provider. Under the threat model we consider, the third-party service is not trusted to respect the integrity or confidentiality of the computation inside the VMs. This could happen when the service provider is dishonest or when the hypervisor has been compromised.

The goal of the attacks is either to compromise the I/O operations themselves or the memory encryption of SEV. Out of scope in this paper are denial-of-service (DoS) attacks, in which the service provider simply refuses to run the VM. SEV is not designed to prevent DoS attacks.

#### 3.2 I/O Security

In this section, we explore the direct consequences of unprotected I/O operations from SEV-enabled guests.

##### 3.2.1 Case Study: Integrity Breaches of Disk I/O

We first present a case study to show how SEV’s guest VMs’ unprotected I/O operations can be exploited to breach I/O security in practice. In this case study, we show that a malicious hypervisor is able to gain control of the guest VMs through an OpenSSH server without passwords by exploiting unprotected disk I/O. Therefore, we assume the disk is *not* encrypted with disk encryption key in this example. However, we note it is recommended by AMD to only use encrypted storage. As such, this case study only serves the purpose of proof-of-concept, rather than a practical attack. We will discuss its security implications in Section 3.2.2.

Specifically, the adversary controls the entire host and launches the SEV-enabled VM using the standard procedure [3]. During the system bootup, the binary code of `sshd` that performs user authentication is loaded into the memory. To monitor the disk I/O streams, whenever the QEMU performs a DMA operation for the guest, the adversary checks the memory buffer used for this DMA operation (*i.e.*, SWIOTLB) and search for the binary code of `sshd`. In our implementation, we used a 32-byte memory content (*i.e.*, `0xff85 0xc041 0x89c4 0x8905 0x4e05 0x2900 0x0f85 0x1b01 0x0000 0x488b 0x3d49 0x0529 0x0089 0xeee8 0xc2bf 0xfdff`) as the signature of the `sshd` binary and no false detection was observed. Once the DMA operation for `sshd` is identified, the adversary modifies the binary code inside SWIOTLB, before the QEMU commits the DMA operation. In particular, this is done by replacing the crucial code used in authentication that corresponds to `callq pam_authenticate`, which is a five-byte binary string `0xe8 0xc2 0xbf 0xfd 0xff`, to `mov $0, %eax` (a binary string of `0xb8 0x00 0x00 0x00 0x00`). `pam_authenticate()` is used to perform user authentication; only when it returns 0 will the authentication succeed. Therefore, by moving 0 to the register `%eax` (the register used to store return value of a function call) directly, the adversary can successfully bypass the user authentication without knowing the password. To validate the attack, we empirically conducted the attack three times and all were successful.

**Performance degradation due to I/O monitoring.** We also conducted experiments to measure the performance degradation due to the hypervisor’s monitoring of disk I/O streams. We used the `dd` command to write 1GB of data to the local

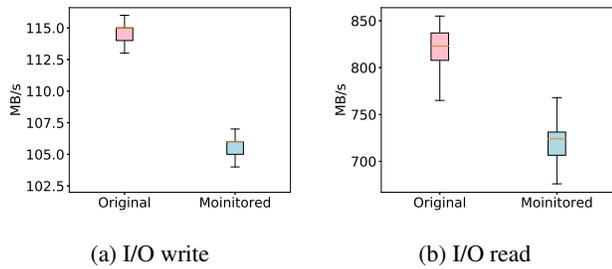

Figure 2: Read/write performance overhead due to I/O monitoring.

disk to measure the I/O write speed. The `dsync` flag of `set` to make sure the data is written to the disk directly, bypassing the page caches. To measure the read speed, we cleaned the page caches in the memory by setting `vm.drop_caches=3` before reading 1GB of data from local disk. In both the read and write experiments, we measured the performance with and without I/O stream monitoring and repeated the measurements 200 times. The results show the performance degradation of I/O read and write is 11.8% and 7.9% respectively (see Figure 2).

### 3.2.2 Estimating The Attack Surface

As shown in the above example, I/O operations that are not encrypted by the software can be intercepted by the malicious hypervisor and manipulated to compromise the SEV-enabled guests. This vulnerability exists in all emulated I/O devices that are commonly used in cloud VMs, such as disk I/O, network I/O, and display I/O, etc. While a straightforward solution is to encrypt I/O streams by software, however, this simple method has many practical limitations in practice:

**Network I/O.** Network traffic can only be partially encrypted, as headers of IP or TCP cannot be encrypted. The adversary is still able to modify the network traffic to forge the IP addresses, port numbers, and encrypted metadata of the network packets. This is true for both TLS traffic and VPN traffic. As we will show in Section 3.3, encrypted traffic like SSH can still be exploited to construct memory decryption oracles.

**Display I/O.** Encrypting I/O traffic cannot be applied when the I/O devices cannot decrypt the I/O stream by themselves. Display I/O is one such example. For instance, Virtual Network Computing (VNC) is a graphical desktop sharing protocol that allows VMs to be remotely controlled. In KVM, the QEMU redirects the VGA display from the guest to the VNC protocol, which is not encrypted. Therefore, if the user of the guest VM uses VNC to control the VM, keystroke and mouse clicking will be learned and manipulated by the adversary. To protect display I/O operations, the guest VM must be modified to encrypt all display I/O traffic and the remote user interface must be modified accordingly to decrypt the traffic.

**Disk I/O.** For disk I/O operations, the method recommended by SEV [4] is for each SEV-enabled VMs to use encrypted

disk filesystems. To use encrypted disks, however, the owner needs to first provision the disk encryption key into the protected VMs by using the `Launch_Secret` [3] command. This command first decrypts a packet sent by the VM owner (that contains the disk encryption key) encrypted using  $K_{tek}$  (Transport Encryption Key), atomically re-encrypts it using the memory encryption  $K_{vek}$ , and then injects it into the guest physical address specified by `GUEST_PADDR` (a parameter of the `Launch_Secret` command). As the address of the disk encryption key is known, if memory confidentiality is compromised (using methods to be described in Section 3.3), the disk encryption key can be learned and used to decrypt the entire image. Therefore, disk I/O is not secure, either.

## 3.3 Decryption Oracles

In this section, we show that the DMA operations under SEV’s memory encryption technology can be exploited to construct a decryption oracle, which allows the adversary to decrypt any memory block encrypted with the guest VMs’ memory encryption key  $K_{vek}$ . The oracle can be frequently and repeatedly queried and thus can be exploited as an attack primitive for more advanced attacks against SEV-enabled guests.

As mentioned in Section 2.3, the DMA operation from the SEV-enabled VM is conducted with the help of memory pages shared with the hypervisor. When DMA operates in the `DMA_TO_DEVICE` mode, data is transferred by the IOMMU hardware to the shared memory, and then copied by CPU in the SEV-enabled VM to its private memory; when DMA operates in the `DMA_BIDIRECTIONAL` mode, the SEV-enabled VM first copies the data from encrypted memory to the shared memory, and then the DMA reads or writes are performed on the shared memory.

Both these modes of operations provide the adversary an opportunity to observe the transfer of data blocks from memory pages encrypted by  $K_{vek}$  to memory pages that is not encrypted (from the hypervisor’s perspective). Therefore, if the adversary alters the ciphertext of the data blocks in the encrypted memory page before they are copied by the guest VM, after the memory copy, the corresponding plaintext can be learned from the shared memory directly.

The construction of such a decryption oracle is shown in Figure 3. The decryption oracle can be constructed in three steps: *pattern matching*, *ciphertext replacement*, and *packets recovery*. We use network I/O as an example. The adversary exploits the network traffic in Secure Shell (SSH) to construct the decryption oracle. But we stress that any I/O traffic can be exploited in similar manners. In the following experiments, we configured the guest VM to use `OpenSSH_7.6p1` with `OpenSSL 1.0.2n`, which is default on Ubuntu 18.04.

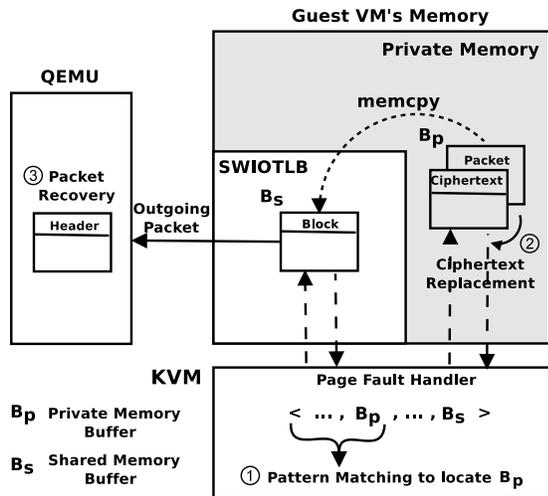

Figure 3: A decryption oracle. Step ①, the hypervisor conducts pattern matching using page-fault side channels to determine the address of  $B_p$ . Step ②, the hypervisor replaces a ciphertext block in  $B_p$  with the target memory block, which will be decrypted when copied to  $B_s$ . Step ③, QEMU recovers the network packet headers.

### 3.3.1 SSH and Network Stacks

To control the SEV-enabled guest remotely, the owner of the VM typically uses SSH protocol to remotely login into the VM and controls its activities. To copy data to and from the VM, protocols like SCP, which is built on top of SSH, is commonly used. Particularly, we consider the SSH traffic after the remote owner has already authenticated with `sshd` and a secure communication channel has been established. Because the SSH handshake protocol is performed in plaintext, the adversary who controls the hypervisor and QEMU can act as a man-in-the-middle attacker and recognize the established the secure channel by its IP addresses and TCP port number. Once the secure channel is established, SSH command and output data will be transferred using encrypted SSH packets that are transmitted in interactive mode [31].

In the interactive mode, each individual keystroke guest owner types will generate a packet that is sent to the SEV-enabled VM, which will be transferred by DMA to a memory buffer shared between the guest and the hypervisor. The packet is then copied by the guest to a private memory page encrypted using  $K_{vek}$ . Then the data is handled by the network stack in the guest OS kernel. The headers of the packet are then removed and the payload data is forwarded to the user-space application. Then the SSH server processes the keystroke and responds with an acknowledgement packet. The acknowledgement packet is copied back to the kernel space, wrapped by the corresponding header information, and then copied to the shared memory buffer. The last memory copying also decrypts the memory using the guest VM's  $K_{vek}$ .

Therefore, our attack primitives target this process. As a result, every network packet generated by the guest VM can be exploited as a decryption oracle that helps the adversary decrypt one or multiple memory blocks.

### 3.3.2 Pattern Matching Using Fine-grained Page-fault Side Channels

Let us denote the private memory buffer as  $B_p$ , whose gPA is  $P_{priv}$ , and the shared memory buffer as  $B_s$ , whose gPA is  $P_{share}$ . The primary challenge in this attack is to identify the  $P_{priv}$ . As this address is never directly leaked, the adversary needs to perform a page-fault side-channel analysis.

**Fine-grained page-fault side channels in SEV.** The page fault side channel was first studied by Xu *et al.* in the context of Intel SGX [36]. As an SGX attacker controls the entire operating system, he or she can manipulate the page table entries (PTE) and set the `present` bit of the PTEs of pages that are mapped to the targeted enclave. By doing so, once the enclave program accesses the corresponding memory pages, the control flow will be trapped into the OS kernel through a page fault exception. On x86 processors, the faulting address will be stored in a control register, CR2 so that the page-fault handler could learn the entire faulting address. To provide secrecy, SGX masks the page offset of the faulting address and leaves only the virtual page number in CR2.

Similarly, on the AMD platform, the adversary that compromises the hypervisor could also exploit the page-fault side channels to track the execution of the SEV-enabled VMs. Although the mapping between the guest VM's guest virtual address (gVA) to gPA is maintained by the guest VM's page table and is encrypted by  $K_{vek}$ , the hypervisor could manipulate the nested page tables (NPT) to trap the translation from gPAs to host physical address (hPA). Unlike SGX, SEV does not mask the page offset, providing more fine-grained observation to the adversary.

Moreover, the page-fault error code returned in the `EXITININFO` field of VMCB can also be exploited in the SEV page-fault side-channel analysis. Specifically, the page-fault error code is a 5-bit value, revealing the information of the page fault. For example, when bit 0 is cleared, the page fault is caused by non-present pages; when bit 1 is set, the page fault is caused by a memory write; when bit 2 is cleared, the page fault takes place in the kernel mode; when bit 3 is set, the fault is generated from a `reserved` bit; when bit 4 is set, the fault is generated by an instruction fetch. The error code provides detailed information regarding the reasons of the page fault, which can be leveraged in side-channel analysis.

**Pattern matching.** With such a fine-grained side channel, the adversary could monitor the memory access pattern of the guest when it receives an SSH packet. Particularly, after delivering an SSH packet to the SEV-enabled VM, the adversary immediately initiates the monitoring process and marks all of

the guest VM’s memory pages inaccessible by clearing the `present` bit of the PTEs. Every time a memory page is accessed by the guest, a page fault takes place and the adversary is able to learn the entire faulting address  $P_i$ . Note here the faulting address in the guest VM refers to the guest physical address as the guest virtual address is not observable by the hypervisor. After the page fault, the adversary resets the `present` bit in the PTE to allow future accesses to the page. Therefore, with the fine-grained page fault side channel, one only needs to collect information regarding the first access to a memory page. The monitoring procedure stops when the acknowledgement packet is copied into  $B_s$ . At this point, the adversary has collected a sequence of faulting addresses  $\langle P_1, P_2, \dots, P_m \rangle$ .

Internally in the guest VM, when `sshd` is sending a packet, the encrypted data is first copied to the buffer of the transport layer, then the buffer of the network layer, and then the buffer of the data link layer. In each layer, new packet headers are added. Eventually, the entire network packet is stored in a data structure called `sk_buff`. Finally, the kernel will call `dev->hard_start_xmit` to transfer the data in `sk_buff` to the device driver, where  $B_p$  is located.

Both  $P_{priv}$  and the address of `sk_buff`,  $P_{sk}$ , should be found in the faulting addresses sequence  $\langle P_1, P_2, \dots, P_m \rangle$ . It is because the memory pages that store the private memory buffer  $B_p$  and `sk_buff` are not otherwise used during the process of sending network packets. The adversary could combine page offsets, page frame numbers, the page-fault error code, and the number of page faults between the two page faults of  $B_p$  and `sk_buff` to create a signature, which can be used to find  $P_{priv}$ . For example, the page-fault error code of  $B_p$  is `0b110` and the page-fault error code of `sk_buff` is `0b100`; the page offset of  $P_{priv}$  is usually `0x0fa` or `0x8fa` and the offset of `sk_buff` usually ends with `0xe8` or `0x00`; and the number of page faults between  $B_p$  and `sk_buff` is roughly 20. With these signatures, the adversary can identify  $P_{priv}$  from the sequence of faulting addresses. Of course, the signature may change from one OS version to another, or change with different OS kernel. However, because the adversary controls the hypervisor, such information can be re-trained offline, before performing the attacks.

It was indicated by AMD researchers (during an offline discussion) that SEV-ES should mask the page offset information when there is a VMEXIT. However, we were not able to find related public documentation. Moreover, as the KVM patch for SEV-ES support is not yet available at the time of writing, we were not able to validate the claim or estimate the remaining leakage (e.g., error code, page offset) after the patch. However, regardless of the hardware changes, a coarse-grained page-fault side channel in which the page frame number of the faulting address is leaked must remain. To show that the demonstrated attack still works, we conducted experiments to perform pattern matching without page fault offsets and error code information. Specifically, we performed pat-

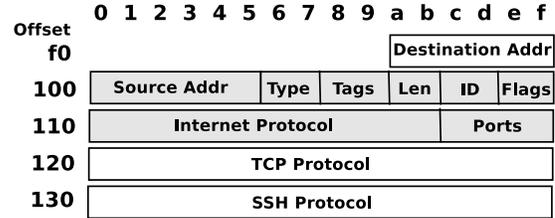

Figure 4: Format of an SSH packet.

tern matching using only the faulting page numbers, with the guest VM running different Ubuntu versions (e.g., 18.04, 18.04.1 and 19.04) and different kernel versions (4.15.0-20-generic, 4.15.0-48-generic and 5.0.0-13-generic). The results show that after training in one virtual machine, the pattern matching rules can work well even in different virtual machines with the same Ubuntu version and kernel version—the attacker is still able to successfully identify the page frame number of  $P_{priv}$ . To determine the complete address of  $P_{priv}$ , the attacker could determine the offset by scanning the entire memory page and looking for content changes (e.g., in a 90-byte buffer).

### 3.3.3 Replacing Ciphertext

After determining  $P_{priv}$ , the adversary replaces aligned SSH header in  $B_p$  with the ciphertext he or she chooses to decrypt. As shown in Figure 4, the packet headers include a 6-byte destination address, a 6-byte source address, a 2-byte IP type (e.g., IPv4 or IPv6), 1-byte IP version and IP header length, 1-byte of differentiated services field, 2-byte packet length, 2-byte identification, 2-byte of IP flags, 1-byte time-to-live, 1-byte protocol type, 2-byte checksum, and 4-byte source IP address and 4-byte destination address, and 20-bytes TCP headers (start with 2-byte source port and 2-byte destination port).

As shown in Figure 4,  $P_{priv}$  has the offset address ending with `0xfa`. Because SEV encrypts data in 16-byte aligned blocks, only part of the TCP/IP header (i.e., header in gray blocks in Figure 4) can be used to decrypt ciphertext. Additional constraints apply if the packet needs to be recovered later. Before replacing the packet header with the chosen ciphertext, the adversary performs a `WBINVD` instruction to flush the guest VM’s cached copy of  $B_p$  back to memory. It is because cache coherence is not maintained by the hardware between cache lines with different ASIDs. To make sure the guest VM’s copy does not overwrite our changes to the memory, `WBINVD` instruction needs to be called first.

The ciphertext replacement takes place before `memcpy`, after  $B_p$  is accessed and before  $B_s$  is accessed.  $B_s$  is located inside the `SWIOTLB` pool, which is the next available address within `SWIOTLB` that can be used by the guest. After replacing a few blocks in  $B_p$ , another `WBINVD` instruction is performed to ensure the guest VM reads and decrypts up-to-date cipher-

text in memory. All replacement operation is achieved by `Ioremap` instead of `Kmap`, since `Kmap` decrypts data with the hypervisor’s key first and `Ioremap` directly operates data in the memory without decryption.

We use the following example to illustrate the attack. Let the ciphertext  $c$  be a 16-byte aligned memory block with the gPA of  $P_c$ . The function which can translate gPA to hPA is called  $hPA()$ . The goal of the attack is to decrypt  $c$ . The adversary replaces a 16-byte data in the SSH header that begins with address  $(P_{priv} + 16)/16 * 16$  with  $c$ . After the data in  $B_p$  is copied to  $B_s$ , the adversary could read the decrypted SSH packet and extract the plaintext of decrypted memory block,  $d$ , from the corresponding location of the packet. However,  $d$  is not the plaintext of  $c$  yet, as SEV’s memory encryption involves a tweak function  $T()$ . That is,  $c = E_{K_{vek}}(m \oplus T(hPA(P_c)))$  but  $d = D_{K_{vek}}(c) \oplus T(hPA((P_{priv} + 16)/16 * 16))$ . Therefore, the plaintext message  $m$  of ciphertext  $c$  can be calculated by  $m = d \oplus T(hPA((P_{priv} + 16)/16 * 16)) \oplus T(hPA(P_c))$ .

### 3.3.4 Packets Recovery

To make the attack stealthy, the adversary needs to recover the network packet with decrypted data before those packets are passed to the physical NIC device. As shown in Figure 4, the SSH header also contains metadata of the packet. When the malicious hypervisor injects chosen ciphertext into the memory block with offset = `0x100`, the adversary only needs to be concerned about a portion of the source IP address, IP protocol type, IP tags, TCP header length, and the identification of the packet. Majority of the fields are determined. The identification of the IP packet increases by 1 every time SSH server replies a packet. So when hypervisor tries to recovery the (plaintext) packet from the QEMU side, it only need to correct the packet length, increase identification by 1 and copy the remaining portion from previous packet such as source address, header length, time to live and protocol number.

## 3.4 Encryption Oracle

We next show the construction of a memory encryption oracle using unprotected I/O operations. The encryption oracle stealthily encrypts a chosen plaintext message using a guest VM’s memory encryption key  $K_{vek}$ . Similar to the construction of the decryption oracle, during the DMA operation of the guest that transfers data from the device to the encrypted memory, the adversary changes the message  $m$  in the shared memory buffer  $B_s$ , waits until it is copied to the private buffer  $B_p$  in the encrypted page, and then extracts the corresponding ciphertext  $E_{k_g}(m)$  from  $B_p$ .

To determine the gPA address of  $B_p$  and retrieve the ciphertext of the plaintext message at address  $P_t$ , the steps shown in Figure 5 are taken. Again, we leverage the fine-grained page-fault side channel we used in the previous section. Specifically,

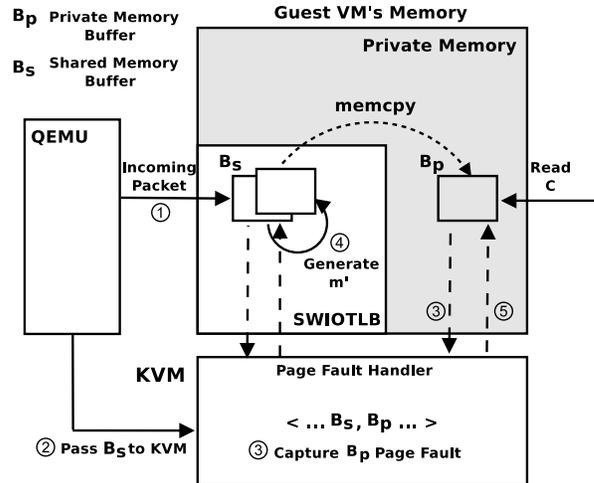

Figure 5: An encryption oracle. Step ①, QEMU forwards an incoming packet to the guest. Step ②, QEMU passes the address of  $B_s$  to the hypervisor. Step ③, a page fault immediately after the fault at  $B_s$  is captured by the page fault handler. Step ④, message  $m'$  is placed in  $B_p$ . Step ⑤, page fault handler returns the control to the guest.

we modified all memory pages’ PTEs right after the QEMU finishes writing the packet into SWIOTLB and before the QEMU notifying guest VM about the DMA write. Then, when the guest VM performs a `memcpy` operation to copy the data, the adversary will observe a sequence of page faults:  $\langle \dots P_{share}, P_{priv} \dots \rangle$ , where  $P_{share}$  is the address of  $B_s$  and  $P_{priv}$  is the address of  $B_p$ . The page fault at  $P_{priv}$  will take place right after the page fault at  $P_{share}$ . When the hypervisor handles the page fault at  $P_{priv}$ , it replaces the 16-byte aligned data block with the message  $m'$ , where  $m' = m \oplus T(hPA(P_{priv})) \oplus T(hPA(P_t))$ , where  $P_t$  is the gPA of the target address to which the adversary wishes to copy  $m$ . The corresponding ciphertext will be  $c = E_{k_g}(m \oplus T(hPA(P_t)))$ , which can be used to replace the ciphertext at address  $P_t$ .

The encryption oracle can be typically exploited to inject code or data into the SEV-enabled VM’s encrypted memory, or it can be used to make guesses of the memory content by providing a probable plaintext. We note that to use the encryption oracle, the adversary may simply generate meaningless packets and send them to the guest VM, which will be discarded. But the oracle can still be constructed and used. The only downside of this approach is that the guest VM will observe large volume of meaningless network traffic and may become suspicious of attacks.

## 4 Evaluation

We implemented our attacks on a blade server with an 8-Core AMD EPYC 7251 Processor, which has SEV enabled on the chipset. The host OS runs Ubuntu 64-bit 18.04 with

Linux kernel v4.17 (KVM hardware-assisted virtualization supported since v4.16) and the guest OS also runs Ubuntu 64-bit 18.04 with Linux kernel v4.15 (SEV supported since v4.15). The QEMU version used was QEMU 2.12. The SEV-enabled guest VMs were configured with 1 virtual CPU, 30GB disk storage, and 2GB DRAM. The OpenSSH server was installed from the default package archives.

#### 4.1 Pattern Matching

We first evaluate the pattern matching algorithm’s accuracy of determining  $P_{priv}$ . To obtain the ground truth, we modified the guest kernel to log the gPA address of `sk_buff`, the source gPA and destination gPA of `memcpy`, as well as the size of each DMA read or write. All the data was recorded in the kernel debug information, which can be retrieved using a Linux command `dmesg`.

The experiments were conducted as follows: We ran a software program *AnJian* [13] (an automated keystroke generation tool) on a remote machine, which opened a terminal that was remotely connected to the SEV-enable VM through an SSH communication channel. *AnJian* automatically typed on the SSH terminal two Linux commands `cat security.txt |grep sev` and `dmesg` at the rate of 10 keystrokes per second. This was used to simulate the remote owner controlling the SEV-enabled VM through SSH. The adversary would make use of the generated SSH packets to perform memory decryption. The `dmesg` command also retrieved the kernel debug message that recorded the ground truth.

At the same time, the pattern matching was performed by the adversary on the hypervisor side. The page-fault side-channel analysis was conducted upon receiving every incoming SSH packet to guess the address  $P_{priv}$ . There were three outcomes of the guesses: a correct guess, an incorrect guess, and unable to make a guess. Because there were 33 keystrokes generated by *AnJian*, the adversary was allowed to guess  $P_{priv}$  for 33 times in each experiment. The experiments were conducted 20 times.

Figure 6 shows the precision and recall of these 20 rounds of experiments. Precision is defined as the ratio of the number of correct guesses and the number of times that a guess can be made. Recall is defined as the ratio of the number of correct guesses and the number of total SSH packets. The average precision is 0.956, the average recall is 0.847 and the average  $F_1$  Score is 0.897.

#### 4.2 Persistent $B_p$

According to our experiments, the  $B_p$  will remain unchanged and reused for multiple network packets. This greatly helps the adversary, either by performing pattern matching once and reusing the same  $B_p$  directly in subsequent packets, or by improving the accuracy of the guesses.

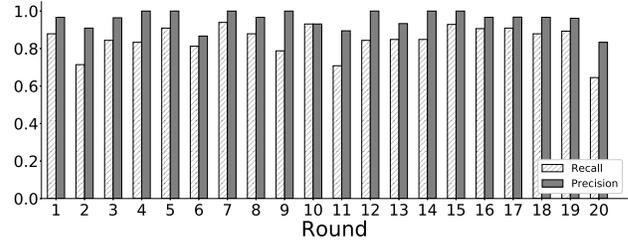

Figure 6: The precision and recall of determining  $P_{priv}$  in 20 rounds of experiments.

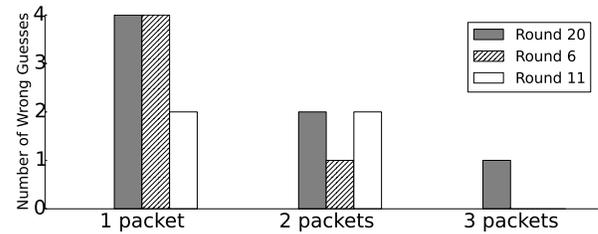

Figure 7: Reduction of incorrect guesses using the N-Streak strategy.

**Improving attack fidelity using persistent  $B_p$ .** The persistent  $B_p$  can be used to reduce the number of incorrect guesses. During a real-world attack, when  $P_{priv}$  is incorrectly guessed, the ciphertext replacement may crash the guest VM (although we have not experienced any crashes in our experiments). As such, a safer strategy of when to perform ciphertext replacement is only after correctly guessing  $P_{priv}$   $N$  times in a streak, which we call the *N-streak strategy*. We then applied this strategy to Round 20, 6 and 11, which have the highest FPR (i.e., 0.167, 0.133, 0.103, respectively). As shown in Figure 7, when by increasing  $N$  (i.e., 1, 2, 3), the number of incorrectly performed ciphertext replacement is reduced.

**Packet rate vs.  $B_p$  persistence.** We further evaluated the effect of  $B_p$  persistence when the rate of SSH packets varies. Again, on the remote machine, we used *AnJian* to generate keystrokes at a fixed rate, ranging from 0.5 keystrokes per second, to 20 keystrokes per second. The rate of SSH acknowledgement packets is close to the keystroke rate. For each keystroke rate, 500 keystrokes were generated and the number of different  $B_p$ s were reported in Figure 8. We can see that as the packet rate increases, fewer number of  $B_p$ s will be used to send SSH packets. We repeated this experiment and collected over 200 different  $B_p$ s after generating 5000 keystrokes with rates ranging from 0.5 to 20 per second. The statistics of the repeated use of  $B_p$ s are shown in Figure 9.

#### 4.3 I/O Performance Degradation

Conducting page-fault based side-channel analysis to guess  $P_{priv}$  and performing ciphertext replacement will slow down

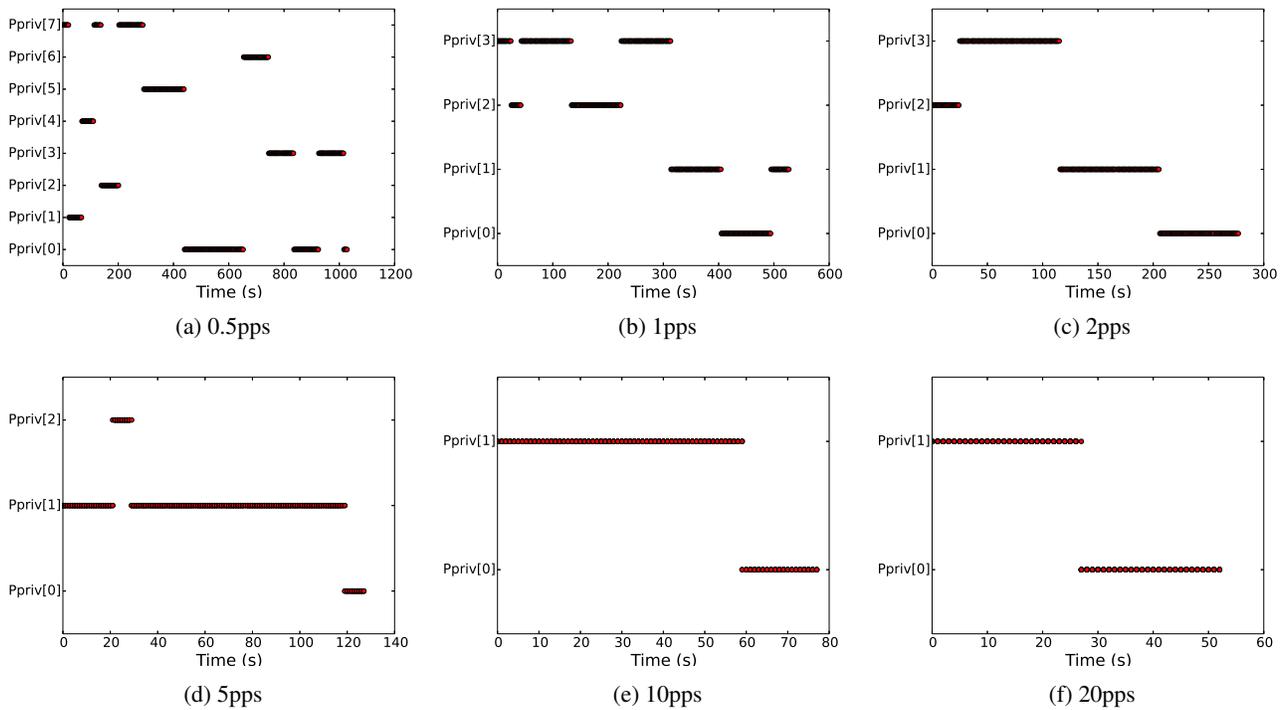

Figure 8: The number of different  $B_p$ s used with various rates of packets (pps).

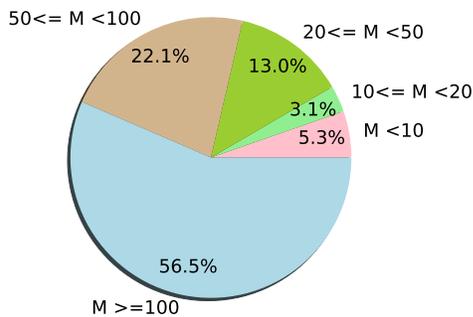

Figure 9: Statistics of repeated  $B_p$ s.

the I/O operations of the guest VM. To evaluate the degree of performance degradation, we evaluate the SSH response time on the server side during the attacks. The SSH response time measures the time interval between the QEMU receives an incoming SSH packet to the time that an SSH response packet is sent to QEMU. Note the measurements do not include network latency.

Figure 10 shows the SSH response time under three conditions: Original (not under attack),  $B_p$  Persistent (assuming  $B_p$  does not change), and Guess Every Time (assuming  $B_p$  changes and making guesses every time). The keystroke rate used in the experiments were 10 keystrokes per second, and

in total 1,000 keystrokes were generated during the tests. We can see from the figure, the average SSH response latency without attack is 2.5ms and the median is 0.99ms. The average latency for SSH connection under a  $B_p$ -persistent strategy is 6.81ms and the median is 2.4ms. The average latency for SSH connection under a guess-every-time strategy is 8.0ms and the median is 8.7ms. Because the typical network latency of cloud servers are 40-60ms within US and more than 100ms worldwide [5], it is very difficult for the VM owners to detect the latency caused by the attacks.

#### 4.4 An End-to-End Attack

We conducted an end-to-end attack in which the adversary decrypts a 4KB memory page that is encrypted with the guest VM's  $K_{vek}$ . The attack assumes a network traffic with the rate of 10 pps, which is simulated using the same method used in the previous sections. Table 2 shows the number of packets and time used to complete the attack, when one or two 16-byte aligned blocks were exploited for the data decryption. We can see that in the four trials we conducted, roughly 300 packets are needed to decrypt the 4KB page, which takes about 40 seconds. The speed of the attack doubles if the first two blocks of the packets were used to decrypt data.

Table 2: End-to-end attack performance.

Round	1 Block		2 Blocks	
	Packets used	Time(s)	Packets used	Time(s)
1	292	43.56	148	21.29
2	329	40.78	177	20.04
3	326	39.21	154	18.99
4	299	33.58	154	16.95

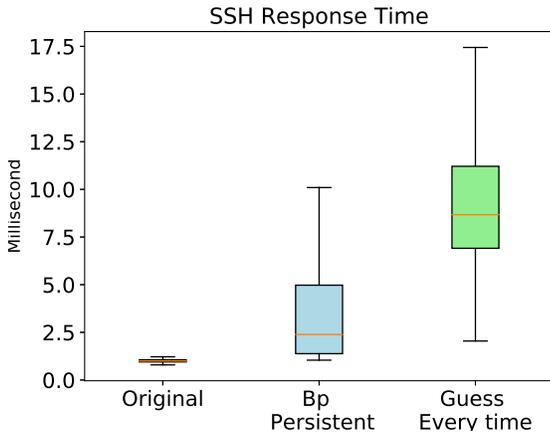

Figure 10: I/O performance degradation evaluated using SSH response time (network latency excluded).

## 5 A Path Towards I/O Security in SEV

The root cause of the problem is the incompatibility between AMD-V’s I/O virtualization with SEV’s memory encryption scheme. Specifically, the primary reason of the attacks described in Section 3 is that existing IOMMU hardware only supports memory encryption with ASID = 0 and the operated memory is encrypted with the hypervisor’s memory encryption key. Therefore, every I/O operation from the guest VM must go through a shared memory page with the hypervisor. To address this limitation, IOMMU must allow DMA operations to be performed under the ASIDs of other contexts. Meanwhile, it must prevent the privileged software from abusing such IOMMU operations. This design, however, will be very challenging to implement in practice. According to our discussion with AMD researchers, future releases of SEV CPUs are *unlikely* to address this issue. Therefore, alternative solutions must be identified.

In addition to this fundamental issue, the decryption oracle is also enabled by two other vulnerabilities of SEV: (1) no integrity protection of the encrypted memory, and (2) knowledge of the tweak function  $T(\cdot)$ . AMD researchers suggested that future SEV CPUs will disable the encryption oracle by providing memory integrity and altering the implementation of the tweak function  $T(\cdot)$ . While authenticated memory encryption disables all known attacks against SEV, details of its implementation are yet to be disclosed. We discuss some of

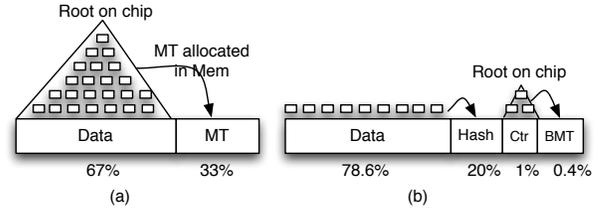

Figure 11: Merkle Tree (a) and Bonsai Merkle Tree used in conjunction with split counter mode encryption (b).

the potential considerations in Section 5.1. Future versions of the tweak function will be implemented as  $T(k, a)$ , where  $a$  is the physical address and  $k$  is a random input that changes after every system reboot. We leave the investigation of these vulnerabilities to future work when the technical details are published. In Section 5.2, we present a temporary software fix that works on existing AMD processors (Section 5.2).

It is worth noting that AMD researchers suggested that SEV-ES masks the page offset during page fault. However, we could not find relevant documentation or validate the claim on our testbed. Nevertheless, our analysis (see Section 3.3.2) suggests that the attack is still effective when the page offset information is unavailable. Specifically, we empirically evaluated the attack method that does not rely on page offsets by repeating the experiments in Section 4.1: the mean precision is 0.900, the mean recall is 0.730 and the mean  $F_1$  score is 0.800, which is only slightly lower.

### 5.1 Authenticated Encryption

Authenticated encryption must be adopted to prevent replay attacks and replacement attacks of the encrypted ciphertext. Merkle Tree (MT) [14] has been proposed for detecting replay and replacement attacks for protecting memory integrity. MT can be built and maintained over any region of memory, and hence it can be used to protect the entire memory or only memory allocated to a VM, or any portion of it. There are two types of MT that can be used, depending on the encryption mode. For direct encryption mode, the MT covers data. For counter-mode encryption, it was shown that replay was only possible if the attacker replays data, its hash, and its counter simultaneously. Hence, protecting counter freshness is sufficient to protect against replay [26]. MT over counters is referred to as Bonsai Merkle Tree (BMT), a variant of which was chosen for implementation in Intel SGX MEE [18].

A fundamental trade off exists between the choice of encryption mode and the overheads of MT. When 128-bit hash is used for MT, MT (and hashes) over data incur memory capacity overhead of 33% (i.e. data-to-MT nodes ratio of 2:1), as illustrated in Figure 11. On the other hand, BMT incurs an overhead of 20% for hashes, plus 0.4% for BMT nodes. Hashes are needed for both encryption modes to pro-

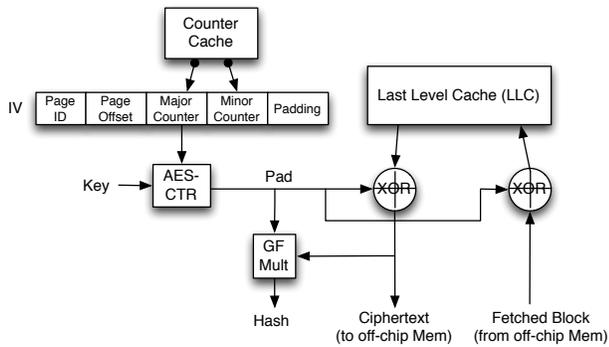

Figure 12: Counter mode encryption with split counters using Galois Counter Mode authentication.

protect against non-replay tampering of memory data. In addition, counter-mode encryption requires additional storage for counters, which depends on the type of counters. 64-bit monolithic counters take up 9% overheads, but split-counters [37] take up only 1%. Taken together, protection against replay incurs 13% memory capacity with direct encryption but only 1.4% with counter mode encryption (Figure 11). For a 1 TB memory, the difference amounts to a substantial 116 GB.

Counter mode encryption is illustrated in Figure 12. Counters are cached on chip, either in regular caches, or in a special “counter cach”. With split counters, each page (4KB) of data has its own major counter, and each block (64B) in a page has its own minor counter. When there is a last level cache (LLC) miss, the counter values (major and minor) are concatenated with the page ID and block address of the page (i.e. page offset of the block) to produce a spatially and temporally unique initial vector (IV) [37]. The IV is then encrypted to produce a pad, which will be XOR-ed with ciphertext of data fetched from memory to yield data plaintext. With Galois Counter Mode, the hash of data is obtained a few clock cycles later. Counter mode encryption is more secure than direct mode encryption due to spatial and temporal uniqueness of ciphertexts even for a single plaintext value. Furthermore, as illustrated in the figure, decryption latency is largely overlapped with LLC miss latency; the only exposed latency is 1-cycle XOR of pad and data ciphertext. In contrast, direct memory mode fully exposes decryption latency in the critical path of memory fetch. Therefore, in terms of security protection against replay, memory capacity costs, and performance, AMD SEV can benefit from counter mode encryption and BMT.

A MT/BMT protects the memory from replay or tampering at all time. It is also possible to selectively protect memory region integrity only at times in which they are “expected” to be vulnerable. For example, the time window in which IOMMU buffer is vulnerable is between the time it is written by the DMA until it is read/consumed by the VM. One could take a hash of the memory region at DMA write and verify it when the VM reads the region. Any tampering or

replay attempts will be detected. Selective integrity protection may obviate the need for full MT/BMT for attacks that occur within the vulnerable window, but leaves the memory integrity unprotected at other time.

## 5.2 A Temporary Software Solution

In this section, we present a software solution that can temporarily solve the I/O insecurity issues discussed in this paper. The key idea is to make sure the hypervisor never observe any unencrypted I/O data to/from the SEV-enabled VM. This can be achieved using SEV’s platform management APIs [3] and the transport encryption key of the VM  $K_{tek}$ .

$K_{tek}$  is a shared Diffie-Hellman (DH) key between the VM owner and the SEV firmware. Particularly, to launch an SEV-enabled VM on an SEV platform, the owner of the VM first requests the Diffie-Hellman (DH) certificate from the platform, which contains the platform’s DH public key. The corresponding private key is kept inside the SEV firmware, which cannot be extracted by the system administrator or the hypervisor. The VM owner then sends her DH public key to SEV platform, so that she establishes a shared transport encryption key  $K_{tek}$  with the SEV firmware.  $K_{tek}$  is only known by the VM owner and the SEV firmware, but not known to the VM itself or hypervisor. `SEND_UPDATE_DATA` and `RECEIVE_UPDATE_DATA` are two commands (among many others) implemented by SEV to assist the hypervisor to launch and manage SEV-enabled VMs [3]. After the VM is launched, the hypervisor may use SEV’s `SEND_UPDATE_DATA` command to *atomically* decrypt a piece of memory with  $K_{vek}$  and re-encrypt with  $K_{tek}$  or use `RECEIVE_UPDATE_DATA` command to decrypt the memory with  $K_{tek}$  and re-encrypt with  $K_{vek}$ .

Our proposed solution retrofits these APIs and  $K_{tek}$  to protect I/O operations. Particularly, the guest VM kernel and the QEMU can be modified so that the guest VM never copies data between the encrypted memory and the unencrypted memory. Instead, to perform any I/O operation to the SEV-enabled VM, the hypervisor issues the `SEND_UPDATE_DATA` and `RECEIVE_UPDATE_DATA` commands to atomically decrypt and re-encrypt data using the two keys  $K_{vek}$  and  $K_{tek}$ . As both keys are protected inside the SEV firmware, the hypervisor is not able to learn the plaintext during the I/O operations. The SEV firmware serves as a trusted relay of the I/O paths.

However, this solution is only a temporary fix of the issue. This is because the I/O traffic is encrypted with  $K_{tek}$ , which is only known to the owner of the VM. Therefore, all I/O operations, including network I/O, disk I/O, and display I/O must be forwarded to a trusted server that is controlled by the VM owner (as shown in Figure 13). Acting as an I/O proxy, the trusted server may limit the application scenarios of SEV and greatly reduce the I/O performance.

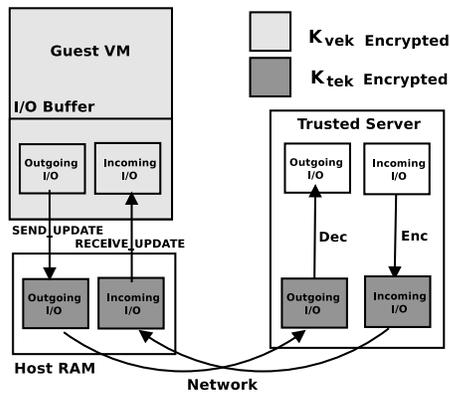

Figure 13: An illustration of the temporary software solution.

## 6 Related Work

### 6.1 Existing Security Studies on SEV

The security issues of AMD’s SEV have been placed under the spotlight since its debut. Demonstrated security attacks mainly targets SEV’s *unencrypted VMCB* [17] and SME’s *unauthenticated memory encryption* [9, 12, 17, 25]. The former issue has been fixed using SEV-ES [19] and the latter could be addressed with integrity protection of the encrypted memory. An implementation bug in the firmware of AMD secure processors have also been reported [11]. But since the issue was not related to a design failure, we leave it as out of scope of the paper. We detail these related work as follows:

**Unencrypted VMCB.** Hetzelt and Buhren analyzed the security of SEV from the perspective of unencrypted virtual machine control block (VMCB) [17]. VMCB is a data structure in memory shared by the hypervisor and the guest VM, which stores the values of guest’s general purpose registers and control bits for handling virtual interrupts. At the time of `VMExit`, a malicious hypervisor may learn the machine state of the guest VM by reading register values stored in the VMCB and subsequently alter their values before `VMRun` to control the registers of the guest VM. Hetzelt and Buhren [17] exploit unencrypted VMCB using code gadgets in the guest memory (similar to return-oriented programming (ROP) [29]) to arbitrarily read and write encrypted memory in the guest VM. The security issue caused by unencrypted VMCB, however, has been mitigated by SEV-ES [19], which adds another indirection layer during `VMExit` that allows the guest VM to be notified before Non-Automatic Exits (NAE)—exits requiring hypervisor emulation—and prepares a new data structure called Guest Hypervisor Communication Block—a subset of VMCB—to communicate with the hypervisor. The machine states stored in the VMCB are instead encrypted with authentication, such that they are inaccessible from the hypervisor.

**Unauthenticated memory encryption.** Because SME does not use authenticated encryption schemes, the integrity of

the encrypted memory is not protected. As such, malicious hypervisors may alter the ciphertext of the encrypted memory without triggering errors in the decryption process of the guest VMs. Prior studies have demonstrated a variety of approaches to exploit such unauthenticated memory encryption:

- *Chosen plaintext attacks.* Du *et al.* discovered that SME uses Electronic Codebook (ECB) mode of operation in its memory encryption [12], which implies that the same plaintext always leads to the same ciphertext after encryption. As the only security measure is a physical address based tweak function XORed with the plaintext before encryption, knowledge of the tweak function will enable the adversary to deduce the relationship between the plaintext of two memory blocks (*i.e.*, of 16 bytes) if their ciphertext are the same. Du *et al.* exploit this weakness by constructing a chosen plaintext attack (via an HTTP server installed on the guest VM) and then replace the ciphertext of an `sshd` program with the ciphertext of instructions specified by the adversary (after applying the tweak functions).
- *Fault injection attacks.* Buhren *et al.* studied fault injection attacks on a simulated SME implementation [9]. Their work considers a different threat model, which assumes that the adversary is able to conduct physical DMA attacks [6] and also run an unprivileged process on the target OS. The unprivileged process performs Prime+Probe side-channel attacks to trace the execution of the SME protected application and, at the proper moment of a cryptographic operation, utilizes DMA attacks to inject memory faults to infer secret keys (or key components). We believe Buhren *et al.*’s attack against SME can be migrated to SEV as well, which is even easier to conduct as the hypervisor can be assumed to be malicious.
- *Page table manipulation.* Remapping guest pages in the nested paging structures to replay previously captured memory pages was first studied by Hetzelt and Buhren [17]. A similar idea was later demonstrated by Morbitzer *et al.* in SEVered, an attack that by manipulating the nested page table alters the virtual memory of the guest VMs to breach the confidentiality of the memory encryption [25]. More specifically, SEVered is carried out in the following steps: First, the malicious hypervisor sends network requests to the guest’s network-facing application, *e.g.*, an HTTP server, which allows the attacker to download files larger than one memory page. Second, using a coarse-grained page-level side channel, the attacker determines which of the encrypted guest VM’s memory pages are used to store the response data. Third, after locating these pages, the malicious hypervisor changes the page mappings in the nested page table so that these virtual pages used by the guest are mapped to different physical pages. As a result, memory content of these pages can be leaked through the responses of the network applications. The same authors further extend SEVered to perform more

realistic attacks [24], by extracting secret keys in real-world protocols and applications such as TLS, SSH, full disk encryption (FDE). Their attack makes use of the same side channels to identify the set of memory pages that are likely to contain those secrets and scans those pages (roughly 100 pages) until the secrets are found. Both these works only present decryption oracles but not encryption oracles.

While the security issues of SEV's I/O operations are orthogonal to the problems of unauthenticated memory encryption, the decryption oracle presented in this paper does rely on the lack of integrity protection for the ciphertext blocks. However, compared to previous memory decryption attacks against SEV [24, 25], our work differs primarily in three aspects. First, Morbitzer *et al.* [24, 25] manipulate unprotected nested page tables to decouple the mapping between the gVAs and the memory contents, while our decryption oracle directly replaces memory blocks used in the I/O buffer. The hardware mechanisms to defend against these two attacks may differ. Our attack highlights the necessity of mitigating both threats. Second, instead of exploiting a network-facing application executed in the guest VM to accept attacker-controlled data, our attack could make use of any I/O traffic, which is more general. Our paper suggests that application-specific defenses, such as pruning secrets after use [24], may not work. Third, the attack in Morbitzer *et al.* requires the attacker to actively generate network traffic to the guest VM, which makes it easily detectable. In contrast, our decryption oracle can make use of existing I/O traffic, which can be very stealthy. Moreover, while the memory integrity issues are expected to be addressed in the next release of SEV CPUs, the fundamental I/O security problem studied in this paper will remain. The encryption oracle will not be mitigated unless the tweak function is completely secured.

**Other studies.** Mofrad *et al.* [23] compare Intel SGX and AMD SEV, in terms of their functionality, use scenarios, security, and performance implications. The study suggests SEV is more vulnerable than SGX as it lacks memory integrity and has a bloated trust computing base (TCB). Moreover, the performance comparison suggests AMD SEV technology performs better than Intel SGX. Wu *et al.* proposes Fidelius [35], a system that leverages a sibling-based protection mechanism to partition an untrusted hypervisor into two components, one for resource management and the other for security protection. The security of guest VMs is enhanced by the "trusted" security protection component, which, while interesting and effective, unfortunately contradicts with SEV's original intention of eliminating the hypervisor from the TCB. Fidelius mentioned a method to protect disk I/O that is similar to our temporary fix (see Section 5.2) but implies that the disk image is shipped to the SEV platform. Thus it requires using the same  $K_{tek}$  every time the disk image is used. Our proxy-style solutions in Section 5.2 is a generalization of their approach.

## 6.2 Security Threats of Intel TEEs

**Intel TME and MKTME.** Intel's counterparts of AMD's SME and SEV are Total Memory Encryption (TME) and Multi-Key Total Memory Encryption (MKTME) [18]. The concept of TME is almost the same as AMD SME: an AES-XTS encryption engine sits between a direct data path and external memory buses to encrypt data when leaving the processor and decrypt it when entering the processor. TME supports a single ephemeral encryption key for the entire processor. In contrast, MKTME supports multiple keys; it labels each page table entry with a KeyID to select one of the ephemeral AES keys generated in the encryption engine. Different from AMD SEV, guest VMs in MKTME may have more than one AES key. KeyID0 is used for guest VM to share pages with hypervisor. KeyID $N$  is assigned to guest the  $N$ th VM by hypervisor for guest's private page. However, the guest VM is able to obtain other KeyIDs to share memory with another guest VMs. As we were not able to purchase a machine with TME and MKTME on the market at the time of writing, we leave the analysis of these Intel's technologies to future work.

**Intel SGX.** Intel Software Guard eXtension (SGX) is an instruction set architecture extension that supports isolation of memory regions of userspace processes. Through a microcode-extended memory management unit, memory accesses to the protected memory regions, dubbed *enclaves*, are mediated so that only instructions belonging to the same enclave are permitted. Software attacks from all privileged software layers, including operating systems, hypervisors, system management software, are prevented by SGX. A hardware Memory Encryption Engine sits between the processor and the memory to encrypt memory traffic on the fly, so that confidentiality of the enclave memory is guaranteed even with physical attackers. Remote attestation is supported in SGX to guard the *integrity* of the enclave code.

Similar to AMD's SEV, SGX constructs TEE on Intel processors. However, it differs from SEV as it only isolates portions of the user processes' memory space, whereas SEV encrypts the memory of the entire virtual machine. Developers of SEV do not need to rewrite the software when using AMD's TEE; but SGX developers have to manually partition applications into trusted and untrusted components, and recompile the source code with the SDKs provided by Intel. SGX machines have been available on market since late 2015. So far, two major types of attacks have been demonstrated to SGX applications.

- *Side-channel attacks.* Prior studies have demonstrated that enclave secrets in SGX can be exfiltrated through side channels on the CPU caches [8, 15, 16, 27], branch target buffers [22], DRAM's row buffer contention [34], page-table entries [33, 34], and page-fault exception handlers [30, 36]. More recently, side-channel attacks exploiting speculative and out-of-order execution have been

shown on SGX as well [10, 32]. Similar to SGX, SEV is not designed to thwart side-channel attacks. Therefore, we expect similar attacks can be carried out on AMD's SEV as well. Because the attacks demonstrated in this paper already completely breaks the confidentiality of SEV-protected VMs, there is no need to rely on side channels to extract secrets. However, in some of the attacks we demonstrate, side channels do facilitate the attacks. We leave the discussion on side-channel surface of SEV to future work.

- *Memory hijacking attacks.* SGX does not guard memory safety inside the enclaves. Studies [7, 21] have shown that attackers could exploit vulnerabilities in enclave programs and perform return-oriented programming (ROP) attacks [29]. Randomization-based security defenses have been proposed to mitigate ROP attacks [28]. However, as pointed out by Biondo *et al.* [7], SGX runtimes inherently contains memory regions that are hard to randomize, and thus completely eliminating the threats of memory hijacking attacks requires eradicating vulnerabilities from the enclave code. As neither SGX nor SEV is designed to provide memory safety, memory hijacking attacks are feasible on SEV as well. We will not further discuss these attacks on SEV in this paper.

AMD SEV is also vulnerable to these attacks. In this paper, we have explored a fine-grained page-fault side channel to locate the memory buffers used in the I/O operations. We leave a comprehensive study of SEV side-channel and memory-hijacking attacks to future work.

## 7 Conclusion

In this paper, we have reported our study of the insecurity of SEV from the perspective of the unprotected I/O operations in SEV-enabled VMs. The results of our study are two fold: First, I/O operations from SEV guests are not secure; second, I/O operations can be used by the adversary to construct memory encryption and decryption oracles. The concrete attacks have been demonstrated in the paper, along with discussion of potential solutions to the underlying problems.

## Abstract

We present the first large-scale characterization of lateral phishing attacks, based on a dataset of 113 million employee-sent emails from 92 enterprise organizations. In a lateral phishing attack, adversaries leverage a compromised enterprise account to send phishing emails to other users, benefiting from both the implicit trust and the information in the hijacked user’s account. We develop a classifier that finds hundreds of real-world lateral phishing emails, while generating under four false positives per every one-million employee-sent emails. Drawing on the attacks we detect, as well as a corpus of user-reported incidents, we quantify the scale of lateral phishing, identify several thematic content and recipient targeting strategies that attackers follow, illuminate two types of sophisticated behaviors that attackers exhibit, and estimate the success rate of these attacks. Collectively, these results expand our mental models of the ‘enterprise attacker’ and shed light on the current state of enterprise phishing attacks.

## 1 Introduction

For over a decade, the security community has explored a myriad of defenses against phishing attacks. Yet despite this long line of work, modern-day attackers routinely and successfully use phishing attacks to compromise government systems, political figures, and companies spanning every economic sector. Growing in prominence each year, this genre of attacks has risen to the level of government attention, with the FBI estimating \$12.5 billion in financial losses worldwide from 78,617 reported incidents between October 2013 to May 2018 [12], and the US Secretary of Homeland Security declaring that phishing represents “the most devastating attacks by the most sophisticated attackers” [39].

By and large, the high-profile coverage around targeted spearphishing attacks against major entities, such as Google, RSA, and the Democratic National Committee, has captured and shaped our mental models of enterprise phishing attacks [35, 43, 46]. In these newsworthy instances, as well as many of the targeted spearphishing incidents discussed in the academic literature [25, 26, 28], the attacks come from external accounts, created by nation-state adversaries who cleverly craft or spoof the phishing account’s name and email address to resemble a known and legitimate user. However, in recent years, work from both industry [7, 24, 36] and academia [6, 18, 32, 41] has pointed to the emergence and

growth of *lateral phishing* attacks: a new form of phishing that targets a diverse range of organizations and has already incurred billions of dollars in financial harm [12]. In a lateral phishing attack, an adversary uses a compromised enterprise account to send phishing emails to a new set of recipients. This attack proves particularly insidious because the attacker automatically benefits from the implicit trust in the hijacked account: trust from both human recipients and conventional email protection systems.

Although recent work [10, 15, 18, 19, 41] presents several ideas for detecting lateral phishing, these prior methods either require that organizations possess sophisticated network monitoring infrastructure, or they produce too many false positives for practical usage. Moreover, no prior work has characterized this attack at a large, generalizable scale. For example, one of the most comprehensive related work uses a multi-year dataset from one organization, which only contains two lateral phishing attacks [18]. This state of affairs leaves many important questions unanswered: How should we think about this class of phishing with respect to its scale, sophistication, and success? Do attackers follow thematic strategies, and can these common behaviors fuel new or improved defenses? How are attackers capitalizing on the information within the hijacked accounts, and what does their behavior say about the state and trajectory of enterprise phishing attacks?

In this joint work between academia and Barracuda Networks we take a first step towards answering these open questions and understanding *lateral phishing* at scale. This paper seeks to both explore avenues for practical defenses against this burgeoning threat and develop accurate mental models for the state of these phishing attacks in the wild.

First, we present a new classifier for detecting URL-based lateral phishing emails and evaluate our approach on a dataset of 113 million emails, spanning 92 enterprise organizations. While the dynamic churn and dissimilarity in content across phishing emails proves challenging, our approach can detect 87.3% of attacks in our dataset, while generating less than 4 false positives per every 1,000,000 employee-sent emails.

Second, combining the attacks we detect with a corpus of user-reported lateral phishing attacks, we conduct the first large-scale characterization of lateral phishing in real-world organizations. Our analysis shows that this attack is potent and widespread: dozens of organizations, ranging from ones with fewer than 100 employees to ones with over 1,000 employees, experience lateral phishing attacks within the span

of several months; in total, 14% of a set of randomly sampled organizations experienced at least one lateral phishing incident within a seven-month timespan. Furthermore, we estimate that over 11% of attackers successfully compromise at least one additional employee. Even though our ground truth sources and detector face limitations that restrict their ability to uncover stealthy or narrowly targeted attacks, our results nonetheless illuminate a prominent threat that currently affects many real-world organizations.

Examining the behavior of lateral phishers, we explore and quantify the popularity of four recipient (victim) selection strategies. Although our dataset's attackers target dozens to hundreds of recipients, these recipients often include a subset of users with some relationship to the hijacked account (e.g., fellow employees or recent contacts). Additionally, we develop a categorization for the different levels of content tailoring displayed by our dataset's phishing messages. Our categorization shows that while 7% of attacks deploy targeted messages, most attacks opt for generic content that a phisher could easily reuse across multiple organizations. In particular, we observe that lateral phishers rely predominantly on two common lures: a pretext of a shared document and a fake warning message about a problem with the recipient's account. Despite the popularity of non-targeted content, nearly one-third of our dataset's attackers invest additional time and effort to make their attacks more convincing and/or to evade detection; and, over 80% of attacks occur during the normal working hours of the hijacked account.

Ultimately, this work yields two contributions that expand our understanding of enterprise phishing and potential defenses against it. First, we present a novel detector that achieves an order-of-magnitude better performance than prior work, while operating on a minimal data requirement (only leveraging historical emails). Second, through the first large-scale characterization of lateral phishing, we uncover the scale and success of this emerging class of attacks and shed light on common strategies that lateral phishers employ. Our analysis illuminates a prevalent class of enterprise attackers whose behavior does not fully match the tactics of targeted nation-state attacks or industrial espionage. Nonetheless, these lateral phishers still achieve success in the absence of new defenses, and many of our dataset's attackers do exhibit some signs of sophistication and focused effort.

## 2 Background

In a *lateral phishing* attack, attackers use a compromised, but legitimate, email account to send a phishing email to their victim(s). The attacker's goals and choice of malicious payload can take a number of different forms, from a malware-infected attachment, to a phishing URL, to a fake payment request. Our work focuses on lateral phishing attacks that employ a malicious URL embedded in the email, which is the most common exploit method identified in our dataset.

**Listing 1:** An anonymized example of a lateral phishing message that uses the lure of a fake contract document.

```
From: "Alice" <alice@company.com>
To: "Bob" <bob@company.com>
Subject: Company X (New Contract)

New Contract

View Document [this text linked to a phishing website]

Regards,
Alice [signature]
```

Listing 1 shows an anonymized example of a lateral phishing attack from our study. In this attack, the phisher tried to lure the recipient into clicking on a link under the false pretense of a new contract. Additionally, the attacker also tried to make the deception more credible by responding to recipients who inquired about the email's authenticity; and they also actively hid their presence in the compromised user's mailbox by deleting all traces of their phishing email.

Lateral phishing represents a dangerous but understudied attack at the intersection of phishing and account hijacking. Phishing attacks, broadly construed, involve an attacker crafting a deceptive email from any account (compromised or spoofed) to trick their victim into performing some action. Account hijacking, also known as account takeover (ATO) in industry parlance, involves the use of a compromised account for any kind of malicious means (e.g., including spam). While prior work primarily examines each of these attacks at a smaller scale and with respect to personal accounts, our work studies the intersection of both of these at a large scale and from the perspective of enterprise organizations. In doing so, we expand our understanding of important enterprise threats, avenues for defending against them, and strategies used by the attackers who perpetrate them.

### 2.1 Related Work

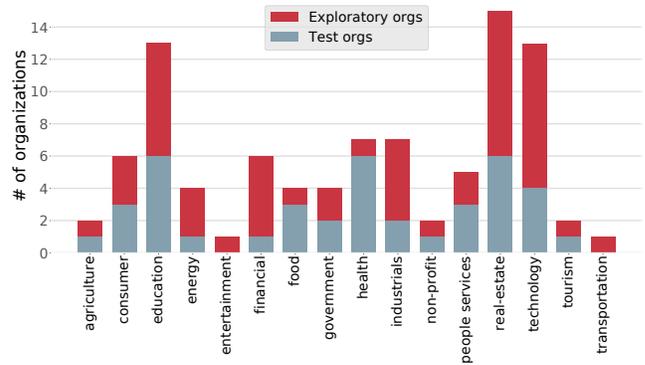

**Detection:** An extensive body of prior literature proposes numerous techniques for detecting traditional phishing attacks [1, 3, 13, 14, 44], as well as more sophisticated spearphishing attacks [8, 10, 23, 41, 47]. Hu et al. studied how to use social graph metrics to detect malicious emails sent from compromised accounts [19]. Their approach detects hijacked accounts with false positive rates between 20–40%. Unfortunately, in practice, many organizations handle tens of thousands of employee-sent emails per day, so a false positive rate of 20% would lead to thousands of false alerts each day. IdentityMailer, proposed by Stringhini et al. [41], detects lateral phishing attacks by training behavior models based on timing patterns, metadata, and stylometry for each user. If a new email deviates from an employee's behavioral model,

their system flags it as an attack. While promising, their approach produces false positive rates in the range of 1–10%, which is untenable in practice given the high volume of benign emails and low base rate of phishing. Additionally, their system requires training a behavioral model for each employee, incurring expensive technical debt to operate at scale.

Ho et al. developed methods for detecting lateral spearphishing by applying a novel anomaly detection algorithm on a set of features derived from historical user login data and enterprise network traffic logs [18]. Their approach detects both known and newly discovered attacks, with a false positive rate of 0.004%. However, organizations with less technical expertise often lack the infrastructure to comprehensively capture the enterprise’s network traffic, which this prior approach requires. This technical prerequisite begs the question, can we practically detect lateral phishing attacks with a more minimalist dataset: only the enterprise’s historical emails? Furthermore, their dataset reflects a single enterprise that experienced only two lateral phishing attacks across a 3.5-year timespan, which prevents them from characterizing the nature of lateral phishing at a general scale.

**Characterization:** While prior work shows that attackers frequently use phishing to compromise accounts, and that attackers occasionally conduct (lateral) phishing from these hijacked accounts, few efforts have studied the nature of lateral phishing in depth and at scale. Examining a sample of phishing emails, webpages, and compromised accounts from Google data sources, one prior study of account hijacking discovered that attackers often use these accounts to send phishing emails to the account’s contacts [6]. However, they concluded that automatically detecting such attacks proves challenging. Onalapo et al. studied what attackers do with hijacked accounts [32], but they did not examine lateral phishing. Separate from email accounts, a study of compromised Twitter accounts found that infections appear to spread laterally through the social network. However their dataset did not allow direct observation of the lateral attack vector itself [42], nor did it provide insights into the domain of compromised enterprise accounts (given the nature of social media).

**Open Questions and Challenges:** Prior work makes clear that account compromise poses a significant and widespread problem. This literature also presents promising defenses for enterprises that have sophisticated monitoring in place. Yet despite these advances, several key questions remain unresolved. Do organizations without comprehensive monitoring and technical expertise have a practical way to defend against lateral phishing attacks? What common strategies and trade-craft do lateral phishers employ? How are lateral phishers capitalizing on their control of legitimate accounts, and what does their tactical sophistication say about the state of enterprise phishing? This paper takes a step towards answering these open questions by presenting a new detection strategy and a large-scale characterization of lateral phishing attacks.

**Figure 1:** Breakdown of the economic sectors across our dataset’s 52 exploratory organizations versus the 40 test organizations.

## 2.2 Ethics

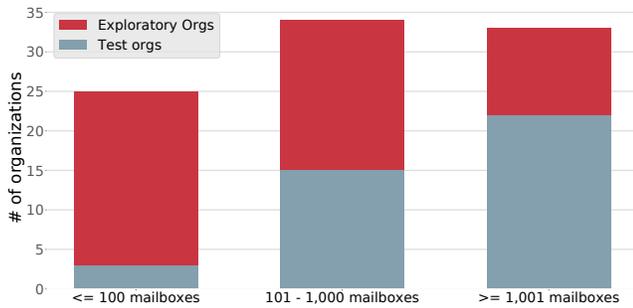

In this work, our team, consisting of researchers from academia and a large security company, developed detection techniques using a dataset of historical emails and reported incidents from 92 organizations who are active customers of Barracuda Networks. These organizations granted Barracuda permission to access their Office 365 employee mailboxes for the purpose of researching and developing defenses against lateral phishing. Per Barracuda’s policies, all fetched emails are stored encrypted, and customers have the option of revoking access to their data at any time.

Due to the sensitivity of the data, only authorized employees at Barracuda were allowed to access the data (under standard, strict access control policies). No personally identifying information or sensitive data was shared with any non-employee of Barracuda. Our project also received legal approval from Barracuda, who had permission from their customers to analyze and operate on the data.

Once Barracuda deployed a set of lateral phishing detectors to production, any detected attacks were reported to customers in real time to prevent financial loss and harm.

## 3 Data

Our dataset consists of employee-sent emails from 92 English-language organizations; 23 organizations came from randomly sampling enterprises that had reports of lateral phishing, and 69 were randomly sampled from all organizations. Across these enterprises, 25 organizations have 100 or fewer user accounts, 34 have between 101–1000 accounts, and 33 have over 1000 accounts. Real-estate, technology, and education constitute the three most common industries in our dataset, with 15, 13, and 13 enterprises respectively; Figures 1 and 2 show the distribution of the economic sectors and sizes of our dataset’s organizations, broken down by *exploratory organizations* versus *test organizations* (§ 3.2).

**Figure 2:** Breakdown of the organization sizes across our dataset’s 52 exploratory organizations versus the 40 test organizations.

### 3.1 Schema

The organizations in our dataset use Office 365 as their email provider. At a high level, each email object contains: a unique Office 365 identifier; the email’s metadata (SMTP header information), which describes properties such as the email’s sent timestamp, recipients, purported sender, and subject; and the email’s *body*, the contents of the email message in full HTML formatting. Office 365’s documentation describes the full schema of each email object [29]. Additionally, for each organization, we have a set of *verified domains*: domains which the organization has declared that it owns.

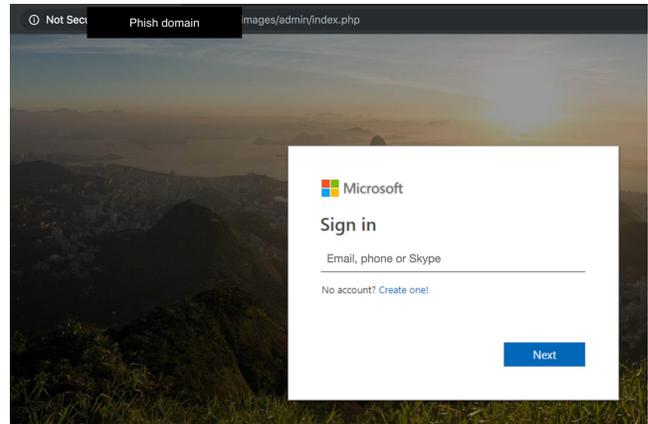

### 3.2 Dataset Size

Our dataset consists of 113,083,695 unique, employee-sent emails. To ensure our detection techniques generalized (Section 5.1), we split our data into a training dataset of emails from 52 ‘exploratory organizations’ during April–June 2018, and a test dataset covering July–October 2018 from 92 organizations. Our test dataset consists of emails from the 52 exploratory organizations (but from a later, disjoint time period than our training dataset), plus data from an additional, held-out set of 40 ‘test organizations’. We selected the 40 test organizations via a random sample that we performed prior to analyzing any data. Our training dataset has 25,670,264 emails, and our test dataset has 87,413,431 emails. Both sets of organizations cover a diverse range of industries and sizes as shown in Figures 1 and 2. The exploratory organizations span a total of 89,267 user mailboxes that sent or received email, and the test organizations have 138,752 mailboxes (based on the data from October 2018).<sup>1</sup>

### 3.3 Ground truth

Our set of lateral phishing emails comes from two sources: (1) attack emails reported to Barracuda by an organization’s security administrators, as well as attacks reported by users to their organization or directly to Barracuda, and (2) emails

<sup>1</sup>The number of mailboxes is an upper bound on the number of employees due to the use of mailing lists and aliases.

**Figure 3:** An anonymized screenshot of the web page that a phishing URL in a lateral phishing email led to.

flagged by our detector (§4), which we manually reviewed and labeled before including.

At a high-level, to manually label an email as phishing, or not, we examined its message content, Office 365 metadata, and Internet Message Headers [33] to determine whether the email contained phishing content, and whether the email came from a compromised account (versus an external account, which we do not treat as lateral phishing). For example, if the Office 365 metadata showed that a copy of the email resided in the employee’s *Sent Items* folder, or if its headers showed that the email passed the corresponding SPF or DKIM [9] checks, then we considered the email to be lateral phishing. Appendix §A.1 describes our labeling procedure in detail.

Additionally, for a small sample of URLs in these lateral phishing emails, employees at Barracuda accessed the phishing URL in a VM-contained browser to better understand the end goals of the attack. To minimize potential harm and side effects, these employees only visited phishing URLs which contained no unique identifiers (i.e., no random strings or user/organization information in the URL path). To handle any phishing URLs that resided on URL-shortening domains, we used one of Barracuda’s URL-expansion APIs that their production services already apply to email URLs, and only visited suspected phishing links that expanded to a non-side-effect URL. Most phishing URLs we explored led to a SafeBrowsing interstitial webpage, likely reflecting our use of historical emails, rather than what users would have encountered contemporaneously. However, more recent malicious URLs consistently led to credential phishing websites designed to look like a legitimate Office 365 login page (the email service provider used by our study’s organizations); Figure 3 shows an anonymized example of one phishing website.

In total, our dataset contains 1,902 lateral phishing emails (unique by subject, sender, and sent-time), sent by 154 hijacked employee accounts from 33 organizations. 1,694 of these emails were reported by users, with the remainder found solely by our detector (§4); our detector also finds many of the

user-reported attacks as well (§ 5). Among the user-reported attacks, 40 emails (from 12 hijacked accounts) contained a fake wire transfer or malicious attachment, while the remaining 1,862 emails used a malicious URL.

We focus our detection strategy on URL-based phishing, given the prevalence of this attack vector. This focus means that our analysis and detection techniques do not reflect the full space of lateral phishing attacks. Despite this limitation, our dataset’s attacks span dozens of organizations, enabling us to study a prevalent class of enterprise phishing that poses an important threat in its own right.

## 4 Detecting Lateral Phishing

Adopting the *lateral attacker* threat model defined by Ho et al. [18], we focus on phishing emails sent by a compromised employee account, where the attack embeds a malicious URL as the exploit (e.g., leading the user to a phishing webpage).

We explored three strategies for detecting lateral phishing attacks, but ultimately found that one of the strategies detected nearly all of the attacks identified by all three approaches. At a high level, the two less fruitful strategies detected attacks by looking for emails that contained (1) a rare URL and (2) a message whose text seemed likely to be used for phishing (e.g., similar text to a known phishing attack). Because our primary detection strategy detected all-but-two of the attacks found by the other strategies, while finding over ten times as many attacks, we defer discussion of the two less successful approaches to our extended technical report [17]; below, we focus on exploring the more effective strategy in detail. In our evaluation, we include the two additional attacks found by the alternative approaches as false negatives for our detector.

**Overview:** We examined the user-reported lateral phishing incidents in our training dataset (April–June 2018) to identify widespread themes and behaviors that we could leverage in our detector. Grouping this set of attacks by the hijacked account (*ATO*) that sent them, we found that 95% of these ATOs sent phishing emails to 25 or more distinct recipients.<sup>2</sup> This prevalent behavior, along with additional feature ideas inspired by the lure-exploit detection framework [18], provide the basis for our detection strategy. In the remainder of this section, we describe the features our detector uses, the intuition behind these features, and our detector’s machine learning procedure for classifying emails.

Our techniques provide neither an all-encompassing approach to finding every attack, nor guaranteed robustness against motivated adversaries trying to evade detection. However, we show in Section 5 that our approach finds hundreds of lateral phishing emails across dozens of real-world organizations, while incurring a low volume of false positives.

<sup>2</sup>To assess the generalizability of our approach, our evaluation uses a withheld dataset, from a later timeframe and with new organizations (§ 5).

**Features:** Our detector extracts three sets of features. The first set consists of two features that target the popular behavior we observed earlier: contacting many recipients. Given an email, we first extract the number of unique recipients across the email’s To, CC, and BCC headers. Additionally, we compute the Jaccard similarity of this email’s recipient set to the closest set of historical recipients seen in any employee-sent email from the preceding month. We refer to this latter (similarity) feature as the email’s recipient likelihood score.

The next two sets of features draw upon the lure-exploit phishing framework proposed by Ho et al. [18]. This framework posits that phishing emails contain two necessary components: a ‘lure’, which convinces the victim to believe the phishing email and perform some action; and an ‘exploit’: the malicious action the victim should execute. Their work finds that using features that target both of these two components significantly improves a detector’s performance.

To characterize whether a new email contains a potential phishing lure, our detector extracts a single, lightweight boolean feature based on the email’s text. Specifically, Baracuda provided us with a set of roughly 150 keywords and phrases that frequently occur in phishing attacks. They developed this set of ‘phishy’ keywords by extracting the link text from several hundred real-world phishing emails (both external and lateral phishing) and selecting the (normalized) text that occurred most frequently among these attacks. The-matically, these suspicious keywords convey a call to action that entices the recipient to click a link. For our ‘lure’ feature, we extract a boolean value that indicates whether an email contains any of these phishy keywords.

Finally, we complete our detector’s feature set by extracting two features that capture whether an email might contain an exploit. Since our work focuses on URL-based attacks, this set of features reflects whether the email contains a potentially dangerous URL.

First, for each email, we extract a *global URL reputation* feature that quantifies the rarest URL an email contains. Given an email, we extract all URLs from the email’s body and ignore URLs if they fall under two categories: we exclude all URLs whose domain is listed on the organization’s *verified domain* list (§ 3.1), and we also exclude all URLs whose displayed, hyperlinked text exactly matches the URL of the hyperlink’s underlying destination. For example, in Listing 1’s attack, the displayed text of the phishing hyperlink was “Click Here”, which does not match the hyperlink’s destination (the phishing site), so our procedure would keep this URL. In contrast, Alice’s signature from Listing 1 might contain a link to her personal website, e.g., [www.alice.com](http://www.alice.com); our procedure would ignore this URL, since the displayed text of [www.alice.com](http://www.alice.com) matches the hyperlink’s destination.

This latter filtering criteria makes the assumption that a phishing URL will attempt to obfuscate itself, and will not display the true underlying destination directly to the user. After these filtering steps, we extract a numerical feature by

mapping each remaining URL to its registered domain, and then looking up each domain’s ranking on the Cisco Umbrella Top 1 Million sites [20];<sup>3</sup> for any unlisted domain, we assign it a default ranking of 10 million. We treat two special cases differently. For URLs on shortener domains, our detector attempts to recursively resolve the shortlink to its final destination. If this resolution succeeds, we use the global ranking of the final URL’s domain; otherwise, we treat the URL as coming from an unranked domain (10 million). For URLs on content hosting sites (e.g., Google Drive or Sharepoint), we have no good way to determine its suspiciousness without fetching the content and analyzing it (an action that has several practical hurdles). As a result, we treat all URLs on content hosting sites as if they reside on unranked domains.

After ranking each URL’s domain, we set the email’s *global URL reputation* feature to be the worst (highest) domain ranking among its URLs. Intuitively, we expect that phishers will rarely host phishing pages on popular sites, so a higher *global URL reputation* indicates a more suspicious email. In principle a motivated adversary could evade this feature; e.g., if an adversary can compromise one of the organization’s verified domains, they can host their phishing URL from this compromised site and avoid an accurate ranking. However, we found no such instances in our set of user-reported lateral phishing. Additionally, since the goal of this paper is to begin exploring practical detection techniques, and develop a large set of lateral phishing incidents for our analysis, this feature suffices for our needs.

In addition to this global reputation metric, we extract a local metric that characterizes the rareness of a URL with respect to the domains of URLs that an organization’s employees typically send. Given a set of URLs embedded within an email, we map each URL to its fully-qualified domain name (FQDN) and count the number of days from the preceding month where at least one employee-sent email included a URL on the FQDN. We then take the minimum value across all of an email’s URLs; we call this minimum value the *local URL reputation* feature. Intuitively, suspicious URLs will have both a low global reputation and a low local reputation. However, our evaluation (§ 5.2) finds that this *local URL reputation* feature adds little value: URLs with a low *local URL reputation* value almost always have a low *global URL reputation* value, and vice versa.

**Classification:** To label an email as phishing or not, we trained a Random Forest classifier [45] with the aforementioned features. To train our classifier, we take all user-reported lateral phishing emails in our training dataset, and combine them with a set of likely-benign emails. We generate this set of “benign” emails by randomly sampling a subset of the training window’s emails that have not been reported as phishing; we sample 200 of these benign emails for each

<sup>3</sup>We use a list fetched in early March 2018 for our feature extraction, but in practice, one could use a continuously updated list.

attack email to form our set of benign emails for training. Following standard machine learning practices, we selected both the hyperparameters for our classifier and the exact downsampling ratio (200:1) using cross-validation on this training data. Appendix A.2 describes our training procedure in more detail.

Once we have a trained classifier, given a new email, our detector extracts its features, feeds the features into this classifier, and outputs the classifier’s decision.

## 5 Evaluation

In this section we evaluate our lateral phishing detector. We first describe our testing methodology, and then show how well the detector performs on millions of emails from over 90 organizations. Overall, our detector has a high detection rate, generates few false positives, and detects many new attacks.

### 5.1 Methodology

**Establishing Generalizability:** As described earlier in Section 3.2, we split our dataset into two disjoint segments: a *training dataset* consisting of emails from the 52 exploratory organizations during April–June 2018 and a *test dataset* from 92 enterprises during July–October 2018; in § 5.2, we show that our detector’s performance remains the same if our test dataset contains only the emails from the 40 withheld test organizations. Given these two datasets, we first trained our classifier and tuned its hyperparameters via cross validation on our training dataset (Appendix A.2). Next, to compute our evaluation results, we ran our detector on each month of the held-out test dataset. To simulate a classifier in production, we followed standard machine learning practices and used a continuous learning procedure to update our detector each month [38]. Namely, at the end of each month, we aggregated the user-reported and detector-discovered phishing emails from all previous months into a new set of phishing ‘training’ data; and, we aggregated our original set of randomly sampled benign emails with our detector’s false positives from all previous months to form a new benign ‘training’ dataset. We then trained a new model on this aggregated training dataset and used this updated model to classify the subsequent month’s data. However, to ensure that any tuning or knowledge we derived from the training dataset did not bias or overfit our classifier, we did not alter any of the model’s hyperparameters or features during our evaluation on the test dataset.

Our evaluation’s temporal-split between the training and test datasets, along with the introduction of new data from randomly withheld organizations into the test dataset, follows best practices that recommend this approach over a randomized cross-validation evaluation [2, 31, 34]. A completely randomized evaluation (e.g., cross-validation) risks training on data from the future and testing on the past, which might lead us to overestimate the detector’s effectiveness. In contrast,

Metric	Training	Testing
	April – June 2018	July – October 2018
Organizations	52 Exploratory	52 Exploratory + 40 Test
Detected Known Attacks	34	47
Detected New Attacks	28	49
Missed Attacks (FN)	8	14
Detection Rate	88.6%	87.3%
Total Emails	25,670,264	87,413,431
False Positives (FP)	136	316
False Positive Rate	0.00053%	0.00036%
Precision	31.3%	23.3%

**Table 1:** Evaluation results of our detector. ‘Detected Known Attacks’ shows the number of incidents that our detector identified, and were also reported by an employee at an organization. ‘Detected New Attacks’ shows the number of incidents that our detector identified, but were not reported by anyone. ‘Missed Attacks (FN)’ shows all incidents either reported by a user or found by any of our detection strategies, but our detector marked it as benign (false negative). Of the 22 incidents our detector misses, 12 are attachment-based attacks, a threat model which our detector explicitly does not target but which we include in our FN and Detection Rate results for completeness.

our methodology evaluates our detector with fresh data from a “future” time period and introduces 40 new organizations, neither of which our detector saw during training time; this also reflects how a detector operates in practice.

**Alert Metric (Incidents):** We have several choices for modeling our detector’s alert generation process (i.e., how we count *distinct* attacks). For example, we could evaluate our detector’s performance in terms of how many unique emails it correctly labels. Or, we could measure our detector’s performance in terms of how many distinct employee accounts it marks as compromised (modeling a detector that generates one alert per account and suppresses the rest). Ultimately, we select a notion commonly used in practice, that of an *incident*, which corresponds to a unique (subject, sender email address) pair. At this granularity, our detector’s alert generation model produces a single alert per unique (subject, sender) pair. This metric avoids biased evaluation numbers that overemphasize compromise incidents that generate many identical emails during a single attack. For example, if there are two incidents, one which generates one hundred emails to one recipient each, and another which generates one email to 100 recipients, a detector’s performance on the hundred-email incident will dominate the result if we count attacks at the email level.

In total, our training dataset contains 40 lateral phishing incidents from our user-reported ground truth sources, and our test dataset contains 61 user-reported incidents. Our detector finds an additional 77 unreported incidents (row 2 of Table 1).

## 5.2 Detection Results

Table 1 summarizes the performance metrics for our detector. We use the term *Detection Rate* to refer to the percentage of

lateral phishing incidents that our detector finds, divided by all known attack incidents in our dataset (i.e., any user-reported incident and any incident found by any detection technique we tried). For completeness, we include the 12 attachment-based incidents in our False Negative and Detection Rate computations, which our detector obviously misses since we designed it to catch URL-based lateral phishing. Additionally, we also include, as false negatives, 2 training incidents that our less successful detectors identified [17]; these two alternative strategies did not find any new attacks in the test dataset. Thus, the *Detection Rate* reflects a best-effort assessment that potentially overestimates the true positive rate of our detector, since we have an imperfect ground truth that cannot account for narrowly targeted attacks that go unreported by users. *Precision* equals the percent of attack alerts (incidents) produced by our detector divided by the total number of alerts our detector generated (attacks plus false positives).

**Training and Tuning:** On the training dataset, our detector correctly identified 62 out of 70 lateral phishing incidents (88.6%), while generating a total of 62 false positives (on 25.7 million employee-sent emails).

Our PySpark Random Forest classifier exposes a built-in estimate of each feature’s relative importance [40], where each feature receives a score between 0.0–1.0 and the sum of all the scores adds up to 1.0. Based on these feature weights, our model places the most emphasis on the *global URL reputation* feature, giving it a weight of 0.42, and the email’s ‘number of recipients’ feature (0.34). In contrast, our model essentially ignores our *local URL reputation*, assigning it a score of 0.01, likely because most globally rare domains tend to also be locally rare. Of the remaining features, the recipient likelihood feature has a weight of 0.17 and the ‘phishy’ keyword feature has a weight of 0.06.

**Test Dataset:** Our detector correctly identified 96 lateral phishing incidents out of the 110 test incidents (87.3%) across our ground truth dataset. Additionally, our detector discovered 49 incidents that, according to our ground truth, were not reported by a user as phishing. With respect to its cost, our detector generated 312 total false positives across the entire test dataset (a false positive rate of less than 0.00035%, assuming that emails not identified as an attack by our ground truth are benign). Across our test dataset, 82 out of the 92 organizations accumulated 10 or fewer false positives across the entire four month window, with 44 organizations encountering zero false positives across this timespan. In contrast, only three organizations had more than 40 total false positives across all four months (encountering 44, 66, and 83 false positives, respectively). Our detector achieves similar results if we evaluate on just the data from our 40 withheld test organizations, with a Detection Rate of 91.0%, a precision of 23.1%, and a false positive rate of 0.00038%.

**Bias and Evasion:** We base our evaluation numbers on the best ground truth we have: a combination of all user-reported

lateral phishing incidents (including some attacks outside our threat model), and all incidents discovered by any detection technique we tried (which includes two approaches orthogonal to our detector’s strategy). This ground truth suffers from a bias towards phishing emails that contact many potential victims, and attacks that users can more easily recognize. Additionally, since our detector focuses on URL-based exploits, our dataset of attacks likely underestimates the prevalence of non-URL-based phishing attacks, which come solely from user-reported instances in our dataset. As a result, our work does not capture the full space of lateral phishing attacks, such as ones where the attacker targets a narrow, select set of victims with stealthily deceptive content. Rather, given that our detector identifies many known and unreported attacks, while generating only a few false positives per month, we provide a starting point for practical detection that future work can extend. Moreover, even if our detector does not capture every possible attack, the fact that the attacks in our dataset span dozens of different organizations, across a multi-month timeframe, allows us to illuminate a class of understudied attacks that many enterprises currently face.

Aside from obtaining more comprehensive ground truth, more work is needed to explore defenses against potential evasion attacks. Attackers could attempt to evade our detector by targeting different features we draw upon, such as the composition or number of recipients they target. Against many of these evasion attacks, future work could leverage additional features and data, such as the actions a user takes within an email account (e.g., reconnaissance actions, such as unusual searches, that indicate an attacker mining the account for targeted recipients to attack) or information from the user’s account log-on (e.g., the detector proposed by Ho et al. used an account’s login IP address [18] to detect lateral phishing). At the same time, future work should study which evasion attacks remain economically feasible for attackers to conduct. For example, an attacker could choose to only target a small number of users in the hopes of evading our detector; but even if this evasion succeeded, the conversion rate of fooling a recipient might be so low that the attack ultimately fails to compromise an economically viable number of victims. Indeed, as we explore in the following section (§ 6), the attackers captured in our dataset already engage in a range of different behaviors, including a few forms of sophisticated, manual effort to increase the success of their attacks.

## 6 Characterizing Lateral Phishing

In this section, we conduct an analysis of real-world lateral phishing using all known attacks across our entire dataset (both training and test). During the seven month timespan, a total of 33 organizations experienced lateral phishing attacks, with the majority of these compromised organizations experiencing multiple incidents. Examining the thematic message content and recipient targeting strategies of the attacks, our

Scale and Success	
# distinct phishing emails	1,902
# incidents	180
# ATOs	154
# organizations w/ 1+ incident	33
# phishing recipients	101,276
% successful ATOs	11%
# employee recip (average) for compromise	542

**Table 2:** Summary of the scale and success of the lateral phishing attacks in our dataset (§ 6.1).

analysis suggests that most lateral phishers in our dataset do not actively mine a hijacked account’s emails to craft personalized spearphishing attacks. Rather, these attackers operate in an opportunistic fashion and rely on commonplace phishing content. This finding suggests that the space of enterprise phishing has expanded beyond its historical association with sophisticated APTs and nation-state adversaries.

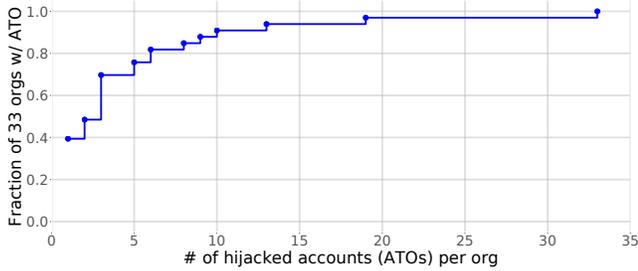

At the same time, these attacks nonetheless succeed, and a significant fraction of attackers do exhibit some signs of sophistication and attention to detail. As an estimate of the success of lateral phishing attacks, at least 11% of our dataset’s attackers successfully compromise at least one other employee account. In terms of more refined tactics, 31% of lateral phishers invest some manual effort in evading detection or increasing their attack’s success rate. Additionally, over 80% of the attacks in our dataset occur during the normal working hours of the hijacked account. Taken together, our results suggest that lateral phishing attacks pose a prevalent enterprise threat that still has room to grow in sophistication.

In addition to exploring attacks at the incident granularity (as done in § 5), this section also explores attacks at the granularity of a lateral phisher (hijacked account) when studying different attacker behaviors. As described in Section 2, industry practitioners often refer to such hijacked accounts as ATOs, and throughout this section, we use the terms *hijacked account*, *lateral phisher*, and *ATO* synonymously.

### 6.1 Scale and Success of Lateral Phishing

**Scale:** Our dataset contains 1,902 distinct lateral phishing emails sent by 154 hijacked accounts.<sup>4</sup> A total of 33 organizations in our dataset experience at least one lateral phishing incident: 23 of these organizations came from sampling the set of enterprises with known lateral phishing incidents (§ 3), while the remaining 10 came from the 69 organizations we sampled from the general population. Assuming our random sample reflects the broader population of enterprises, over 14% of organizations experience at least one lateral phishing incident within a 7 month timespan. Furthermore, based

<sup>4</sup>Distinct emails are defined by having a fully unique tuple of (sender, subject, timestamp, and recipients).

**Figure 4:** Fraction of organizations with  $x$  hijacked accounts that sent at least one lateral phishing email. 13 organizations had only 1 ATO; the remaining 20 saw lateral phishing from 2+ ATOs (§ 6.1).

on Figure 4, over 60% of the compromised organizations in our dataset experienced lateral phishing attacks from at least two hijacked employee accounts. Given that our set of attacks likely contains false negatives (thus underestimating the prevalence of attacks), these numbers illustrate that lateral phishing attacks are widespread across enterprise organizations.

**Successful Attacks:** Given our dataset, we do not definitively know whether an attack succeeded. However, we conservatively (under)estimate the success rate of lateral phishing using the methodology below. Based on this procedure, we estimate that at least 11% of lateral phishers successfully compromise at least one new enterprise account.

Let Alice and Bob represent two different ATOs at the same organization, where  $P_A$  and  $P_B$  represent one of Alice’s and Bob’s phishing emails respectively, and  $Reply_B$  represents a reply from Bob to a lateral phishing email he received from Alice. Intuitively, our methodology concludes that Alice successfully compromised Bob if (1) Bob received a phishing email from Alice, (2) shortly after receiving Alice’s phish, Bob then subsequently sent his own phish, and (3) we have strong evidence that the two employees’ phishing emails are related (reflected in criteria 3 and 4 below).

Formally, we say that  $P_A$  succeeded in compromising Bob’s account if *all* of the following conditions are true:

1. Bob was a recipient of  $P_A$
2. After receiving  $P_A$ , Bob subsequently sent his own lateral phishing emails ( $P_B$ )
3. Either of the following two conditions are met:
  - (a)  $P_B$  and  $P_A$  used similar phishing content: if the two attacks used identical subjects or if both of the phishing URLs they used belonged to the same fully-qualified domain
  - (b) Bob sent a reply ( $Reply_B$ ) to  $P_A$ , where his reply suggests he fell for Alice’s attack and where Bob sent  $Reply_B$  prior to his own attack ( $P_B$ )
4. Either of the following two conditions are met:
  - (a)  $P_B$  was sent within two days after Bob received  $P_A$

- (b)  $P_B$  and  $P_A$  used identical phishing messages or their phishing URLs’ paths followed nearly identical structures (e.g., ‘http://X.com/z/office365/index.html’ vs. ‘http://Y.com/z/office365/index.html’)

Unpacking the final criteria (#4), in the first case (4.a), we settled on a two-day interarrival threshold based on prior literature [21, 22], which suggests that 50% of users respond to an email within 2 days and roughly 75% of users who click on a spam email do so within 2 days. Assuming that phishing follows similar time constants for how long it takes a recipient to take action, 2 days represented a conservative threshold to establish a link between  $P_A$  and  $P_B$ . At the same time, both prior works show there exists a long tail of users who take weeks to read and act on an email. The second part (4.b) attempts to address this long tail by raising the similarity requirements between Alice and Bob’s attacks before concluding that former caused the latter. For successful attackers labeled by heuristic 4.b, the longest observed time gap between  $P_A$  and  $P_B$  is 17 days, which falls within a plausible timescale based on the aforementioned literature.

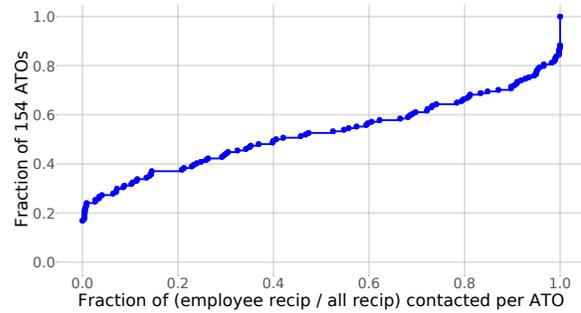

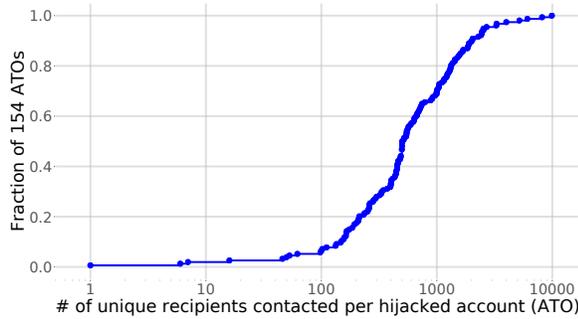

From this methodology, we conclude that 17 ATOs successfully compromised at least 23 future ATOs. While our procedure might erroneously identify cases where an attacker has concurrently compromised both Alice and Bob (rather than compromising Bob’s account via Alice’s), the first two criteria (requiring Bob to be a recent recipient of Alice’s phishing email) help reduce this error. Our procedure likely underestimates the general success rate of lateral phishing attacks, since it does not identify successful attacks where the attacker does not subsequently use Bob’s account to send phishing emails, nor does it account for false negatives in our dataset or attacks outside of our visibility (e.g., compromise of recipients at external organizations).

## 6.2 Recipient Targeting

In this section, we estimate the conversion rate of our dataset’s lateral phishing attacks, and discuss four recipient targeting strategies that reflect the behavior of most attackers in our dataset.

**Recipient Volume and Estimated Conversation Rate:** Cumulatively, the lateral phishers in our dataset contact 101,276 unique recipients, where 41,740 belong to the same organization as the ATO. As shown in Figure 5, more than 94% of the attackers send their phishing emails to over 100 recipients; with respect to the general population of all lateral phishers, this percentage likely overestimates the prevalence of high “recipient-volume” attackers, since our detector draws on recipient-related features.

Targeting hundreds of people gives attackers a larger pool of potential victims, but it also incurs a risk that a recipient will detect and flag the attack either to their security team or

**Figure 5:** The left CDF shows the distribution of the total number of phishing recipients per ATO. The right CDF shows the fraction of ATOs where  $x\%$  of their total recipient set consists of fellow employees.

their fellow recipients (e.g., via Reply-All). To isolate their victims and minimize the ability for fellow recipients to warn each other, we found that attackers frequently contact their recipients via a mass BCC or through many individual emails. Aside from this containment strategy, we also estimate that our dataset’s lateral phishing attacks have a difficult time fooling an individual employee, and thus might require targeting many recipients to hijack a new account. Earlier in Section 6.1, we found that 17 ATOs successfully compromised 23 new accounts. Looking at the number of accounts they successfully hijacked divided by the number of fellow employees they targeted, the median conversation rate for our attackers was one newly hijacked account per 542 fellow employees; the attacker with the best conversation rate contacted an average of 26 employees per successful compromise. We caution that our method for determining whether an attack succeeded (§ 6.1) does not cover all cases, so our conversation rate might also underestimate the success of these attacks in practice. But if our estimated conversion rate accurately approximates the true rate, it would explain why these attackers contact so many recipients, despite the increased risk of detection.

**Recipient Targeting Strategies:** Anecdotally, we know that some lateral phishers select their set of victims by leveraging information in the hijacked account to target familiar users; for example, sending their attack to a subset of the account’s “Contact Book”. Unfortunately our dataset does not include information about any reconnaissance actions that an attacker performed to select their phishing recipients (e.g., explicitly searching through a user’s contact book or recent recipients).

Instead, we empirically explore the recipient sets across our dataset’s attackers to identify plausible strategies for how these attackers might have chosen their set of victims. Four recipient targeting strategies, summarized in Table 3 (explained below), reflect the behavior of all but six attackers in our dataset. To help assess whether a recipient and the ATO share a meaningful relationship, we compute each ATO’s *recent contacts*: the set of all email addresses whom the ATO sent at least one email to in the 30 days preceding the ATO’s phishing emails. While some attackers (28.6%) specifically

Recipient Targeting Strategy	# ATOs
Account-agnostic	63
Organization-wide	39
Lateral-organization	2
Targeted-recipient	44
Inconclusive	6

**Table 3:** Summary of recipient targeting strategies per ATO (§ 6.2).

target many of an account’s recent contacts, the majority of lateral phishers appear more interested in either contacting many arbitrary recipients or sending phishing emails to a large fraction of the hijacked account’s organization.

**Account-agnostic Attackers:** Starting with the least-targeted behavior, 63 ATOs in our dataset sent their attacks to a wide range of recipients, most of whom do not appear closely related to the hijacked account. We call this group *Account-agnostic attackers*, and identify them using two heuristics.

First, we categorize an attacker as Account-agnostic if less than 1% of the recipients belong to the same organization as the ATO, and further exploration of their recipients does not reveal a strong connection with the account. Examining the right-hand graph in Figure 5, 37 ATOs target recipient sets where less than 1% of the recipients belong to the same organization as the ATO. To rule out the possibility that these attackers’ recipients are nonetheless related to the account, we computed the fraction of recipients who appeared in each ATO’s recent contacts; for all of the 37 possible Account-agnostic ATOs, less than 17% of their attack’s total recipients appeared in their recent contacts. Among these 37 candidate Account-agnostic ATOs, 33 of them contact recipients at 10 or more organizations (unique recipient email domains), 2 of them exclusively target either Gmail or Hotmail accounts, and the remaining 2 ATOs are best described as Lateral-organization attackers (below).<sup>5</sup> Excluding the 2 Lateral-organization attackers, the 35 ATOs identified by this

<sup>5</sup>Our extended technical report provides the distribution of recipient domains contacted by all ATOs [17].

first criteria sent their attacks to predominantly external recipients, belonging to either many different organizations or exclusively to personal email hosting services (e.g., Gmail and Hotmail), and only a small percentage of these recipients appeared in the ATO's recent contacts; as such, we label these 35 attackers as Account-agnostic.

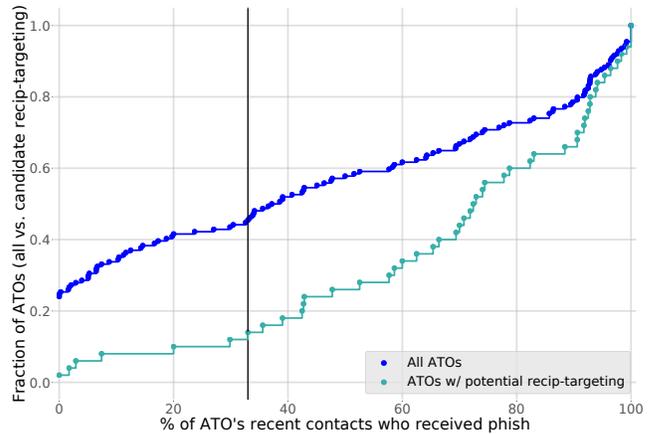

Second, we expand our search for Account-agnostic attackers by searching for attackers where less than 50% of the ATO's total recipients also belong to the ATO's organization, and where the ATO contacts recipients at many different organizations; specifically, where the ATO's phishing recipients belonged to over twice as many unique domains as all of the email addresses in ATO's recent contacts. This search identified 63 ATOs. To filter out attackers in this set who may have drawn on the hijacked account's recent contacts, we exclude any ATO where over 17% of their attack's total recipients also appeared in the ATO's recent contacts (17% was the maximum percentage among ATOs from the first Account-agnostic heuristic). After applying this last condition, our second heuristic identifies 54 Account-agnostic attackers.

Combining and deduplicating the ATOs from both criteria results in a total of 63 Account-agnostic attackers (40.9%): lateral phishers who predominantly target recipients without close relationships to the hijacked account or its organization.

**Lateral-organization Attackers:** During our exploration of potential Account-agnostic ATOs, we uncovered 2 attackers whom we label under a different category: *Lateral-organization attackers*. In both these cases, less than 1% of the attacker's recipients belonged to the same organization as the ATO, but each attacker's recipients did belong to organizations within the same industry as the ATO's organization. This thematic characteristic among the recipients suggests a deliberate strategy to spread across organizations within the targeted industries, so accordingly, we categorize them as Lateral-organization attackers.

**Organization-wide Attackers:** Office 365 provides a "Groups" feature that lists the different groups that an account belongs to [30]. For some enterprises, this feature enumerates most, if not all, employees at the organization. Thus, lateral phishers who wish to cast a wide phishing net might adopt a simple strategy of sending their attack to everyone at the organization. We call these ATOs *Organization-wide attackers* and identify them through two ways.

First, we search for any attackers where at least half of their phishing recipients belong to the ATO's organization, and where at least 50% of the organization's employees received the phishing email (i.e., the majority of a phisher's victims were employees and the attacker targeted a majority of the enterprise); this search yielded a total of 16 ATOs. We estimate the list of an organization's employees by building a set of all employee email addresses who sent or received email from

**Figure 6:** CDF: the x-axis displays what % of the ATO's recent contacts received a lateral phishing email (§ 6.2). The bottom teal graph filters the ATOs to *exclude* any ATO identified as Account-agnostic, Lateral-organization, and Organization-wide attackers; at the vertical black line, 88% of these filtered ATOs send phishing emails to at least  $x = 33\%$  of addresses from their recent contacts.

anyone during the entire month of the phishing incident.<sup>6</sup> For all of these 16 ATOs, less than 11% of the recipients they target also appear in their recent contacts. Coupled with the fact that each of these ATOs contacts over 1,300 recipients, their behavior suggests that their initial goal focuses on phishing as many of the enterprise's recipients as possible, rather than targeting users particularly close to the hijacked account. Accordingly, we categorize them as Organization-wide attackers.

Our second heuristic looks for attackers whose recipient set consists nearly entirely of fellow employees, but where the majority of the organization does not necessarily receive a phishing email. Revisiting Figure 5, 36 candidate Organization-wide ATOs sent over 95% of their phishing emails to fellow employee recipients. However, we again need to exclude and account for ATOs who leverage their hijacked account's recent contacts. From the first Organization-wide heuristic discussed previously, we saw that less than 11% of the recipients of that heuristic's Organization-wide attackers came from the ATO's recent contacts. Using this value as a final threshold for this second candidate set of Organization-wide attackers, we identify 29 Organization-wide attackers where over 95% of their recipients belong to the ATO's organization but less than 11% of the recipients came from the ATO's recent contacts; a combination that suggests the attacker seeks primarily to compromise other employees, but who do not necessarily have a personal connection with the hijacked account.

Aggregating and deduplicating the two sets of lateral phishers from above produces a total of 39 Organization-wide attackers (25.3%), who take advantage of the information in a hijacked account to target many fellow employees.

<sup>6</sup>This collection likely overestimates the actual set of employees because of service addresses, mailing list aliases, and personnel churn.

**Targeted-recipient Attackers:** For the remaining, uncategorized 50 ATOs, we cannot conclusively determine the attackers’ recipient targeting strategies because our dataset does not provide us with the full set of information and actions available to the attacker. Nonetheless, Figure 6 presents some evidence that 44 of these remaining attackers do draw upon the hijacked account’s prior relationships. Specifically, 44 attackers sent their attacks to at least 33% of the addresses in the ATO’s recent contacts.<sup>7</sup> Since these ATOs sent attacks to at least 1 out of every 3 of the ATO’s recently contacted recipients, these attackers appear interested in targeting a substantial fraction of users with known ties to the hijacked account. As such, we label these 44 ATOs as Targeted-recipient attackers.

### 6.3 Message Content: Tailoring and Themes

Since lateral phishers control a legitimate employee account, these attackers could easily mine recent emails to craft personalized spearphishing messages. To understand how much attackers do leverage their privileged access in their phishing attacks, this section characterizes the level of tailoring we see among lateral phishing messages. Overall, only 7% of our dataset’s incidents contain targeted content within their messages. Across the phishing emails that used non-targeted content, the attackers in our dataset relied on two predominant narratives (deceptive pretexts) to lure their victim into performing a malicious action. The combination of these two results suggests that, for the present moment, these attackers (across dozens of organizations) see more value in opportunistically phishing as many recipients as possible, rather than investing time to mine the hijacked accounts for personalized spearphishing fodder.

**Content Tailoring:** When analyzing the phishing messages in our dataset, we found that two dimensions aptly characterized the different levels of content tailoring and customization. The first dimension, “Topic tailoring”, describes how personalized the topic or main idea of the email is to the victim or organization. The second dimension, “Name tailoring”, describes how specifically the attacker addresses the victim (e.g., “Dear user” vs. “Dear Bob”). For each of these two dimensions, we enumerate three different levels of tailoring and provide an anonymized message snippet below; we use Bob to refer to one of the attack’s recipients and FooCorp for the company that Bob works at.

1. Topic tailoring: the uniqueness and relevancy of the message’s topic to the victim or organization:

<sup>7</sup>When examining and applying thresholds for the Account-agnostic and Organization-wide Attackers, we used a slightly different fraction: how many of the ATO’s phishing recipients also appeared in their recent contacts? Here, we seek to capture attackers who make a specific effort to target a considerable number of familiar recipients. Accordingly, we look at the fraction of the ATO’s recent contacts that received phishing emails, where the denominator reflects the number of users in the ATO’s recent contacts, rather than the ATO’s total number of phishing recipients.

	Generic	Enterprise	Targeted
No naming	90	35	9
Organization named	23	16	4
Recipient named	0	3	0

**Table 4:** Distribution of the number of *incidents* per message tailoring category (§ 6.3). The columns correspond to how unique and specific the message’s topic pertains to the victim or organization. The rows correspond to whether the phishing email explicitly names the recipient or organization.

- (a) Generic phishing topic: an unspecific message that could be sent to any user (“You have a new shared document available.”)
  - (b) Broadly enterprise related topic: a message that appears targeted to enterprise environments, but one that would also make sense if the attacker used it at many other organizations (“Updated work schedule. Please distribute to your teams.”)
  - (c) Targeted topic: a message where the topic clearly relies on specific details about the recipient or organization (“Please see the attached announcement about FooCorp’s 25th year anniversary.”, where FooCorp has existed for exactly 25 years.)
2. Name tailoring: whether the phishing message specifically uses the recipient or organization’s name:
    - (a) Non-personalized naming: the attack does not mention the organization or recipient by name (“Dear user, we have detected an error in your mailbox settings...”)
    - (b) Organization specifically named: the attack mentions just the organization, but not the recipient (“New secure email message from FooCorp...”)
    - (c) Recipient specifically named: the attack specifically uses the victim’s name in the email (“Bob, please review the attached purchase order...”)

Taken together, this taxonomy divides phishing content into nine different classes of tailoring; Table 4 shows how many of our dataset’s 180 incidents fall into each category. From this categorization, two interesting observations emerge. First, only 3 incidents (1.7%) actually address their recipients by name. Since most ATOs (94%) in our dataset email at least 100 recipients, attackers would need to leverage some form of automation to both send hundreds of individual emails and customize the naming in each one. Based on our results, it appears these attackers did not view that as a worthwhile investment. For example, they might fear that sending many individual emails might trigger an anti-spam or anti-phishing mechanism, which we observed in the case of one ATO who attempted to send hundreds of individual emails. Second,

Word	# Incidents	Word	# Incidents
document	89	sent	44
view	76	review	43
attach	56	share	37
click	55	account	36
sign	50	access	34

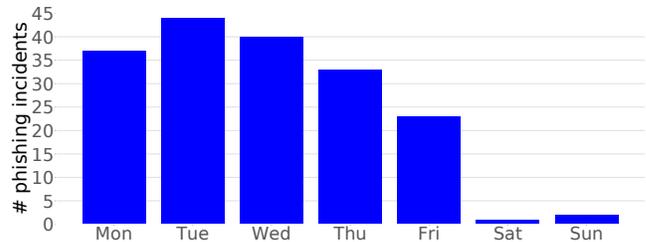

**Table 5:** Top 10 most common words across all 180 lateral phishing incidents.

looking at the last column of Table 4, only 13 incidents (7%) use targeted content in their messages. The overwhelming majority (92.7%) of incidents opt for more generic messages that an attacker could deploy at a large number of organizations with minimal changes (e.g., by only changing the name of the victim organization).

While our attack dataset captures a limited view of all lateral phishing attacks, it nonetheless reflects all known lateral phishing incidents across 33 organizations over a 7-month timeframe. Thus, despite the data’s limitations, our results show that a substantial fraction of lateral phishers do not fully draw upon their compromised account’s resources (i.e., historical emails) to craft personalized spearphishing messages. This finding suggests these attackers act more like an opportunistic cybercriminal, rather than an indomitable APT or nation-state. However, given the arms-race and evolutionary nature of security, these lateral phishers could in the future increase the sophistication and potency of their attacks by drawing upon the account’s prior emails to craft more targeted content.

**Thematic Content (Lures):** When labeling each phishing incident with a level of tailoring, we noticed that the phishing messages in our dataset overwhelmingly relied on one of two deceptive pretexts (lures): (1) an alarming message that asserts some problem with the recipient’s account (and urges them to follow a link to remediate the issue); and (2) a message that notifies the recipient of a new / updated / shared document. For the latter ‘document’ lure, the nature and specificity of the document varied with the level of content tailoring. For example, whereas an attack with generic topic tailoring will just mention a vague document, attacks that use enterprise-related tailoring will switch the terminology to an invoice, purchase order, or some other generic but work-related document.

To characterize this behavior further, we computed the most frequently occurring words across our dataset’s phishing messages. First, we selected one phishing email per incident, to prevent incidents with many identical emails from biasing (inflating) the popularity of their lures. Next, we normalized the text of each email: we removed auto-generated text (e.g., user signatures), lowercased all words, removed punctuation, and discarded all non-common English words; all of these can be done with open source libraries such as Talon [27] and

**Figure 7:** Number of lateral phishing incidents per day of week.

NLTK [5]. Finally, we built a set of all words that occurred in any phishing email across our incidents and counted how many incidents each word appeared in.

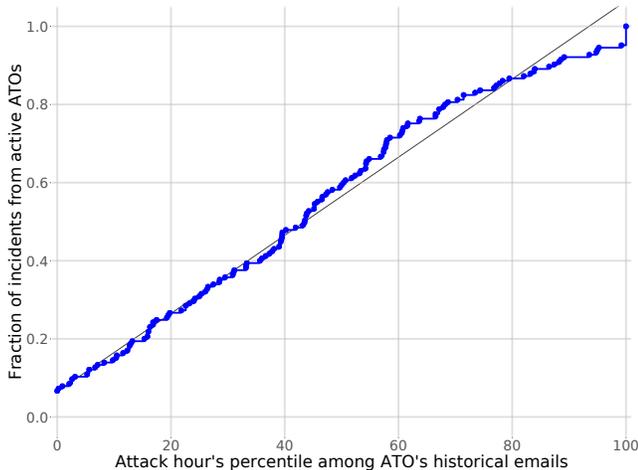

Interestingly, our dataset’s phishing messages draw on a relatively small pool of words: there are just 444 distinct, common English words across the texts of every phishing message in our dataset (i.e., every phishing email’s text consists of an arrangement from this set of 444 words). In contrast, a random sample of 1,000 emails from our dataset contained a total of 2,516 distinct words, and only 176 of these emails consisted entirely of words from the phishing term set.

Beyond this small set of total words across lateral phishing emails, all but one incident contained at least one of the top 20 words, illustrating the reliance on the two major lures we identified. Our extended technical report shows the occurrence distribution of each word [17]. Focusing on just the top ten words and the number incidents that use them (Table 5), the dominance of these two thematic lures becomes apparent. Words indicative of the “shared document” lure, such as ‘document’, ‘view’, ‘attach’, and ‘review’, each occur in over 23% of incidents, with the most popular (document) occurring in nearly half of all incidents. Similarly, we also see many words from the account-related lure in the top ten: ‘access’, ‘sign’ (from ‘sign on’), and ‘account’.

Overall, while our dataset contains several instances of targeted phishing messages, the majority of the lateral phishing emails we observe rely on more mundane lures that an attacker can reuse across multiple organizations with little effort. The fact that we see this behavior recur across dozens of different organizations suggests either the emergence of a new, yet accessible, form of enterprise phishing, or an evolution in the way “ordinary” cybercriminals execute phishing attacks (moving from external accounts that use clever spoofing to compromised, yet legitimate accounts).

## 6.4 Temporal Aspects of Lateral Phishing

Because attackers might not live or operate in the same geographic region as the hijacked account, prior work has suggested using features that capture unusual timing properties inherent in phishing emails [11, 15, 41]. Contrary to this intuition, in our dataset most lateral phishing attacks occur at “normal” times of the day and week. First, for 98% of lateral phishing incidents, the attacker sent the phishing email dur-

**Figure 8:** CDF of the fraction of incidents from active ATOs where the time (hour) of day fell within the  $x$ 'th percentile of the hours at which the ATO's benign emails in the preceding 30 days were sent. Active ATOs are hijacked accounts that sent at least 1 non-phishing email within the 30 days preceding their lateral phishing email.

ing a weekday. Additionally, the majority of attackers in our dataset send their phishing emails during the true account's normal working hours.

**Day of the Week:** From Figure 7, all but three lateral phishing incidents occurred during a work day (Monday–Friday). This pattern suggests that attackers send their phishing emails on the same days when employees typically send their benign emails, and that the day of the week will provide an ineffective or weak detection signal. Moreover, 67% of incidents occur in the first half of the week (Mon–Wed), indicating that the lateral phishers in our dataset do not follow the folklore strategy where attackers favor launching their attacks on Friday (hoping to capitalize on reduced security team operations over the coming weekend) [37].

**Time (Hour) of Day:** In addition to operating during the usual work week, most attackers tend to send their lateral phishing emails during the typical working hours of their hijacked accounts. To assess the (ab)normality of an attack's sent-time, for each ATO, we gathered all of the emails that the account sent in the 30 days prior to their first lateral phishing email. We then mapped the sent-time of each of these historical (and presumably benign) emails to the hour-of-day on a 24 hour scale, thus forming a distribution of the typical hour-of-day in which each hijacked account usually sent their emails. Finally, for each lateral phishing incident, we computed the percentile for the phishing email's hour-of-day relative to the hour-of-day distribution for the ATO's historical emails. For example, phishing incidents with a percentile of 0 or 100 were sent at an earlier or later hour-of-day than any email that the true account's owner sent in the preceding 30 days.

Across all lateral phishing incidents sent by an active ATO, Figure 8 shows what hour-of-day percentile the phishing inci-

dent's first email occurred at, relative to the hijacked account's historical emails. Out of the 180 incidents, 15 incidents were sent by an “inactive” (quiescent) ATO that sent zero emails across all 30 days preceding their lateral phishing emails; Figure 8 excludes these incidents. Of the remaining 165 incidents sent by an active ATO, 18 incidents fall completely outside of the hijacked account's historical operating hours, which suggests that a feature looking for emails sent at atypical times for a user could help detect these attacks. However, for the remaining 147 incidents, the phishing emails' hour-of-day evenly cover the full percentile range. As shown in Figure 8, the percentile distribution of phishing hours closely resembles the CDF of a uniformly random distribution (a straight  $y = x$  line); i.e., the phishing email's hour-of-day appears to be randomly drawn from the true account's historical hour-of-day distribution. This result indicates that for the majority of incidents in our dataset (147 out of 180), the time of day when the ATO sent the attack will not provide a significant signal, since their sent-times mirror the timing distribution of the true user's historical email activity.

Thus, based on the attacks in our dataset, we find that two weak timing-related features exist: searching for quiescent accounts that suddenly begin to send suspicious emails (15 incidents), and searching for suspicious emails sent completely outside of an account's historically active time window (18 incidents). Beyond these two features and the small fraction of phishing attacks they reflect, neither the day of the week nor the time of day provide significant signals for detection.

## 6.5 Attacker Sophistication

Since most of our dataset's lateral phishers do not mine the hijacked account's mailbox to craft targeted messages, one might naturally conclude that these attackers are lazy or unsophisticated. However, in this subsection, we identify two kinds of sophisticated behavior that required some investment of additional time and manual effort: attackers who continually engage with their attack's recipients in an effort to increase the attack's success rate, and attackers who actively “clean up” traces of their phishing activity in an attempt to hide their presence from the account's legitimate owner. In contrast to the small number of attackers who invested time in crafting tailored phishing messages to a personalized set of recipients, nearly one-third (31%) of attackers engage in at least one of these two sophisticated behaviors.

**Interaction with potential victims:** Upon receiving a phishing message, some recipients naturally question the email's validity and send a reply asking for more information or assurances. While a lazy attacker might ignore these recipients' replies, 27 ATOs across 15 organizations actively engaged with these potential victims by sending follow-up messages assuring the victim of the phishing email's legitimacy. For example, at one organization, an attacker consistently sent brief follow-up messages such as “Yes I sent it to you” or “Yes,

have you checked it yet?”. In other cases, attackers replied with significantly more elaborate ruses: e.g., “Hi [Bob], its a document about [X]. It’s safe to open. You can view it by logging in with your email address and password.”

To find instances where a phisher actively followed-up with their attack’s potential victims, we gathered all of the messages in every lateral phishing email thread and checked to see if the attacker ever received and responded to a recipient’s reply (inquiry).<sup>8</sup> In total, we found that 107 ATOs received at least one reply from a recipient. Of these reply-receiving attackers, 27 ATOs (25%) sent a deceptive follow-up response to one or more of their recipients’ inquiries.

**Stealthiness:** Separate from interacting with their potential victims, attackers might expend manual effort to hide their presence from the account’s true owner by removing any traces of their phishing emails, particularly since lateral phishers appear to operate during the hijacked account’s normal working hours (§ 6.4). To estimate the number of these ATOs, we searched for whether any of the following emails ended up in the hijacked account’s Trash folder, and were deleted within 30 seconds of being sent or received: any phishing emails, replies to phishing emails, or follow-up emails sent by the attacker. The 30 second threshold distinguishes stealthy behavior from deletion resulting from remediation of the compromised account. In total, 30 attackers across 16 organizations engage in this kind of evasive clean-up behavior.

Of the 27 ATOs who interactively responded to inquiries about their attack, only 9 also exhibited this stealthy clean-up behavior. Thus, counting the number of attackers across both sets, 48 ATOs engaged in at least one of these behaviors.

The sizeable fraction of attackers who engage in a sophisticated behavior creates a more complex picture of the attacks in our dataset. Given that these attackers do invest dedicated and (often) manual effort in enhancing the success of their attacks, why do so many of them (over 90% in our dataset) use non-targeted phishing content and target dozens to hundreds of recipients? One plausible reason for this generic behavior is that the simple methods they currently use work well enough under their economic model: investing additional time to develop more tailored phishing emails just does not provide enough economic value. Another reason might be that growth of lateral phishing attacks reflects an evolution in the space of phishing, where previously “simple” external phishers have moved to sending their attacks via lateral phishing because attacks from (spoofed) external accounts have become too difficult, due to user awareness and/or better technical mitigations against external phishing. Ultimately, based on our work’s dataset, we cannot soundly answer why so many lateral phishers employ simple attacks, and leave it as an interesting question for future work to explore.

<sup>8</sup>Office 365 includes a *ConversationID* field, and all emails in the same thread (the original email and all replies) get assigned the same *ConversationID* value.

## 7 Summary

In this work we presented the first large-scale characterization of lateral phishing attacks across more than 100 million employee-sent emails from 92 enterprise organizations. We also developed and evaluated a new detector that found many known lateral phishing attacks, as well as dozens of unreported attacks, while generating a low volume of false positives. Through a detailed analysis of the attacks in our dataset, we uncovered a number of important findings that inform our mental models of the threats enterprises face, and illuminate directions for future defenses. Our work showed that 14% of our randomly sampled organizations, ranging from small to large, experienced lateral phishing attacks within a seven-month time period, and that attackers succeeded in compromising new accounts at least 11% of the time. We uncovered and quantified several thematic recipient targeting strategies and deceptive content narratives; while some attackers engage in targeted attacks, most follow strategies that employ non-personalized phishing attacks that can be readily used across different organizations. Despite this apparent lack of sophistication in tailoring and targeting their attacks, 31% of our dataset’s lateral phishers engaged in some form of sophisticated behavior designed to increase their success rate or mask their presence from the hijacked account’s true owner. Additionally, over 80% of attacks occurred during a typical working day and hour, relative to the legitimate account’s historical emailing behavior; this suggests that these attackers either reside within a similar timezone as the accounts they hijack or make a concerted effort to operate during their victim’s normal hours. Ultimately, our work provides the first large-scale insights into an emerging, widespread form of enterprise phishing attacks, and illuminates techniques and future ideas for defending against this potent threat.

## A Detector Implementation and Evaluation Details

### A.1 Labeling Phishing Emails

**Labeling an email as phishing or benign:** When manually labeling an email, we started by examining five pieces of information whether the email was a reported phishing incident, the message content, the suspicious URL flagged and if its domain made sense in context, the email's recipients, and the sender. With the exception of a few incidents, we could easily identify a phishing email from the above steps. For example: an email about a "shared Office 365 document" sent to hundreds of unrelated recipients and whose document link pointed to a bit.ly shortened [non-Microsoft] domain; or an

email describing an “account security problem” sent by a non-IT employee, where the “account reset” URL pointed to an unrelated domain. For the more difficult cases, we analyzed all replies and forwards in the email chain, and labeled the email as phishing if it either received multiple replies / forwards that expressed alarm or suspicious, or if the hijacked account eventually sent a reply saying that they did not send the phishing email. Finally, as described in Section 3.3 we visited the non-side-effect, suspicious URLs from a sample of the labeled phishing emails; All of the URLs we visited led to either an interstitial warning page (e.g., Google SafeBrowsing), or a spoofed log-on page. For the emails flagged by our detector, but which appeared benign based on examining all the above information, we conservatively labeled them as false positives. In many cases, false positives were readily apparent; e.g., emails where the “suspicious URL” flagged by our detector occurred in the sender’s signature and linked to their personal website.

**Training exercises vs. actual phishing emails:** In addition to distinguishing between a false positive and an attack, we checked to ensure that our lateral phishing incidents represented actual attacks, and not training exercises. First, based on the lateral phishing emails’ headers, we verified that all of the sending accounts were legitimate enterprise accounts. Second, all but five of the attack accounts sent one or more unrelated-to-phishing emails in the preceding month. These two points gave us confidence that the phishing emails came from existing, legitimate accounts, and thus represented actual attacks; i.e., training exercises will not hijack an existing account, due to the potential reputational harm this could incur (and enterprise security teams we’ve previously engaged with do not do this). Furthermore, none of our dataset’s lateral phishing incidents are training exercises known to Barracuda, and none of the lateral phishing URLs used domains of known security companies.

## A.2 Model Tuning and Hyperparameters

Most machine learning models, including Random Forest, require the user to set various (hyper)parameters that govern the model’s training process. To determine the optimal set of hyperparameters for our classifier, we followed machine learning best practices by conducting a three-fold cross-validation grid search over all combinations of the hyperparameters listed below [4].

1. Number of trees: 50–500, in steps of 50 (i.e., 50, 100, 150, . . . , 450, 500)
2. Maximum tree depth: 10–100, in steps of 10
3. Minimum leaf size: 1, 2, 4, 8
4. Downsampling ratio of (benign / attack) emails: 10, 50, 100, 200

Because our training dataset contained only a few dozen incidents, we used three folds to ensure that each fold in the cross-validation contained several attack instances. Our experiments used a Random Forest model with 64 trees, a maximum depth of 8, a minimum leaf size of 4 elements, and a downsampling of 200 benign emails per 1 attack email, since this configuration produced the the highest AUC score [16]. But we note that many of the hyperparameter combinations yielded similar results.

# High Precision Detection of Business Email Compromise

## Abstract

Business email compromise (BEC) and employee impersonation have become one of the most costly cyber-security threats, causing over \$12 billion in reported losses. Impersonation emails take several forms: for example, some ask for a wire transfer to the attacker's account, while others lead the recipient to following a link, which compromises their credentials. Email security systems are not effective in detecting these attacks, because the attacks do not contain a clearly malicious payload, and are personalized to the recipient.

We present BEC-Guard, a detector used at Barracuda Networks that prevents business email compromise attacks in real-time using supervised learning. BEC-Guard has been in production since July 2017, and is part of the Barracuda Sentinel email security product. BEC-Guard detects attacks by relying on statistics about the historical email patterns that can be accessed via cloud email provider APIs. The two main challenges when designing BEC-Guard are the need to label millions of emails to train its classifiers, and to properly train the classifiers when the occurrence of employee impersonation emails is very rare, which can bias the classification. Our key insight is to split the classification problem into two parts, one analyzing the header of the email, and the second applying natural language processing to detect phrases associated with BEC or suspicious links in the email body. BEC-Guard utilizes the public APIs of cloud email providers both to automatically learn the historical communication patterns of each organization, and to quarantine emails in real-time. We evaluated BEC-Guard on a commercial dataset containing more than 4,000 attacks, and show it achieves a precision of 98.2% and a false positive rate of less than one in five million emails.

## 1 Introduction

In recent years, email-borne employee impersonation, termed by the FBI "Business Email Compromise" (BEC), has become a major security threat. According to the FBI, US organizations have lost \$2.7 billion in 2018 and cumulatively

\$12 billion since 2013 [13]. Numerous well-known enterprises have fallen prey to such attacks, including Facebook, Google [41], and Ubiquiti [44]. Studies have shown that BEC is the cause of much higher direct financial loss than other common cyberattacks, such as ransomware [11, 13]. BEC attacks have also ensnared operators of critical government infrastructure [39]. Even consumers have become the targets of employee impersonation. For example, attackers have impersonated employees of real-estate firms to trick home buyers to wire down payments to the wrong bank account [1, 7, 17].

BEC takes several forms: some emails ask the recipient to wire transfer money to the attacker's account, others ask for W-2 forms that contain social security numbers, and some lead the recipient to follow a phishing link, in order to steal their credentials. The common theme is the impersonation of a manager or colleague of the target [12]. In this work, we focus on attacks where the attacker is external to the organization, and is trying to impersonate an employee. In §6 we discuss other scenarios, such as where the attacker uses a compromised internal email account to impersonate employees [18, 19].

Most email security systems are not effective in detecting BEC. When analyzing an incoming email, email security systems broadly look for two types of attributes: *malicious* and *volumetric*. Examples of malicious attributes are an attachment that contains malware, a link pointing to a compromised website, or an email that is sent from a domain with a low reputation. There are various well-known techniques to detect malicious attributes, including sandboxing [49], and domain reputation [2, 48]. Volumetric attributes are detected when the same email format is sent to hundreds of recipients or more. Examples include the same text or sender email (e.g., spam), and the same URL (e.g., mass phishing campaigns). However, employee impersonation emails do not contain malicious or volumetric attributes: they typically do not contain malware, are not sent from well-known malicious IPs, often do not contain a link, and are sent to a small number of recipients (with the explicit intent of evading volumetric filters). When employee impersonation attacks do contain a link, it is typically

a link to a fake sign up page on a legitimate website that was compromised, which does not appear on any IP black lists. In addition, the text of the attacks is tailored to the recipient, and is typically not caught by volume-based filters.

Our design goal is to detect and quarantine BEC attacks in real-time, at a low false positive rate (1 in a million emails) and high precision (95%). We make the observations that popular cloud email systems, such as Office 365 and Gmail, provide APIs that enable account administrators to allow external applications to access historical emails. Therefore, we design a system that detects BEC by relying on historical emails available through these APIs.

Prior work on detecting impersonation has been conducted either on very small datasets [10, 14, 20, 45]), or focused on stopping a subset of BEC attacks (domain spoofing [14] or emails with links [20]). In addition, most prior work suffers from very low precision (only 1 in 500 alerts is an attack [20]) or very high false positive rates [10, 45]), which makes prior work unsuitable for detecting BEC in real-time.

The main challenge in designing a system that can detect BEC at a low false positive rate is that *BEC emails are very rare* as a percentage of all emails. In fact, in our dataset, less than one out of 50,000 emails is a BEC attack. Therefore, in order to achieve low false positives, we design a system using supervised learning, which relies on a large training set of BEC emails. However, bootstrapping a supervised learning systems presents two practical challenges. First, it is difficult to label a sufficiently large training dataset that includes millions of emails. Second, it is challenging to train a classifier on an *imbalanced dataset*, in which the training dataset contains almost five orders of magnitude fewer positive samples (i.e., BEC attacks) than negative samples (i.e., innocent emails).

In this paper, we present how we initially trained BEC-Guard, a security system that automatically detects and quarantines BEC attacks in real-time using historical emails. BEC-Guard is part of a commercial product, Barracuda Sentinel, used by thousands of corporate customers of Barracuda Networks to prevent BEC, account takeover, spear phishing and other targeted attacks. BEC-Guard does not require an analyst to review the detected emails, but rather relies on offline and infrequent re-training of classifiers. The key insight of BEC-Guard is to split the training and classification into two parts: header and body.

Instead of directly classifying BEC attacks, the *impersonation classifier* detects impersonation attempts, by determining if an attacker is impersonating an employee in the company by inspecting the header of the email. It utilizes features that include information about which email addresses employees typically utilize, how popular their name is, and characteristics of the sender domain. The *content classifiers* are only run on emails that were categorized as impersonation attempts, and inspects the body of the email for BEC. For emails that do not contain links, we use a k-nearest neighbors [43] (KNN) classifier that weighs words using term frequency-

inverse document frequency [28, 42] (TFIDF). For emails with links, we train a random forest classifier that relies on the popularity as well as the position of the link in the text. Both of the content classifiers can be retrained frequently using customer feedback.

To create the initial classifiers, we individually label and train each type of classifier: the labels of the impersonation classifier are generated using scripts we ran on the training dataset, while the content classifiers are trained over a manually labeled training dataset. Since we run the content classification only on emails that were detected as impersonation attempts, we need to manually label a much smaller subset of the training dataset. In addition, to ensure the impersonation classifier is trained successfully over the imbalanced dataset, we develop an under-sampling technique for legitimate emails using Gaussian Mixture Models, an unsupervised clustering algorithm. The classifiers are typically re-trained every few weeks. The dataset available for initial training consists of a year worth of historical emails from 1500 customers, with an aggregate dataset of 2 million mailboxes and 2.5 billion emails. Since training the initial classifiers, our dataset has been expanded to include tens of millions of mailboxes.

BEC-Guard uses the APIs of cloud-based email systems (e.g., Office 365 and Gmail), both to automatically learn the historical communication patterns of each organization within hours, and to quarantine emails in real-time. BEC-Guard subscribes to API calls, which automatically alert BEC-Guard whenever a new email enters the organization's mailbox. Once notified by the API call, BEC-Guard classifies the email for BEC. If the email is determined to be BEC, BEC-Guard uses the APIs to move the email from the inbox folder to a dedicated quarantine folder on the end-user's account.

To evaluate the effectiveness of our approach, we measured BEC-Guard's performance on a dataset of emails taken from several hundred organizations. Within this labeled dataset, BEC-Guard achieves a precision of 98.2%, a false positive rate of only one in 5.3 million. To summarize, we make the following contributions:

- First real-time system for preventing BEC that achieves high precision and low false positive rates.
- BEC-Guard's novel design relies on cloud email provider APIs both to learn the historical communication patterns of each organization, and to detect attacks in real-time.
- To cope with labeling millions of emails, we split the detection problem into two sets of classifiers run sequentially.
- We use different types of classifiers for the header and text of the email. The headers are classified using a random forest, while the text classification relies primarily on a KNN model that is not dependent on any hard-coded features, and can be easily re-trained.
- To train the impersonation classifier on an imbalanced dataset, we utilize a sampling technique for the legitimate emails using a clustering algorithm.

BEC Objective	Link?	Percentage
Wire transfer	No	46.9%
Click Link	Yes	40.1%
Establish Rapport	No	12.2%
Steal PII	No	0.8%

**Table 1:** The objective of BEC attacks as a percentage of 3,000 randomly chosen attacks. 59.9% of attacks do not involve a phishing link.

Role	Recipient %	Impersonated %
CEO	2.2%	42.9%
CFO	16.9%	2.2%
C-level	10.2%	4.5%
Finance/HR	16.9%	2.2%
Other	53.7%	48.1%

**Table 2:** The roles of recipients and impersonated employees from a sample of BEC attacks chosen from 50 random companies. C-level includes all executives that are not the CEO and CFO, and Finance/HR does not include executives.

## 2 Background

Business email compromise, also known as employee impersonation, CEO fraud, and whaling,<sup>1</sup> is a class of email attacks where an attacker impersonates an employee of the company (e.g., the CEO, a manager in HR or finance), and crafts a personalized email to a specific employee. The intent of this email is typically to trick the target to wire money, send sensitive information (e.g., HR or medical records), or lead the employee to follow a phishing link in order to steal their credentials or download malware to their endpoint.

BEC has become one of the most damaging email-borne attacks in recent years, equaling or surpassing other types of attacks, such as spam and ransomware. Due to the severity of BEC attacks, the FBI started compiling annual reports based on US-based organizations that have reported their fraudulent wire transfers to the FBI. Based on the FBI data, between 2013 and 2018, \$12 billion have been lost [13]. To put this in perspective, a Google study estimates that the total amount of ransomware payments in 2016 was only \$25 million [11].

In this section, we review common examples of BEC, and provide intuition on how their unique characteristics can be exploited for supervised learning classification.

### 2.1 Statistics

To better understand the goals and methodology of BEC attacks, we compiled statistics for 3,000 randomly selected BEC attacks in our dataset (for more information about our dataset, see §4.2). Table 1 summarizes the objectives of the attacks. The results show that the most common BEC in the sampled attacks is try to deceive the recipient to perform a wire transfer to a bank account owned by the attacker, while about 0.8% of the attacks ask the recipient to send the attacker

<sup>1</sup>We refer to this attack throughout the paper as *BEC*.

personal identifiable information (PII), typically in the form of W-2 forms that contain social security numbers. About 40% of attacks ask the recipient to click on a link. 12% of attacks try to establish rapport with the target by starting a conversation with the recipient (e.g., the attacker will ask the recipient whether they are available for an urgent task). For the “rapport” emails, in the vast majority of cases, after the initial email is responded to the attacker will ask to perform a wire transfer.

An important observation is that about 60% of BEC attacks do not involve a link: the attack is simply a plain text email that fools the recipient to commit a wire transfer or send sensitive information. These plain text emails are especially difficult for existing email security systems, as well as prior academic work to detect [20], because they are often sent from legitimate email accounts, tailored to each recipient, and do not contain any suspicious links.

We also sampled attacks from 50 random companies in our dataset, and classified the roles of the recipient of the attack, as well as the impersonated sender. Table 2 presents the results. Based on the results, the term “CEO fraud” used to describe BEC is indeed justified: about 43% of the impersonated senders were the CEO or founder. The targets of the attacks are spread much more equally across different roles. However, even for impersonated senders, the majority (about 57%) are not the CEO. Almost half of the impersonated roles and more than half of targets are not of “sensitive” positions, such as executives, finance or HR. Therefore, simply protecting employees in sensitive departments is not sufficient to protect against BEC.

### 2.2 Common Types of BEC

To guide the discussion, we describe the three most common examples of BEC attacks within our dataset: wire transfer, rapport, and impersonation phishing. In §6 we will discuss other attacks that are not covered by this paper. All three examples we present are real BEC attacks from within our dataset, in which the names, companies, email addresses and links have been anonymized.

#### Example 1: Wire transfer example

```
From: "Jane Smith" <jsmith@acrne.com>
To: "Joe Barnes" <jbarnes@acme.com>
Subject: Vendor Payment

Hey Joe,

Are you around? I need to send a wire
transfer ASAP to a vendor.

Jane
```

In Example 1, the attacker asks to execute a wire transfer. Other similar requests include asking for W-2 forms, medical information or passwords. In the example the attacker spoofs the name of an employee, but uses an email address that

### Example 2: Rapport example

```
From: "Jane Smith" <jsmith@acme.com>
Reply-to: "Jane Smith" <ceo.executive@outlook.com>
To: "Joe Barnes" <jbarnes@acme.com>
Subject: At desk?

Joe, are you available for something urgent?
```

### Example 3: Spoofed Name with Phishing Link

```
From: "Jane Smith" <greyowl1234@comcast.net>
To: "Joe Barnes" <jbarnes@acme.com>
Subject: Invoice due number 381202214

I tried to reach you by phone today but I
couldn't get through. Please get back to me
with the status of the invoice below.

Invoice due number 381202214:
[http://firetruck4u.net/past-due-invoice/]
```

does not belong to the organization's domain. Some attackers even use a domain that looks similar to the target organization's domain (e.g., instead of acme.com, the attacker would use acrne.com). Since many email clients do not display the sender email address, some recipients will be deceived even if the attacker uses an unrelated email address.

Example 2 tries to create a sense of urgency. After the recipient responds to the email, the attacker will typically ask for a wire transfer. The email has the from address of the employee, while the reply-to address will relay the response back to the attacker. Email authentication technologies such as DMARC, SPF and DKIM can help stop spoofed emails. However, the vast majority of organizations do not enforce email authentication [25], because it can be difficult to implement correctly and often causes legitimate emails to be blocked.<sup>2</sup> Therefore, our goal is to detect these attacks without relying on DMARC, SPF and DKIM.

Example 3 uses a spoofed name, and tries to get the recipient to follow a phishing link. Such phishing links are typically not detected by existing solutions, because the link is unique to the recipient ("zero-day") and will not appear in any black lists. In addition, attackers often compromise relatively reputable websites (e.g., small business websites) for phishing links, which are often classified as high reputation links by email security systems. The link within the email will typically lead the recipient to a website, where they will be prompted to log in a web service (e.g., an invoicing application) or download malware.

## 3 Intuition: Exploiting the Unique Attributes of Each Attack

The three examples all contain unique characteristics, which set them apart from innocent email messages. We first de-

<sup>2</sup>Many organizations have legitimate systems that send emails on their behalf, for example, marketing automation systems, which can be erroneously blocked if email authentication is not setup properly.

scribe the unique attributes in the header of each example, and then discuss the attributes of the email body and how they can be used to construct the features of a machine learning classifier. We also discuss legitimate corner cases of these attributes that might fool a classifier and cause false positives.

**Header attributes.** In Example 1 and 3, the attacker impersonates the name of a person, but uses a different email address than the corporate email address. Therefore, if an email contains a name of an employee, but uses an email address that is not the typical email address of that employee, there is a higher probability that the sender is an imposter.

However, there are legitimate use cases of non-corporate emails by employees. First, an employee might use a personal email address to send or forward information to themselves or other employees in the company. Ideally, a machine learning classifier should be able to learn all the email addresses that belong to a certain individual, including corporate and personal email addresses. Second, if an external sender has the same name as an internal employee, it might seem like an impersonation.

In Example 2, the attacker spoofs the legitimate email address of the sender, but the reply-to email address is different than the sender address, which is unusual (we will also discuss the case where the attacker sends a message from the legitimate address of the sender without changing the reply-to field in §6). However, such a pattern has legitimate corner cases as well. Some web services and IT systems, such as LinkedIn, Salesforce, and other support and HR applications, "legitimately impersonate" employees to send notifications, and change the reply-to field to make sure the response to the message is recorded by their system.

Other header attributes might aid in the detection of BEC attacks. For example, if an email is sent at an abnormal time of day, or from an abnormal IP or from a foreign country. However, many BEC attacks are designed to seem legitimate, and are sent in normal times of day and from seemingly legitimate email addresses.

**Body attributes.** The body of Example 1 contains two unique semantic attributes. First, it discusses sensitive information (a wire transfer). Second, it is asking for a special, immediate request. Similarly, the text of Example 2 is asking whether the recipient is available for an urgent request. Such an urgent request for sensitive information or availability might be legitimate in certain circumstances (for example, in an urgent communication within the finance team).

The unique attribute in the body of Example 3 is the link itself. The link is pointing to a website that does not have anything to do with the company: it does not belong to a web service the company typically uses, and it is not related to the company's domain.

Finally, all three examples contain certain textual and visual elements that are unique to the identity of the sender. For example, Example 1 contains the signature of the CEO and all of the emails contain a particular grammar and writing

style. If any of these elements deviate from the style of a normal email from a particular sender, they can be exploited to detect an impersonation. Since in many BEC emails the attackers take great care in making the email appear legitimate, we cannot overly-depend on detecting stylistic aberrations.

As shown above, each of the examples has unique anomalous attributes that can be used to categorize it as a BEC attack. However, as we will show in §7, none of these attributes *on its own* is sufficient to classify an email with a satisfactory false positive rate.

**Leveraging historical emails.** Much of prior work in detecting email-borne threats relies on detecting malicious signals in the email, such as sender and link domain reputation [2, 48], malicious attachments [49], as well as relying on link click logs and IP logins [20]. However, as Table 1 and the examples we surveyed demonstrate, most BEC attacks do not contain any obviously malicious attachments or links. Intuitively, access to the historical emails of an organization would enable a supervised learning system to identify the common types of BEC attacks by identifying anomalies in the header and body attributes. We make the observation that popular cloud-based email providers, such as Office 365 and Gmail, enable their customers to allow third party applications to access their account with certain permissions via public APIs. In particular, these APIs can enable third-party applications to access historical emails. This allows us to design a system that uses historical emails to identify BEC attacks.

## 4 Classifier and Feature Design

In this section, we describe BEC-Guard’s design goals, and its training dataset. We then describe the initial set of classifiers we used in BEC-Guard, and present our approach to training and labeling.

### 4.1 Design Goals

The goal of BEC-Guard is to detect BEC attacks in real-time, without requiring the users of the system to utilize security analysts to manually sift through suspected attacks. To meet this goal, we need to optimize two metrics: the false positive rate, and the precision. The false positive rate is the rate of false positives as a percentage of total received emails. If we assume an average user receives over 100 emails a day, in an organization with 10,000 employees, our goal is that it will be infrequent to encounter a false positive (e.g., once a day for the entire organization). Therefore, our target false positive rate is less than one in a million. The precision is the rate of true positives (correctly detected BEC attacks) as a percentage of attacks detected by the system, while the false positive rate is a percentage of false positives of all emails (not just emails detected by the system). If the precision is not high, users of BEC-Guard will lose confidence in the validity of its predictions. In addition to these two metrics, we need to ensure high coverage, i.e., that the system catches the vast

majority of BEC attacks.

### 4.2 Dataset and Privacy

We developed the initial version of BEC-Guard using a dataset of corporate emails from 1,500 organizations, which are actively paying customers of Barracuda Networks. The organizations in our dataset vary widely in their type and size. The organizations include companies from different industries (healthcare, energy, finance, transportation, media, education, etc.). The size of the organization varies from 10 mailboxes to more than 100,000. Overall, to train BEC-Guard, we labeled over 7,000 examples of BEC attacks, randomly selected from the 1,500 organizations.

To access the data, these organizations granted us permission to access to the APIs of their Office 365 email environments. The APIs provide access to all historical corporate emails. This includes emails sent internally within the organization, and from all folders (inbox, sent, junk, etc.). The API also allows us to determine which domains are owned by each organization, and even whether an email was read.

**Ethical and privacy considerations.** BEC-Guard is part of a commercial product, and the 1,500 customers that participate in the dataset provided their legal consent to Barracuda Networks to access their historical corporate emails for the purpose identifying BEC. Customers also have the option of revoking access to BEC-Guard at any time.

Due to the sensitivity of the dataset, it was only exposed to the five researchers who developed BEC-Guard, under strict access control policies. The research team only accessed historical emails for the purposes of labeling data to develop BEC-Guard’s classifiers. Once the classifiers were developed, we permanently deleted all of the emails that are not actively used for training the classifiers. The emails used for classification are stored encrypted, and access to them is limited to the research team.

### 4.3 Dividing the Classification into Two Parts

The relative rare occurrence of BEC attacks influenced several of our design choices. Our first design choice was to rule out unsupervised learning. Unsupervised learning typically uses clustering algorithms (e.g., k-means [15]) to group email categories, such as BEC emails. However, a clustering algorithm would typically categorize many common categories (e.g., social emails, marketing emails), but since BEC is so rare, it results in low precision and many false positives. Therefore, supervised learning algorithms are more suitable for detecting BEC at a high precision. However, using supervised learning presents its own set of challenges.

In particular, BEC is an extreme case of *imbalanced data*. When sampled uniformly, in our dataset, “legitimate” emails are 50,000× more likely to appear than the BEC emails. This presents two challenges. First, in order to label a modest number of BEC emails (e.g., 1,000), we need to label a corpus

on the order of 50 million legitimate emails. Second, even with a large number of labeled emails, training a supervised classifier over imbalanced datasets is known to cause various problems, including biasing the classifier to prefer the larger class (i.e., legitimate emails) [24, 26, 47, 51]. To deal with this extreme case of imbalanced data, we divided the classification and labeling problem into two parts. The first classifier looks only at the metadata of the email, while the second classifier only examines the body and subject of the email.

The first classifier looks for *impersonation* emails. We define an impersonation as an email that is sent with the name of a person, but was not actually sent by that person. Impersonation emails include malicious BEC attacks, and they also include emails that legitimately impersonate an employee, such as internal systems that send automated emails on behalf of an employee. The impersonation classifier only analyzes the metadata of the email (i.e., sender, receiver, CC, BCC fields). The impersonation classifier detects both spoofed name (Example 1 and 3) and spoofed emails (Example 2). The second set of classifiers, the *content* classifiers, only classify emails that were detected as impersonation emails, by examining the email’s subject and body to look for anomalies. We use two different content classifiers that each look for different types of BEC attacks.<sup>3</sup> The two content classifiers are: the text classifier, which relies on natural language processing to analyze the text of the email, and the link classifier, which classifies any links that might appear in the email.

All of our classifiers are trained globally on the same dataset. However, to compute some of the features (e.g., the number of time the sender name and email address appeared together), we rely on statistics that are unique to each organization.

#### 4.4 Impersonation Classifier

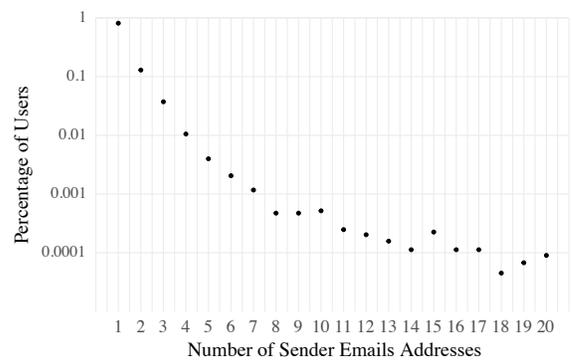

Table 3 includes the main features used by the impersonation classifier. The features describe the number of times specific email addresses and names have appeared before in the sender and reply-to fields, as well as statistics about the sender’s identity.

To demonstrate why it is helpful to maintain historical statistics of a particular organization, consider Figure 1. The figure depicts the number of email addresses that were used by each sender in an organization with 44,000 mailboxes over three months. 82% of the users had emails sent from only one address, and the rest had emails that were sent from more than one address. The reason that some of the senders used a large number of email addresses, is that they were repeatedly impersonated in BEC attacks. For instance, the CEO is a common target for impersonation. and is often targeted dozens of times. However, this signal alone is not

<sup>3</sup>There is no inherent advantage in using multiple content classifiers in terms of the false positive rate or precision. We decided to use two different content classifiers, because it made it easier for us debug and maintain them separately.

Feature	Description
Sender has corp domain?	Is sender address from corp domain?
Reply-to != sender address?	Reply-to and sender addresses different?
Num times sender and email	Number of times sender name and email address appeared
Num times reply-to address	Number of times reply-to address appeared
Known reply-to service?	Is reply-to from known web service (e.g., LinkedIn)?
Sender name popularity	How popular is sender name

**Table 3:** Main features used by the impersonation classifier, which looks for impersonation attempts, including spoofed names and emails.

**Figure 1:** Number of unique emails addresses that were observed for each user in an organization with 44,400 mailboxes. The X axis is the number of unique email addresses that were observed, as a percentage (in the Y axis) of the total number of users of the organization.

sufficient to detect impersonation. For example, some of the senders that have a large number of email addresses represent shared mailboxes (e.g., “IT” or “HR”), and are legitimate.

Hence, several of the features in the impersonation classifier rely on the historical communication patterns of the organization. This influenced BEC-Guard’s architecture. In addition, we maintain a list of known web services that “legitimately” send emails with reply-to addresses that are different than the sender address (e.g., LinkedIn, Salesforce), in order to capture the response. The original list of commonly-used services was populated from a list of the domains of the major web services. We then augmented this list with additional services when we encountered them during the labeling process (in §6 we discuss possible evasion techniques related to this list of legitimate reply-to senders). The sender name popularity score is computed offline by maintaining a list of how frequently names appear across different organizations in our dataset. The more popular a name, the higher the likelihood that a name with an email address the employee typically does not use is another person (a name collision).

**Name and nickname matching.** In order to detect name spoofing, the impersonation classifier needs to match the

sender name with a name of an employee. However, names can be written in various forms. For example: “Jane Smith” can be written as: “Smith, Jane”, “Jane J. Smith” or “Jane Jones Smith”. In addition, we need to deal with special characters that might appear in names, such as ì or ä.

To address these problems, BEC-Guard normalizes names. It stores employee name as <first name, last name> tuples, and checks all the variants of the sender name to see if it matches a name of an employee with a corporate email address. These variants include stripping the middle name or initial, reversing order of the first name and surname, and stripping suffixes. Suffixes include examples like “Jr.” or when the email address is sent as part of the sender name. In addition, we match the first name against a publicly available list of nicknames [36], to catch cases for example when the attacker sends an email as “Bill Clinton”, and the name of the employee is stored as “William Clinton”.

**Content classifiers.** Our system uses two content classifiers: the *text classifier* and *link classifier*. The text classifier catches attacks similar to Example 1 and 2, and the link classifier stops attacks that are similar to Example 3. By design, the content classifiers are meant to be updated more frequently than the impersonation classifier, and should be easily re-trained based on false negatives and false positives reported by users.

**Text classifier.** In BEC attacks similar to Example 1 and 2, the body contains words that are indicative of a sensitive or special request, such as “wire transfer” or “urgent”. Therefore, our first iteration of the text classifier was designed to look for specific words that might imply a special request or a financial or HR transaction. The features of the classifiers described the position in the text of a list of sensitive words and phrases. However, over time, we noticed this approach suffered from several problems. First, a classifier that relies on hard-coded keywords can miss attacks when attackers slightly vary a specific word or phrase. Second, to successfully retrain the classifier, we had to modify the lists of keywords that it looks for, which required manually updating the keyword list on a daily basis.

Instead, we developed a text classifier that learns expressions that are indicative of BEC on its own. The first step is to pre-process the text. BEC-Guard removes information from the subject and body of the email that would not be useful for classifying the email. It removes regular expression patterns that include salutations (“Dear”, “Hi”), pre-canned headers, as well as footers (“Best,”) and signatures. It also removes all English stopwords, as well as any names that may appear in the email.

The second step is to compute the frequency-inverse document frequency [42] (TFIDF) score of each word in the email. TFIDF represents how important each word is in an email, and is defined as:

$$TF(w) = \frac{\text{num times } w \text{ appears in email}}{\text{num words in email}}$$

$$IDF(w) = \frac{\log(\text{num emails})}{\text{num emails with } w}$$

Where  $w$  is a given word in an email.  $TF(w) \cdot IDF(w)$  gives a higher score to a word that appears frequently in a specific email, but which is relatively rare in the whole email corpus. The intuition is that in BEC emails, words for example that denote urgency or a special request would have a high TFIDF score, because they appear frequently in BEC emails but less so in legitimate emails.

When training the text classifier, we compute the TFIDF score of each word in each email of the training set. We also compute the TFIDF for pairs of words (bigrams). We store the global statistics of the IDF as a *dictionary*, which contains number of emails in the training set that contain unique phrases encountered in the training of the text classifier. We limit the dictionary size to 10,000 of the top ranked words (we evaluate how the size of the dictionary impacts classification precision in §7.2).

The feature vector of each email is equal to the the number of words in the dictionary, and each number represents the TFIDF of each one of the words in the dictionary. Words that do not appear in the email, or that do not appear in the dictionary have a TFIDF of zero. The last step is to run a classifier based on these features. Table 4 presents the top 10 phrases (unigram and bigram) in the BEC emails in our dataset. Note that the top phrases all indicate some form of urgency.

Top phrases in BEC emails by TFIDF	
1. got moment	6. need complete
2. response	7. ASAP
3. moment need	8. urgent response
4. moment	9. urgent
5. need	10. complete task

**Table 4:** The top 10 phrases of BEC emails, sorted by their TFIDF ranking from our evaluation dataset (for more information on evaluation dataset see §7.1). The TFIDF was computed for each word in all of the BEC emails in our evaluation dataset.

**Link classifier.** The link classifier detects attacks similar to Example 3. In these attacks, the attacker tries to get the recipient to follow a phishing link. As we described earlier, these personalized phishing links are typically not detected by IP blacklists, and are usually unique to the recipient. In this case, since the content classifier only classifies emails that were already classified as impersonation emails, it can mark links as “suspicious”, even if they would have a high false positive rate otherwise. For example, a link that points to a

small website, or one that was recently registered, combined with an impersonation attempt would have a high probability of being a BEC email.

Feature	Description
Domain popularity	How popular is the link's least popular domain
URL field length	Length of least popular URL (long URLs are more suspicious)
Domain registration date	Date of domain registration of least popular domain (new domains are suspicious)

**Table 5:** Main features used by the link request classifier, which stops attacks like in Example 3.

Table 5 describes the main features used by the link request classifier. The domain popularity is calculated by measuring the Alexa score of the domain. In order to deal with link shorteners or link redirections, BEC-Guard expands the URLs before computing their features for the link classifier. In addition, several of the URL characteristics require determining information about the domain (popularity and score). For the domain popularity feature, we cache a list of the top popular domains, and update it offline. To determine the domain registration date, BEC-Guard does a real-time WHOIS lookup. Note that unlike the impersonation classifier, which needs to map the distribution of email address per sender name, none of the features of the text and link classifier are organization-specific. This allows us to easily retrain them based on user reported emails.

## 4.5 Classifier Algorithm

The impersonation and link classifiers use random forest [5] classification. Random forests are comprised of randomly formed decision trees [40], where each tree contributes a vote, and the decision is determined by the majority of the trees. Our system uses random forests rather than individual decision trees, since we found they provide better precision, but for offline debugging and analysis we often visualize individual decision trees. We decided to use KNN for the text classifier, because it had slightly better coverage than random forests. However, we found that since the text classifier uses a very large number of features (a dictionary of 10,000 phrases), its efficacy was similar across different classifiers. In §7.2 we evaluate the performance of the different classifier algorithms.

In addition, we have explored deep-learning based techniques, such as word2vec [34] and sense2vec [46], which expand each word to a vector that represents its different meanings. We currently do not use such deep-learning techniques, because they are computationally heavy both for training and online classification.

**Detecting impersonation of new employees.** When a new employee joins the organization, the impersonation classifier will not have sufficient historical information about that

employee, since they will not have any historical emails. As that employee receives more emails, BEC-Guard will start compiling statistics for the employee. A similar problem may also arise in organizations that periodically purge their old emails. In practice, we found that the classifier performs well after only one month of data.

## 4.6 Labeling

In order to label the initial training set, we made several assumptions about the BEC attack model. First we assumed attackers impersonate employees using their name (under a set of allowed variations, as explained above). Second, we assumed the impersonation does not occur more than 100 times using the same email address. Third, we assumed the attacker uses an email address that is different than the corporate address, either as the from address or the reply-to address. We discuss other types of attacks that do not fit these assumptions, as well as how attackers may evade these assumptions in §6. Under these constraints, we fully covered all of the possible attacks and manually labeled them. In addition, we incorporated missed attacks reported from customers (we discuss this process in §7.3).

The reason we assumed a BEC email does not impersonate an employee using the same email address more than 100 times is that BEC-Guard is designed with the assumption that the organization is already using a spam filter, which provides protection against volume-based attacks (e.g., the default spam protection of Office 365 or Gmail). Therefore, an attacker that would send an email from an unknown address more than 100 times to the same recipient would likely be blocked by the spam filter. In fact, in our entire dataset, which is only composed of post spam-filtered emails, we have never witnessed an attacker using the email address to impersonate an employee more than 20 times. Note that we only used this assumption for labeling the original training set, and do not use it for ongoing retraining (since retraining is based on customer reported attacks).

**Impersonation classifier.** In order to label training data for the impersonation classifier, we ran queries on the headers of the raw emails to uncover all emails that might contain BEC attacks under our labeling assumptions (see above). We then labeled the results of all the queried emails as impersonation emails, and all the emails that were not found by the queries as legitimate emails.

**Content classifiers.** The training dataset for the content classifiers is constructed by running a trained impersonation classifier on a fresh dataset, which is then labeled manually. The initial training set we used for the content classifiers included 300,000 impersonation emails from randomly selected organizations over a year of data. Even within this training data set, we were able significantly further limit the number of emails that needed to be manually labeled. This is due to the fact that the vast majority of these emails were obviously

not BEC attacks, because they were due to a legitimate web services that impersonates a large number of employees (e.g., a helpdesk system sending emails on behalf of the IT staff).

After constructing the initial dataset, training content classifiers is very straightforward, since we continuously collect false negative and false positive emails from users and add them into the training set. Note that we still manually review these samples before retraining as a measure of quality control, to ensure that adversaries do not “poison” our training set, as well as to make sure that users did not label emails erroneously.

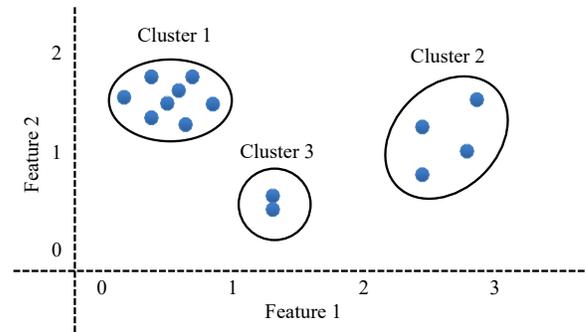

**Sampling the dataset.** Naïvely training a classifier over an imbalanced dataset typically biases the classifier to prefer the majority class. Specifically, it can result in a classifier that will simply always choose to predict the majority class, i.e., legitimate emails, and will thus achieve very high accuracy (i.e.,  $accuracy = (tp + tn) / (tp + tn + fp + fn)$ , where  $tp$  is true positives,  $tn$  is true negatives,  $fp$  is false positives, and  $fn$  is false negatives). Since BEC is so rare in our dataset, a classifier that always predicts that an email is legitimate would achieve a high accuracy. This problem is especially acute in the case of our impersonation classifier, which needs to do the initial filtering between legitimate and BEC emails. In the case of content classifiers, we did not have to sample the dataset, because it deals with a much smaller training dataset.

There are various methods of dealing with imbalanced datasets, including over-sampling the minority class and under-sampling the majority class [6, 24, 27, 29, 30], as well as assigning higher costs to incorrectly predicting the minority class [9, 38].

Our second major design choice was to under-sample the majority class (the legitimate emails). We made this decision for two reasons. First, if we decided to over-sample the BEC attacks, we would need to do so by a large factor. This might overfit our classifier and bias the results based on a relatively small number of positive samples. Second, over-sampling makes training more expensive computationally.

A naïve way to under-sample would be to uniformly sample the legitimate emails. However, this results in a classifier with a low precision, because the different categories of legitimate emails are not well represented. For example, uniformly sampling emails might miss emails from web services that legitimately impersonate employees. The impersonation classifier will flag these emails as BEC attacks, because they are relatively rare in the training dataset.

The main challenge in under-sampling the majority class is how to represent the entire universe of legitimate emails with a relatively small number of samples (i.e., comparable or equal to the number of BEC email samples). To do so, we cluster the legitimate emails using an unsupervised learning algorithm, Gaussian Mixture Models (GMM). The clustering algorithm splits the samples into clusters, each of which is represented by a Normal distribution, projected onto the impersonation classifier feature space. Figure 2 illustrates an

**Figure 2:** Depiction of running clustering algorithm on a set legitimate emails in a two-dimensional feature space with three clusters. After clustering the legitimate emails, we choose the number of samples from each cluster in proportion to the size of the cluster.

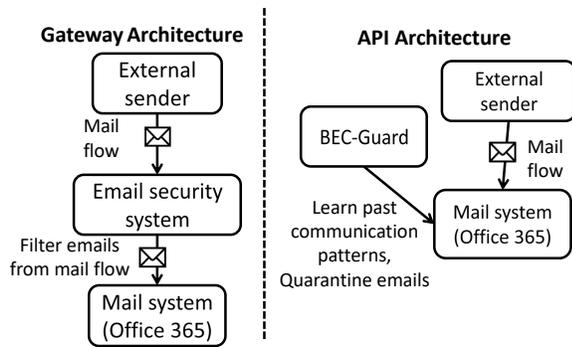

example with two features and 14 legitimate email samples. In this example, the samples are split into three clusters. To choose a representative sample of legitimate emails, we randomly pick a certain number of samples from each cluster, proportional to the number of legitimate emails that belong to each cluster. If for example our goal is to use a total of 7 samples, we would choose 4 samples from the first cluster, 2 samples from the second cluster, and 1 sample from the third cluster, because the original number of samples in each cluster is 8, 4, and 2, respectively.

We chose the number of clusters that guarantee a minimal representation for each major “category” of legitimate email. We found that using 85 clusters was sufficient for capturing the legitimate emails in our dataset. When we tried using more than 85 clusters, the clusters beyond the 85th one would be nearly or entirely empty. Even after several iterations of retraining the impersonation classifier, we have found that 85 clusters are sufficient to represent our dataset.

## 5 System Design

BEC-Guard consists of two key stages: an online classification stage and an offline training stage. Offline training is conducted periodically (every few days). When a new email arrives, BEC-Guard combines the impersonation and content classifiers to determine whether the email is BEC or not. These classifiers are trained ahead of time in the offline training stage. We describe the key components of our system design in more detail below.

Traditionally, commercial email security solutions have a gateway architecture, or in other words, they sit in the data path of inbound emails and filter malicious emails. As described above, some of BEC-Guard’s impersonation classifier features rely on historical statistics of internal communications. The gateway architecture imposes constraints on detecting BEC attacks for two reasons. First, a gateway typically cannot observe internal communications. Second, the gateway usually does not have access to historical communications, so it would require several months or more of observing the communication patterns before the system would be able to detect

**Figure 3:** Comparison between the architecture of traditional email security systems, which sit as a gateway that filters emails before they arrive in the mail system, and BEC-Guard’s architecture, which relies on APIs for learning the historical communication patterns of each organization, and detecting attacks in real-time.

incoming BEC attacks. Fortunately, cloud-based email services, such as Office 365 and Gmail, provide APIs that enable access to historical communications, as well as to monitor and move emails in real-time. BEC-Guard leverages these APIs both to gain access to historical communication, and also to do near real-time BEC detection. Figure 3 compares the gateway architecture with BEC-Guard’s API based architecture. We describe BEC-Guard’s design and implementation using the Office 365 APIs.

**Warmup phase.** We name the process of analyzing each organization’s historical communications, the *warmup* phase. In order to start the warmup, the organization enables BEC-Guard to get access to its Office 365 account with an authentication token using OAuth with an Office 365 administrator account. This allows BEC-Guard to access the APIs for all the users associated with the account. Once authenticated, BEC-Guard starts collecting statistics necessary for the impersonation classifier (e.g., number of times a certain user sent an email from a certain email address). The statistics collected by BEC-Guard go back one year. We found that the classifier performs well with as little as one month of historical data.

**Online classification.** After the warmup phase, BEC-Guard is ready to detect incoming BEC attacks in real-time. To do so, BEC-Guard waits for a webhook API call from any of the users in the organization’s Office 365 account. The webhook API calls BEC-Guard anytime there is any new activity for a specific user. When the webhook is triggered, BEC-Guard checks if there is a new received email. If so, BEC-Guard retrieves the email, and classifies it, first using the impersonation classifier, using a database that contains the historical communication statistics unique to each organization. Then, only if it was classified as an impersonation email, BEC-Guard classifies the email using the content classifiers.

If at least one of the content classifiers classifies the email as a BEC attack, BEC-Guard quarantines the email. This is performed by removing the email from the folder where it was received by the user (typically the inbox folder), and moving it into a designated quarantine folder in the end user’s

mailbox. Since the email is quarantined on the server side, when the user’s email clients synchronize the email it will also get quarantined on the user’s email clients. In addition, the vast majority of emails get quarantined by BEC-Guard before they are synchronized to the user’s email client.

## 6 Evasion

In this section we discuss attacks that are currently not stopped by BEC-Guard, and evasion techniques that can be used by attackers to bypass BEC-Guard and how they can be addressed.

BEC-Guard is a live service in production, and has evolved rapidly since it was first launched in 2017. We have deployed additional classifiers to augment the ones described in this paper in response to some of the evasion techniques presented below, and the existing classifiers have been retrained multiple times. Another benefit of the API-based architecture is that if we find some attacks were missed by an evasion we can go back in time and find them, and update the system accordingly. The email threat landscape is rapidly changing, and while it is important that the detectors maintain high precision, it is equally important that the security system can be easily adapted and retrained.

### 6.1 Stopping Other Attacks

BEC-Guard focuses on stopping BEC attacks, in which an external attacker impersonates an employee. However, there are other types of BEC that are not covered by BEC-Guard.

**Account takeover.** When attackers steal the credentials of an employee, they can login remotely to send BEC emails to other employees. We term this use case “account takeover”. There are several approaches to detecting account takeover, including monitoring internal emails for anomalies (e.g., an employee suddenly sending many emails to other employees they typically do not communicate with), monitoring suspicious IP logins, and monitoring suspicious inbox rule changes (e.g., an employee suddenly creates a rule to delete outbound emails) [18–20]. This scenario is not the focus of BEC-Guard, but is covered by our commercial product.

**Impersonating both sender name and email without changing reply-to address.** It is possible that external attackers could send emails that impersonate both the sender’s name and email address, without using a different reply-to address. We have not observed such attacks in our dataset, but they are possible, especially in the case where the attacker asks the recipient to follow a link to steal their credentials. Similar to account takeover, such attacks can be detected by looking for abnormal email patterns. Another possible approach, used by Gascon et al., is to look for anomalies in the actual MIME header [14].

**Impersonation of external people.** BEC-Guard’s impersonation classifier currently relies on having access to the historical inbound email of employees. In order to detect impersonation of external people that frequently communicate

with the organization, BEC-Guard can incorporate emails that are sent from external people to the company.

**Text classification in any language.** BEC-Guard is currently optimized to catch BEC in languages that appear frequently in our dataset. Both the impersonation classifier and the link classifier are not language-dependent, but the text classifier relies on the TFIDF dictionary is dependent on the language of the labeled dataset. There are a few possible ways to make BEC-Guard's text classifier completely language agnostic. One is to deliberately collect sufficient samples in a variety of languages (either based on user reports or generate them synthetically), and label and train on those emails. Another potentially more scalable approach is to translate the labeled emails (e.g., using Google Translate or a similar tool).

**Generic sender names.** BEC-Guard explicitly tries to detect impersonations of employee names. However, attackers may impersonate more generic names, such as "HR team" or "IT". This attack is beyond the scope of this paper, but we address it using a similar approach to BEC-Guard in order to detect these attacks: we combine our content classifiers with a new impersonation classifier, which looks for sender names that commonly occur across different organizations, but are sent from a non-corporate email address or have a different reply-to address.

**Brand impersonation.** Similar to the "generic sender" attack, attackers often impersonate popular online services (e.g., Google Drive or DocuSign). These types of attacks are out of the scope for this paper, but we detect them using a similar methodology of combining content classifier, with an impersonation classifier that looks for an anomalous sender (e.g., the sender name has "DocuSign", but the sender domain has no relation to DocuSign).

## 6.2 Evading detection

Beyond BEC attacks that BEC-Guard is not designed to detect (as noted above), there are other several ways attackers can try to evade BEC-Guard. We discuss these below and discuss how we have adapted BEC-Guard to address them.

**Legitimizing the sender email address.** Any system that uses signals based on anomaly detection is vulnerable to attackers that invest extra effort in not appearing "anomalous". For example, when labeling our dataset, we assume that the impersonated employee was not impersonated by the same sender email address more than 100 times. While this threshold is not hard coded into the impersonation classifier, it was a threshold we used to filter emails for the initial training set, and therefore may bias the classifier. Note that we have never observed an attacker impersonating an employee with the same email more than 20 times.

We believe this assumption is valid since BEC-Guard assumes that the organization is already using a volume-based security filter (e.g., the default spam protection of O365 or

Gmail or another spam filter), which would pick up a "volumetric" attack. Typically these systems would flag an email that was sent at once from an unknown address to more than 100 employees as spam.

However, a sophisticated attacker may try to bypass these filters by sending a large number of legitimate emails from the impersonated email address to a particular organization, and only after sending hundreds of legitimate emails they would send a BEC using that address. Of course the downside of this approach is that it would require more investment from the attacker, and increase the economic cost of executing a successful BEC campaign. One way to overcome such an attack, is to add artificial samples to the impersonation classifier that have higher thresholds, in order to remove the bias. Of course this may reduce the overall precision of BEC-Guard.

**Using infrequent synonyms.** Another evasion technique is to send emails that contain text that is different or has a lower TFIDF than the labeled emails used to train our text classifier. For example, the word "bank" has a higher TFIDF, than the word "fund". As mentioned before, one way to overcome these types of attacks is to cover synonyms using a technique, such as word2vec [34].

**Manipulating fonts.** Attackers have employed various font manipulations to avoid text-based detectors. For example, one technique is to use fonts with a size of zero [35], which are not displayed to the end user, but can be used to obfuscate the impersonation or meaning of the text. Another technique is to use non-Latin letters, such as letters in Cyrillic, which appear similar to the Latin letters to the end user, but are not interpreted as Latin by the text-based detector [16].

In order to deal with these types of techniques, we always normalize any text before feeding it to BEC-Guard's classifiers. For example, we ignore any text with a font size of zero. If we encounter Cyrillic or Greek in conjunction with Latin text, we normalize the non-Latin letters to match the Latin letter that is closest in appearance to it. While these techniques are heuristic based, they have proved effective in stopping the common forms of font-based evasion.

**Hiding text in an image.** Instead of using text within the email, attackers can hide the text within an embedded image. We have observed this use case very rarely in practice, most likely because these attacks are probably less effective. Many email clients do not display images by default and even when they do, the email may seem odd to the recipient. Therefore, we currently do not address this use case, but a straightforward way to address it would be to use OCR to extract the text within the image.

**Using a legitimate reply-to address.** As mentioned in §4.4 BEC-Guard relies on a list of legitimate reply-to domains to reduce false positives. This list could potentially be exploited. For example, attackers could craft a LinkedIn or Salesforce profile with the same name of the employee being impersonated and send an impersonation email from that service.

	Precision	FP	Recall
BEC-Guard (Combined)	98.2%	0.000019% (1 in 5,260,000)	96.9%
Impersonation Only	11.7%	0.016% (1 in 6,300)	100%

**Table 6:** Precision, false positive rate, and recall of BEC-Guard compared to the impersonation classifier alone.

While this is indeed a potential evasion technique, these third party services often have their own anti-fraud mechanisms to stop impersonation. In addition, we believe an impersonation attempt is less likely to succeed if it going through a third-party service, since it would probably seem much less natural than simply sending an email from the email account of the employee. Regardless, we have never seen this evasion technique being used by attackers.

## 7 Evaluation

In this section, we evaluate the efficacy of BEC-Guard. We first analyze the end-to-end performance of BEC-Guard, using a combination of the impersonation and content classifiers. We then break down the performance of each set of classifiers, and analyze the performance of different classifier algorithms. We also try to estimate the extent of unknown attacks that are not caught by BEC-Guard, by comparing the number of reported missed attacks by customers to the number of true positives.

### 7.1 End-to-end Evaluation

For the end-to-end evaluation, we randomly sampled emails that were processed by BEC-Guard in June 2018. We manually labeled the emails, and evaluated BEC-Guard’s classifiers on the labeled data. We labeled the emails for the evaluation dataset similar to the way we labeled the training data for BEC-Guard’s classifiers (see §4.6). We first ran a set of queries that uncover all the BEC attacks that we could find under our labeling assumptions. We then manually labeled the resulting emails, and found 4,221 BEC emails. The entire process took about a week of work for one person. The emails that were not labeled as BEC attacks were assumed to be innocent (In §7.3 we discuss emails that might have been missed by our labeling process).

To evaluate the classifiers, we randomly split the evaluation dataset in half: we used half of the emails for training, and the rest to test the classifiers. The dataset includes 200 million emails from several hundred organizations.

To test the end-to-end efficacy of BEC-Guard, we ran the content classifiers only on the emails that were detected as impersonation emails by the impersonation classifier. Table 6 summarizes the efficacy results. The recall of BEC-Guard is high within the emails we labeled: 96.9% of the BEC emails we labeled were successfully classified by the impersonation classifier as well as one of the content classifiers. The combined false positive rate is only one in 5.3 million emails are

Text classifier			
Algorithm	Precision	FP	Recall
Logistic Regression	97.1%	$6.1 \cdot 10^{-5}\%$	98.4%
Linear SVM	98.3%	$3.6 \cdot 10^{-5}\%$	98.7%
Decision Tree	96.0%	$8.5 \cdot 10^{-5}\%$	97.1%
Random Forest	99.2%	$1.7 \cdot 10^{-5}\%$	96.4%
KNN	98.9%	$2.3 \cdot 10^{-5}\%$	97.5%

**Table 7:** Text classifier algorithm efficacy using a dictionary of 10,000 words. There is very little difference between the efficacy of the algorithms for the text classifier.

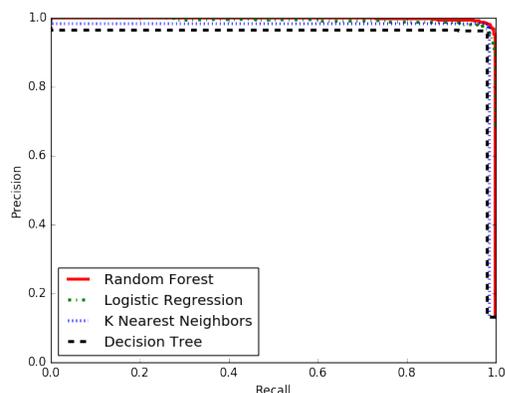

Link classifier			
Algorithm	Precision	FP	Recall
Logistic Regression	33.3%	$85.7 \cdot 10^{-5}\%$	96.0%
Linear SVM	92.3%	$3.2 \cdot 10^{-5}\%$	90.8%
Decision Tree	94.9%	$2.3 \cdot 10^{-5}\%$	96.3%
Random Forest	97.1%	$1.3 \cdot 10^{-5}\%$	96.0%
KNN	92.5%	$3.3 \cdot 10^{-5}\%$	93.5%

**Table 8:** Link classifier algorithm efficacy. Random forest provides superior results over the other algorithms.

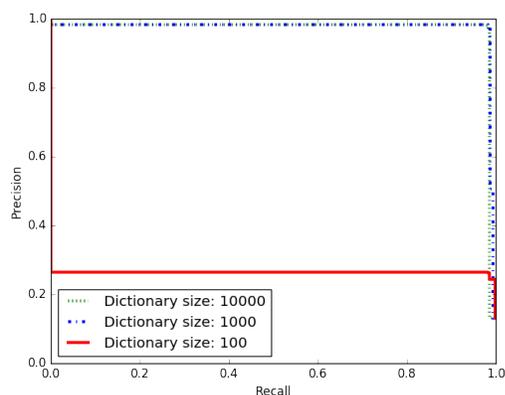

falsely detected, which is above our design goal of 1 in a million email. The precision is 98.2%.

The false positives of the combined classifiers were due to unlikely incidents where the impersonation classifier detected the email (e.g., due to a personal email address) that also contained anomalous content (e.g., an employee uses a personal email to forward links with low popularity domains to a colleague). Another common false positive occurs when employees leave the organization, and request W-2 forms for tax purposes or other personal information. We plan on addressing such false positives by incorporating features that would indicate whether a sender is no longer an employee of the organization (e.g., if they have stopped sending emails from their corporate address). The false negatives are mostly due to instances where the URL is not deemed suspicious, because it belongs to a domain that got compromised that had a relatively high domain popularity, or because the text of the email is not classified as suspicious. The latter case is typically because the attacker did not use phrases that were similar to any of the BEC attacks that were used to train the text classifier. For example, one of the false negatives asked the recipient for gift card information, which was not a request that was used in any prior attacks.

We also ran the impersonation classifier on the evaluation dataset. Its precision is 11.7%, and its false positive rate is 0.016%. Organizations that are only concerned about recall and have the ability to tolerate a relatively large number of false alerts can run the impersonation classifier on its own. The vast majority of false positives of the impersonation classifier are due to employees using their personal or university (alumni) email addresses.

**Figure 4:** ROC curve of text classifier with different algorithms. All four algorithms perform very similarly, and reach a precision cliff at about 99% recall.

**Figure 5:** ROC curve of text classifier using KNN with different dictionary sizes. A dictionary size of 1,000 already provides most of the benefit.

## 7.2 Classifier Algorithms

Table 7 compares the results of the text classifier using different classifier algorithms. As the results show, there is a very small difference between the different classifiers. This is primarily due to the fact that we use a dictionary with a large number of features (10,000). Table 8 shows the results for the link classifier. In the case of the link classifier, random forest more clearly provides superior results than the other classifiers, including KNN. The link classifier is more sensitive to the classification algorithm, because it uses a smaller number of features. Figure 4 presents the ROC curve for four of the classifier algorithms that have a probabilistic output. The ROC curve shows the how each classifier can be tweaked to trade-off precision for recall. All four algorithms behave almost identically: they provide a high level of precision, until a recall level close to 99% where their precision drops. Note that to generate the ROC curves we ran the text classifier only on the emails that were already classified as impersonations. Therefore, its minimum precision in the ROC curve is equal to about 11.7%, which is equal to the precision of the

Org	TPs	FNs	Reason
A	31	1	Generic Sender Name
B	4	1	Misclassified Content
C	12	1	External Impersonation
D	8	1	External Impersonation
E	5	1	Misclassified Content
Total	60	5	

**Table 9:** True positives (TPs) and reported false negatives (FNs) among five organizations, where the administrator has reported at least one false negative.

impersonation classifier.

To analyze the effect of the dictionary size on the classification, Figure 5 plots the efficacy of the text classifier using KNN with different dictionary sizes. The graph shows that most of the marginal benefit is achieved with a dictionary size of 1,000. We observed no noticeable difference in efficacy when using a dictionary larger than 10,000.

## 7.3 Evaluating Missed Attacks

A general limitation of evaluating imbalanced datasets is that it is difficult to accurately estimate the true false negative rate. In our evaluation dataset, we can only estimate the false negative rate in relation to the data that we labeled. If we missed an attack during labeling, and it was not detected by the classifiers, we would not count it as a false negative.

To deal with “unknown” attacks, our production system allows users to report attacks that it did not detect. We estimate the number of missed attacks *among organizations that have reported missed attacks*. We selected five random organizations that reported missed attacks, and analyzed their detections in the month during which they reported missed attacks. Table 9 provides the number of true and missed detections among these five organizations, as well as the reason for each false negative.

In organization A the attack was missed because the email did not impersonate an employee name, but rather the sender name had a generic title (e.g., “Accountant”). BEC-Guard only detects the impersonation of an employee’s name. As we explained in our labeling assumptions (see §4.6), BEC-Guard is only designed to detect attacks that explicitly impersonate an employee name. We speculate that this type of email would be less successful, because the recipient might find it unusual to get an email from a sender name with a generic title, which is not normally used in their company. Nevertheless, our commercial product utilizes other detectors that find “generic titles” as well (see §6). In organization B and E the impersonation classifier successfully detected an impersonation, but the text classifier did not deem the text of the email as suspicious. In both instances, we have since retrained BEC-Guard’s text classifiers using the reported emails. In the case of organization C and D, the reported missed email was due to the impersonation of an external colleague (e.g., a vendor the company works with that got impersonated). In §6 we

discuss how to extend BEC-Guard to detect such attacks.

## 8 Related Work

The growing threat of BEC is widely known and has been described in many in industry and government reports [13, 22, 23]. However, the existing academic work uses very small or synthetic datasets, and suffers from high false positives. In addition, since existing related work is based on limited datasets, it fails to address many of the real-world issues discussed in our paper, such as dealing with the imbalanced dataset, the usage of personal email addresses by employees or “legitimate” impersonations. We believe the reason for the small body of related work is that BEC primarily affects corporate users (not consumers), and it is generally difficult for academic researchers to obtain access to corporate email data.

EmailProfiler [10] builds a behavioral model on incoming emails in order to stop BEC. However, it is based on only 20 mailboxes, has no examples of real-world attacks and does not report false positive rates. In addition, there is prior work on systems that detect emails, which compromise employee credentials with a phishing link [20, 45]. There is some overlap between BEC attacks and emails that compromise credentials: in our dataset, 40% of BEC attacks try to phish employee credentials with links. However, the remaining BEC attacks do not contain a phishing link that compromises credentials, and cannot be detected by these systems.

Gascon et al. [14] design a model to stop emails that spoof the domain of the receiver. Similar to BEC-Guard, they base their model on the historical communication patterns of senders. However, in our dataset, spoofing emails represent only about 1% of BEC attacks. Therefore, their model would not catch the other 99% of BEC attacks. The reason domain spoofing represents a small percentage of our dataset, is our dataset only contains emails that were already filtered by an existing spam filter (e.g., Office 365’s default filter). Domain spoofing emails contain a mismatch between the sender and reply-to domains, or between the sender domain and the from email envelope. For this reason, traditional spam filters already stop a large number of spoofing emails [33]. In addition, their model is based on a dataset of only 92 mailboxes.

DAS [20] uses unsupervised learning techniques to identify that result in credential theft, which are a subset of BEC attacks. However, it cannot detect attacks that contain only plain text, and is based on a dataset from a single organization with only 19 known attacks. It also suffers from a 0.2% precision, and a much higher false positive rate than BEC-Guard. Similarly, IdentityMailer [45] tries to prevent employee credential compromise by modeling employee behavior, and detecting anomalies in outbound emails. Once an anomaly is detected, the employee is asked to re-authenticate with two-factor authentication. However, their technique suffers from very high false positive rates (1%-8%, compared with 1 in millions of emails in BEC-Guard), and the analysis is based on a small corpus of emails.

Another contemporaneous study done at Barracuda Networks by Ho et al. [18, 19] examines the behavior of attackers using compromised accounts and possible ways to detect account takeover incidents. The techniques presented in this paper are complimentary with the other study, and focus on a different type of attack.

Finally, there is a large body of work on adversarial learning in the context of spam detection [3, 4, 8, 21, 31, 32, 37, 50] that is relevant to our work. In the future, we plan to incorporate some of the evasion techniques introduced in past work, including randomization and the use of honey pots to trick adversaries.

## 9 Conclusions

BEC is a significant cyber security threat that results in billions of dollars of losses a year. We present the first system that detects a wide variety of BEC attacks at a high precision and false positives, and is used by thousands of organizations. BEC-Guard prevents these attacks in real-time using a novel API-based architecture combined with supervised learning.

One of the main lessons we have learned in developing and deploying BEC-Guard, is that attackers constantly adapt their tactics and approaches. While our supervised learning approach does require continuously retraining our classifiers, and is not fully generalizable, we have found the general approach of using historical email patterns via an API-based architecture has been very useful in quickly developing new classifiers for evolving threats. We have employed a similar approach to the one described in this paper in other contexts, such as detecting brand impersonation, generic sender names and account takeover.

## Abstract

In this paper we employ quantitative measurements of *cognitive vulnerability triggers* in phishing emails to predict the degree of success of an attack. To achieve this we rely on the cognitive psychology literature and develop an automated and fully quantitative method based on machine learning and econometrics to construct a triaging mechanism built around the cognitive features of a phishing email; we showcase our approach relying on data from the anti-phishing division of a large financial organization in Europe. Our evaluation shows empirically that an effective triaging mechanism for phishing success can be put in place by response teams to effectively prioritize remediation efforts (e.g. domain takedowns), by first acting on those attacks that are more likely to collect high response rates from potential victims.

## 1 Introduction

Phishing attacks represent a significant threat to organizations and their customers [36]. The problem of phishing detection has been addressed multiple times in the literature [16, 18, 32], yet classification is only part of the issue. A timely and efficient *reaction* to phishing attempts (e.g. performing takedown actions on phishing domains, blacklisting, or notifying customers) could save hundreds or thousands of customers from fraud or theft, and associated costs for all involved stakeholders. For this reason, most ‘large enough’ organizations operate a phishing-response team whose task is to promptly investigate potential impacts, identify rogue domains and attack vectors, and act to contain or neutralize the attack [8]. The size of this effort often requires the full time operation of several experts within the response team [46].

Unfortunately, these teams currently lack of an objective and quantitative way of prioritizing response activities, which can lead to large inefficiencies in the response process. Technical mechanisms are often in place to *a-posteriori* quantify the success of a phishing attack, but these are technically limited to attacks ‘in scope’ of the measuring mechanism (e.g.

evaluating the requests for internal resources received by the organization’s servers and originating from remote domains) and, importantly, cannot *predict* how successful the attack is likely to be if no immediate mitigation is put in place.

Key to predicting phishing success is the likelihood that a human will *comply* with whatever instruction is in the phishing email. Cialdini pioneered the definition of ‘*principles of influence*’, namely Reciprocity, Consistency, Social Proof, Authority, Liking, and Scarcity as ‘cognitive triggers’ that, once engaged, can greatly impact the likelihood of a human’s decision to comply with what he or she is being requested to do [6]. These principles have been used as a theoretical framework to investigate persuasion in different domains, such as sales and marketing [7], organizational behaviour [41], and wellbeing [51], as well as being linked to phishing effectiveness [53, 54] in (synthetic) experimental settings [55]; however no means to automatically measure the cognitive features of a phishing email, and estimate their relation to phishing success ‘in the wild’, currently exists.

In this paper we employ techniques from natural language processing and econometrics to build a method and estimation process to measure cognitive triggers in phishing emails, and to build a *cognitive triaging model* of how successful an attack can be expected to be. We demonstrate empirically that the resulting estimations can be used to efficiently prioritize phishing response actions, by addressing first the (few) attacks that are likely to be highly successful. To do this, we extensively analyze more than eighty thousand phishing emails received by the anti-phishing division of a very large European financial organization, quantify the ‘cognitive vulnerability triggers’ embedded in the attacks, and relate them to the number of accesses to the remote phish domain that the anti-phishing division measured. This allows us to empirically derive a triaging model that, only based on cognitive features of the incoming phishing email, can predict how many ‘clicks’ it can be expected to generate.

**Scope and contribution of this work.** With this work we aim at building a principled analysis that explains *why* one can expect a certain phishing email to be successful, as opposed to

building a method that ‘blindly’ maps mail bodies to success of attack. Importantly, with this work we do *not* aim to build a classifier to distinguish phishing from non-phishing emails; instead, we propose a method to *predict* to what extent a *known* phishing attack can be expected to lure users in falling for it. Our contributions can be summarized as follows:

- we provide the first empirical analysis of cognitive vulnerabilities as exploited in the wild by attackers launching phishing attacks;
- we employ a robust measurement methodology to identify cognitive vulnerability triggers in phishing emails, using supervised Latent Dirichlet Allocation, and a set of bootstrapped econometric simulations to build robust estimations of model coefficients and predictions;
- we show empirically the correlation between exploited cognitive factors and spoofed `From:` addresses with an objective evaluation of phishing success;
- we quantitatively show that triaging phishing emails to prioritize remediation action is possible and effective in an operational setting.

This paper proceeds as follows: Section 2 sets the background for this work in both the cognitive psychology and information security literature; Section 3 details the employed data and methodology, and Section 4 reports the exploratory and cognitive analysis of the data. The cognitive model and predictions are presented in Section 5. Section 6 provides a discussion of our results, and Section 7 concludes the paper.

## 2 Background and Related Work

The general objective of a phishing attack is to convince a target to comply with a request, such as clicking a link to a phishing domain, downloading malware, or providing personal credentials. The effectiveness of these attacks significantly relies on how quickly the message can generate the desired response [55]. Moreover, both cognitive [54, 56] and technical [27, 30, 42] features are employed to lure users into falling for the phish and are known to be relevant to explain phishing effectiveness.

### 2.1 Cognitive characterizations

**Believability.** Phishers apply several techniques to increase believability of their phishing messages. For example, they may craft their phishing messages to resemble communications of the impersonated organizations as closely as possible [56]. This is commonly done by duplicating the look and feel of these communications by including logos and other branded graphics extracted from their legitimate counterparts, and by adopting a formal writing style [15]. Furthermore, the context of phishing messages is generally highly personalized to appeal to the targeted population [55]. These practices are enhanced by more technical measures, such as spoofing of

the phishing source address, and the use of shortened URLs to hide the destination of the embedded phishing link [24].

**Persuasiveness.** Persuasiveness is associated with the text content of the email. These techniques work by exploiting fundamental vulnerabilities of human cognition [31] that can be explained by ‘shortcuts’ in human cognitive processes that determine decisions on the basis of previous experiences, biases, or beliefs [48]. Despite the clear benefits of these mental-shortcuts, they can result in irrational decision-making as well [52]. Cialdini [6] identified several principles that explain how these mental shortcuts can be exploited for the persuasion of others (e.g. for marketing purposes). Indeed, these principles are applied regularly in multiple domains, including marketing (e.g. to purchase a product or solution) [7], organizational behaviour (e.g. to comply to policies) [41], and health and wellbeing (e.g. to adopt healthy lifestyles) [51]. As these are foundational to human decision-making processes [33], these principles may not be effectively applied to *distinguish* legitimate from illegitimate resources (e.g. a website, email, or conversation): any activity aiming at ‘influencing’ one’s behaviour (that being through spam or organization policies, phishing or advertisement) will employ some variation of these principles. On the other hand, these provide a solid foundation to evaluate how *effective* an attempt at convincing a human can be expected to be. Table 1 provides examples and definitions of these principles.

Cialdini’s principles of persuasion are strongly related to the successfulness of face-to-face social engineering efforts in the real world [44] as well. Akbar [2] performed a quantitative analysis on 207 unique phishing emails to identify the application of Cialdini’s persuasion principles in phishing emails. The results show the `Authority`, `Scarcity` and `Liking` principles to be most popular. A similar study was performed by Ferreira et al. [12], who found the `Liking` principle to be most popularly used, followed distantly by the principles of `Scarcity` and `Authority`. Differences can be explained by different experimental settings and application domains. Several other studies [3, 13, 55] have addressed the prevalence and efficacy of Cialdini’s principles in phishing attacks. Others have evaluated phishing campaigns against specific users [23], discussing some of the techniques used by phishers to lure their victims. Unlike these works, we integrate quantitative measures of cognitive attacks and measures of phishing success to predict attack effectiveness in operational settings.

### 2.2 Phishing effectiveness

Previous work considered the inclusion of forged quality marks, images, and logos from trusted organizations as well as other signals of credibility as means to increase the effectiveness of a phishing attack [9]. Other more technical measures are employed to enhance the credibility of phishing as well, for example spoofing of the source email address, adoption

Table 1: Definitions and examples of Cialdini’s principles of influence in phishing emails

Principle	Definition [6]	Phishing text example <sup>2</sup>
Reciprocity	Tendency to feel obliged to repay favours from others. “I do something for you, you do something for me.”	“While we work hard to keep our network secure, we’re asking you to help us keep your account safe.”
Consistency	Tendency to behave in a way consistent with past decisions and behaviours. After committing to a certain view, company or product, people will act in accordance with those commitments.	“You agreed to the terms and conditions before using our service, so we ask you to stop all activities that violate them. Click here to unflag your account for suspension.”
Social Proof	Tendency to reference the behaviour of others, by using the majority behaviour to guide their own actions.	“We are introducing new security features to our services. All customers must get their accounts verified again.”
Authority	Tendency to obey people in authoritative positions, following from the possibility of punishment for not complying with the authoritative requests.	“Best regards, Executive Vice President of <company name>”
Liking	Preference for saying “yes” to the requests of people they know and like. People are programmed to like others who like them back and who are similar to them.	“We care for our customers and their online security. Confirm your identity .. so we can continue protecting you.”
Scarcity	Tendency to assign more value to items and opportunities when their availability is limited, not to waste the opportunity.	“If your account information is not updated within 48 hours then your ability to access your account will be restricted.”

<sup>2</sup> Examples drawn from anti-phishing database at <http://www.millersmiles.co.uk>.

of HTTPS instead of HTTP to convince the user the webpage is ‘safe’ [36], or cloning of the original webpage. Several works have considered such visual similarities between phishing landing pages and their legitimate counterparts based on different features, including DOM tree structures [42], CSS styling [27, 30], content signatures [1, 17], and pixel and/or image properties [5, 10]. Whereas these technical features constitute additional relevant information for the identification of a phishing attack, in this study we focus on the cognitive attacks embedded in an email text (as opposed to the visual clues included in a landing webpage) that affect the human decision making. Additionally, a number of user-studies has been conducted on the impact of client-side detection-assistance tools [20, 57] and how people evaluate phishing web pages [9]. Various phishing detection mechanisms have been proposed based on technical features such as signatures of user email behaviour [49], email-header properties [16], impersonation limitations of attackers [28], search engine rankings [25], and botnet effects [35]. Additionally, [29] presents a set of research guidelines for design and evaluation of such detection systems. These works have predominantly focused on the detection of phishing domains and emails by means of technical traces in order to prevent phishing attacks from happening in the first place. Unlike these studies, we focus on the evaluation of the potential of those attacks that, despite the countermeasures in place, make it through and must be timely addressed.

On the cognitive-side we can consider the impact of user demographics. Oliveira et al. [34] found age to be an important feature, finding younger adults to be more susceptible to Scarcity, whereas older adults were more susceptible to Reciprocity. Other results of this study indicate the relevance of gender by finding older women to be most susceptible of all of the studied user groups. Furthermore, Wash and Cooper [53] demonstrated the impact of message presentation by showing how phishing training methods based on

giving facts-and-advice were more effective when presented by an expert figure (Authority), whereas methods based on personal stories benefited more from presentation by people perceived as similar to the user (Liking). In the context of social media, user activity, consumption behaviour, and clicking norms in the social network were found to be important factors for phishing success [40]. As opposed to focusing on the characteristics of the individuals that receive the phishing (as this information for the population of customers is generally unknown to organizations, or may be impossible to collect due to legal and ethical challenges), in this work we consider the expected aggregate responses of the phishing recipients as a function of the phishing emails.

### 3 Methodology and Data collection

Our analysis relies on a unique dataset from a large phishing email database provided by Org, a large financial organization in Europe with more than 8 million customers and a multi-billion Euro turnover. Org customers that suspect they have received a phishing email in their personal email accounts are instructed by the organization to forward these emails to an internal Org functional mailbox. In parallel, Org’s phishing response team runs a service to detect phishing domains (not necessarily linked with the received phishing emails) by means of internal heuristics and limited to external domains requesting resources internal to Org (e.g. images, forms, logos, CSS files/javascript, etc.). This data is generated by a third party service hired by Org that monitors *all* requests generated towards Org’s resources. Through this mechanism Org can detect the number of visits to the detected domains by accounting for the unique sessions opened between the (rogue) external and the (legitimate) internal services. Access to this data allows us to perform a rich analysis of the arrival of phishing emails, their characteristics, and to evaluate how often users have accessed malicious domains as a proxy mea-

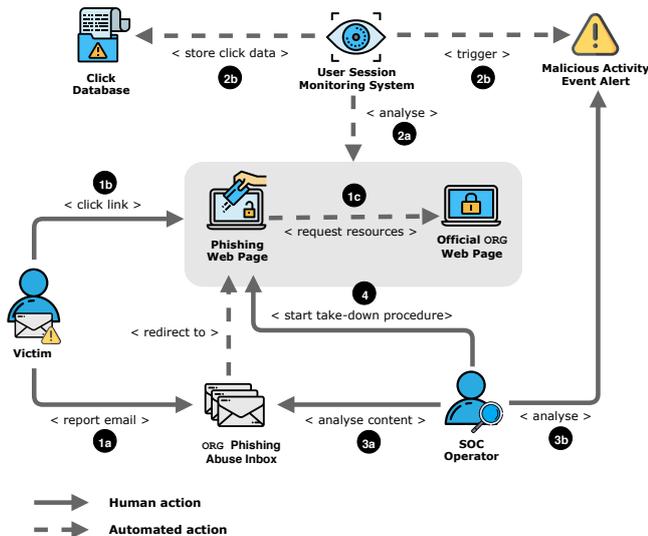

Figure 1: Overview of phishing-related activities at Org

sure of ‘phishing success’. Figure 1 depicts Org’s internal process to handle suspect phishing emails.

Overall, we extracted 115,698 reported emails and 11,936 alerts for malicious links between February 1st, 2018 and 15 December 2018, with the exception of the period August-September 2018 due to infrastructural limitations at Org. For this same reason, our sample only includes data for ‘clicks’ collected from end of July onwards.

**Data limitations and ethical aspects.** From the data structure, the link between a clicked URL and the specific email from which that click originated is not explicit and can only be reconstructed by exact match of the destination URL. This has the effect of limiting the scope of this study to the comparison of the effectiveness of cognitive influence techniques between phishing emails that are likely to have generated the click (as we cannot fully reproduce the process generating the detection of URLs that *could* have been clicked, but have not). This also limits the number of matches between URLs reported in event alerts and URLs linked in emails. Further, the results of this work are limited to the emails that have been *reported* (and therefore identified at least once) by Org’s customers. Despite the large number of active reporting customers, particularly well-crafted emails may not be represented in our dataset. Further, we can only observe data captured by the *User Session Monitoring System*, i.e. related to emails pointing to domains that ‘call back’ to Org’s systems. This may represent a limitation if emails that do not ‘call back’ also exploit different ‘cognitive vulnerabilities’, or with different distributions. However, an analysis on the available data does not show apparent biases between emails

for which a ‘click’ has been recorded, and those for which we do not know of any (ref. Figure 10). These limitations are akin to those outlined by Pitsillidis *et al.* [37]. Aware of these, we compensate by means of the analysis methodology that explicitly accounts for the potential biases in the data. Finally, the collected data did not contain sensitive subject information and all data handling has been performed within allowance from Org and within the scope of work previously approved by the department IRB.

### 3.1 Data sanitization and processing

As our email dataset contains messages forwarded by users, we first sanitize the data by removing mobile text messages ( $n = 18,817$ ) that likely result from erroneous forwards to the functional mailbox from a related banking service; as they are irrelevant in our setting, we discarded them. Further, users may have reported emails that target financial organizations different from Org. To capture this, we identify targeted organizations in our dataset by a string search operation within email bodies for the names of the most prominent financial organizations in the country where Org is located, and remove all records that do not belong to Org ( $n = 15,623$ ). To identify phishing email subjects, dates, and recipient/sender information, we recursively searched through each raw email message to find header matches of the first original email arrived in the user’s inbox,<sup>1</sup> and extract information on From, To, Date, and Subject values. Table 2 reports summary statistics of the final dataset.<sup>2</sup>

#### 3.1.1 Identification of suspicious and landing URLs

**Suspicious URLs.** We check emails for the presence of suspicious URLs that point to any domain that does not belong to Org, as these would not normally appear in a legitimate email originated by the organization. We exclude from the heuristic general-purpose domains with no direct phishing correlation (e.g. [youtube.com](https://www.youtube.com)). Based on this classification we flag emails that contain at least one suspicious URL as Suspicious, whereas the remaining ones are considered uninteresting within our scope (as we can neither count nor estimate clicks for URLs that do not exist).

**Landing URLs.** These are landing URLs that load resources internal to Org, as detected and reported by the *User Session Monitoring System* (ref. Fig.1). Whereas they are related to a click on a suspicious URL, this relation is not immediate in the data and needs to be reconstructed.

<sup>1</sup>This is necessary as emails can be forwarded multiple times (e.g. if originally forwarded by the customer to an Org employee) before ending up in the phishing inbox.

<sup>2</sup>We notice that the upper 2.5% of the distribution of email length is disproportionately long w.r.t. the remainder of the distribution, suggesting a few outliers in the data. Manual inspection reveals malformed email corpora (e.g. with HTML tags embedded in the body); as no obvious ‘upper limit’ for email length is apparent, we keep these in the dataset for the sake of transparency.

Table 2: Descriptive statistics of the collected dataset

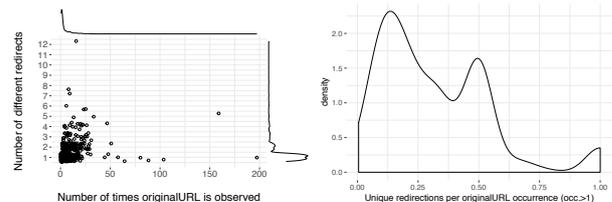

The column `type` indicates whether the variable is a factor (f) or numeric (n). The column `n` reports number of levels for factors, and number of records with at least one observation for numerical variables. We do not report summary statistics for factors. The standard deviation for variable `Date` is reported in days. All dates are in 2018 and in format `%m - %d`.

Variable	type	Feb-Jul 2018							Oct-Dec 2018

### 3.1.2 Landing URL extraction

To reconstruct the association between Landing URLs and Suspicious URLs we adopt the following method:

1. First, we traverse the suspicious URL embedded in the phishing email (`suspiciousURL`) multiple times by visiting all URLs arriving to `Org`'s inbox. These typically generate a number of redirections (generally HTTP 3xx) that lead to a landing webpage, where the actual phishing resource is located. We record the association  $\langle \text{suspiciousURL}, \text{landingUrl} \rangle$  for *all* visited URLs, and for *all* emails; if the redirection mechanism is not deterministic, we obtain a 1 to *n* association between `suspiciousURL` and a set of `landingURLs`. As we cannot know how many 'redirection chains' exist from a single `suspiciousURL`, we traverse the URL opportunistically every time it appears in `Org`'s inbox. To minimize confoundings in the redirection, each visit session is independent from the previous. Figure 2 shows that the number of different redirections stops growing quickly regardless of how many time we traverse a given URL, suggesting that the dataset of collected `landingURLs` does not suffer from systematic censoring problems.
2. When `landingURL` is visited, a third party contractor of `Org` records a 'click' for `landingURL` (see Fig 1 and discussion in *data limitations*), and reports it to `Org`.
3. We link clicked `landingURLs` with the original email body by matching them with the `landingURLs` we found by traversing the `suspiciousURLs` in the mail corpus; if there are multiple clicked `landingURLs` for a single `suspiciousURL`, we keep record of all matches.

The redirection count for all observed suspiciousURLs (left) shows that new landingURLs stop appearing after only few suspiciousURL visits. The density plot on the right shows ratio of unique landingURL per suspiciousURL for suspiciousURLs visited more than once, and confirms that new redirects stop appearing regardless of number of visits.

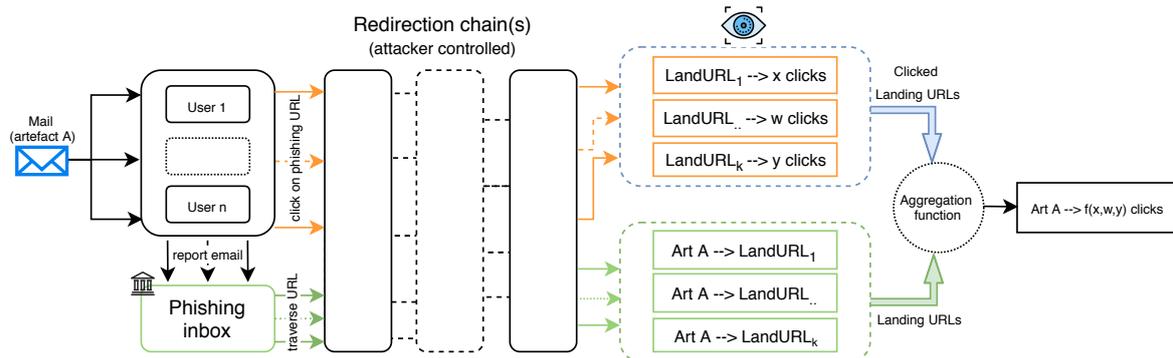

Figure 2: Redirection count (left) and density ratio (right) from observed suspiciousURLs.

4. To aggregate clicks to a single suspiciousURL, we considered: average, sum, and max no. of clicks across all `landingURLs` for a given `suspiciousURL`. We ran our experiments using all aggregation strategies, and obtained qualitatively identical results. In this paper we report average clicks as it is the most conservative choice to make (e.g. summing `landingURL` clicks is more susceptible to over-reporting multiple clicks by the same user).

Figure 3 provides a bird's eye view of the data generation process for the landing URL extraction.

### 3.1.3 Duplicate detection

One complexity of our unstructured dataset is the possible occurrence of multiple duplicates of the same suspect phishing email. In this paper we consider 'similar' emails received by

Data generation process for an example email leading to  $k$  distinct clicked landingURLs. Users may click on the suspiciousURL link in the email and, usually through a series of redirections, reach the phishing domain hosted at one of the landingURLs. Through the dynamics described in Figure 1, an association between each distinct landingURL and recorded number of clicks is reported. The same email can also be reported to Org's phishing inbox. When it arrives, we opportunistically traverse the redirection chain and record the association between the original email and the final landingURL(s). To reconstruct the association between suspiciousURLs and clicked landingURLs, we aggregate the two datasets.

Figure 3: Data generation process for matched URLs and click data aggregation

users over long periods of time as belonging to the same ‘campaign’.<sup>3</sup> Although the overall textual content of these duplicate emails is similar, they can still contain slight differences, for instance because of the presence of a recipient’s name in the salutation of an email or other minor syntactic features. In order to detect, and subsequently remove, as many of these duplicate emails as possible, we used a fuzzy string matching approach to determine the pairwise similarity for each of the emails in our dataset. We employ a *bag-of-words* model to calculate, for each document, the frequency of each unique word in the document. We build the word-by-document matrix of our email corpora for the term frequency values for all emails in our dataset. As an additional pre-processing step all input was cleaned by removing special characters, urls, email addresses and line breaks from the text. We use  $L^2$  normalization to the term frequencies to limit the impact of differences in email lengths [47].

To evaluate email similarity we employ a measure of cosine similarity. This similarity measure expresses the similarity between two vectors in terms of the cosine of the angle between the two vectors; the evaluation results in a score between  $[0, 1]$ , where 0 constitutes low similarity, and 1 constitutes high similarity. To define the cutoff threshold for similar emails we manually marked 300 randomly sampled emails from the dataset and assigned them to ‘similarity IDs’ to track which emails were replicas of which others. We then performed a bootstrapped ( $n = 100,000$ ) sensitivity analysis of the threshold level to determine the optimal level for the cutoff. This procedure tunes the categorization to very satisfactory sensitivity and specificity levels higher than 90%. Full details on procedure and results are reported in the Appendix.

The duplicate detection procedure identifies 1,293 and 424

<sup>3</sup>This is only based on the email text, and we use it as a term to group together emails that are likely to have a common denominator (e.g. a phishing tool, a specific market/phishing pool, or actual attacker).

Table 3: Topic model performance results

We perform LLDA using Gibbs sampling iterations for parameter estimation and inference initialised with hyper parameters  $\alpha = 1.0$ ,  $\beta = 0.001$ ,  $k_{labels} = 6$  and  $N_{iterations} = 1000$ .

	Macro (sd)	Micro (sd)
Sensitivity	0.709 ( $\pm 0.016$ )	0.807 ( $\pm 0.016$ )
Specificity	0.714 ( $\pm 0.042$ )	0.813 ( $\pm 0.038$ )
Precision	0.718 ( $\pm 0.025$ )	0.755 ( $\pm 0.024$ )
F1	0.725 ( $\pm 0.020$ )	0.760 ( $\pm 0.020$ )

unique emails in the data collection of Feb-Jul 2018 and Oct-Dec 2018 respectively (ref. Table 2). Of these 952 and 329 respectively are classified as ‘suspicious’.<sup>4</sup>

### 3.2 Cognitive evaluation

To identify the presence of cognitive vulnerabilities in email bodies and the *intensity* of the employed cognitive attacks, we construct a supervised topic model based on Labeled LDA [39] (LLDA). LLDA models each input document as a mixture of topics inferred from labeled input data and outputs probabilistic estimates of label-document distributions, i.e.  $P(label_l | document_m)$ , and word counts of label-specific triggers for each input document. In our application the labels correspond to Cialdini’s principles of influence, detailed in Table 1, whereas documents correspond to the emails.

For model training, we randomly sampled 99 emails (38 with clicks and 61 suspicious) out of the set of unique and suspicious emails in the dataset ( $n = 1,281$ ),<sup>5</sup> and manually

<sup>4</sup>Note that otherwise identical emails may lead to different phishing domains.

<sup>5</sup>To have an indication of the effect of sample size on model performance, we first ran the training on 70 emails and added 29 (+40%) at a second time, obtaining virtually identical results. To rule out sampling issues, we also performed a cross-validation procedure (reported) which suggested stable

labelled them for presence of cognitive vulnerabilities. Due to language restrictions, we adopted a mixed approach whereby one author performed the labelling on the original data, and the second author blindly re-performed the labelling on an automatically-translated random sample (20 emails) of the labelled data. To assess model performance we performed a 5 times repeated 5-fold cross validation over the data. Numerous approaches exist to evaluate the performance of multilabel classification problems like ours. Following [43], we consider our problem as a label-pivoted binary classification problem, where the aim is to generate for each label strict yes/no predictions based on the document ranking for that label. For each label, we sort on the per document prediction values, and use the PROPORTIONAL method [14, 43] to define a rank-cutoff value that determines the top  $N$  ranked items that will receive a positive prediction. For each label, we set  $TOPN_i$  equal to the expected number of positive predictions based on training-data frequencies: For label  $l_i$ ,  $TOPN_i = \text{ceil} \left( \frac{N_{test}^d}{N_{train}^d} * N_i^{train} \right)$  where  $N_{train}^d$  and  $N_{test}^d$  refer to the total number of training and testing documents and  $N_i^{train}$  is the number of training documents assigned label  $l_i$ .

We have aggregated the performance results of our topic model using the PROPORTIONAL rank-cutoff method in Table 3. Unlike other rank-cutoff methods, this approach relies solely on labeling information from the training set, which makes it appropriate for use in real-world production settings as well. We report both macro scores (averages computed over each result of the cross-validation procedure), and micro scores (computed over the aggregate of all cross-validation results). The obtained scores indicate a satisfactory fit over both projections. A manual analysis on randomly sampled emails confirms that the procedure appropriately assigns ‘topics’ to emails. The final model is trained on the complete set of 99 labeled training documents that were previously used in cross-validation, and then applied to the unseen and unlabeled remainder of the full dataset. Standard text cleaning procedures have been applied for removal of special characters and stop-words, sentence tokenization, and word stemming.

In this paper we refer to the ‘topics’ assigned by LLDA to an email as the **cognitive vulnerabilities** exploited in that text, and to the words associated with that topic and present in the text as the **vulnerability triggers** for that cognitive vulnerability. With this we aim at distinguishing the *presence* of a cognitive attack from its *intensity* in the email text.

**Example of training results** We report below an example of a phishing email (translated to English) and its association with different cognitive vulnerabilities. We have indicated the relevant vulnerability triggers in *italics* and refer to (1) Liking, (2) Consistency, (3) Authority, (4) Social Proof, (5) Reciprocity and (6) Scarcity:

results. Finally, manual checks on a random sample from the dataset of predicted labels found no obvious miscategorization.

Table 4: Example of extracted keywords for each topic

Reciprocity		Consistency		Social Proof	
Word	p	Word	p	Word	p
free	0.024	update	0.026	all	0.035
participate	0.016	improve	0.024	customer	0.011
program	0.011	recycle	0.018	current	0.005
request	0.010	renew	0.015	require	0.004
Authority		Liking		Scarcity	
Word	p	Word	p	Word	p
safety	0.017	valued	0.022	after	0.031
regulate	0.013	friendly	0.012	charge	0.027
european	0.010	strive	0.008	direct	0.020
must	0.007	environment	0.005	debit	0.019

(1) *As a valued customer of Org we always want to inform you of the latest updates and innovations in our system.*

We have recently switched to a new system that requires (4) *all current customers* to replace their (2) *current debit cards* by our newly-produced ones.

In connection with the new changes to the (3) *European Safety Regulations*, Org wishes to alert all its customers to the availability of the new and improved debit cards that adhere to all (3) *environmental and safety regulations*.

(1) *Org strives to be environmentally friendly.* Therefore, our service team will recycle all current debit cards by mounting your (2) *current AES Encryption Chip* on your renewed biological RFID payment card. For this reason, all current payment cards must be replaced. (5) *By participating in our recycling program, the new debit card can be requested free of charge.* (6) *After October 19th, 2018, a direct debit will be charged.*

From the example we can observe that the different cognitive vulnerabilities often appear alongside each other, and that a single vulnerability can even occur multiple times within an email body. Table 4 reports an excerpt of the classification results for the above message, and the learned keywords (translated in English) for each topic.<sup>6</sup>

## 4 Exploratory analysis

In this section we provide an exploratory analysis of the obtained email data set reported in Table 2.

We first give a look at the time of suspicious email arrivals in victims’ inboxes. Figure 4 reports the CDF distribution of email arrivals to Org’s phishing inbox. We observe a steady arrival rate through April and the first cutoff date in July 2018, suggesting that email arrival is approximately constant and uniformly distributed in time. As per the time of day of their arrival (not depicted here for brevity) we observe that few suspicious emails arrive in the users’ inboxes during the

<sup>6</sup>As the original text is not in English, to provide an accurate translation we report keyword matches for an example.

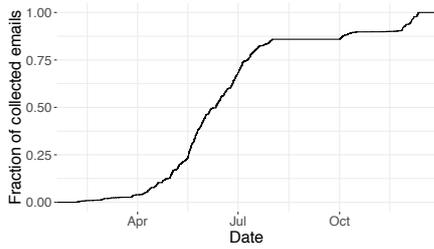

Figure 4: Arrival of notified emails to Org’s inbox

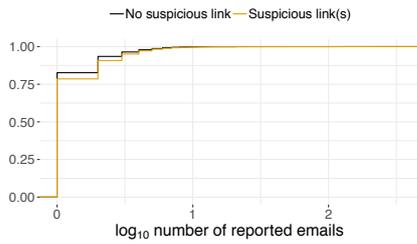

Figure 5: CDF of emails reported by victim addresses

weekend, with most phishing activity happening during the working days. This may suggest a strategic aspect of these campaigns aimed at increasing the credibility of the email source. On this same line, we find that most emails arrive between 9am and 5pm (business hours), and most arriving between 9am and 11am. Interestingly, these findings are all in line with optimal email send days and times for newsletters as reported by analyses from multiple popular online email marketing services [4, 26, 38, 45], and is an indication that attackers may follow similar strategies.

#### 4.1 Spoofing and victimization

Figure 5 depicts the distribution of suspicious and non suspicious reported emails. The CDF is on a log scale to better represent the distribution’s log tail. The vast majority of users report only one email, with almost all reporting less than 10 emails. This suggests that the distribution of phishing emails is uniform across victims, as is generally the case with untargeted phishing attacks [23, 36]. Only 122 addresses out of about 40 thousand report more than 10 emails, and only nine report more than 100 emails.

Figure 6 reports the distribution of spoofed and non-spoofed From: domains for reported emails with and without a suspicious URL in the body. An email is classified as spoofed based on the Levenshtein distance of the (spoofed) From: domain the original attack was sent to, w.r.t. the actual name of the organization. This captures exact string matches as well as small variations that may remain undetected by the user [50]. We find attacks employing a range of domains resembling Org’s: from less similar (e.g. [org-safety.com](#),

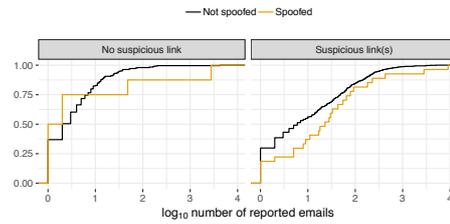

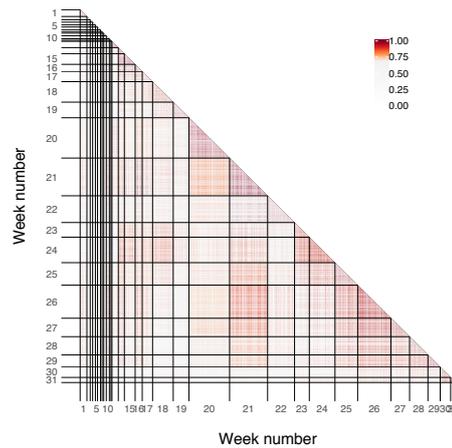

Figure 6: CDF of spoofed and non-spoofed From: domains

For visualization purposes we report random samples per week of 10% of the emails received in that week. Red represent high similarities above the threshold. We do not observe specific cycles of similar emails, suggesting that any sufficiently long period of time (3-4 weeks) would cover a diverse set of phishing attacks.

Figure 7: Pair-wise cosine similarity between email samples

[org-customersupport.com](#)), to more closely spoofed domain variations (e.g. [theorg.com](#), [Org.com](#)). We observe a clear differentiation, whereby emails with no suspicious URL are approximately as likely to have a spoofed From: address as a non-spoofed one. On the other hand, emails with suspicious URLs are more likely to be delivered from non-spoofed than from spoofed addresses, as can be observed from the areas under the two curves. This is compatible with a model of a relatively unsophisticated attacker. Here it is also relevant to consider that the pool of ‘spoofed’ addresses is much smaller than the pool of ‘non-spoofed’ addresses (as there are many fewer viable choices similar to Org than otherwise), suggesting that as spoofed domains get blacklisted, attackers may be forced to move to less well-spoofed From: addresses.

#### 4.2 Phishing campaigns

Figure 7 reports a visualization of the similarity scores between emails received during the observation period. Dark red indicates high similarity.<sup>7</sup> We do not observe specific and sys-

<sup>7</sup>For details on the identification of similar emails see the Appendix.

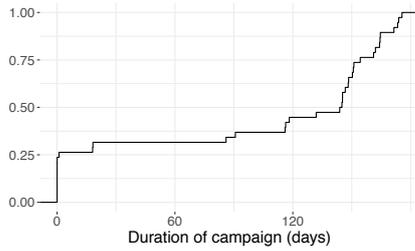

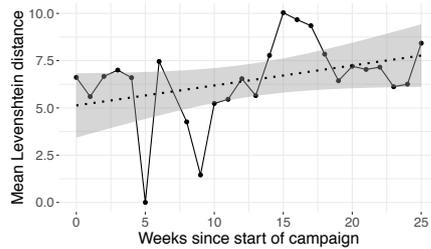

Figure 8: Duration of a phishing campaign

As phishing campaigns progress, the spoofed `From:` domains appear to be more dissimilar w.r.t. the original domain.

Figure 9: Average weekly decrease in similarity between spoofed domains and name of target organization

tematic cycles of campaigns emerging with repeating patterns across several weeks. This also suggests that any sufficiently long observation period (in the order of 3-4 weeks) may suffice to collect a diverse set of attacks for analysis. A first look suggests that some attacks seem to re-appear after a few weeks in slightly different forms, perhaps to increase chances of passing updated spam filters (see for example emails from week 21 reappearing slightly modified in week 26, or those from week 18 reappearing in week 24). To evaluate this, Figure 8 reports the distribution of suspicious emails that likely belong to the same campaign. Most campaigns are relatively long, with approximately 50% of similar emails arriving more than 120 days apart, and 25% of emails arriving more than 150 days apart with a relatively long left tail. From the distribution it appears that *single-day* campaigns are relatively common, whereas long campaigns extend for more than 100 days. Mid-range campaigns lasting between 2 and 100 days are by comparison only few, suggesting that attacks may either be extremely quick and disappear the next day, or last for long periods. Table 5 reports summary statistics of suspected phishing campaigns. We identify 38 distinct campaigns lasting on average 150 days (approx 5 months) and up to 175 days in the observation period.

To investigate how address spoofing evolves during campaigns, Figure 9 reports the weekly average similarity between the domain of the attacker `From:` address and the domain of the victim organization (measured as their Levenshtein distance) for LONG campaigns. Lower scores indicate

more closely spoofed domains. We observe an average increase in dissimilarity between spoofed `From:` addresses and organization domain, which suggests an overall deterioration of a phishing campaign as it progresses or is replicated by phishers ( $cor = 0.31, p = 0.08$ ). This is in line with the intuition that spoofed domains are limited in number, and attackers may therefore run out of options as domains get blacklisted as the campaign progresses.

### 4.3 Cognitive effects

Figure 10 reports the distribution of triggered cognitive vulnerabilities in each unique email (left) and the corresponding vulnerability triggers identified in the corpus (right). We observe a clear relation between the two plots: the most common vulnerabilities and triggers in emails appear to be linked to the Consistency and Scarcity vulnerabilities, regardless of whether a ‘click’ has been recorded for that link or not. Liking and Social proof triggers appear to be particularly rare on the average, with most emails targeting none.<sup>8</sup> This is consistent with the intuition that in one-shot interactions (as opposed to prolonged or repeated exchanges as in spear-phishing attacks [23]) cognitive attacks linked to the target’s social context and personal preferences (ref. Table 1) are rare. By contrast, exploiting Consistency may only require reference to previous actions that the group of potential victims will have likely performed, such as buying an insurance or receiving a debit card from the organization. Authority appears to be a relatively common trigger in our sample, albeit not for all emails. Common triggers here refer to European and national-level legislation and often come together with the threat of a punishment if certain actions are not completed. Overall, we find that few cognitive triggers are present in the median email, suggesting that the median reported attack may not be highly effective, whereas few emails embed more ‘intense’ cognitive attacks.

#### Effect of cognitive vulnerabilities on phishing success.

To evaluate the effect of the cognitive features of the email(s) embedding the ‘clicked’ URL links, we first report in Figure 11 the distribution of average clicks generated by emails for which at least one click has been recorded ( $n = 40$ ). Most emails generate fewer than 150 clicks, with two emails generating more than 200 clicks ( $min = 1, median = 37, max = 220, sd = 51.9$ ). Figure 12 displays the relation between triggered cognitive vulnerabilities and generated clicks, for which we observe a clear positive relation.<sup>9</sup> Following common prac-

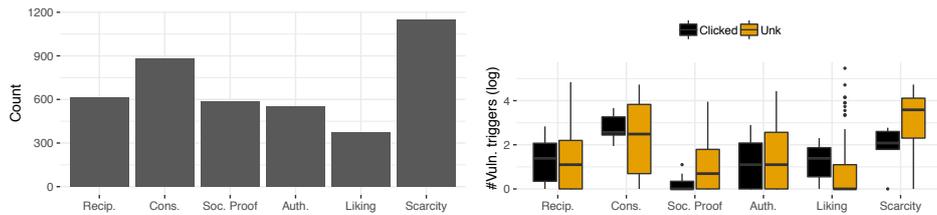

<sup>8</sup>The descriptive statistics reported in Table 2 also suggest stable distributions between the collection periods; for Liking we observe more extreme values (upper 97.5% = 7,  $max = 504$  in the Feb-Jul data collection); this is caused by the outliers in the email corpora for which we measure disproportionate email lengths.

<sup>9</sup>A possibility is that some emails may be distributed to substantially more users than other emails, generating greater aggregate click counts. As we have no access to the victim’s inboxes, we cannot directly measure this.

Table 5: Descriptive statistics of duration and intensity of phishing campaigns

SINGLE-DAY campaigns last up to one day; SHORT campaigns up to 100 days; LONG campaigns more than 100 days. Most phishing campaigns are either very short (one day) or long, with only a handful lasting more than one day but less than 100.

Type	n	Phishing samples (#reported emails)							Campaign duration (days)						
		Min	1stQ	Mean	Med	3rdQ	Max	sd	Min	1stQ	Mean	Med	3rdQ	Max	sd
SING.	10	1	1.0	1.3	1.0	1.0	3	0.7	0.0	0.0	0.1	0.0	0.0	1.0	0.3
SHORT	4	2	2.0	36.0	3.0	37.0	136	66.7	18.1	18.2	53.3	52.1	87.2	90.8	40.6
LONG	24	46	86.2	783.4	226.5	929.5	4827	1207.5	116.1	145.2	150.9	150.6	164.2	175.6	17.3

Most phishing attempts trigger Scarcity, Consistency, and Reciprocity vulnerabilities. Social Proof, Authority, and Liking are the least common. Relative frequency of cognitive vulnerabilities is reflected in the distribution of vulnerability triggers identified in the emails. We do not identify specific biases in presence of vulnerability triggers between emails for which a ‘click’ has been registered, and emails for which it has not (i.e. that received an unknown number of clicks).

Figure 10: Distribution of triggered cognitive vulns. (left), and of vuln. triggers (right) for emails

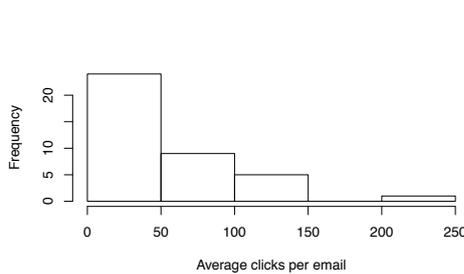

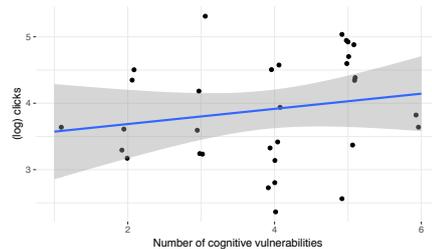

Figure 11: Histogram distribution of clicks per email

tice [21], to avoid dispersion we here only consider URLs clicked at least ten times, removing six emails. A simple Poisson regression of the form  $\log(\text{clicks}_i) = \alpha + \beta(\text{cogvulns}_i)$  reveals a strong positive correlation between the variables ( $\beta = 0.12, p < 0.001$ ). This suggests that the more cognitive vulnerabilities are exploited in an email body, the more that email can be expected to generate compliant user behaviour, even when not considering the type of cognitive attack, or its intensity.

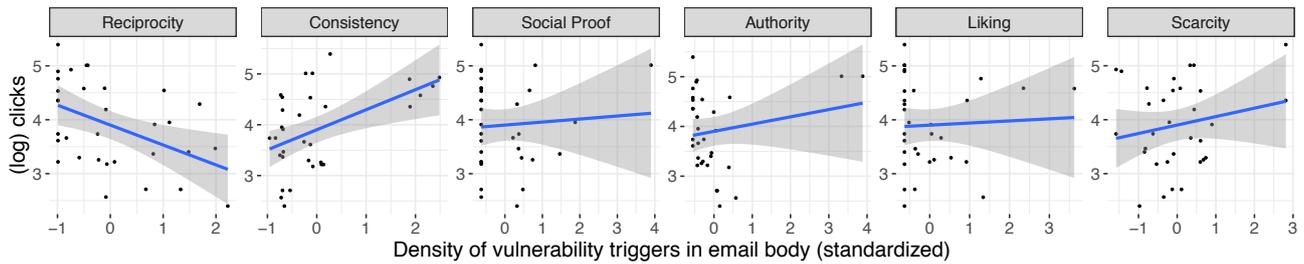

However, the data does not show specific biases in the likelihood of users reporting emails (Figure 5), suggesting that major skews are not realistic. This is consistent with previous findings in the literature [36, 58]. Further, due to the very low click-through rates of spam and phishing campaigns [19], this difference should be of several orders of magnitude to have a visible effect (as opposed to be undetectable noise in the data generation process). Regardless, in the Appendix we build a data generation model to evaluate the effect this bias would have in the data if present; our analysis finds no evidence.

We observe a clear relation between the presence of exploited cognitive vulnerabilities and the clicks generated by the embedded URL(s). The shifted position of points in the pictures is to clear overlaps and is only presentational.

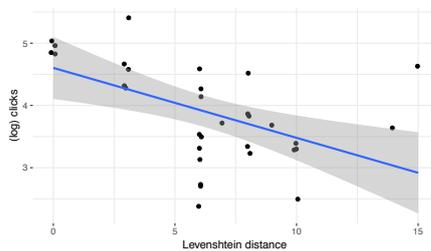

Figure 12: Relation between number of cognitive vulnerabilities in an email and average clicks ( $\log_{10}$ )

**Effect of vulnerability triggers.** We now consider the relation of the intensity of each cognitive attack (i.e. measured by the presence of vulnerability triggers) with the measured ‘success’ of the phishing email. Figure 13 reports the results. The data reports a clear positive relation between Consistency, and Scarcity vulnerability triggers with the expected (log) number of clicks. Reciprocity shows a negative relationship. Additionally Social proof, Liking and Authority show no evident effect, whereby the majority of emails have relatively small counts of associated vulnerability triggers (see also Figure 10). On the other hand, looking at the right extreme of the scale, the few available data points are always related to highly-clicked emails; this may indicate that triggering these vulnerabilities (in this application domain) may be particularly difficult, for example as decisions related to

The data shows the effect of different cognitive vulnerability triggers on expected number of clicks. Consistency and Scarcity have a clear positive association with the expected number of clicks they generate. Social proof, Authority and Liking do not show any evident trend. Interestingly, we find that Reciprocity appears to be counterproductive.

Figure 13: Correlation between vulnerability triggers and observed clicks

We identify a negative relation between the dissimilarity of the spoofed From: domain in an email against the original one, and the expected number of clicks the email entices.

Figure 14: Relation between spoofing dissimilarity and average clicks ( $\log_{10}$ )

personal finance may have a smaller attached ‘social’ component, or as adding additional ‘authoritative’ effects in the banking domain may be challenging for an attacker.

**Effect of spoofing distance.** Apart from the cognitive vulnerabilities exploited in the text, a second relevant factor could be the similarity between the From: address displayed to a user and Org’s legitimate one. Figure 14 reports the relation between Levenshtein distance of the spoofed From: domain and the expected number of clicks. We find an inverse relation between the two variables, suggesting that the greater the dissimilarity between the spoofed and the original domain, the lower the average number of generated clicks ( $\beta = -0.13, p < 0.001$ ). This suggests that both cognitive attacks and the degree of spoofing in an email may have an effect on the relative success of a phishing email and could be considered to build a triaging model for phishing emails.

## 5 Modelling phishing success

We now evaluate the relative impact of each cognitive variable in the collected dataset. We estimate coefficients for a Poisson process of the (aggregate) form:

$$\log(\text{clicks}_i) = \alpha + \beta_1 \text{cogvulns}_i + \beta_2 \text{spoofdist}_i + \epsilon_i \quad (1)$$

whereby, for each email  $i$ ,  $\text{clicks}$  represents the number of measured clicks,  $\text{cogvulns}$  is the array of counts of the vulnerability triggers identified in the email body, and  $\text{spoofdist}$  indicates the degree of (dis-)similarity between the spoofed From: address and the original Org domain.  $\epsilon_i$  is the error term. To monitor and account for overfitting problems related to the few available datapoints, we combine a step analysis of each model (M1..M7) with regression bootstrapping to generate robust confidence intervals for the coefficient estimations. For model selection we report coefficients, 95% confidence intervals, residual deviance, and Adjusted McFadden Pseudo- $R^2$ , to reduce the statistical bias in the performance metrics for model selection.<sup>10</sup> Results are reported in Table 6.

All models have relatively stable coefficient estimations showing no evident interaction effects between the regressors (correlation matrix presented in Table 9 in the Appendix). Coefficients should be interpreted relative to each other as opposed to in absolute terms. Because of the relatively small sample size, we refrain from drawing direct conclusions on the model coefficients. For this reason statistical significance is better served in the analysis reported in Figure 13 and is only detailed in Table 6 for the reader’s reference. Within our sample, model coefficients can be interpreted as the relative change in number of clicks for every additional vulnerability trigger of that type in an email. For example, the M7 coefficient for Scarcity (0.02) indicates an increase of 2% in the number of expected clicks for every new trigger of that category. Likewise, an increase in one point on the Levenshtein distance scale is related to a decrease in clicks of 10%. A first informal look at the McFadden’s Pseudo- $R^2$ s, Reciprocity, Consistency, and Spoof dist. appear to have the strongest effect in increasing the explanatory power

<sup>10</sup>Importantly, with this procedure we do not aim at identifying a definitive model and coefficients to forecast phishing success: regardless of the amount of observations in the dataset, that would not be possible because the ‘click generation process’ generating the observations necessarily varies from domain to domain (e.g. finance vs health), from organization to organization (e.g. national vs international), and from customer base to customer base (e.g. sensibility of application domain). Therefore, coefficient estimations out of this type of models cannot be ‘plug-and-play’ across organizations and domains and will require tuning before being applied in-house.

Table 6: Regression results for Eq. 1

All model coefficients estimations are relatively stable across the seven models. Coefficients for the Poisson models are presented with 95% confidence intervals in parentheses. Social proof and Spooof distance of From: addresses appear to have the largest effects on predicted number of clicks. Higher spooof distances (i.e. higher dissimilarity between From: domain and original domain) result in a lower number of expected clicks. We only report coefficient significance (indicated by a \* for significance at the 0.1% level) for the reader’s reference; however due to the relatively small sample size coefficient estimations should only be interpreted relative to each other as opposed to in absolute terms. Model power w.r.t. the baseline model is reported by the adjusted McFadden Pseudo- $R^2$ ; a  $\chi^2$  test is employed for model comparison (\* :  $p \leq 0.001$ ; † :  $0.001 < p \leq 0.01$ ). Standard model checks do not reveal issues or biases in the model fit.

	M1	M2	M3	M4	M5	M6	M7

of the model. Scarcity appears to contribute modestly, whereas Liking appears to have the smallest effect on the model. The negative effect of Reciprocity as shown in Figure 13 is confirmed in the model as well.

### 5.1 Cognitive triaging of phishing success

We now extend the model evaluation to estimate the amount of clicks generated by other emails for which Org has detected no click (e.g. because no call-back to Org resources has originated from the phishing website, remaining therefore invisible to Org’s detection infrastructure, ref. Fig 1). Recall however that our model estimates are likely subject to overfitting issues due to the inevitably small sample size. This only means that predicted outcomes could be unreliable over arbitrarily diverse email corpora (i.e. not represented in the training data); on the other hand, predictions over similar emails to those provided to the fitted models will not suffer from unmodelled biases and will generate reliable estimations. For this reason we only limit our analysis to emails with a distribution of vulnerability triggers within plus or minus one standard deviation from the mean for that trigger in the model’s respective training set.

To choose the model for the prediction we perform a set of ANOVA tests ( $\chi^2$ ), which indicate all factors add significant information to the model, albeit Liking only marginally. However, due to the statistical limitations of estimations in our

Table 7: Bootstrapped regression coefficients

dataset, we also consider a second model that considers only isolated factors for which we observe a clear effect as reported in Figure 13. Based on these observations we consider two different prediction models (PM), each with different regressors, namely: PM1: Reciprocity, Consistency, Scarcity and Spoofing distance; PM2 all six cognitive vulnerabilities + Spoofing distance (i.e. equal to M7 as suggested by the ANOVA tests). This leaves us with  $n = 334$  and  $n = 189$  suspicious emails on which to run the predictions for PM1 and PM2 respectively. To build robust confidence intervals around the estimations, we run a bootstrap simulation ( $n = 5,000$ ). Table 7 reports median coefficients and 95% confidence intervals of the estimations. Notice that the estimated coefficients remain largely similar to those of the original models for most coefficients. PM1 shows much tighter confidence intervals

Table 8: Descriptive statistics of average predicted clicks  
 Estimations are generated from 50,000 simulations run on the bootstrapped model coefficients (Table 7).

26	43	50	53	60	129

for the estimated coefficients in comparison with PM2, suggesting more reliable predictions. Notice that the distribution of the coefficient estimations in PM1 tends to remain on the same side of zero, again suggesting statistically robust results for this model. This suggests the exclusion of *Liking*, *Authority* and *Social proof* in PM1 may lead to more realistic estimations.

We simulate model predictions for the undetected clicks by randomly sampling ( $n = 50,000$ ) model coefficients from the two distributions and report aggregate statistics (Table 8) of the estimated number of generated clicks. Figure 15 reports the results. The simulation results indicate that the average ‘undetected’ email has potentially generated 50 - 55 clicks, with a long tail of (few) emails generating up to 100 clicks.<sup>11</sup> This suggests that prioritization efforts based on the cognitive characteristics of a phishing email could help in more efficiently addressing attacks (e.g. by means of takedown actions), by targeting first attacker resources that are likely to generate more impact on the organization’s customer base: by targeting first the emails that are most likely to engage users in compliant behaviour, organizations can effectively triage the stream of incoming phishing attacks to minimize the impact on their customer base.

## 6 Discussion

The previous sections have demonstrated how quantitative measurements of cognitive vulnerabilities employed in phishing attacks can be used to develop a model to make predictions about the expected efficacy of these attacks. This characterization allows one to assess the threat of these attacks in an automated way such that instant prioritization of phishing incident responses becomes possible. This paper’s contributions go beyond the scope of earlier works on cognitive factors for phishing by providing an empirical estimation and operable implementation to estimate phishing success.

<sup>11</sup>Notice that additional organization-specific features of the email (e.g. presence of the company logo), may also have an effect on the number of clicks. Whereas this is out of the scope of this paper, which only looks at the cognitive effects, a fully-operative model within an organization can easily integrate other factors in the prediction.

In this work we identified several correlations between different cognitive vulnerabilities and the average number of clicks an email can be expected to generate. In line with the hypothesis that the presence of any individual cognitive vulnerability increases user response to the phish, we found that *Consistency* and *Scarcity* exercise a clear positive effect on the number of generated clicks. We find no evident effect from *Social proof* and *Liking*, whereas *Authority* appears to have a positive effect albeit driven by only a few non-zero data points. Interestingly, *Reciprocity* even shows a counterproductive effect, albeit only marginal. This difference may well be explained by the specific application domain, as corporate customers subject to financial threats from phishing can generally be expected to have different sensitivity to specific principles of influence than other groups [22]. Although this suggests that full generalizability can not be expected for any one set of results, conclusions similar to ours could be drawn for specific contexts close in nature to the one in which *Org* operates. In particular, our finding of the reduced effect of *Authority* in the banking domain is in contrast with results from Wash and Cooper [53], who found *Authority* to be the most effective strategy for the presentation of certain phishing education materials. This difference may illustrate the context-dependency of the relative efficacy of these influence tactics, and indicates a need for careful consideration of such differences across domains. For example, the effect of *Authority* can be mediated here by the already relatively high authoritative position a bank has on its customers; this suggests that, on one side, depending on the domain it may be more difficult for an attacker to devise effective attacks *adding* to baseline cognitive effects; on the other, this also suggest that a relevant metric to evaluate could be the *relative increase* (or decrease) in the cognitive effect w.r.t. the baseline. A similar consideration could be drawn for *Reciprocity*, whereby we observe a negative effect on the generated ‘clicks’. An explanation could be that these type of triggers rise a red flag in the context of banking operations, for example as a bank’s ‘environmental friendliness’ may not be a convincing-enough reason to act on a request (e.g. to renew one’s debit card).

These observations also provide useful input to training campaigns regularly run by medium and large organizations in an attempt to increase their customers and employee’s awareness of the social engineering threat. Replications of this study in specific domains could reveal which principles of influence the ‘average’ customer of an organization is more vulnerable to; awareness campaigns run by the organization could then target those specific traits by providing specific examples or information material built ad-hoc for the consumer base (or targeting sections of it). For example, consumers particularly vulnerable to *Scarcity* may benefit from knowing the organization’s policies in terms of change deadlines and processes, such that an email stating unrealistic and short cutoff dates to react lose credibility.

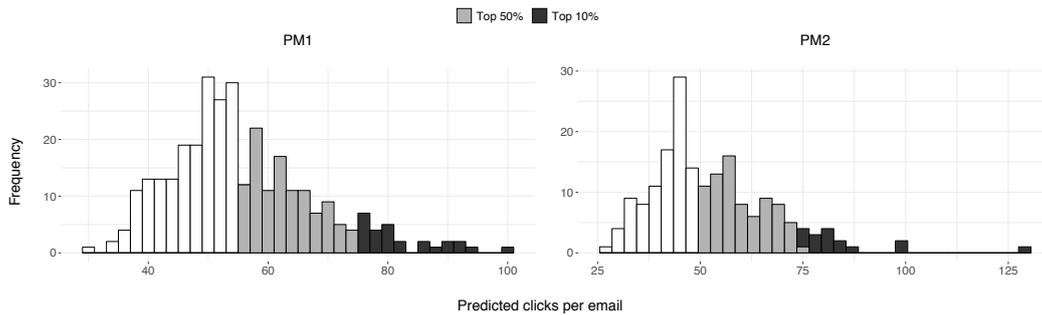

Figure 15: Distribution of predicted average clicks

Operationally, the presented procedure could be applied both client and server side to automate the risk evaluation of potential phishing emails for the enforcement of security policies; for example, mail client plugins or server-side processes could automatically divert or forward high-risk emails to phishing investigation and response teams for further evaluation, while delaying the delivery of messages waiting for a diagnosis. Furthermore, we have described how these observed effects can be used in the construction of a prediction model for the triaging of incoming phishing attacks. By enabling the triaging of incoming phishing attacks, our results will enable incident response teams to focus on the most prominent threats immediately, without having to manually filter out the noise from the bulk of low priority emails in their phishing abuse inbox, thereby minimizing reaction costs and increasing response effectiveness. The practicality of this is evidenced in Figure 15, where by addressing the small fraction of emails associated with the highest expected click counts one can mitigate a large fraction of potential attacks. This is critical to minimize overall victimization rates, as the short-lived nature of phishing domains stresses a need for prompt identification of which domains are most likely to be reached by customers falling for the phish. By contrast, addressing attacks in no particular order would most likely result in wasting valuable time and resources by addressing first the vast majority of attacks that are likely to generate few clicks only (ref. Figure 15 and Table 8).

Finally, our method opens up new opportunities in terms of automated incident handling and security orchestration, e.g. by enabling incident handlers to apply automated follow up procedures to incoming phishing attacks that fall within a certain threat range; for example, reported measures on the vulnerability triggers could be used to implement dynamic risk-based access control policies to limit immediate follow-up actions. Similarly, CSIRTs (*Computer Security Incident Response Team*) could implement automated network-level containment procedures based on the profile of incoming emails, and avoid additional (and unnecessary) victimization by delaying follow-up actions by the users until the risk is cleared.

## 7 Conclusions

In this work we presented an empirical method and evaluation of the effect of cognitive vulnerability triggers in phishing emails on the expected ‘success’ of an attack. We employed a unique dataset from a large European financial organization with data from their phishing response division. Our results indicate that response teams’ operations, such as takedown actions against rogue phishing domains, could largely benefit from a (fully automated) cognitive assessment of the email body to predict relative success of the attack, given the relevant user base. Our findings and method could also be employed to deploy more effective training and awareness campaigns in response to the more prominent threats suffered by the potential victims. Future work could explore automated response strategies to contain potential attacks and/or delay user response where needed.

## Bootstrap analysis for similar email detection

The optimal threshold was found at 0.91 based on the intersection of the mean sensitivity and specificity metrics at all decimal thresholds in  $[0,1]$  across 10,000 bootstrap simulations with sample size 300.

Figure 16: Simulated optimal cosine similarity threshold for duplicate detection

After computation of the full pairwise similarity matrix for all suspect emails in our dataset, a threshold value was used to determine the lower-bound for the similarity score of emails we consider to be duplicates. In order to determine the most optimal threshold value for our specific dataset we performed a *bootstrap analysis* [11]. A bootstrap analysis generally involves repeatedly running simulations on samples drawn with replacement from an original sample set in order to estimate statistics on a larger population. This is a fitting solution for problems concerning dataset of large sizes like ours, which do not generally allow for efficient derivation of the full set of results that qualify as “ground-truth”.

We started our bootstrap analysis with a random sample of 300 suspect phishing emails for which we made a manual assessment of all pairwise similarities to test the performance of our cosine similarity algorithm across different thresholds. Then, we repeatedly ( $n = 10,000$ ) drew samples with replacement of size 300 from our manually classified sample and computed the pairwise cosine similarity matrix for all decimal thresholds in the interval  $[0,1]$ . For each combination of bootstrap sample and threshold value we computed the performance using the sensitivity (true positive rate) and specificity

metrics (true negative rate). A high sensitivity score refers to a high probability of duplicate detection, measured by the proportion of actual duplicates that are correctly identified as being similar, whereas a high specificity score refers to a high probability of non-duplicate rejection, measured by the proportion of actual non-duplicates that are correctly identified as not being similar. The intersections of the mean results for these two performance measures indicate that 0.91 is the optimal threshold value for our dataset, as is visualized more elaborately in Figure 16.

We use this threshold to calculate the pairwise similarity matrix for all emails in our dataset and assign emails that are found to be similar the same *duplicate ID* to allow us to filter for unique emails.

## Distribution of phishing emails by user

We perform a robustness check to evaluate the robustness of our results against large biases in the distribution of phishing emails across potential victims (whereby higher reported clicks may relate to higher email delivery volumes). We base the following on the sole assumption that attackers “sample” victims from the same pool (i.e. *Org* customers). As we of course cannot measure email delivery rates in user inboxes, our aim is to ask how would the dataset look like if large sample biases were present, and look for evidence in the data.

We developed the following data generation model to formalize and test this: a phishing email  $e \in E$  can reach a user  $u \in U$  with probability  $P_e(u)$ . A suspicious email will be detected by a user with a certain probability  $P_{u,e}^{det} = P_u(DET|e)$ . Notice that this depends on the email and the specific user that receives it, as different users may have different sensibilities to emails with different characteristics. The probability of remaining undetected is simply the complement, and is defined as  $P_{u,e}^{und} = 1 - P_u(DET|e)$ .

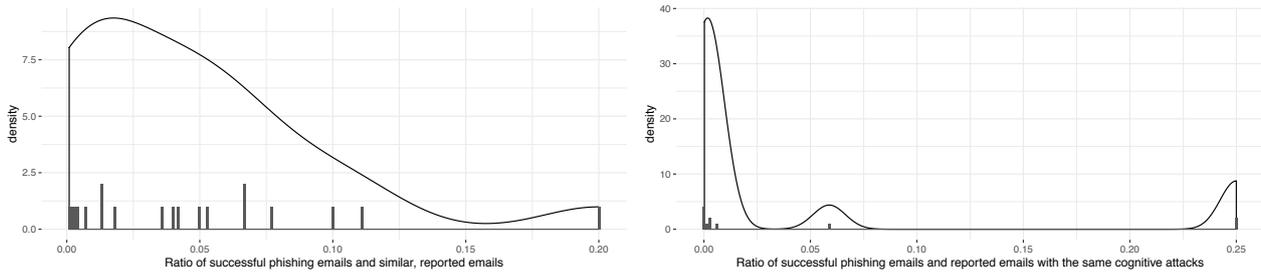

Further, each user has a certain probability  $P_u(notify|DET,e)$  and  $P_u(click|\neg DET,e)$  of, respectively, notifying a detected email, and clicking on a link if the email is not detected. Hence, the probability of an email being reported by a user is  $P_e(u) \cdot P_u(DET|e) \cdot P_u(notify|DET,e)$ . Conversely,  $P_e(u) \cdot (1 - P_u(DET|e)) \cdot P_u(click|\neg DET,e)$  is the probability of a click for each  $e \in E$  and  $u \in U$ .

Let  $C$  be the set of clicked emails, and  $D$  the set of reported emails, we’d then have:

$$|C| = |E| \sum_{\forall e \in E} \sum_{\forall u \in U} P_e(u) \cdot P_{u,e}^{und} \cdot P_u(click|\neg DET,e) \quad (2)$$

$$|D| = |E| \sum_{\forall e \in E} \sum_{\forall u \in U} P_e(u) \cdot P_{u,e}^{det} \cdot P_u(notify|DET,e) \quad (3)$$

$|D|$  corresponds to the whole set of suspicious emails reported in the organization’s phishing inbox.  $|C|$  corresponds to the set of emails clicked (of which we observe  $C' = D \cap C$ ).

The distribution is calculated over similar emails (as per their cosine similarity, left), and over emails that share the same cognitive attacks (right). We observe a stable ratio across all emails, suggesting no significant skew in the probability of an email reaching a user's inbox.

Figure 17: Estimation of rates of arrival of phishing emails to users

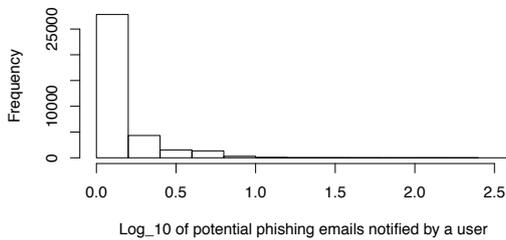

Figure 18: Number of users reporting  $|D_u|$  emails ( $\log_{10}$ )

Notice that  $P_e(u)$  (i.e. the probability of an email arriving to a user's inbox) is the only variable that is outside of the direct influence of the user. On the contrary,  $P_{u,e}^{det}$ ,  $P_{u,e}^{und}$ ,  $P_u(notify|DET, e)$  and  $P_u(click|\neg DET, e)$  directly depend on the characteristics of the user and of the email. Hence, we would expect them to be approximately constant as long as within the comparison the users are the same, and the emails are similar to each other. As we can control for 'similar' emails (Section 3.1.3) and users are all pooled from the set of Org's clients, we can isolate large effects on  $|C'|$  and  $|D|$  as being caused by large fluctuations in  $P_e(u)$ .

Specifically, we would expect  $|C'_{similar}|/|D_{similar}| \approx constant$  iff also  $P_e(u) \approx constant \forall e \in E_{similar}$  as all other terms in the two equations will remain approximately the

same for similar emails and the users sampled from the same pool. Hence, we measure the ratio of  $|C'_{similar}|/|D_{similar}|$  as a proxy to estimate how much  $P_e(u)$  can be expected to vary across emails. This holds under the sole assumption that emails in  $D \setminus C$  are indistinguishable (from the perspective of the user) from those in  $D \cap C = C'$ ; this is uncontroversial as the detection mechanism for the inclusion of an email in  $C'$  only depends on the phishing webpage and not on the email per se.

Figure 17 reports the ratio distribution calculated over emails with cosine similarity above the defined threshold (left), and over emails employing the same cognitive attacks (right). The ratios are small (i.e. only a small fraction of reported emails of a certain type can be expected to generate at least one click). This is qualitatively and quantitatively in line with previous findings in the literature [19]. Importantly, we observe that under both measures of similarity the rate is essentially constant and settles around 1-5% for all emails. This observation is incompatible with a significantly skewed distribution of emails per user. Breaking down the figure by users receiving the phishing email does not reveal any additional pattern as most users report only a few emails each (ref Figure 5 and Figure 18).

This is in line with previous literature on phishing attacks [9, 16] suggesting that no specific pre-selection of users characterizes untargeted phishing attacks. We therefore do not expect significant biases in the analysis to emerge by the otherwise unmeasurable distribution of emails in users' inboxes.

# Users Really Do Answer Telephone Scams

## Abstract

As telephone scams become increasingly prevalent, it is crucial to understand what causes recipients to fall victim to these scams. Armed with this knowledge, effective countermeasures can be developed to challenge the key foundations of successful telephone phishing attacks.

In this paper, we present the methodology, design, execution, results, and evaluation of an ethical telephone phishing scam. The study performed 10 telephone phishing experiments on 3,000 university participants without prior awareness over the course of a workweek. Overall, we were able to identify at least one key factor—spoofed Caller ID—that had a significant effect in tricking the victims into revealing their Social Security number.

## 1 Introduction

The rise of telephone spam, scams, fraud, phishing, or vishing, is a significant and growing problem. According to FTC reports for 2018, phone impersonation scams have increased significantly in the recent years. The national Do-Not-Call Registry received more than 5.78 million unwanted call complaints [1], with fraud and imposter scam in the top spots and more than 69% of all reported frauds were attempted over the phone [2].

With the growing dissatisfaction of telephone scams, however, little research has been done to study *why* people fall for telephone scams and how to combat the problem. In this paper, inspired by the work of Tischer et al. [3] on USB drives, we present the results of an empirical telephone phishing study, designed to systematically measure different attributes in relation to the success rate of telephone scams. Although the current understanding of telephone scams might be accepted as conventional wisdom, no prior work has specifically validated such claims with a systematic study. From this study, we hope to dispel some myths about what is “scammy” and what is not. With the understanding of the key attributes that make a scam convincing, the research community can focus

on developing prevention methods to challenge the fundamentals of telephone phishing attacks. The key takeaway from this study is that caller ID spoofing is an incredibly effective feature in telephone scams, and, therefore, authenticated caller ID [4, 5] is likely to be an important countermeasure.

The main contributions of this paper are the following:

- We describe a systematic approach to test the significance of various telephone phishing scam attributes and conduct an empirical study.
- We present our evaluation of the phishing study and provide our recommendations for combating the telephone phishing problem.

## 2 Background

With the emergence of distribution technology, decreasing economic cost, high reachability, and automation, the telephone has become an attractive medium for disseminating unsolicited information. As with any form of spam, there are three key ingredients: the recipient list, the content, and the distribution channel [6]. Telephone scams rely on distributing *deceitful* voice content, whereas telephone spam or telemarketing primarily distributes marketing and advertising content. In telephone scams, fraud, phishing, or vishing, the goal of the voice content is to trick the human victim into performing harmful actions for the benefit of the attacker (while other types of fraud are possible on telephone networks [7–9]).

Compared to other forms of phishing, such as email and website phishing [10–15], telephone phishing differs by having the potential to make the scam more convincing by falsifying both visual and auditory perceptions to induce the victims into falling for the scam. Visually, the scam can be made more convincing by altering the caller ID, such as by spoofing the caller ID, manipulating the area code (e.g., in “neighbor spoofing” attacks [16]), and impersonating a familiar contact name. Once the recipient has answered the call, the attacker then switches to using deceitful voice content to exploit the human recipient [17, 18]. Within the voice content, an attacker can spoof or duplicate the speech from a known organization

or a familiar personal contact. To provide a motivation for the recipient to divulge confidential or personal information, the scammer can present a demanding scenario that forces the victim to divulge sensitive information.

By looking at telephone phishing from a perspective that can be characterized by the visual and voice attributes which it embodies, a systematic approach can be used to study and understand why some scams work better than others. Understanding why telephone phishing works can help us design solutions that challenge the core foundations of telephone scams.

### 3 Study Design

The goal of the study is to design a systematic approach that can reveal the effective factors in telephone scams by conducting our own telephone phishing scam. Our approach to designing the study is to first identify the attributes that could lead to an effective telephone phishing scam. After that, we design a set of experiments and procedures that allow comparison of different variations of an attribute. Each experiment followed a standardized procedure that was conducted on each group simultaneously (all calls were distributed in a randomized order throughout the experiment). Finally, we provide a discussion on what could be learned from the analysis and provide our recommended solutions for combating the telephone phishing problem. The study was conducted with significant ethical consideration and with IRB approval (see Section 3.5 for an in-depth discussion of ethics).

#### 3.1 Attributes

To identify the telephone scam attributes, we gathered and reviewed more than 150 existing real-world telephone scam samples from various Internet sources, including the FTC website, IRS website, news websites, YouTube, SoundCloud, user comments, and industry surveys. While reviewing the scams, we identified the following attributes used in telephone scams:

**Area Code:** In North America, the area code is the first three digits on the caller ID. The area code specifies the geographic location associated with the caller's phone number, e.g., 202 is associated with Washington, DC. In addition, a toll-free phone number is also identified by the three-digit prefix similar to a geographic area code, e.g., 800, 888, 877, etc. According to reports of real-world IRS impersonation scams [19, 20], many scammers appeared to have either spoofed or obtained a 202 area code or toll-free area code on their caller IDs to make it appear as if the IRS is calling. To test the hypothesis that the area code could effect telephone phishing success, in our experiments we varied the caller ID area code between: 202 (Washington, DC), 800 (Toll-free), and 480 (local area code of the university location).

**Caller Name:** Today, most telephone terminals have the capability of associating a name with a telephone number. With a stored contact, an incoming call from the stored contact would show the name associated with the caller ID. To perform a spear phishing attack [21, 22], a malicious caller could spoof the caller ID of a known stored contact. A known stored contact can be identified for an organization by studying the publicly available phone numbers or for an individual by manually analyzing social network information. For legal, ethical, and IRB approval reasons, we did not actually spoof a known caller name. Instead, we asked our telephone service department to temporarily create a new contact in the university's internal phone directory and associated a legitimate sounding name with the telephone number. We used that telephone number in our scam experiments to produce a similar effect to caller name spoofing.

**Voice Production:** According to reports of real-world telephone scams, some used a robotic (synthesized) voice, while others used a pre-recorded human voice [20, 23]. To test the effect of synthesized voices vs. human voices, we recreated known scams using a text-to-speech synthesizer to generate a speech similar to the real-world scams. To mimic the human voice version of the scams, we recorded human voices speaking the exact same announcement message.

**Gender:** From listening to recordings of actual telephone scams, some used a male voice, and some used a female voice. To test if the vocal gender of the voice could have an effect on the telephone scam, we varied the voice gender between male and female in the text-to-speech synthesizer.

**Accent:** From the reports of telephone scams, some spoke with an Indian accent, and some others spoke with an American accent. It seems possible that recipients would be more wary of scams that speak in a foreign accent, and would be less suspicious of scams that speak in an American accent. To test if this could have an effect on the telephone scam, we varied the recorded voice accent between Indian and American in our experiments.

**Entity:** From gathering real-world telephone scams, two types of scams stood out in terms of the number of reports: IRS impersonation scams [24] and HR impersonation scams [25]. In these scams, the scammer claimed to be from the IRS or the company's HR department. While the IRS scams can affect any taxpayer in the US, the HR scams are usually targeted toward people in a specific company. Intuitively, it seems that a more targeted attack would have more success. Thus, we varied the impersonated entity of our scams between the IRS and ASU's HR department<sup>1</sup>. To simulate the real-world HR scams as closely as possible, we initially wanted to impersonate our university's HR department. However, our HR department had strong objections about using their name to conduct the scam experiments. As a compromise, our experiments claimed to be from a fake

<sup>1</sup>ASU is the university acronym for Arizona State University

but legitimate-sounding HR-like department called the “W-2 Administration”<sup>2</sup>.

**Scenario:** Real-world telephone scams create various scenarios to motivate their victims to fall for the scam, such as tax lawsuits, payroll issues, or credit card verification. The type of motivation are generally either *fear-based* or *reward-based*. In our study, we crafted a fear-based and a reward-based scenario related to each entity. These scenarios were inspired by real-world IRS scams and HR scams. To test each type of scenario, our message announcements varied between Tax Lawsuit (IRS fear-based), Unclaimed Tax Return (IRS reward-based), Payroll Withheld (HR fear-based), and Bonus Issued (HR reward-based).

### 3.2 Experiments

To test these attributes, we designed the experiments such that variations of each attribute can be compared under similar environmental conditions. When performing experiments under the same environmental conditions, one of the design issues is to decide whether to counterbalance the environmental conditions such that all variations of background attributes are tested. This would theoretically avoid possible interference due to a specific set of background conditions.

However, performing a counterbalanced measures design does not come without costs. Counterbalancing the conditions is performed by splitting the experiments into groups of every possible order of attribute conditions. Given the large number of attributes that we have identified, and of each attribute with 2–4 variations that we have identified, would require us to create 384 separate groups of experiments. This is unfeasible for an empirical study with real-world time and resource constraints.

As a solution to this problem, instead of experimenting with a large number of background conditions, we compare variations of each attribute under a specific set of background conditions that seem to be the most popular in the real world. We decided on a standard background condition: a phishing scam with area code 202, with no caller name, speaking in a synthesized, male voice, in an American accent, impersonating the IRS, motivating the recipient with a tax lawsuit. The set of 10 experiments and the variations of each attribute are listed in Table 1.

### 3.3 Population

To comply with legal requirements [26], our own ethical considerations, and our IRB (Section 3.5), we conducted experiments on our university’s internal population (rather than the general population). This population was unaware of our study (and we discuss the ethical implications of this deceptive non-consent study in Section 3.5). The population of the

<sup>2</sup>The W-2 is the income tax form currently used in the United States, so this name has associations with payroll and taxes.

study were work telephone numbers that are associated with university staff and faculty. We decided on a population of 3,000 recipients (300 per experiment) for the study. To compile the list of telephone numbers, we wrote a custom tool to download the university’s internal phone directory. For a real-world scammer, our university’s phone directory is also publicly available for crawling.

To minimize selection bias, the telephone numbers were randomly chosen from the university telephone directory, and then the chosen contacts were randomly put into one of the 10 experiment groups. The sample selection procedure was as follows: (1) Compile the list of work telephone numbers associated with university staff and faculty, (2) remove telephone numbers of people already aware of the study, and (3) randomly assign 300 numbers to each of the 10 experiments.

### 3.4 Procedure

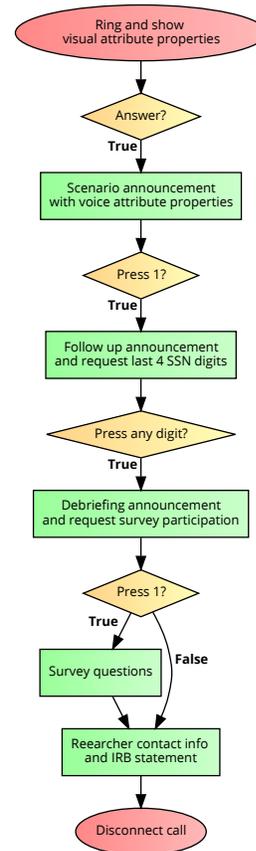

Figure 1: Procedure of each experiment.

Several considerations went into the design of the procedure. First, we need to ensure that the procedure is standardized across all experiments, such that the results are directly comparable to each other. Second, we need to ensure that the process minimizes false positives and false negatives, otherwise, the study results could be unreliable. Finally, the

No.	Caller ID	Area Code Location	Caller Name	Voice Production	Gender	Accent	Entity	Scenario
E1	202-869-XXX5	Washington, DC	N/A	Synthesizer	Male	American	IRS	Tax Lawsuit

E10	480-462-XXX7	University Location	N/A	Synthesizer	Male	American	ASU	Bonus Issued

Table 1: Table of all experiments and their attributes.

procedure also must be carried out ethically and minimize potential harm to the participants.

To ensure that the procedure is standardized, we used an autodialer to automate the process of sending out the telephone calls and collecting the recipients’ responses.

Every experiment followed a standard procedure that is summarized in Figure 1. The procedure has several steps that require inputs from the recipient. The purpose of this action is to reduce the likelihood of recipients making random input actions without hearing the announcement. The action also helps to filter out answers from answering machines. Note that a recipient could break off from the procedure at any point by simply disconnecting the phone, hence not every recipient follows the procedure until the end.

The procedure first begins with a ring on the recipient’s work phone (the recipient does not expect the call). When the phone is ringing, the incoming call screen shows the caller ID and, in experiment E9, the caller name. An example of the incoming call screen is shown in Figure 2a. In all of our experiments, the caller ID showed up as 91XXXXXXXXXX, where XXXXXXXXXXXX is the caller ID used in the respective experiment. Our university’s work phone adds a 91 prefix to every incoming phone call from an external source as all of the calls were distributed from an external telephone service provider, similar to what a real-world scammer would do.

For Experiment 9, the incoming call screen also shows a caller name as shown in Figure 2b. This experiment was designed to simulate a scammer spoofing a known caller name. For legal and ethical reasons, we did not actually spoof a phone number. Instead, we asked our telephone service department to temporarily create a new contact in the university’s internal phone directory and associated a legitimate sounding HR department name “W-2 Administration” with the telephone number. In a normal external call, there is no caller ID displayed, however, IT was able to help us create the caller ID shown in Figure 2b. While a scammer would not be able to create a new name, they can spoof the caller ID of a known caller with a targeted spearphishing scam.

If the call is answered, it starts by playing a prerecorded scenario announcement message (which is different for each scenario). The prerecorded scenario announcement message incorporates the voice attribute properties of each particular experiment. We crafted the four different announcement

messages to mimic what a real-world scammer would say by using words and sentences from our collected scam samples.

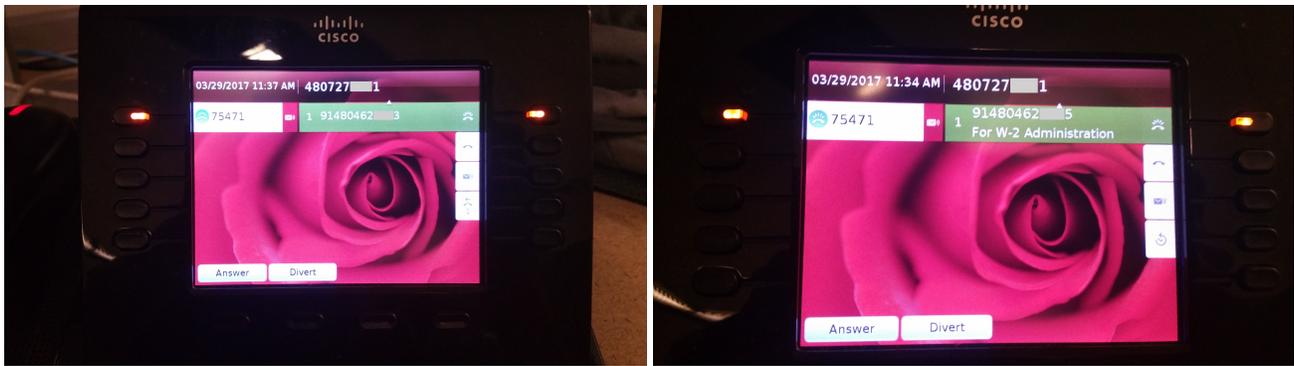

In the *Tax Lawsuit* scenario, we claimed to be the IRS and presented a scenario where the recipient had to act because of a tax lawsuit. The transcript of the announcement message is in Appendix A.1. In the *Unclaimed Tax Return* scenario, we claimed to be the IRS and presented a scenario where the recipient had to act because of an unclaimed tax return. The transcript of the announcement message is in Appendix A.2. In the *Payroll Withheld* scenario, we claimed to be ASU “HR” department and presented a scenario where the recipient had to act because pay would be withheld. Our university has a publicly available payroll calendar on the HR department’s website<sup>3</sup>, hence a real-world scammer could also use this information to craft an announcement message based on the payroll information. The transcript of the announcement message is in Appendix A.3. In the *Bonus Issued* scenario, we claimed to be ASU “HR” department and presented a scenario where the recipient had to act because a performance bonus was issued. The transcript of the announcement message is in Appendix A.4.

Every scenario announcement message requests the recipient to enter 1 to continue to the next step for a follow-up message (same for every participant). After pressing 1, the follow-up message asks the recipient to enter the last four digits of their Social Security number and mimics the process of connecting the phone call to a live agent. The transcript of the follow-up announcement message is in Appendix B.

In the real world, the last four digits of the Social Security number can be used to perpetrate financial and identity fraud [27]. Other parts of the Social Security number can also be inferred from the recipient’s phone number [28]. To minimize potential risk to the recipient (with cooperation and consultation with our IRB), we did not record which digits were pressed, we instead recorded only if any digit was pressed.

This then led to a debriefing announcement and a request to participate in our phone survey. The transcript of the debriefing message is in Appendix C. To emphasize the fact that whatever they listened to was not a real scam, the debriefing announcement and survey questions were recorded with the researcher’s real voice. The post-debriefing survey

<sup>3</sup><https://cfo.asu.edu/payroll-calendars>

(a) All experiments except experiment E9

(b) Experiment E9 with caller name displayed

Figure 2: Incoming call screen of different experiments.

consisted of two questions: (1) a survey question that asked whether the recipient was convinced by the scam (transcript in Appendix D.1) and, depending on how they responded, (2) asked what factor convinced them of the scam (Appendix D.2) or convinced them not to believe the scam (Appendix D.3). We recorded the participant’s voice recording for the second question. After the second survey question, the autodialer system plays an ending message stating the researcher’s contact information (transcript in Appendix E).

In summary, during each step of the procedure, the autodialer was configured to collect the following inputs from the recipient: Continued, Entered SSN, Convinced, Unconvinced, and Recording.

### 3.5 Ethics

These experiments were a deceptive study on involuntary participants, and therefore we deeply considered the ethical issues. To address the ethical issues inherent in our experiments, we carefully designed the experiments and worked with our university’s IRB, to not simply obtain approval but to conduct the study minimizing harm. This is important because, to have scientifically valid results, we could not obtain informed consent (this would bias the results of the study) and we must deceive the participants (they would need to believe that the call was an actual scam call). To protect our participants, we implemented several safeguards in the experimental design.

The nature of this experiment, studying telephone phishing attacks, involves deception as well as involuntary participation. Both aspects are critical to receiving scientifically valid results—informing the participants of the study would significantly bias the results. However, the use of deception can harm the recipients, by wasting their time, confusing them, or leading them to believe they fell victim to a scam. Therefore, our debriefing served to not only inform the participants of the study, but to also educate recipients about the dangers of telephone scams. In addition, we only called each participant

once throughout the entire study duration (to minimize the disruption).

Before proceeding with the study, we also worked with our university’s IT security group to provide them with information that would help to alleviate the concerns of our participants. This IT security group at ASU is responsible for the security of all aspects of the university. We shared with the security group the experiment contact list, the experimental design, and the incoming phone numbers (that we used to send the calls) so that the help desk personnel could be prepared to handle any requests and reports. In this way, our participants who reported the scam calls to IT would be assured that it was part of a study.

In recording the results, we also strove to do so ethically and in accordance with established IRB protocols. One of the major safeguards is that we did not record the Social Security number. While a spammer would typically want the Social Security number, all that we record is the fact that they pressed any digit. In fact, we did not even ask for the full Social Security number, and we performed no analysis to see if they provided nonsensical last four Social Security numbers. This has the drawback of decreasing the validity of our data—participants may have felt safe to input only the last four of their Social Security number (when they would not input the full number) or they input fake last four digits of their Social Security number. Although these measures may diminish the strength of our data, we believe ethics is a more important aspect of designing a telephone phishing study.

### 3.6 Dissemination

We ran the previously described procedure using the 10 described experiments during a workweek in the late March of 2017, during core working hours of 10:00am–5:00pm each day. We used an Internet-hosted autodialer<sup>4</sup> to automate the process of sending out the telephone calls to the 3,000 recipients. Each experiment’s calls were simultaneously distributed

<sup>4</sup><https://www.callfire.com/>

during the experiment period at a rate of 1–3 live calls per experiment.

We associated each experiment with a unique caller ID. In all experiments, the vast majority of the outbound calls did not reach a live recipient and were answered by a voicemail answering machine. If a recipient could not answer the phone, the recipient could use the caller ID in their call history to call us back. As each experiment had a unique caller ID, the return call would be directed to that particular experiment’s procedure. When a recipient called back, the same procedure was administered where a prerecorded scenario announcement message is first played.

While disseminating the phone calls, several unexpected events impacted our study.

The ASU school of journalism and mass communication identified the scam call incidents only 2 hours and 45 minutes from the launch of the experiments on the first day. Instead of reporting it to the university help desk (who were prepared and aware of our study), the school sent out a mass email warning all journalism staff and faculty at 4 hours 28 minutes from launch. However, we did not notice a significant dip in the number of recipients that continued with our scam calls as the portion of work phones at the journalism department represents less than 2% of our sample population.

At 4 hours and 22 minutes from the launch of the experiments, our university’s telephone service office also started blocking some of our phone calls as they were receiving system alerts of too many incoming phone calls exhausting the telephone trunk routes. We worked with the telephone service office to get our calls unblocked within the next 4 hours as we decreased the simultaneous call rate of our phone calls to one per experiment.

The IRB office also received some complaints (we were not told exactly how many) regarding the scam call experiments, which resulted in our experiments being paused for roughly 12 hours (start to finish) starting on day 2, as we waited for the IRB committee to review the complaints. The IRB examined our procedures and decided that, as our study was originally designed, the beneficence outweighed the harm (as evidenced by the complaints) and allowed the study to proceed.

A summary showing how these events affected our calls is shown in Figure 3. In the end, despite the unexpected events, we finished sending out the telephone calls to the 3,000 recipients as planned before the end of the workweek.

## 4 Results and Analysis

The input data collected from the 3,000 recipients are presented in Table 2. Across all 10 experiments of 3,000 total recipients, 8.53% (256/3000) of all recipients continued after listening to the scam scenario announcement, 3.73% (112/3000) of all recipients called back after receiving the initial call from us, 4.93% (148/3000) of all recipients entered at least a digit when requested to enter the last four digits of

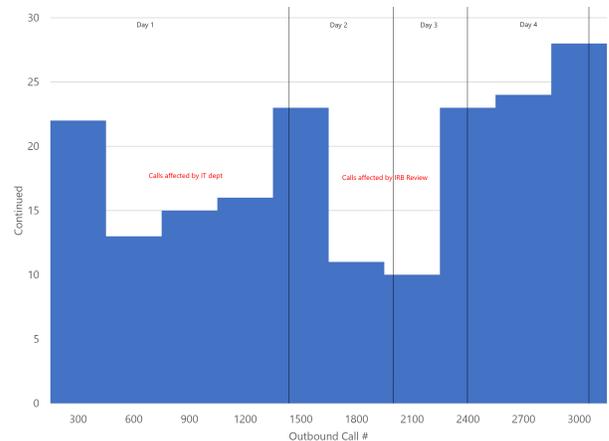

Figure 3: No. of recipients pressed 1 to continue the received calls over the experiment time.

their Social Security number, 1.17% (35/3000) of all recipients explicitly stated that they were convinced by the scam, and 1.23% (27/3000) of all recipients explicitly stated that they were not convinced by the scam.

Before presenting our analysis of the experiments, we first discuss our methodology to systematically analyze their relative effectiveness. The first step of performing the analysis is to decide on metric(s) that will be used as the standard of measurement. To choose an ideal metric, we believe a good metric should not only be quantifiable but also be a proxy for what ultimately matters. From the telephone scammers’ perspective, the ultimate goal is to collect as many Social Security numbers as possible for the purpose of conducting identity fraud.

We could use the metric of *Entered SSN*, which is the number of participants that entered any value for their Social Security number (SSN). However, as discussed in Section 3.5, we did not collect the SSNs input by the user. Although this seems to be an ideal metric to estimate the number of SSNs collected, there is still the possibility that the recipient may have tried to enter a fake Social Security number. In fact, in some of the recordings, a few recipients stated that they did not enter their real Social Security number information.

Therefore, we need to derive a metric that could provide a reasonable estimate of the actual number of real SSNs given to us in each experiment. *Convinced* is the metric of the number of recipients that explicitly stated that they were convinced by the scam after the first survey question. This metric is the most conservative for estimating attack success. However, with the low number of responses, participants rarely made it to that step. Using this metric would exclude a large number of recipients that fell for the scam but declined to participate in the phone survey after the debriefing announcement.

Because we cannot assume that all SSNs entered were real, to reduce these types of false positives, we could create a new metric and remove the participants that entered their SSNs and then subsequently stated that they were unconvinced by

No.	Continued	Callbacks	Entered SSN	Convinced	Recordings	Unconvinced	Recordings

Table 2: Summary of recipient inputs from all experiments.

the scam during the survey process. This metric, which we call *Possibly Tricked*, provides a reasonable estimate of the actual number of recipients that fell for the scam by entering the last four digits of their Social Security number. Compared to the previous metrics, this metric provides a good balance of conservativeness and sample size, and, therefore, we use this metric for our analysis.

No.	Entered SSN	Unconvinced	Possibly Tricked
E9	35	4	31 10.33%
E8	30	9	21 7.00%
E10	22	4	18 6.00%

E7	9	6	3 1.00%
E1	6	4	2 0.67%
E5	2	1	1 0.33%
Total	148	37	111 3.70%

Table 3: Estimating the number of recipients possibly tricked into entering their real SSN information

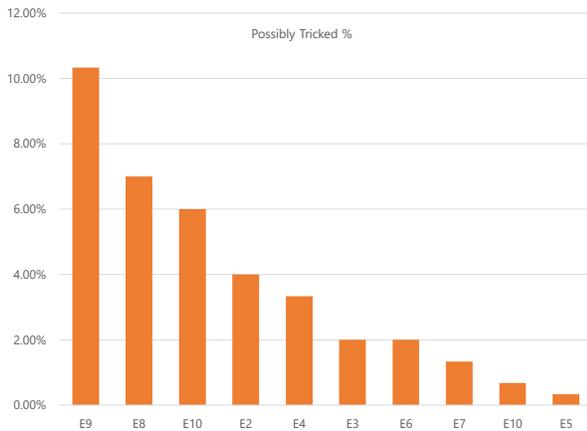

Figure 4: Recipients possibly tricked into entering their real SSN information.

Figure 4 presents a view of the number of *possibly tricked* recipients for each experiment, ranked from most successful to least successful. The tabulated data is in Table 3. Comparing the possibly tricked result between experiments, experiment E9 (spoofed caller ID) had the highest possibly tricked rate among all experiments, with an estimate of 10.33% (31/300) of recipients possibly tricked into entering the last four digits

of their Social Security number. Experiment 5 (202 area code, unclaimed tax return) had the lowest success rate among all experiments, with an estimate of only 0.33% (1/300) of recipients possibly tricked into entering the last four digits of their Social Security number.

Attribute	Property	Linear Regression Coefficient

	Bonus Issued	2.67

Table 4: Linear regression coefficients of all attribute properties overfitted on possibly tricked.

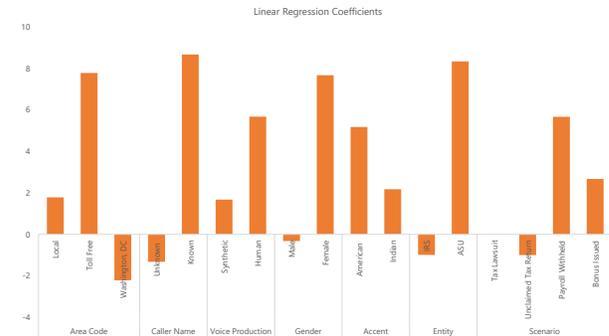

Figure 5: Linear regression coefficients of all attribute properties overfitted on possibly tricked.

The next step is to decide on an appropriate method of data analysis on the chosen metric. With a myriad of possible data analysis methods, we decided to use both linear regression and statistical hypothesis testing analysis. Linear regression is a model-based analysis can produce a model that can fit an optimal mapping of attribute properties to the results (i.e. possibly tricked). However, such method tend to overfit the spurious correlations that occur in training data since it is a

Small Data problem [29]. Furthermore, the attribute properties used in our experiments are also not conditionally independent. Nonetheless, the results of linear regression analysis are shown in Table 4 and Figure 5.

Alternatively, we used a statistical hypothesis testing approach for analysis. Before doing statistical hypothesis testing, we asked, “what are the hypothesis questions that our data can provide an answer for?” We will provide a discussion on the hypothesis questions we decided to ask and how we applied a data analysis method to provide a contextual answer to the hypothesis questions. Because we are testing several hypotheses, we perform the Holm-Bonferroni step-down correction [30] on the significance tests. The results are shown in Table 5 sorted by the individual  $p$ -value.

#### **Can manipulating the area code have a significant effect on the attack success of a telephone scam?**

In the real world, we observed that telephone scammers used area code manipulation in many instances (in particular in Neighbor Spoofing scams [16]). To provide an answer to this question, we can compare the number of possibly tricked between similar experiments that used different area codes, i.e., E1, E2, and E3. We see that E1 had 0.67% possibly tricked, E2 had 4% possibly tricked, and E3 had 2% possibly tricked.

In our question concerning the significance of area code, since E1 and E2 have the greatest difference in the number of possibly tricked recipients, we test if using a toll-free area code is significantly more effective than Washington, DC area code in the context of the IRS scam example. So we perform a right-tailed  $p$ -value hypothesis testing approach on the chosen experiment groups (E1 vs. E2) using the adjusted  $p$ -value corrected with Holm-Bonferroni’s step-down method [30].

The use of right-tailed  $p$ -value statistical hypothesis testing approach is a method to answer if it is “likely” or “unlikely” to observe the improved alternative hypothesis (i.e. E2 possibly tricked) – assuming that the null hypothesis is true (i.e. probability distribution of E1 possibly tricked).

With regards to the choice of using Bayesian vs. Frequentist methods, since we are aware of no similar prior experiments, we can only use Frequentist methods to calculate the statistical significance on the underlying truths using only data from the current experiment.

In addition, not only do we want to know if the improvement to attack success is significant, it is also important to know the magnitude of improvement. To avoid making statements such as “E2 is 5 times more effective than E1”, instead of measuring the relative difference, we calculated Cohen’s  $d$  to measure the effect size for comparison between the two groups.

Using the right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 7.314 and an adjusted  $p$ -value of 0.00684. Using an arbitrary confidence level of 95%, it is very likely that using a toll-free area code can result in a more successful attack than using a Washington, DC area code in the context of the

IRS scam example. The two groups also have a Cohen’s  $d$  of 0.222, which suggests it has a small effect according to Cohen [31] and has a somewhat educationally significant effect according to Wolf [32]. Therefore, we could say that the area code can have a statistically significant yet somewhat minor effect on the attack success of telephone phishing scam.

#### **Can manipulating the type of voice production have a significant effect on the attack success of a telephone scam?**

To provide an answer to this question, we can compare the number of possibly tricked between similar experiments that used different types of voice production, i.e., E1 and E6. In our question concerning the significance of voice production, we test if using a recorded human voice is significantly more effective than using synthesized voice in the context of the IRS scam example.

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 2.027 and an adjusted  $p$ -value of 0.155. Using an arbitrary confidence level of 95%, we cannot conclude that using a recorded human voice can result in a more successful attack than using synthesized voice in the context of the IRS scam example. The two groups have a Cohen’s  $d$  of 0.117, which also suggests the effect size is very small and not educationally significant. Therefore, we are not able to conclude at this time if the type of voice production has a significant effect on the attack success of a telephone phishing scam.

#### **Can manipulating the voice gender have a significant effect on the attack success of a telephone scam?**

For the telephone scammer, the voice gender of the voice synthesizer can be easily changed with a simple option click in the autodialer. To provide an answer to this question, we compare the number of possibly tricked between similar experiments that used different voice genders, i.e., E1 and E4. In our question concerning the significance of voice gender, we test if using a female synthesized voice is significantly more effective than using male synthesized voice in the context of the IRS scam example.

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 5.442 and an adjusted  $p$ -value of 0.0197. Using an arbitrary confidence level of 95%, it is unlikely that using a female synthesized voice can result in a more successful attack than using a male synthesized voice in the context of the IRS scam example. The two groups have a Cohen’s  $d$  of 0.192, which suggests the effect size is small and not educationally significant. Therefore, it is difficult for us to conclude at this time if the voice gender has a significant effect on the attack success of a telephone phishing scam.

#### **Can manipulating the voice accent have a significant effect on the attack success of a telephone scam?**

To provide an answer to this question, we compare the number of possibly tricked between similar experiments that used different accents, i.e., E6 and E7. In our question concerning the significance of voice accent, we test if speaking with an American accent is significantly more effective than speaking with an Indian accent in the context of the IRS scam example.

Hypothesis	Group A	Possibly Tricked	Group B	Possibly Tricked	$p$ -value	Adjusted $p$ -value <sup>1</sup>	Significant <sup>1</sup>	Cohen's $d$	Effect Size <sup>2</sup>	Conclusive
Entity Scenario (IRS vs. HR)	E1 + E5	3/600	E8 + E9	39/600	1.56E-8	1.09E-7	Yes	0.331	Small & educationally significant	Yes
Area Code (202 vs. 800)	E1	2/300	E2	12/300	0.00684	0.0410	Yes	0.222	Small & somewhat educationally significant	Somewhat
Voice Gender (Male vs. Female)	E1	2/300	E4	10/300	0.0197	0.0985	No	0.192	Small & not educationally significant	No
Caller Name (Unknown vs. Known)	E8	21/300	E9	31/300	0.147	0.588	No	0.119	Very small & not educationally significant	No
Voice Production (Synthetic vs. Human)	E1	2/300	E6	6/300	0.155	0.465	No	0.117	Very small & not educationally significant	No
Voice Accent (Indian vs. American)	E7	3/300	E6	6/300	0.314	0.628	No	0.082	Very small & not significant	No
Motivation (Reward vs. Fear)	E5 + E10	19/600	E1 + E8	23/600	0.530	0.530	No	0.036	Very small & not significant	No

Table 5: Summary of statistical hypothesis testing results ordered individual  $p$ -value.

<sup>1</sup>Using  $p$ -values corrected with Holm-Bonferroni's step-down method [30].

<sup>2</sup>Using effect size descriptors by Cohen [31] & Wolf [32]

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 1.015 and an adjusted  $p$ -value of 0.314. Using an arbitrary confidence level of 95%, we cannot conclude that speaking with an American accent can result in a more successful attack than speaking with an Indian accent in the context of the IRS scam example. The two groups also have a Cohen's  $d$  of 0.082, which suggests the effect size is very small and not educationally significant. Therefore, we are not able to conclude at this time if the voice accent has a significant effect on the attack success of a telephone phishing scam.

#### Can spoofing a known caller name have a significant effect on the attack success of a telephone scam?

To provide an answer to this question, we compare the number of possibly tricked between similar experiments that show a difference in the display of a caller name, i.e., E8 and E9. In our question concerning the significance of spoofing caller name, we test if displaying a HR-department caller name "W-2 Administration" is more effective than not displaying a caller name in the context of the HR scam example.

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 2.106 and an adjusted  $p$ -value of 0.147. Using an arbitrary confidence level of 95%, we cannot conclude that displaying a HR-department caller name can result in a more successful attack than displaying a caller name in the context of the HR scam example. The two groups also have a Cohen's  $d$  of 0.119, which suggests the effect size is very small and not educationally significant. Therefore, we are not able to conclude at this time if spoofing a known caller name has a significant effect on the attack success of a telephone phishing scam.

#### Can manipulating the entity scenario have a significant effect on the attack success of a telephone scam?

Any form of spear phishing involves impersonating an internal entity that the recipient is familiar with. The scammer has to create a spoofed caller ID and devise a scenario that is tailored to the entity, as the "Entity" cannot be set independently from "Scenario". To provide an answer to the hypothesis

question, we compare the number of possibly tricked between similar experiments that used different entity-scenarios, i.e. comparing E1 and E5 with E8 and E10. In our question concerning the significance of impersonating an internal entity, we test if impersonating an internal entity is more effective than impersonating the IRS with the context of the scenarios tested.

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 31.976 and an adjusted  $p$ -value of 1.56E-8. Using an arbitrary confidence level of 95%, it is likely that impersonating an internal entity can result in a more successful attack than impersonating the IRS with the context of the scenarios tested. The two groups also have a Cohen's  $d$  of 0.331, which suggests the effect size is small and educationally significant. Therefore, we could say that impersonating an internal entity had a significant effect on the attack success of a telephone phishing scam.

#### Can manipulating the type of motivation have a significant effect on the attack success of a telephone scam?

To motivate the recipient into taking some harmful action, the scammer could either use fear or reward. To provide an answer to the hypothesis question, we compare the number of possibly tricked between similar experiments that used different types of motivation, i.e., comparing E1 and E8 with E5 and E10. In our question concerning the significance of the type of motivation, we test if fear-based scenarios are more effective than reward-based scenarios the context of the entities tested.

Using the same right-tailed  $p$ -value approach, we have a  $\chi^2$  statistic of 0.395 and an adjusted  $p$ -value of 0.530. Using an arbitrary confidence level of 95%, we cannot conclude that fear-based scenarios can result in a more successful attack than reward-based scenarios with the context of the entities tested. The two groups also have a Cohen's  $d$  of 0.036, which suggests the effect size is very small and not educationally significant. Therefore, we are not able to conclude at this time if manipulating the type of motivation has a significant effect on the attack success of a telephone phishing scam.

## Summary

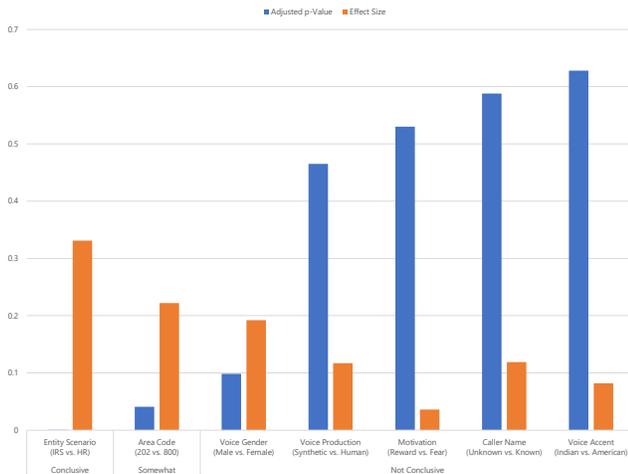

Figure 6: Summary of statistical hypothesis testing results.

The summary of our statistical hypothesis testing results is shown in Figure 6. Based on the statistical hypothesis results, we found that impersonating an internal entity had the most significant effect on the attack success of a telephone phishing scam. We also found that manipulating the area code (using a toll-free vs. a 202 area code) can have a somewhat significant effect.

On the contrary, manipulating the type of motivation, voice production, voice accent, and caller name, individually had an insignificant effect on the attack success. It is also difficult for us to conclude whether manipulating the voice gender has a significant effect even though the result was statistically significant.

## 5 Survey Responses

In this section, we highlight the recorded survey responses that asked the participants for the reasons they were convinced or unconvinced to enter the last four digits of their Social Security number. We listened to all 44 recorded voice responses and tabulated their responses in Table 6.

Based on the voice responses from the survey respondents, no one provided an explicit voice response on why they were convinced by the IRS scams. The four recordings we received were either silent or contained no useful information. We believe that participants were less willing to report the reasons why they were convinced by the scam after they were explicitly told that they had fallen victim to an attack.

On why the IRS scams were unconvincing, most of the survey respondents stated that they already knew that the IRS would not make a call like this or that they were already vigilant about IRS scam calls. This is understandable because there are numerous media reports about the IRS scams, and the IRS posted many public warnings not to trust these types

of scams. This further supports the hypothesis that the impersonated identity and the corresponding scenario was the most significant factor. In experiment E7, two respondents also mentioned that the Indian accent was one of the reasons they were unconvinced.

On why the ASU imposer scams convinced them, most of the survey respondents described something related to the scam scenario, which means that the impersonated entity and the scenario were the key factors. Three respondents also believe that the caller ID was from ASU and stated caller ID was one of the reasons they believed in the scam, even though none of the caller IDs were actually from ASU.

On why the ASU scams did not convince them, most of the survey respondents stated that they were quite certain that ASU would not make a call like this or they were already vigilant about giving their SSN information over an incoming call. Two respondents in experiment E9 mentioned that the scenario only asked for the last four digits of their SSN, and should have asked for their complete SSN if it was really payroll related, which quite possibly meant that those two might have given out their complete SSNs if the phishing scam had asked for it. The external caller ID and synthetic voice were also mentioned as factors that made the survey respondents suspicious.

## 6 Limitations

The experiments were conducted in a university setting where the recipients are university staff and faculty. The demographics of the recipients in our study are not representative of the general population of telephone users in the US.

The experiments only sent out calls to a specific brand of work phones. The type of phone in our study is not representative of the entire population of telephones in the US. The vast majority of telephones in the US are mobile phones [33], and it is possible that these have different actual tricked rates than work phones. In addition, the participants had to be in their office when receiving the phone call (or to return our call if they listened to the voicemail), which is a different usage behavior compared to mobile phones.

The experiments requested only partial SSN information without storing it. The experiments had several safeguards, and the process was carefully designed and tightly regulated to ensure risks and harm to the human research subjects were minimized. This prevented us from collecting any actual Social Security numbers from the recipients. Collecting actual Social Security numbers might have changed the results of the study: more people might be willing to give out their full Social Security numbers, or more people could be skeptical of providing their full Social Security number.

As we did not collect the Social Security numbers directly, we derived a metric called “possibly tricked.” While the goal is to provide an estimate of the number of Social Security numbers that a real scammer would collect, this metric may

No.	Reasons Convinced	Reasons Unconvinced
E1		Would never enter SSN on incoming call; No name mentioned for the charge
E2		IRS won't make a call like this (x2); Already aware of scams like this
E3		IRS won't make a call like this
E4		IRS won't make a call like this; Didn't sound legitimate
E5		IRS won't make a call like this
E6		IRS won't make a call like this; Already aware of scams like this
E7		IRS won't make a call like this (x4); Indian accent (x2)
E8	To get paid (x2); Sounded legitimate; Trusted work phone; Only asked for last 4 SSN; Caller ID showed local ASU number	ASU won't make a call like this (x5); Not from ASU number (x2); Synthetic voice;
E9	Sounded legitimate; Only asked for last 4 digits of SSN; Caller ID showed ASU W-2	Should have asked for complete SSN (x2); Would never enter SSN on incoming call
E10	To get bonus (x2); Trusted work phone; From ASU number; Asked to do so	ASU won't make a call like this; Not ASU number

Table 6: Summary of recorded survey responses.

be under or overestimating the number of real collected Social Security numbers. With the data presented in this paper (Table 2), others can choose to use different metrics to calculate significance. These new metrics and hypotheses should be corrected to prevent *p*-hacking.

## 7 Discussion

Our results show that automated telephone phishing attacks can be effective. One experiment, E9, which simulated a targeted phishing attack with caller name spoofing, achieved a 10.33% possibly tricked rate, where recipients possibly divulged the last four digits of their Social Security numbers.

We have also validated some potential key attributes that can have a significant effect on the scam effectiveness: impersonating an internal entity and announcing a relevant scenario. Manipulating the caller ID to a toll-free area code may also somewhat improve the scam effectiveness for certain scams. Other attribute properties such as human voice, female voice, American accent, caller name spoofing, and fear-based scenario also improved the scam effectiveness in our empirical study, however, at this time we are not able to conclusively demonstrate that they have a significant effect. Nonetheless, given how easy it is for a scammer to manipulate all these attributes, a scammer would seek to incorporate all attribute properties that made an improvement to the attack success, i.e. a phishing scam with toll-free area code, spoofing known a caller name, speaking in a recorded human, female voice, in American accent, impersonating an internal entity, motivating the recipient with a relevant fear-based scenario.

To prevent falling victim to these types of phishing scams, we believe that the key is to target and prevent *impersonation*. Our statistical results have shown that impersonating an internal entity had a significant effect on the scam. To address the impersonation issue, feedback from our survey participants suggests that vigilance was an important reason for not falling for a scam. Many surveyed subjects expressed distrust towards our scam calls when they were already vigilant about the scam scenario. Therefore, we recommend education and awareness of telephone phishing as a countermeasure.

On technical solutions, we recommend a similar approach to help the subjects stay vigilant against phishing calls. There

are solutions that can provide early warnings against impersonated calls, such as, caller ID authentication [4, 34, 35], which has strong safeguards against caller ID impersonation and could help to warn the users against malicious calls with a reputation system.

## 8 Related Work

To our knowledge, there have been no prior empirical user studies on telephone phishing. The most similar work we found was by Aburrous et al. [36], who performed a phone phishing experiment on a group of 50 employees contacted by female colleagues assigned to lure them into giving away their personal e-banking usernames and passwords. They were able to deceive 32% of the employees to give out their e-banking credentials. In the experiment, the 50 employees already knew the female colleagues that contacted them, which suggests an insider attack rather than an impersonation attack.

Other related work studied phishing using different channels. Dhamija et al. performed a website phishing study on 22 university participants and their best phishing site was able to fool more than 90% of participants [37]. Egelman et al. performed an email and website phishing experiment on 60 in-person participants to test the effectiveness of various web browser phishing warnings at that time, and it was found that 79% of Internet Explorer 7.0 participants heeded the active phishing warnings and only 13% of them obeyed the passive warnings [38]. Jagatic et al. performed a social media spear phishing study on 481 targeted Indiana University student emails obtained by crawling social network websites and it had a 72% success rate of recipients authenticating themselves on a redirected website [13]. Vidas et al. performed a QR code phishing study where the experiment distributed 139 posters containing QR codes at various locations at Carnegie Mellon University and the city of Pittsburgh, the experiment was able to trick 225 individuals to visit the associated website in four weeks [39].

## 9 Conclusion

This paper presented the methodology, design, execution, results, analysis, and evaluation of a study exploring why tele-

phone phishing works and how to defend against it. The study was executed using 10 experiments simulating telephone phishing attacks, administered to 3,000 work phones of university staff and faculty over the course of a workweek. The results were collected from the inputs and survey responses of the phone recipients. We analyzed the results by performing linear regression and statistical hypothesis testing methods on a chosen metric derived from the inputs, and we were able to identify at least one attribute that had a significant effect. We provided a discussion on how to effectively prevent such types of telephone phishing scams, and we believe that the best countermeasures should target impersonation and instill vigilance.

## Appendix

### A Announcement Messages

#### A.1 Tax Lawsuit scenario

This is an urgent notice! This is a final notice from the IRS. The reason for this call is to inform you that the IRS is filing a lawsuit against you. Your action is required immediately, or a penalty will be assessed. To speak to an IRS agent and get more information about this case, please press 1 on your phone now.

#### A.2 Unclaimed Tax Return scenario

This is an urgent notice! This is a final notice from the IRS. The reason for this call is to inform you that the IRS has an unclaimed tax return for you that is due to expire within three days. Your action is required immediately. To speak to an IRS agent and get more information about claiming your tax refund, please press 1 on your phone now.

#### A.3 Payroll Withheld scenario

Dear ASU employee. This is an urgent notice! This is a final notice from the ASU W-2 administration office. The reason for this call is to inform you that to process your next Friday payroll, you are required to update your 2017 tax information immediately. To speak to a staff agent and get more information, please press 1 on your phone now.

#### A.4 Bonus Issued scenario

Dear ASU employee. This is an urgent notice! This is a final notice from the ASU W-2 administration office. The reason for this call is to inform you a performance bonus has been issued to your account. Your action is required immediately. To speak to a staff agent and get more information, please press 1 on your phone now.

### B Follow-up Message

Please wait for the next available agent. Thank you for holding. Your call will be connected shortly. Please enter the last four digits of your Social Security number on your phone now.

## C Debriefing Message

Hi, I am [redacted for anonymity] in the Department of Computer Science at Arizona State University. I am conducting a research study to measure the effectiveness of telephone phishing. The reason you are receiving this message is because I would like to inform you that what you just did could potentially lead you becoming exploited in a real telephone scam. However, I would like to assure you that this is not an actual scam, none of your social security information was actually collected.

We would like to invite you to participate in our phone survey, to help us better understand your thoughts about the scam. You will be able to listen to the survey questions right after this message. Your participation in this survey is voluntary. There are no foreseeable risks for your participation. If you choose not to participate or to withdraw from the survey at any time, there will be no penalty. Your responses will be anonymous. The results of this study may be used in reports, presentations, or publications but your identity will not be used. Please press 1 to listen to the survey questions or participate in the phone survey.

## D Survey Questions

### D.1 Did the scam convince you

Thank you. Could you please help us understand if the scam was able to convince you to enter your Social Security number? Please use the number on your keypad to answer this question. If "yes", please press 1. If "no" please press 0.

### D.2 What factor made the scam convincing

Thank you. Could you please help us understand what was the most important factor that made the scam convincing? We will record your voice response for this question. At the tone, please state briefly what you thought was the most important factor. When you are finished, please press the pound key to end recording.

### D.3 What reason made the scam unconvincing

Thank you. Could you please help us understand what was the most important reason you did not believe in the scam? We will record your voice response for this question. At the tone, please state briefly what you thought was the most important reason. When you are finished, please press the pound key to end recording.

## E Ending Message

Thank you. This is the end of the research experiment. If you have any questions concerning the research study, please contact the research team at [redacted for anonymity]. If you have any questions about your rights as a participant in this research, or if you feel you have been placed at risk, you can contact the Chair of the Human Subjects Institutional Review Board, through the ASU [redacted for anonymity], at [redacted for anonymity]. Thank you for your participation. Goodbye.

# Platforms in Everything: Analyzing Ground-Truth Data on the Anatomy and Economics of Bullet-Proof Hosting

Arman Noroozian<sup>1</sup> ✉, Jan Koenders<sup>2</sup>, Eelco van Veldhuizen<sup>2</sup>,

<sup>(3)</sup> *King Saud University and International Computer Science Institute*, <sup>(4)</sup> *New York University*

## Abstract

This paper presents the first empirical study based on ground-truth data of a major Bullet-Proof Hosting (BPH) provider, a company called `MaxiDed`. BPH allows miscreants to host criminal activities in support of various cybercrime business models such as phishing, botnets, DDoS, spam, and counterfeit pharmaceutical websites. `MaxiDed` was legally taken down by law enforcement and its backend servers were seized. We analyze data extracted from its backend databases and connect it to various external data sources to characterize `MaxiDed`'s business model, supply chain, customers and finances. We reason about what the “inside” view reveals about potential chokepoints for disrupting BPH providers. We demonstrate the BPH landscape to have further shifted from agile resellers towards marketplace platforms with an oversupply of resources originating from hundreds of legitimate upstream hosting providers. We find the BPH provider to have few choke points in the supply chain amendable to intervention, though profit margins are very slim, so even a marginal increase in operating costs might already have repercussions that render the business unsustainable. The other intervention option would be to take down the platform itself.

## 1 Introduction

“Bullet-proof” hosting (BPH) is a part of the hosting market where its operators knowingly enable miscreants to serve abusive content and actively assist in its persistence. BPH enables criminals to host some of their most valuable resources, such as botnet command-and-control (C&C) assets, exploit-kits, phishing websites, drop sites, or even host child sexual abuse material [1–5]. The name refers to the fact that BPH provides “body armor” to protect miscreants against interventions and takedown efforts by defenders and law enforcement.

Much of the prior work in this area has focused on how to identify such malicious providers. Initially, BPH providers served miscreants directly from their own networks, even though this associated them with high levels of abuse. Famous examples of such providers include `McColo Corp.` [6], the `Russian Business Network (RBN)` [7], `Troyak` [3] and `Freedom Hosting` [8]. This operational model enabled AS-

reputation based defenses, such as `Fire` [9], `BGP Ranking` [10] and `ASwatch` [11]. These defenses would identify networks with unusually high concentrations of abuse as evidence for the complicity of the network owner, and thus of BPH.

AS-reputation defenses became largely ineffective when a more “agile” form of BPH emerged. In this new form, providers would rent and resell infrastructure from various legitimate upstream providers, rather than operate their own “monolithic” network. Concentrations of abuse were diluted beyond detection thresholds by mixing it with the legitimate traffic from the ASes of the upstream providers.

In response, researchers developed a new detection approach, which searched for concentrations of abuse in sub-allocated IP blocks of legitimate providers [4, 5]. This approach assumes that honest upstream providers update their WHOIS records when they delegate a network block to resellers. It also assumes that the BPH operator functions as a reseller of the upstream providers.

A key limitation of this prior work is that it is based on external measurements. This means that we have little inside knowledge of how BPH operations are actually run and whether assumptions behind the most recent detection approaches are valid. A second, and related, limitation is the lack of ground-truth data on the actions of the provider. There are minor exceptions, but even those studies contain highly sparse and partial ground-truth data [2, 5].

This paper presents the first empirical study of BPH based on comprehensive internal ground-truth data. The data pertains to a provider called `MaxiDed`, a significant player in the BPH market. It unearths a further, and previously unknown, evolution in the provisioning of BPH, namely a shift towards platforms. Rather than `MaxiDed` renting and reselling upstream resources on its own, it offered a platform where external merchants could offer, for a fee, servers of upstream providers to `MaxiDed` customers, while explicitly indicating what kinds of abuse were allowed. By operating as a platform, `MaxiDed` externalizes to the merchants the cost and risk of acquiring and abusing infrastructure from legitimate upstream providers. The merchants, in turn, externalize the risk of customer acquisition, contact and payment handling to the marketplace. This new BPH model is capable of evading the state-of-the-art detection methods. Our analysis shows that

in most cases, there are no sub-allocations visible in WHOIS that can be used to detect abuse concentrations, rendering the most recent detection method [5] much less effective.

Before we can develop better detection and mitigation strategies, we need an in-depth empirical understanding of how this type of provider operates and what potential choke-points it has. To this end, we analyze a unique dataset captured during the takedown of *MaxiDed* by Dutch and Thai law enforcement agencies in May 2018 [12]. The confiscated data includes over seven years of records (Jan 2011 – May 2018) on server packages on offer, transactions with customers, provisioned servers, customer tickets, pricing, and payment instruments. In addition to the confiscated systems, two men were arrested: allegedly the owner and admin of *MaxiDed*.

The central question of this paper is: *how can we characterize the anatomy and economics of an agile BPH provider and what are its potential chokepoints for disruption?* We first describe how the supply chain is set up. Then, we characterize and quantify the supply, demand, revenue, payment instruments and profits of the BPH services offered by *MaxiDed*. All of this will be analyzed longitudinally over seven years. We also explore what *MaxiDed*'s customers used servers for.

Our main contributions may be summarized as follows:

- We provide the first detailed empirical study of the anatomy and economics of an agile BPH provider based on ground-truth data.
- We map the supply of BPH services and find a highly diversified ecosystem of 394 abused upstream providers.
- Contrary to conventional wisdom, we find that the provider's BP services are not expensive and priced at a 40-54 % markup to technically similar non-BP offers.
- We quantify demand for BPH services and find it resulting in a revenue of 3.4M USD over 7 years. We conclude the market to be constrained by demand, not by supply, i.e. demand for this type of agile BPH seems limited.
- We estimate profits to amount to significantly less than 280K USD over 7 years. This belies the conventional wisdom of BPH being a very lucrative business.
- We find disruptable pressure points to be limited. Payment instruments were sensitive to disruption, but a recent shift to crypto-currencies limits this option. We identified 2 merchants and a set of 15 abused upstream hosting providers as pressure points though their identification would have been difficult based on external measurements. The only remaining viable options are raising operational costs and taking down the provider's platform.

We should note that the “bullet-proof” metaphor seems less suited for this new model of BPH provider that we study. Commonly, BPH is understood to include two aspects: (i) intentionally enabling abuse, and (ii) providing resilience

against takedowns. The BP metaphor directs attention to the resilience. This new business model, however, primarily focuses on the agile enabling of abuse at low cost. *MaxiDed* and its external merchants provide servers for abuse at close to the market price for legitimate servers. Customers then prepay the rent for these servers. This means that the risk of takedown, in terms of a prepaid server being prematurely shut down by the upstream provider, is borne by the customer. Most customers manage this risk by opting for short lease times and treating servers as disposable and cheaply replaceable resources. They take care of the resilience of their services themselves, using these disposable resources. Some forms of resilience – e.g., reinstalling an OS and moving files to a new server – are provided by the BPH provider as a premium service for an additional fee. The ‘bullet-proof’ metaphor is less suitable for this business model. A more fitting alternative may be “agile abuse enabler”. That being said, in this paper we retain the existing term. The market of intentionally provisioning hosting services for criminals is still widely referred to as BPH and we want to maintain the connection with prior work.

The remainder of this paper is structured as follows. First, we provide a high-level overview of *MaxiDed*'s business (§.2). We then discuss the ethical issues related to our study (§.3). Next, we describe our datasets (§.4) and the integrity checks we performed to ensure the validity of our analysis (§.5). We then outline *MaxiDed*'s anatomy and business model (§.6). Next, we turn to the substantive findings and analyze the supply and demand around *MaxiDed*'s platform, with a specific focus on identifying choke points (§.7). We also analyze *MaxiDed*'s customer population (§.8). We then take a look at longitudinal patterns in terms of use and abuse of BP servers by customers (§.9). The final part of the analysis is on *MaxiDed*'s revenue, costs and profits (§.10). We conclude by locating our study within the related work (§.11) and by discussing its implications for the problem of BPH (§.13). Additional material are provided in Appendices (§.14)

## 2 Background

*MaxiDed* Ltd. was a hosting company legally registered in the Commonwealth of Dominica, an island state in the West Indies that is also known for its offshore banking and payments processing companies. *MaxiDed*'s operators publicly advertised the fact that customers were allowed to conduct certain abusive activities upon purchasing its hosting solutions. While WHOIS information of the *MaxiDed* domain shows that it has existed since 2008, web archive data suggest that initially it was just a small hosting provider with no mention of allowing illicit activities. It underwent a major transformation in 2011 towards becoming an agile BPH service. *MaxiDed* does not have its own Autonomous System, nor does it have any IP address ranges assigned to it by RIRs, according to our analysis of WHOIS data at the time of its disruption. This implies that IP addresses are provisioned to customer servers by upstream providers, rather than by *MaxiDed*. This underlines

BPH	Advertised BPH Services			
	Dedicated Servers	VPS	Shared Hosting	Total
66host	0	0	3	3
outlawservers	1	6	4	11
abusehosting	47	5	3	55
bpw	5	4	0	9
bulletproof-web	7	9	0	16
MaxiDed	1,855	1,066	0	2,921

**Table 1:** MaxiDed in comparison with previously studied BPH by Alrwais et al.[5] that appear to be still operational

MaxiDed’s agile nature, i.e., its reliance on reselling upstream infrastructure. Table 1 compares MaxiDed with several previously studied agile BPH providers in terms of the quantity and types of services they offered. It highlights that its scale of operations is around two orders of magnitude larger. It is reasonable to view the provider as a major player in this market which others have similarly pointed to [13].

### 3 Ethics

Our data is similar in nature to that used in prior studies of criminal backends [14–16]. It originates from legal law enforcement procedures to seize infrastructure. Using such data raises ethical issues. We operated in compliance with and under the approval of our institution’s IRB. We discuss further issues using the principles identified in the *Menlo Report* [17].

**(Respect for persons.)** The data contains personally identifiable information (PII) on customers, merchants and employees. Access has been controlled and limited to authorized personnel within the investigative team, and later granted to several of the co-authors. Since ‘participation’ in this study is not voluntary and cannot be based on informed consent, we took great care not to analyze PII on customers, because they form the most vulnerable party involved and not all of them may have used servers for illicit purposes. We only compiled aggregate statistics. For merchants, we have masked identities using pseudonyms to prevent identifiability. We did not analyze the data in terms of MaxiDed employee names.

**(Beneficence.)** We believe that our analysis does not create further harm. We did not purchase services from the provider and thus did not contribute to any criminal revenue. The authors and police investigators believe the benefits of a better understanding of BPH operations, most notably in terms of better countermeasures, outweigh the potential cost of making this kind of knowledge more widely known, as the model of agile BPH itself is already well-documented in prior work.

**(Justice.)** The benefits of the work are distributed to the wider public, in terms of helping to reduce crime. It especially helps to protect persons who are more vulnerable to being victimized. We see no impact to persons from being included in the study itself.

**(Respect for law and public interest.)** This study has been conducted with the approval of, and in collaboration with, the investigative team and public prosecutors. It is im-

portant to note, that while captured information may point to certain illegal conduct, establishing legal proof of criminal conduct is *not* the purpose of this study.

### 4 Data

From the servers seized during the takedown, the Dutch investigative team has been able to resurrect MaxiDed’s administrative backend (CRM and database). They have granted us access to the data and corresponding source code. We analyzed the source code to ensure correct interpretation of the stored data. We observed how various resurrected administrative pages queried specific records to display information.

The revived single-instance Postgres database contains longitudinal information on several key aspects of MaxiDed’s operations. On the supply side, it includes data on what server packages were on offer, which merchants were offering these packages, and the internal and externally-advertised prices of each package. On the demand side, there is customer contact information, order placements, rented servers, server assigned IP addresses, financial transactions, and type of payment instruments used and available over time.

Communications between MaxiDed operators, customers, merchants, and upstream providers were captured as CRM system tickets. Ticket contents and email communications also include instances of abuse complaint emails that MaxiDed administrators received and forwarded to their customers. We should note that the operators also operated a live-chat channel for customers on the site. They were also known to use ICQ, Jabber and Skype contact channels at some point in time. These communications were not stored on the seized servers, if they were stored at all. Communications data, often the most sensitive, have not been analyzed in favor of the ethical principles that we followed.

Overall, the retrieved data represents information over the course of MaxiDed’s life span from Jan.- 2011 to May-2018, when its operation was disrupted. High level statistics and descriptions of the ground-truth data is presented in Table 2.

To enrich the ground-truth data, we deployed several additional data sources. Domain-based resources operating from the customer IPs, were identified using historical passive DNS data collected via Farsight Security’s (DNSDB [18]). To identify upstream providers of servers and IPs, we used historical WHOIS IP allocation data from Maxmind [19]. A set of domain and IP-based blacklists have been used to gain further insights into abuse emanating from customer servers.

### 5 Data Integrity

Since we did not gather the information ourselves, we need to evaluate its accuracy and authenticity: how do we know that MaxiDed admins did not manipulate data, for reasons of operational security or otherwise?

Our data resulted from the legal seizure of servers, in close coordination with apprehension of two individuals who had

Data on	Description	Total Nr.
Suppliers	60 directly listed upstream hosters and 14 listed merchants supplying server packages	74
Server Packages	Customizable server packages on offer during 2011-2018	56113
Payment Instruments	Supported payment instruments/methods	23
Orders	Customer placed orders for various server packages and other administrative services	66886
Users	Number of registered users	308396
Transactions	Financial transactions including 30938 received payments and 33124 payments made to other entities	64602
Tickets	CRM system tickets capturing communications between various entities	26562

**Table 2:** High-level statistics of *MaxiDed* backend data

administrative control over these systems. This ensured that the data was not manipulated during or after the seizure. To ensure that data was not manipulated in the course of *MaxiDed*'s operation, we have examined data integrity in several ways. We first discuss the correspondence of the seized data with external (third-party) data. Next, we analyze the internal consistency of the seized data itself.

The strongest indicator of integrity is that the seized server data was consistent with the data that was collected via legal intercept prior to the takedown. A wiretap had been running for over two years on the backend CRM server.

We also compared the data to snapshots of *MaxiDed*'s webshop archives on Internet Archive between 2015-2018. We extracted all server package IDs that were on offer. All these IDs were present in our back-end data as well.

For a sample of over 50 server packages on sale in April 2018, we compared the internally recorded price with the prices of the entities listed as the upstream providers. These included packages from a Dutch and a German upstream hosting provider. For each package, we visited the supplier's website, customized a server package to match, and found its price to be correctly reflected by the internal price.

For the payment data, we were able to compare the *WebMoney* transactions logged in the database with data that was subpoenaed by Dutch law enforcement from *WebMoney* on transactions during a period of 10 days involving one particular *WebMoney* wallet address. Of 31 internally recorded transactions during this period via *WebMoney*, 17 were matched with the external data.

Together, these external checks provide confidence that the internal data has not been manipulated. Multiple *internal* data consistency checks were also carried out. We cross referenced customer order placements against server package data, to determine if all order placements consistently point to an existing package. Of the 14,702 customer orders for servers, we found 431 referencing package IDs that were not listed, indicating a 2.9% proportion of inconsistent order placement records. These references point to a set of 306 unique server packages (a 0.5% proportion of all server packages).

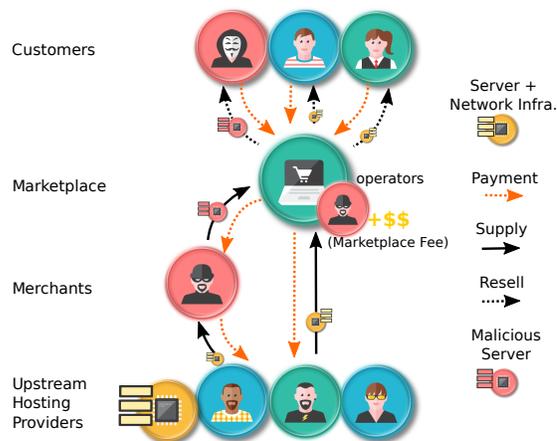

We also cross referenced *MaxiDed* operators' payments to their merchants, against server package data. These indirectly referenced specific server packages, thereby indicating what each payment is for. Of the 33,124 outgoing payments, we found 345 referencing packages that were not listed among the set of offered server packages (a 1.0% proportion of inconsistent payment records). Cross referencing the same payment data against customer orders, we found 474 outgoing

payments referencing servers that were not listed among the orders of customers (a 1.5% of inconsistent payment records).

The timestamps of order placement and transactions were also analyzed, to check for suspicious gaps in the timeline. The longest gap was observed to be 76 days from 2011-03-31 to 2011-06-15. All remaining gaps (37) were at most 2 days long. Approximately an average number of 26 order placements per day were observed. For payment events, the longest timeline gap was observed to be 135 days pertaining to the data from the period between 2011-01-29 and 2011-06-13. The remaining gaps (5) were no longer than 1 day. An average number of 24 transactions per day were observed in the payment data.

The minor inconsistencies and timeline gaps for the most part relate to records from 2011 and 2012, a period corresponding to the initial set up and early growth phase of *MaxiDed*. A certain amount of inconsistency in database records is to be expected, but more so during the initial set up and growth phase of any organization. All in all, the internal and external consistency of the data merits confidence in its validity for the purposes of characterizing the overall anatomy and economics of *MaxiDed*'s BPH operation.

## 6 Anatomy of *MaxiDed*'s business

**Figure 1:** *MaxiDed* in a glance.

Figure 1 provides a high-level overview of *MaxiDed*'s anatomy and business model. We take a close look at each of its components.

### 6.1 Hosting Business Components

(Marketplace) *MaxiDed* was a marketplace which connected merchants offering server packages that allowed abuse, with

customers looking for an abuse-tolerant provider. It captured a fixed 20% fee from each sale between a merchant and a customer. Customers did not see the merchants' identities or even that an offer came from a separate entity. All they knew was that they contracted with `MaxiDed`. The merchants advertised server packages from legitimate upstream providers and put these on the `MaxiDed` market with a markup. Server packages specified default server configurations that were further customizable by customers. In addition to the technical specification, each package indicated what type of abuse, if any, was allowed. The majority of the packages explicitly allowed certain forms of abuse. `MaxiDed` itself also put server packages from certain upstream providers for sale in the webshop, de facto operating as merchant on its own platform. For its own packages, profits varied between 0 to 40% of the cost of packages at the upstream providers. What's more, `MaxiDed` also operated as a customer on its own platform, acquiring offers from merchants for its side business, a highly permissive and lucrative file sharing service called `DepFile`. This file sharing service was a major hub for distributing child sexual abuse material.

The platform approach means `MaxiDed` can externalize the cost and risks of acquiring and supplying upstream server infrastructure to third-party merchants. As such it is decoupled from the upstreams. The advantage for merchants, on the other hand, was that they could externalize the responsibility and risks of acquiring customers and processing their payments. Beside the fee that `MaxiDed` charged on top of the merchant's price, it also charged customers for performing additional administrative tasks, like re-installing servers after a takedown by the upstream provider. From these fees, it needed to recoup the cost of its staff and backend systems.

The main components of the marketplace were a frontend webshop, a backend Customer Relationship Management (CRM) system, accounts for merchants who could offer server packages on in the webshop, and payment handling of customers paying to `MaxiDed` and, in turn, `MaxiDed` paying the merchants when their offers resulted in a sale. The CRM, a series of webpages implemented in PHP, was used by both `MaxiDed` and merchants to create the server packages displayed on the webshop. It was also used to facilitate communications between customers and merchants through customer tickets. Merchants were responsible for handling customer tickets of their own server packages. Communications also took place through multiple `MaxiDed` support email addresses which were automatically imported into the backend database and live-chat functionality which was not retrievable from our data.

Different payment options have been supported over time by `MaxiDed`; 23 in total. Some from third-party payment providers like `Paypal` and `WebMoney` to cryptocurrencies such as `Bitcoin` and `Zcash`.

**(Merchants)** Third-party merchants supplied server packages that were re-branded and sold, with a mark-up, un-

der `MaxiDed`'s name. Many offered packages were directly scraped by the merchants from retail auction sites run by certain upstream providers. As far as we could tell, most merchants had no established reseller relationship with the upstream provider and no delegation was visible in IP WHOIS. (We explore this more systematically in §.7.3.) This invalidates a key assumption in prior work, i.e., that agile BPH providers operate on the basis of established reseller relationships that are visible in sub-allocations. In some cases, merchants did establish reseller relationships with an upstream provider. This allowed them to hook into an API and automate the importing and advertising process of upstream packages, rather than having to manually scrape other hosting provider's websites, in addition to receive certain discounts.

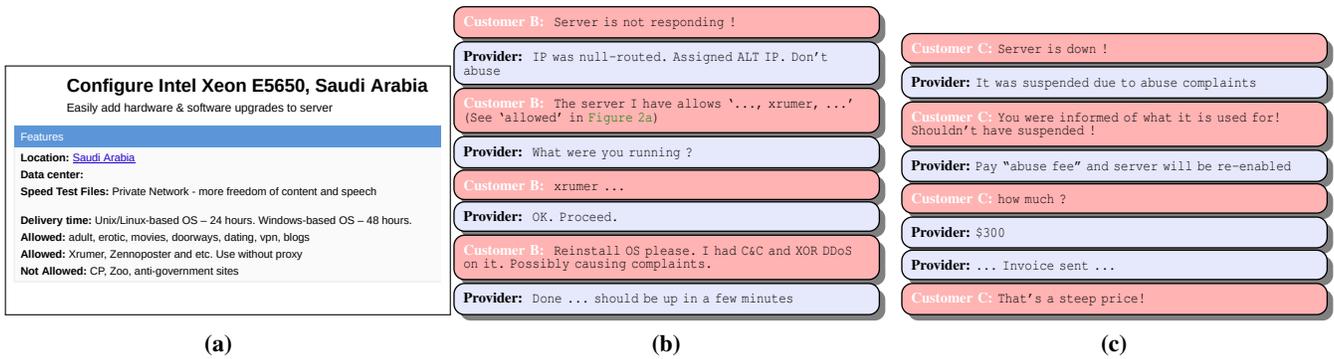

**(Upstream Providers)** These are legitimate hosting companies that offer server packages, via retail channels, auctions or reseller programs, which are put into the `MaxiDed` marketplace by the merchants. Once sold, the merchant acquires the package from the upstream provider. In §.7.3, we use WHOIS IP allocation information to infer from which upstream providers the merchants bought their packages.

**(Customers)** Customers were elicited for their preferences and guided towards server packages upon visiting `MaxiDed`'s webshop. This occurred via standard search filters or via live chat with administrators. Customers were able to request more powerful hardware, additional IP addresses, pre-installation of a specific OS, and decide on the physical location of the servers. Figure 15 (see §.14 Appendix-A) provides an excerpt of a live chat conducted by one of the authors with `MaxiDed` operators prior to its takedown demonstrating this process.

Customers would first deposit funds into a USD denominated "wallet" and then use these wallet funds to pay for the invoices that `MaxiDed` issued to them. In other words, purchases were prepaid. This structure allows merchants to place orders only after receiving payments and to shift the risks of premature contract termination to customers as they have received payments in full. Customers were not reimbursed for lost server-day usage due to premature service suspension at the upstream.

## 6.2 Side Business

`MaxiDed`'s administrators also operated a file sharing platform, known as `DepFile` [13, 20], run on servers which they rented through the `MaxiDed` marketplace. Some of these servers were also seized during the law enforcement action. Data shows that `DepFile` infrastructure was acquired using a single `MaxiDed` customer account which never paid its invoices. Over time, the account accrued approximately 400,000 USD in debt. `DepFile` allowed its customers to host and access content, some of which included child sexual abuse material, on a monthly subscription basis. Our separate analysis of internal `DepFile` data, suggest that it resembled a so called "affiliate program" [15, 21, 22] with affiliates bringing in new subscribers. The profits from subsequent sign-ups

**Figure 2:** Examples of MaxiDed’s bullet-proof behavior. (a) screenshot of server publicly advertised to customers. (b) and (c) are excerpts of a conversation between customer and administrator (edited for readability).

were shared between DepFile (a.k.a. MaxiDed) and the affiliates. As an aside: these profits were much higher than those of MaxiDed. One could argue that the MaxiDed was more valuable to its owners as a way to acquire cheap and risk-free server infrastructure than as its own profit model.

### 6.3 Examples of Bullet-Proof Behavior

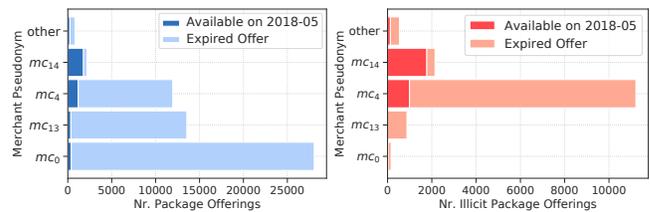

Figure 2a shows a screenshot of one of MaxiDed’s publicly advertised server packages along with descriptions of its location, network/IP-address information, price, in addition to explicit descriptions of abusive activities that were (dis-)allowed upon purchasing. Figure 2b illustrates a conversation (lightly edited for spelling) that took place between an admin and a customer in the context of a CRM ticket. Xrumer is a tool aimed at boosting search engine rankings by auto-registering accounts and posting link spam. It demonstrates that MaxiDed operators were not only explicitly tolerating abuse, but that they were informed about the abusive activities of their customers and actively supported them. This is also the case for DepFile. It knows the file sharing service is supporting illegal content, including child sexual abuse material. The customer interaction also shows the admin ignoring abuse complaints, then assisting the customer by migrating resources to a different network location. Figure 2c is another example of a (lightly-edited) conversation excerpt, demonstrating that certain customers were asked to pay an ‘abuse fee’ to continue accessing their rented server upon receiving abuse complaints.

## 7 Supply and Demand for BPH

MaxiDed’s operations deviate from certain assumptions underlying recent detection techniques. This warrants a more detailed analysis of its characteristics to understand if this new form of agile BPH exhibits chokepoints that allow for disruption. Most disruption strategies rely either on taking down the provider as a whole or on cutting off the supply of resources that it needs: servers, connectivity, payment instruments, customers. In MaxiDed’s case, the former occurred. These kinds of takedowns however, are rare and hard to scale. This section explores the alternative strategy: squeezing potential chokepoints in the supply chain.

## 7.1 Merchants

In a period of seven years, merchants offered 56,113 different server packages. Around a quarter of all packages (14,931) explicitly allowed certain kinds of abuse. We refer to these as bullet-proof (BP) packages. Note that non-BP packages were also abused, as we learned from customer tickets when servers were suspended. Admins frowned on this practice. Not because of the abuse itself, but because these customers should have purchased a more expensive abuse-allowing package. MaxiDed admins listed offers as well in the role of a merchant on their own platform. We label MaxiDed as *merchant zero* ( $mc_0$ ) and 14 third-party merchants as  $mc_{1..14}$ , identified by connecting MaxiDed’s user and supplier database tables.

**Figure 3:** Merchant Package Offerings. (left) All packages; (right) Subset of illicit packages

Figure 3 (left) illustrates the total number of server packages offered by the top 4 merchants, which accounted for 98% of all packages. At the moment of takedown (May 2018), there were 3,957 available packages. Of these, 2,921 (74%) explicitly allowed abuse. Packages expired when corresponding upstream provider packages expired or when operators no longer maintained relationships with the upstreams.

Figure 3 (right) shows the subset of server packages that allowed abuse, from the same top four merchants. This figure highlights that two merchants,  $mc_4$  and  $mc_{14}$  were responsible for 89% of all the BP packages offered on MaxiDed’s platform and 94% of the BP packages available at the moment of the takedown. Interestingly, MaxiDed itself ( $mc_0$ ) supplied only 29 BP packages (1%), relying almost exclusively on its merchants to supply BP infrastructure. This fits with our interpretation that moving to a platform model allowed MaxiDed to externalize the risk and cost of managing the relationships with upstream providers around abusive practices.

Of the 14,931 BP packages on offer, only 3,066 (20%)

were ever sold. There were 9,439 customer orders for these. This indicates that there was an oversupply of BP packages on *MaxiDed*. Sales followed a similar distribution to supply, with  $mc_4$  and  $mc_{14}$  accounting for 70% of all sales. (Of the packages that did not explicitly allow abuse, 2,006 were sold 4,832 times.)

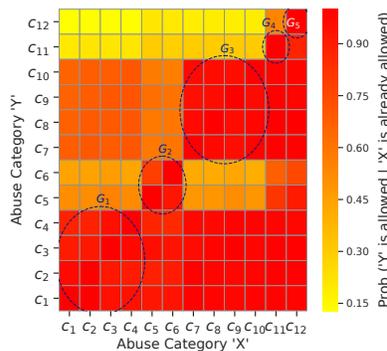

In sum, only around 20% of offers were ever sold, showing that the market for BPH is, unfortunately, not supply-constrained. *MaxiDed* externalized the supply of BP packages to merchants and two of these were dominant, in terms of supply and sales. Merchants  $mc_4$  and  $mc_{14}$  would have been viable candidates for disrupting the supply chain of the marketplace as a whole, had they been identified prior to *MaxiDed*'s takedown. This might be feasible if, as prior work assumed, they are resellers of upstream providers and WHOIS records are updated to show which network blocks are delegated to them. We later discuss evidence that, in most cases, there is no such delegation. The takedown of *MaxiDed* itself is unlikely to have disrupted these merchants. They may have taken some losses from outstanding due payments from *MaxiDed*. Except for these losses, merchants could migrate to other marketplaces, resulting in a game of whack-a-mole. This demonstrates the advantages of merchants externalizing part of their risks to the *MaxiDed* platform.

## 7.2 BP Package Categories

BP packages were differentiated in terms of what types of abuse was allowed. The platform pre-defined 12 categories of abusive activities. Merchants could tick the boxes of whatever categories they were comfortable with for their packages. The activities ranged from the distribution of pornographic content or copyrighted material, to Internet-wide scanning, running counterfeit pharmacies, running automated spamming software such as *Xrumer*, and doing IP spoofing, typically to conduct amplification DDoS attacks. *Table 3* lists these activities along with associated category labels  $C_{1..12}$ .

We suspect merchant choices for certain types of abuse to have been partly driven by what they could handle in terms of their relationship with the upstream provider of a package. Some forms of abuse trigger more backlash than others. Plus, certain upstreams might be less vigilant regarding certain forms of abuse, depending on jurisdiction or other factors.

To analyze the relationships among the allowed forms of abuse, we calculate the correlations between all categories. In other words,

**Figure 4:** Correlation of abuse categories. (See *Table 3* for  $c_i$  labels).

if category ' $c_X$ ' is allowed, what is the probability that category ' $c_Y$ ' is also allowed? The results are plotted in *Figure 4*. Five groups of server packages can be identified, each with a different type of abuse profile, which roughly corresponds to a certain risk profile. At the top end of the risk profile is "spoofing" ( $x = c_{12}$ ). Where this was allowed, everything else was also allowed with high probability (i.e., all values along the y-axis indicate high probability for  $x = c_{12}$ ). As such a highest risk group label  $G_5$  was assigned to packages that allow "spoofing". One step down are packages that allow "scanning" ( $x = c_{11}$ ): everything else is typically allowed, except "spoofing" ( $x = c_{11}, y = c_{12}$ ), which has a lower probability. This is group  $G_4$ . Next,  $G_3$  was assigned to a group composed of 4 categories,  $C_{7..10}$  which were allowed in conjunction with a high probability, and disallowed the higher risk  $c_{11..12}$  categories with a high probability. The remaining groups were created using a similar logic.

Cat.	Description	All packages	Avail. before takedown	Risk Group	Avail. per-group
$C_1$	File Sharing	12,344	2,724	$G_1$	404
$C_2$	Content Streaming	11,891	2,629		
$C_3$	WAREZ	11,856	2,615		
$C_4$	Adult Content	10,732	2,557		
$C_5$	Double VPN	10,099	1,529	$G_2$	630
$C_6$	Seedbox	8,835	1,298		
$C_7$	Gambling	2,663	1,862	$G_3$	1,279
$C_8$	Xrumer	3,120	1,849		
$C_9$	DMCA ignore	2,978	1,841		
$C_{10}$	Pharma	2,620	1,821		
$C_{11}$	Scanning	629	565	$G_4$	254
$C_{12}$	Spoofing	396	354	$G_5$	354

**Table 3:** Statistics on packages allowing each category of illicit activity and associated risk groups

For each risk group, *Table 3* lists the abuse types and the number of packages that allowed it, over the whole period of *MaxiDed* ('all packages') or at the moment of the takedown ('Avail. before takedown'). Note that packages are counted multiple times, as they often allowed multiple forms of abuse. The last column, 'Avail. per group', counts each package as belonging uniquely to one group, namely the group with the highest risk profile – e.g., if a package allows spoofing, it will be counted in  $G_5$ , but not in others, even though it likely also allows those types of activities. We can see that *MaxiDed* had a significant amount of supply in each category, with a clear peak in group 3.

A side note: the tickets and live chats clearly showed that other types of abuse were also allowed, such as running botnet C&C servers. The admins did not wish to list these forms of abuse publicly (see *Figure 15* in *S.14 Appendix-A*).

## 7.3 Merchant Upstream Providers

To understand how *MaxiDed*'s supply of BP infrastructure was distributed over legitimate upstream providers, we narrowed our analysis to 5 merchants, namely  $mc_0$ ,  $mc_4$ ,  $mc_{10}$ ,  $mc_{12}$ ,

and  $mc_{14}$ , who jointly had 94% of the BP package sales.

Merchant  $mc_{14}$  sold most of the servers associated with risk groups  $G_3$  or higher, the others sold mostly packages of group  $G_3$  and below. So  $mc_{14}$  appears to have specialized in higher risk packages.

We determined each merchant's set of upstream providers by first extracting from the data the IP addresses provisioned once the server was sold. Maxmind's historical IP WHOIS data was then used to lookup organizations to which these IP address belonged. This way, we could see how each merchant's supply chain was composed of multiple upstream providers. The variance was significant. The two dominant merchants ( $mc_{10}$  and  $mc_{14}$ ) abused 134 and 276 upstream providers, respectively. The others connected with 4 to 26 upstreams. Overall, MaxiDed's supply chain comprised of servers at 394 upstream providers.

Figure 5 show how much, or rather how little, the supply chains of merchants overlapped in terms of upstreams. Figure 6 shows a CDF of how each merchant's sold BP servers were distributed across its own set of upstream providers. Across all merchants, 15 upstream hosted 50% of all sold BP servers and 57 account for 80% of all sold servers.

At first glance, the concentration in 15 upstream providers suggests a choke-point that could be leveraged, but the long tail of available upstreams makes this strategy not very promising. Merchants could shift supply to those hundreds of alternatives. The 15 top ones might have certain advantages in terms of location, price and quality, but only 5 of them are shared between the two top merchants, so there does not seem to be a unique advantage to these providers.

Recent BPH detection approaches [5] have relied on upstream providers updating WHOIS records when they delegate network blocks to resellers. As stated, our data suggested that merchants often do not enter into reseller agreements with upstream. That would seriously undermine the effectiveness of these detection methods. To test this more systematically, we looked at the set of upstream providers that hosted 80% of the BP servers (57). In this set, we found 22 which are reputable upstream providers and more likely to reflect sub-allocations to their clients in WHOIS. We randomly sampled 10 BP servers for each of these 22 providers and manually inspected their IP WHOIS information. In only

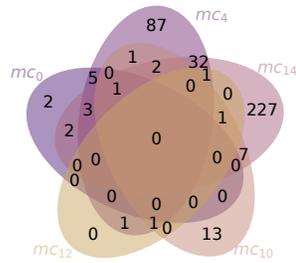

Figure 5: Upstream Overlaps

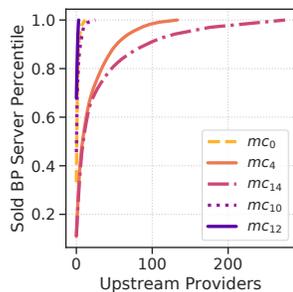

Figure 6: BP Server Distribution over Upstream Providers

24% of the cases did the WHOIS information reflect sub-allocation to downstream entities. Note that these downstream entities might also be legitimate resellers who sold to the merchants, rather than being the merchants themselves. Also, none of the records pointed to MaxiDed. This means that in 76% of the cases, the BP activities could not be associated with a sub-allocation, thus evading the current best detection method. Abuse on these addresses would be counted against the upstream provider, typically diluting the detectable concentration of abuse. Establishing a relationship between the upstream provider, their downstream customers, merchants and, ultimately, MaxiDed, would have been impossible with this kind of data.

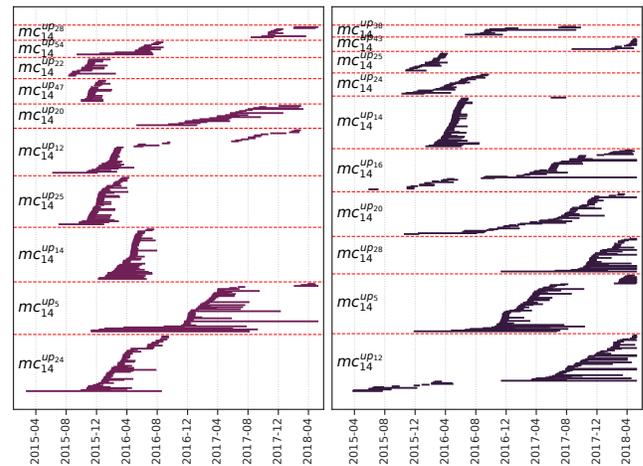

Figure 7: 10 most misused upstream providers via which  $mc_{14}$  provisioned BP servers of risk group  $G_4$  (allowing "scanning" - left) and  $G_5$  ("spoofing" - right), plotted against server lifespans at each provider. Each colored line represents the lifespan of one server.

We next examined the distribution of each merchant's sold BP servers and server life spans across their corresponding upstream providers longitudinally. We visualize some of the results for  $mc_{14}$ , who was specialized in selling higher risk BP servers. Figure 7 plots the lifespan of  $mc_{14}$ 's sold BP servers that allowed "scanning" (left) and "spoofing" (right) for its 10 most misused upstream providers.

Figure 7 demonstrates that the merchant's BP customer servers were spatially as well as temporally spread across multiple upstream providers. It also shows that at no point in time, was there a shortage in the supply of servers even for the higher risk server packages. We observe no timeline gap during which servers of a particular group were not provisioned and active. We clearly observe a supply chain that was diversified, yet proportionally concentrated on a limited set of upstream providers. This approach of the merchant seems to be driven by a combination of efficiency in working with a limited set of upstreams and the flexibility of migrating from one upstream to the next, once the cost of working with that provider went up, perhaps because of mounting abuse complaints.

## 7.4 Payment Instruments

Next, we analyze the various payment instruments to identify potential chokepoints. From analyzing the source code of the webshop and the transactions in the database, we know that MaxiDed accepted payments via 23 different instruments. Three of these were actually never used by customers: Bitcoin Gold, Electroneum and Kubera Coin. Eight payment options were provided for a limited time and then discontinued by MaxiDed. At the moment of its takedown, 12 payment options were available. Some of these instruments, e.g., Paypal, were later restricted to specific groups of customers. Payments through Yandex Money were generally restricted to clients from Russia.

Figure 8 reconstructs transaction volumes over time for 20 payment instruments based on timestamps of financial transactions in the data. It plots a logscale of the number of transactions in each month. The Y-axes are the same for all instruments. First, we see that WebMoney has been a consistent and reliable payment provider for MaxiDed, basically from the start. Other instruments from that period proved more problematic. For example, Paypal became much more difficult to use in the course of 2015 and was abandoned completely in early 2018. We can see the operators deploying new ones and also abandoning some of them again. This process seems to suggest responding to potential or manifest disruptions via payment providers. Consistent with this interpretation is the increase in options to pay with cryptocurrencies. We first see a major shift to bitcoin at the end of 2013. Then, around the end of 2017, MaxiDed added 8 new cryptocurrencies. A preference to move to cryptocurrencies was also observed in backend data, where MaxiDed’s operators maintained an explicit preference order for the different payment methods.

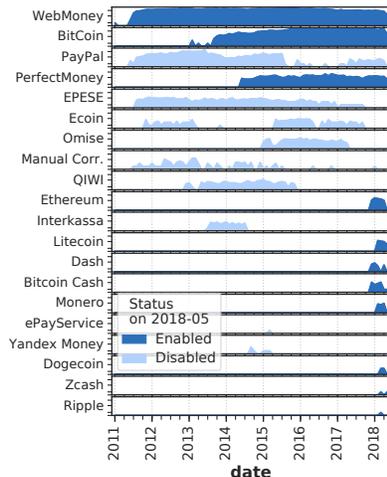

Figure 8: Payment instrument monthly transaction volume

Figure 9 plots the cumulative generated revenue for the top 5 most popular payment instruments. While WebMoney had brought in the most revenue, the total amount of bitcoin payments was growing rapidly and poised to overtake the leading position, until the takedown happened.

All in all, MaxiDed’s revenue was generated through a small set of payment methods. The bulk of their cus-

tomers used only one payment method. Disruption of MaxiDed’s payment flow via WebMoney would have been a viable chokepoint in earlier phases. The self-imposed limits on using Paypal probably reflect the fact that those payments were vulnerable to countermeasures by Paypal.

The shift towards cryptocurrency payments demonstrates that MaxiDed recognized this dependency, as well as illustrates how it was attempting to remediate it. It is clear that this shift makes

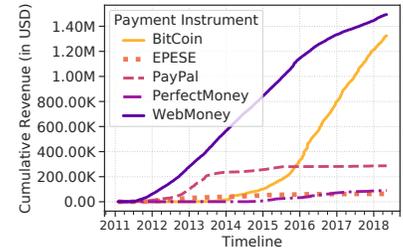

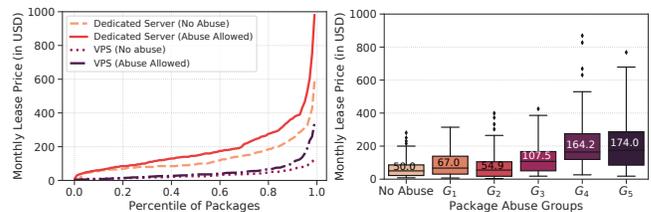

Figure 9: Revenue

disruption more difficult, though it is hard to gauge how resilient the bitcoin payment option actually was. This would require a study of the blockchain and the role of currency exchanges, which is out of scope for this study. That being said, the proliferation of cryptocurrency options might counteract the vulnerabilities associated with each specific instrument.

## 7.5 Package Pricing

BPH businesses are typically understood as charging customers high markup prices for allowing illicit activities and offering protection against takedowns. There is anecdotal evidence (e.g., [2, 5]) that suggests prices are well above those for bonafide services. Our data, however, questions this widely-held understanding.

We first distinguished VPS packages from physical dedicated servers. In each category, we then compared the distribution of the monthly lease price of packages that allowed abuse versus those that did not. The results are plotted in Figure 10a. We observe that indeed abuse-enabling servers cost more, but the difference are modest across most of the distribution. For dedicated servers, the median price was 95.00 USD for non-BP packages and 146.00 USD for BP packages. For virtual servers, the median prices were 25.00 USD versus 35.00 USD. These numbers suggest that customers paid a median markup ranging from 40% to 54% for being allowed to abuse. This includes both the fee of MaxiDed as well as the margin of the merchant. The rest goes to the upstream provider.

(a) Price per package type (b) Price per risk group

Figure 10: Package pricing (See Table 3 for risk group labels).

We also compared package prices based on associated risk

groups of their packages. Figure 10b illustrates the results with median group prices indicated in the plot. Here, we observe larger prices differences. The median price of the highest risk packages are 3.5 times higher than those for the non-abuse packages.

The limited markup seen in the lower risk packages might reflect the fact that the platform has an oversupply of BP packages. Many packages never got sold. The platform also sets up the merchants to compete with each other. All of this might push prices down, towards the cost of the upstream package. Relatively low markup might also reflect less cost on the side of the merchant and marketplace because of takedown. Low prices may also be the result of MaxiDed's business model which pushes takedown risks to customers by requiring prepayment.

## 8 Customers

Law enforcement takedowns of online anonymous markets (a.k.a., dark markets) have targeted the platforms, the supply chains, but also the customers on these platforms, in an attempt to disrupt the demand side. The most ambitious operation was the coordinated Alphabay-Hansa market action, which de-anonymized many merchants and buyers [23]. As of yet, it is unclear if these actions will have any impact on the demand for these services. Nevertheless, we will take a closer look at the population of MaxiDed customers to understand how demand has evolved over time and whether it offers starting points for disruption.

MaxiDed's registration data shows that 308,396 unique users signed up to its platform. Figure 11 plots the cumulative number of registered, active and paying users over time. We find three outlier events, during which a large number of users appear to have been artificially created, that distort the numbers. Only 6,782 of the user population ever purchased server packages. Of these, 4,498 users were active in the sense that they logged into the platform's CRM at least once after having signed up. On average, the platform saw a daily growth of 3 user sign ups, excluding the three outlier events.

Cross referencing the user data, customer orders, and server package data, we find that the majority of the customers were interested in and may have engaged in abusive activities.

This is observable in Figure 12 (left) which plots the cumulative number of customers, separating out those that eventually ended up purchasing BP servers. In the earlier stage of MaxiDed's evolution, they still had a significant number of customers

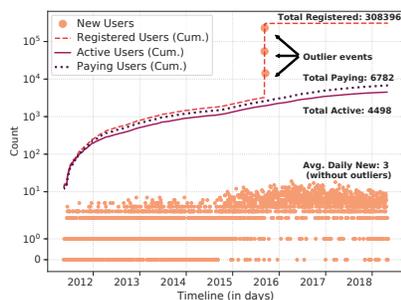

Figure 11: User number over time

who never bought BP packages. A few years in, they attract an increasing number of users that do buy BP packages. At the time of its disruption, 66% of all customers ever to register had purchased BP packages. The remaining 34% was a mix of bonafide customers and customers who may have undertaken abusive activities on non-BP packages.

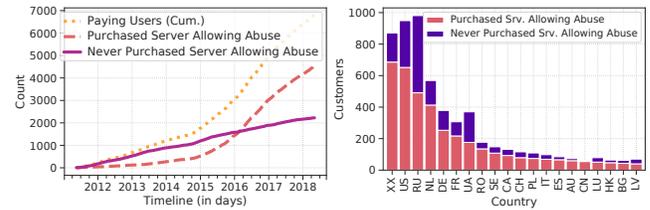

Figure 12: (left) Customer types; (right) Customer locations (XX = Location not specified)

Customers could specify language preferences in their profile: 5,085 selected English and 1,697 selected Russian. They were also asked to supply location information. Assuming that user-specified locations are correct, a crude assumption, then most users came from 3 countries, namely RU, US and NL (see Figure 12 - right), followed by a long tail of other countries.

## 9 Use and Abuse

Next, we explore server use and abuse by customers. We examine how customers manage takedown risks transferred to them by MaxiDed and look at the measure of last-resort, namely blacklisting BP servers once they are detected.

### 9.1 In Demand Abuse Categories

Our data contains timestamps of when servers were provisioned and when they were taken offline. Servers were deactivated when their lease expired or when abuse complaints caused the upstream provider to terminate the lease early.

Figure 13 plots the number of active servers across various risk profiles. It shows what customers mostly sought to purchase.

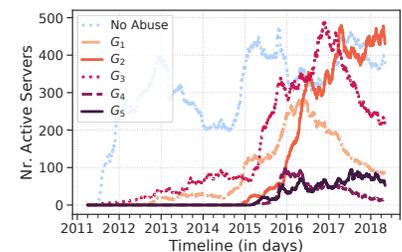

Figure 13: Active servers

After a start as a legitimate provider, BP servers become dominant over time (see Figure 13). Initially, customers were interested in spamming, operating phishing domains (which triggered DMCA complaints), running counterfeit pharma and gambling sites (risk profile  $G_3$ ). Then we see a steady growth in demand for  $G_1$ : file sharing, streaming, adult content, and WAREZ forums. The rapid growth of MaxiDed, starting around the end of 2014, saw a diversification of the abuse and an increase of VPNs and seedboxes for file sharing ( $G_2$ ),

scanning ( $G_4$ ), and spoofing ( $G_5$ ). These shifts reflect a wider trend towards commoditization of cybercrime services, such as the provisioning of DDoS-as-a-Service [1]. At its peak, MaxiDed administered 1,620 active BP and non-BP servers.

## 9.2 Abusive Server Uptime

MaxiDed and its merchants shifted the risk of takedown to their customers. They required prepayment, offered no reimbursements, and provided minimal resilience support with considerable attached “abuse fees”.

Risk Profile	Payment Cycle (days)	Premature Termination (%)	Expired (%)	Extended (%)	Lost Usage (Median # days)	Total (# servers)
No Abuse	91.0	15.69	38.77	45.54	10	4,831
$G_1$	92.0	18.23	47.39	34.38	23	1,437
$G_2$	90.0	23.04	52.22	24.74	28	2,834
$G_3$	61.0	19.59	45.86	34.55	13	3,792
$G_4$	46.0	15.41	48.39	36.20	3	558
$G_5$	31.0	19.15	54.73	26.12	6	804

Table 4: Server lifespan statistics

How do customers deal with this risk? In essence: by choosing shorter lease periods for more risky activities. Table 4 lists the median lease periods that customers opt for across various risk groups. The more risky the abuse, i.e., the higher the probability of a takedown, the shorter the lease time. The table also provides statistics on the proportions of BP servers that were prematurely terminated due to abuse complaints, proportions of lease expirations, extensions, in addition to the number of usage days that customers lost from termination of their lease. Customers with the most risky activities manage to mitigate the cost of takedown to a median of 6 lost days.

We also see that at most 23% of the BP servers were prematurely taken down. Most BP server ran uninterrupted for their entire lease period. This speaks to the low rate of blacklisting, questioning the effectiveness of this practices in disincentivizing abuse. An interesting pattern is that customers also abused servers that did not allow abuse. 15% of these servers were also taken down.

Overall 2,656 servers were deactivated prior to the expiry of their lease plan. Another 6,483 active servers were deactivated when they reached their normal expiry term. 5,117 servers remained active beyond their initial lease plan.

## 9.3 Detected Abusive Resources

We next explore a final chokepoint: blocking the BP servers and abusive content hosted on them once they are discovered.

We triangulated these results by looking directly at several blacklists. We used three years of passive DNS data from Farsight Security’s DNSDB to identify domain based resources on MaxiDed’s IP addresses: fully qualified domain names (FQDNs) and 2<sup>nd</sup>-level domains (2LDs). Table 5 lists the quantities of resources associated with MaxiDed from 2016 to 2018. This period corresponds to when MaxiDed had the

highest number of active servers. We examined the intersection between these resources and those flagged or blocked by several leading industry abuse feeds. The feeds capture a mix of spam, phishing, malware and botnet C&C abuse. Detailed information on these feeds is provided in Table 5. The quantities of flagged MaxiDed customer resources within each of these abuse feeds are also listed in the table. When no historical feed data was available, we left the cell empty.

While coverage of blacklists is known to be limited, it is quite disappointing to see the small fraction of the abuse that gets picked up by the feeds. This confirms, with ground truth, the observation in prior work that blacklisting is generally ineffective in disrupting abuse.

## 10 Marketplace Finances

Disruption of BPH is also determined by how profitable the business is. Lower margins mean that the provider is more vulnerable to raised operating costs in the supply chain. In this section, we analyze MaxiDed’s revenue, costs and profits. To get a sense of the company as a whole, we include both BP and non-BP services.

**(Revenue.)** From the 23 different payment instruments employed by MaxiDed, most of its revenue was received via WebMoney payments (1,493,876 USD) followed by direct BitCoin payments (1,324,449 USD, MaxiDed itself logged these in USD). Around 577,118 USD was received through the remaining payment instruments. The total amount of revenue from 2011 up to May 2018, adds up to 3.4M USD.

**(Operating Costs.)** We have no data on personnel cost at MaxiDed. Here, we analyze the outgoing payments to merchants, upstreams and outstanding debts recorded in the database.

i) *Payments to Merchants.* A main component of MaxiDed’s cost structure consists of payments to merchants. Merchant payments were exclusively deposited on WebMoney and Epayments wallets. After MaxiDed took their 20% fee, the remaining 80% went to the merchants. Analyzing outgoing MaxiDed payments show 11 of the 14 operating merchants to have received payments, adding up to 1,588,810 USD. Figure 14 illustrates the distribution of payments made to each merchant. The two largest suppliers of server packages,  $mc_4$  and  $mc_{14}$ , received the bulk of the earnings. Most of the merchants were completely unsuccessful. The lowest earners, combined, generated less than 190K USD over all years.

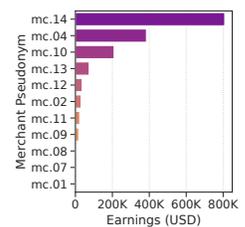

Figure 14: Payments to merchants.

ii) *Payments to Upstreams.* We cannot see the payments of third-party merchants to their upstreams, only the payments where MaxiDed is itself a merchant on the platform ( $mc_0$ ). Data shows that  $mc_0$  payments to their upstreams add up to 1,526,015 USD, paid via WebMoney

Year	Hosted resources			Number flagged resource in abuse feed																	
	IPs FQDN 2LD			PHTK <sup>1</sup>			APWG <sup>2</sup>			SBW <sup>3</sup>			GSB <sup>4</sup>			DBL <sup>5</sup>			CMX <sup>6</sup>		
	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)	(IP)	(FQDN)	(2LD)
2016	985	9,902	3,378	2	1	32	29	45	75	12	10	23	.	.	.	.	.	.	85	185	201
2017	906	15,494	3,573	5	2	18	1	4	23	.	.	.	4	63	71	40	644	696	22	20	51

Table 5: Statistics on flagged or blocked MaxiDed customer resources

and PayPal. Note that 99% of these payments were not for BP servers, as those were almost exclusively provided by the third-party merchants.

iii) *Debtors.* The final component of MaxiDed’s costs structure is that of outstanding debts due from its customers. The operators have vigilantly banned customers with outstanding debts. One customer was the exception to this rule. Actually, this was not a real customer, but a customer account through which MaxiDed operators themselves purchased servers from merchants on their platform. These were used to host DepFile, their large file-sharing platform side-business. This customer entity accumulated debts amounting to 399,123 USD.

(Profits.) Table 6 details MaxiDed’s yearly finances, alongside finances of their side business DepFile. Despite the common understanding of BPH services being lucrative, we clearly observe MaxiDed’s earnings to be modest and declining. In total, over seven years, MaxiDed made just over 280K USD in profit. If we take out the debt incurred for the DepFile side-business (399,123 + 280,618), then the profit would have been 679,741 USD. This is still an underwhelming figure for 7 years of operating a BPH platform. Recall that the cost of personnel, office space, and equipment also has to be taken from this amount. These combined costs would have to be substantially lower than 100K USD per year to leave even a tiny profit on the balance sheet.

Year	MaxiDed			DepFile			$(\Sigma Prof_{.i})$
	Revenue	Costs	Prof <sub>mx</sub>	Revenue	Costs	Prof <sub>dp</sub>	
2011	79,987	1,312	78,675	.	.	.	78,675
2012	345,213	72,418	272,794	.	.	.	272,794
2013	458,028	17,9761	278,266	334,540	248,307	86,233	364,499
2014	419,739	328,757	90,981	1,646,568	712,442	934,125	1,025,106
2015	615,046	570,895	44,150	2,205,687	1,396,820	808,867	853,017
2016	733,151	726,040	7,111	3,153,553	2,188,634	964,919	972,030
2017	566,471	872,520	-306,048	3,998,244	2,841,322	1,156,922	850,874
2018	177,806	363,118	-185,312	1,547,078	1,129,586	417,492	232,180
<b>Total</b>	<b>3,395,444</b>	<b>3,114,825</b>	<b>280,618</b>	<b>12,885,673</b>	<b>8,517,113</b>	<b>4,368,560</b>	<b>4,649,178</b>

Note: (mx: MaxiDed) (dp: DepFile)

Table 6: Yearly finances

The side-business DepFile, on the other hand, generated much better margins. We could even speculate that MaxiDed was more valuable to its owners as a way to acquire cheap and risk-free server infrastructure than as its own profit model.

## 11 Related Work

(Underground Ecosystems.) Several ecosystems and marketplaces of a malicious nature have been studied in the literature via captured datasets. Stone-Gross et al. analyzed credential stealing malware [29] and spam botnets [14] by taking over part of the botnet infrastructure to understand their inner workings. Wang et al. studied SEO campaigns to sell counterfeit luxury goods and the effectiveness of various interventions to combat such activities [30]. Alrwais et al. [34] investigate illicit activities in the domain parking industry by interacting with the services to collect ground truth data. Christin [31] analyzed the Silk Road marketplace by running daily crawls of its webservices for 6 months to understand merchants, customers, and what was being sold. A followup study by Soska and Christin [32] examined 16 anonymous market places also by periodically crawling their webservices and found that marketplace takedowns may be less effective than pursuing key merchants that may migrate to others. Another followup study by Wegberg et al. [33] augments previous studies by examining evidence for commoditization of entire cybercrime value-chains in underground marketplaces and finds that only niche value-chain components are on offer.

Datasets on the underground can also be leaked by criminal competitors. McCoy et al. used leaked databases of three affiliate programs to study pharmaceutical affiliate programs [15]. More recently, Brunt et al. [35] analyzed data from a DDoS-for-hire service and found that disrupting their regulated payment channel reduced their profitability but that they were still profitable by switching to unregulated cryptocurrency payments. Hao et al. [16] analyzed a combination of leaked and legally seized data to understand the ecosystem for monetizing stolen credit cards. Our dataset resulted from the aftermath of the legal takedown of the BPH provider MaxiDed. To the best of our knowledge, there has been no prior academic work on BPH using such ground-truth data. Our study uniquely provides a comprehensive picture of the supply, demand and finances of the entire BPH operation.

(Bulletproof hosting.) Earlier efforts on detecting BPH have relied heavily on identifying autonomous systems. Fire [9] was one of the first systems for detecting BP ASes by temporally and spatially aggregating information from multiple blacklists in order to detect elevated concentrations of persistent abuse within an AS’s IP blocks. Shue et al. [36] noted that BP ASes often fast-flux their BGP routing information to evade detection. ASwatch [11] leveraged fast-fluxing

BGP routing as strong indicator of a BP AS to build a classifier and detect BP ASes before they appear on blacklists. Others have developed security metrics to compare concentrations of abuse on various hosting networks and to identify negligent providers that may be suspected of operating BPH services [37, 38], while Tajalizadehkhoob et al. developed techniques to analyze abuse concentration on the hosting market as a whole by identifying providers from their WHOIS information rather than BGP data [39]. BPH however, has evolved over time. Alrwais, et al.[5] studied a recent approach of BPH abusing legitimate hosting providers through reseller packages to provide a more agile BP infrastructure. Our work complements this work by providing a unique perspective into to the the ecosystem of BPH. Based on our analysis, we can better reason about which mitigation techniques might be effective and which are likely ineffective for undermining modern agile BPH marketplaces.

## 12 Limitations and Future Work

In comparison to other underground marketplaces studied previously (cf. [32, 33]), `MaxiDed` may be seen as a specialized marketplace for provisioning BP servers. While comparisons with other underground markets may be drawn, direct comparisons are difficult due to differences in how `MaxiDed`'s marketplace operated. For example its customers were not aware that merchants were involved in supplying the marketplace with resources. This also explains why in comparison no reputation mechanisms were in place for customers to differentiate packages based on their quality (or differentiate good/bad merchants).

Despite such differences, we do still observe patterns similar to what other studies of criminal endeavors have reported. For example, we have observed a concentrated supply pattern around a handful of merchants in `MaxiDed`'s case, which is a similar to what other studies of underground market places have observed ([32, 33]). We have also observed demand to gravitate towards the resources supplied by successful merchants. The number of successful merchants being limited, also agrees with studies of other criminal operations, e.g. in studying spam botmasters and their operations [14].

Given that this study has focused on an in-depth analysis of the anatomy and economics of `MaxiDed`, future work may draw more systematic comparisons to better understand the implications of what we has been reported here. Furthermore, `MaxiDed`'s prominence within the ecosystem has also not been systematically explored in our study, albeit the limited comparisons with other BPH providers in addition to anecdotal evidence [4, 13] suggest that `MaxiDed` may be reasonably considered as a major provider within the ecosystem. Nevertheless, some of our findings, particularly those relating to the economics and profitability of BPH services may require further research to better understand the BPH ecosystem as a whole.

## 13 Discussion and Implications

**(Discussion.)** We found `MaxiDed` to have developed a new agile model in response to detection and disruption strategies. Its operations had matured to the point of a new innovation, namely operating a marketplace-like platform for selling BPH services. This model transfers the risks of acquiring the BP server infrastructure from upstream providers to merchants. `MaxiDed`'s main role was to take on the risks of acquiring customers, communicating with them and processing their payments. The 14 merchants on the platform (over)-supplied the market with more than 50K different server packages, many of which expired without being purchased. They abused a total of set 394 different upstream providers, thus allowing merchants to spread out and rotate abuse across many different legitimate networks.

We see some concentration in this supply chain, with 15 upstreams providing infrastructure for over 50% of the BP servers sold. Most of these upstream resources are not shown to be delegated in WHOIS, drastically curtailing the effectiveness of the most recent detection approaches. Another point of concentration is in the merchant pool: two merchants offered 89% of all BP servers and made 94% of the BP packages sales. Most other `MaxiDed` merchants failed to generate any meaningful sales. The platform deployed 23 different instruments to transact with customers over various periods. Revenue was initially largely processed by one payment settlement system: `WebMoney`. We also saw an increased volume of `BitCoin` payments and the adoption of other cryptocurrencies in response to disruptions in other instruments, such as `PayPal`. A lack of product differentiation on the market is likely to have created a fierce price competition across the merchants which in turn has led a great proportion of merchants to fail. This competition also decreases the profits of not only the merchants, but also of `MaxiDed` itself. Its profits, over seven years, amounted to a mere 280K USD (or 680K USD if we ignore cross subsidies to their other business, `DepFile`). The actual profits are even lower, as this amount also has to cover the cost of personnel, office space and equipment, on which we had no data.

**(Implications.)** Bullet-proof hosting (BPH) companies remain a difficult problem as their operators adapt to evade detection and disruption. Prior work in this area has largely relied on external measurements and generally lacks ground-truth data on the internal operations of such providers. Recent detection techniques rely on certain assumptions, namely that agile BPH operates under reseller relationships, and that upstream providers accurately reflect such relationships in their WHOIS information. We found `MaxiDed` to deviate from both assumptions, thus rendering detection less effective.

Prior BPH instances were mainly disrupted by pressuring upstream providers to sever ties with downstream BPH providers. Given the number of available substitute upstream providers of `MaxiDed`, this is unlikely to be an effective choke-

point. Drawing parallels with other underground markets suggest that, other than taking down the platform itself, disruption may also be achieved by pressuring other chokepoints: merchants, revenue and demand. MaxiDed's dominant merchants would have been a viable chokepoint, yet, identifying them most likely required internal operational knowledge as their existence and identities were not externally visible. As for disrupting payment channels, the transition to mostly unregulated cryptocurrencies payments suggest that this is no longer a straightforward option. Surprisingly, MaxiDed's low profits indicate that an increase in transaction or operating costs may be viable a pressure point to disrupt revenue and demand. Future work could explore how to raise these costs. Being aware of the threat of criminal prosecution might, ironically, be one way.

The final remaining pressure point would be to take down the platform. Such takedowns however are hard to replicate, let alone scale. That being said, MaxiDed explicitly marketed bullet proof services on the clear web. Even in cases when criminal prosecution itself is not feasible, if the threat can be made plausible, it might force the company to operate within higher op sec requirements, raising the cost of doing business. This suggests that what appears the more difficult strategy might actually be the best option in light of the supply chain becoming even more agile and evasive. Our hope is that by further studying and understanding of these emerging agile BPH services we can inform new and potentially more effective directions for mitigating this threat. To orient future work in this area, researchers might be better off deprecating the increasingly misleading metaphor of "bullet-proof" hosting in favor of a term like "agile abuse enablers".

**Acknowledgments** The authors would like to thank the anonymous reviewers of our study for their feedback and suggestions to improve the quality of our manuscript. We greatly appreciate the data sharing efforts of Farsight Security, and other organizations including Phishtank, APWG, Stopbadware, Spamhaus and CleanMX that have provided us with passive DNS and the abuse data on which parts of this study are based. We would like to thank the Dutch National High-Tech Crime Police unit for making this study possible as well as the Dutch Ministry of Economic Affairs and SIDN for supporting our research. Finally, we acknowledge funding support under NSF award number 1717062, DHS S&T FA8750-19-2-0009, and gifts from Comcast and Google.

## 14 Appendices

### A - Customer Preference Elicitation

Figure 15: Chat excerpt illustrating customer preference elicitation.

Figure 15 illustrates an excerpt of a live chat (edited for readability) conducted by one of the authors with MaxiDed

operators prior to its takedown. It shows the process of preference elicitation by `MaxiDed` operators.

The conversation was conducted using the live-chat functionality on their webshop. It demonstrates that `MaxiDed` operators may have also allowed other forms of abuse which they did not publicly mention on their webshop along side the various BP server packages that the platform advertised.

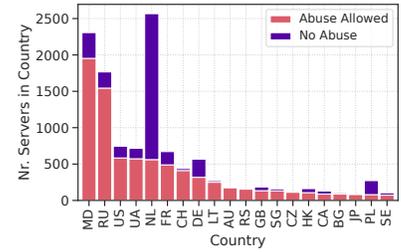

### B - Geographical distribution of Customer Servers

In analyzing `MaxiDed`'s platform, we also examined where its customer servers were located. We used Maxmind's commercial historical geo-location data for this purpose. This data is available on a weekly basis. For each customer server we first found the closest matching Maxmind IP geolocation database with the timespan during which the server was active. We then determined where each server was located based on its IP address and Maxmind's datasets. [Figure 16](#)

plots the top-20 locations for `MaxiDed`'s customer servers.

We found that the majority of the BP servers geolocated to Moldova followed by Russia, the US, Ukraine, the Netherlands and a long tail of other countries.

[Figure 16](#) also displays the number of non-BP servers in each of these top-20 locations. We observed that the Netherlands in particular hosted a substantial number of the non-BP servers.

**Figure 16:** Top-20 locations for `MaxiDed` customer servers

# Protecting Cloud Virtual Machines from Commodity Hypervisor and Host Operating System Exploits

## Abstract

Hypervisors are widely deployed by cloud computing providers to support virtual machines, but their growing complexity poses a security risk as large codebases contain many vulnerabilities. We have created HypSec, a new hypervisor design for retrofitting an existing commodity hypervisor using microkernel principles to reduce its trusted computing base while protecting the confidentiality and integrity of virtual machines. HypSec partitions the hypervisor into an untrusted host that performs most complex hypervisor functionality without access to virtual machine data, and a trusted core that provides access control to virtual machine data and performs basic CPU and memory virtualization. Hardware virtualization support is used to isolate and protect the trusted core and execute it at a higher privilege level so it can mediate virtual machine exceptions and protect VM data in CPU and memory. HypSec takes an end-to-end approach to securing I/O to simplify its design, with applications increasingly using secure network connections in the cloud. We have used HypSec to retrofit KVM, showing how our approach can support a widely-used full-featured hypervisor integrated with a commodity operating system. The implementation has a trusted computing base of only a few thousand lines of code, many orders of magnitude less than KVM. We show that HypSec protects the confidentiality and integrity of virtual machines running unmodified guest operating systems while only incurring modest performance overhead for real application workloads.

## 1 Introduction

The availability of cost-effective, commodity cloud providers has pushed increasing numbers of companies and users to move their data and computation off site into virtual machines (VMs) running on hosts in the cloud. The hypervisor provides the VM abstraction and has full control of the hardware resources. Modern hypervisors are often integrated with a host operating system (OS) kernel to leverage existing kernel functionality to simplify their implementation and

maintenance effort. For example, KVM [44] is integrated with Linux and Hyper-V [56] is integrated with Windows. The result is a huge potential attack surface with access to VM data in CPU registers, memory, I/O data, and boot images. The surge in outsourcing of computational resources to the cloud and away from privately-owned data centers further exacerbates this security risk of relying on the trustworthiness of complex and potentially vulnerable hypervisor and host OS infrastructure. Attackers that successfully exploit hypervisor vulnerabilities can gain unfettered access to VM data, and compromise the privacy and integrity of all VMs—an undesirable outcome for both cloud providers and users.

Recent trends in application design and hardware virtualization support provide an opportunity to revisit hypervisor design requirements to address this crucial security problem. First, modern hardware includes virtualization support to protect and run the hypervisor at a higher privilege level than VMs, potentially providing new opportunities to redesign the hypervisor to improve security. Second, due to greater security awareness because of the Snowden leaks revealing secret surveillance of large portions of the network infrastructure [49], applications are increasingly designed to use end-to-end encryption for I/O channels, including secure network connections [29, 50] and disk encryption [14]. This is decreasing the need for hypervisors to themselves secure I/O channels since applications can do a better job of providing an end-to-end I/O security solution [68].

Based on these trends, we have created HypSec, a new hypervisor design for retrofitting commodity hypervisors to significantly reduce the code size of their trusted computing base (TCB) while maintaining their full functionality. The design employs microkernel principles, but instead of requiring a clean-slate rewrite from scratch—a difficult task that limits both functionality and deployment—applies them to restructure an existing hypervisor with modest modifications. HypSec partitions a monolithic hypervisor into a small trusted core, the *corevisor*, and a large untrusted host, the *hostvisor*. HypSec leverages hardware virtualization support to isolate and protect the corevisor and execute it at a higher privilege

level than the hostvisor. The corevisor enforces access control to protect data in CPU and memory, but relies on VMs or applications to use end-to-end encrypted I/O to protect I/O data, simplifying the corevisor design.

The corevisor has full access to hardware resources, provides basic CPU and memory virtualization, and mediates all exceptions and interrupts, ensuring that only a VM and the corevisor can access the VM's data in CPU and memory. More complex operations including I/O and interrupt virtualization, and resource management such as CPU scheduling, memory management, and device management are delegated to the hostvisor, which can also leverage a host OS. The hostvisor may import or export encrypted VM data from the system to boot VM images or support hypervisor features such as snapshots and migration, but otherwise has no access to VM data. HypSec redesigns the hypervisor to improve security but does not strip it of functionality. We expect that HypSec can be used to restructure existing hypervisors by encapsulating much of their codebase in a hostvisor and augmenting security with a corevisor.

We have implemented a HypSec prototype by retrofitting KVM. Our approach works with existing ARM hardware virtualization extensions to provide VM confidentiality and integrity in a full-featured commodity hypervisor with its own integrated host OS kernel. Our implementation requires only modest modifications to Linux and has a TCB of only a few thousand lines of code (LOC), many orders of magnitude less than KVM and other commodity hypervisors. HypSec significantly reduces the TCB of an existing widely-used hypervisor and improves its security while retaining the same hypervisor functionality, including multiprocessor, full device I/O, multi-VM, VM management, and broad ARM hardware support. We also show that HypSec provides strong security for VMs running unmodified guest operating systems while only incurring modest performance overhead for real application workloads.

## 2 Assumptions and Threat Model

**Assumptions.** We assume VMs use end-to-end encrypted channels to protect their I/O data. We assume hardware virtualization support and an IOMMU similar to what is available on x86 and ARM servers in the cloud. We assume a Trusted Execution Environment (TEE) provided by secure mode architectures such as ARM TrustZone [7] or a Trusted Platform Module (TPM) [38] is available for trusted persistent storage. We assume the hardware, including a hardware security module if applicable, is bug-free and trustworthy. We assume the HypSec TCB, the corevisor, does not have any vulnerabilities and can thus be trusted. Given the corevisor's modest size as shown in Section 6.3, it may be possible to formally verify the codebase. We assume it is computationally infeasible to perform brute-force attacks on any encrypted VM data, and any encrypted communication protocols are assumed to be designed to defend against replay attacks. We assume the system is initially benign, allowing signatures and keys

to be sealed in the TEE before a compromise of the system.

**Threat Model.** We consider an attacker with remote access to a hypervisor and its VMs, including administrators without physical access to the machine. The attacker's goal is to compromise the confidentiality and integrity of VM data, which includes: the VM boot image containing the guest kernel binary, data residing in memory addresses belonging to guests, guest memory copied to hardware buffers, data on VM disks or file systems, and data stored in VM CPU registers. VM data does not include generic virtual hardware configuration information, such as the CPU power management status or the interrupt level being raised. An attacker could exploit bugs in the hostvisor or control the VM management interface to access VM data. For example, an attacker could exploit bugs in the hostvisor to execute arbitrary code or access VM memory from the VM or hypervisor host. Attackers may also control peripherals to perform malicious memory access via direct memory access (DMA). We consider it out of scope if the entire cloud provider, who provides the VM infrastructure, is malicious.

A remote attacker does not have physical access to the hardware, so the following attacks are out of scope: physical tampering with the hardware platform, cold boot attacks [31], memory bus snooping, and physical memory access. These threats are better handled with on-site security and tamper-resistant hardware; cloud providers such as Google go to great lengths to ensure the physical security of their data centers and restrict physical access even for administrators [28]. We also do not defend against side-channel attacks in virtualized environments [39, 53, 65, 93, 94], or based on network I/O [10]. This is not unique to HypSec and it is the kernel's responsibility to obfuscate such patterns with defenses orthogonal to HypSec.

We assume a VM does not voluntarily reveal its own sensitive data whether on purpose or by accident. A VM can be compromised by a remote attacker that exploits vulnerabilities in the VM. We do not provide security features to prevent or detect VM vulnerabilities, so a compromised VM that involuntarily reveals its own data is out of scope. However, attackers may try to attack other hosted VMs from a compromised VM for which we provide protection.

## 3 Design

HypSec introduces a new hypervisor design that reduces the TCB necessary to protect VM confidentiality and integrity while retaining full-fledged hypervisor functionality. We observe that many hypervisor functions can be supported without any access to VM data. For example, VM CPU register data is unnecessary for CPU scheduling. Based on this observation, HypSec leverages microkernel design principles to split a monolithic hypervisor into two parts, as depicted in Figure 1: a trusted and privileged corevisor with full access to VM data, and an untrusted and depriveleged hostvisor delegated with most hypervisor functionality. Unlike previous microkernel approaches [1, 13, 51], HypSec is designed

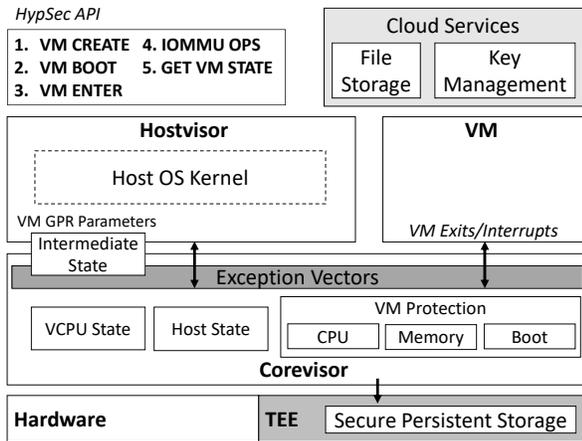

Figure 1: HypSec Architecture

specifically to restructure existing hypervisors with modest modifications as opposed to requiring a clean-slate redesign. Splitting the hypervisor this way results in a significantly smaller TCB that is still flexible enough to implement modern hypervisor features, as discussed in Section 4.

The corevisor is kept small by only performing VM data access control and hypervisor functions that require full access to VM data: secure VM boot, CPU virtualization, and page table management. With applications increasingly using secure communication channels to protect I/O data, HypSec takes an end-to-end approach to simplify its TCB and allows the hostvisor to provide I/O and interrupt virtualization. The hostvisor also handles other complex functions which do not need access to VM data, including resource management such as CPU scheduling and memory allocation. The hostvisor may even incorporate a full existing OS kernel to support its features.

HypSec leverages modern hardware virtualization support in a new way to enforce the hypervisor partitioning. HypSec runs the corevisor in a higher privileged CPU mode designed for running hypervisors, giving it full control of hardware, including virtualization hardware mechanisms such as nested page tables (NPTs).<sup>1</sup> The corevisor deprives the hostvisor and VM kernel by running them in a less privileged CPU mode. For example, in HypSec’s implementation using ARM Virtualization Extensions (VE) shown in Figure 3, the corevisor runs in hypervisor (EL2) mode while the hostvisor and VM kernel run in a less privileged kernel (EL1) mode. The corevisor interposes on all exceptions and interrupts, enabling it to provide access control mechanisms that prevent the hostvisor from accessing VM CPU and memory data. For example, the corevisor has its own memory and uses NPTs to enforce memory isolation between the hostvisor, VMs, and itself. A compromised hostvisor or VM can neither control hardware virtualization mechanisms nor access corevisor memory and thus cannot disable HypSec.

**HypSec Interface.** As shown in Figure 1, the corevisor

exposes a simple API to the hostvisor and interposes on all hostvisor and VM interactions to ensure secure VM execution throughout the lifecycle of a VM. The life of a VM begins when the hostvisor calls the corevisor’s *VM CREATE* and *VM BOOT* calls to safely bootstrap it with a verified VM image. The hostvisor is deprived and cannot execute VMs. It must call *VM ENTER* to request the corevisor to execute a VM. When the VM exits execution because an interrupt or exception occurs, it traps to the corevisor, which examines the cause of the exit and if needed, will return to the hostvisor. The corevisor provides the *IOMMU OPS* API to device drivers in the hostvisor for managing the IOMMU, as discussed in Section 3.3. While the hostvisor has no access to VM data in CPU or memory, it may request the corevisor to provide an encrypted copy of VM data via the *GET VM STATE* hypercall API. The hostvisor can use the API to support virtualization features that require exporting VM data to disk or across the network, such as swapping VM memory to disk or VM management functions like VM snapshot and migration. The corevisor only uses encryption to export VM data. It never uses encryption, only access control, to protect VM data in CPU or memory.

### 3.1 Boot and Initialization

**Corevisor Boot.** HypSec ensures that the trusted corevisor binary is booted and the bootstrapping code itself is secure. To ensure only the trusted corevisor binary is booted, HypSec relies on Unified Extensible Firmware Interface (UEFI) firmware and its signing infrastructure with a hardware root of trust. The hostvisor and corevisor are linked as a single HypSec binary which is cryptographically (“digitally”) signed by the cloud provider, similar to how OS binaries are signed by vendors like Red Hat or Microsoft. The HypSec binary is verified using keys in secure storage provided by the TEE, guaranteeing that only the signed binary can be loaded.

To ensure the bootstrapping code is secure, HypSec could implement it in the trusted corevisor, but does not. Bare-metal hypervisors implement bootstrapping, but this imposes a significant implementation and maintenance burden. The code must be manually ported to each different device, making it more difficult to support a wide range of systems. Instead, HypSec relies on the hostvisor bootstrapping code to install the corevisor securely at boot time since the hostvisor is initially benign. At boot time, the hostvisor initially has full control of the system to initialize hardware. The hostvisor installs the corevisor before entering user space; network and serial input services are not yet available, so remote attackers cannot compromise the corevisor’s installation. After its installation, the corevisor gains full control of the hardware and subsequently deprives the hostvisor, ensuring the hostvisor can never control the hardware or access the corevisor’s memory to disable HypSec. Using information provided at boot time, the corevisor is self-contained and can operate without any external data structures.

**VM Boot.** HypSec also guarantees the confidentiality and in-

<sup>1</sup> Intel’s Extended Page Tables or ARM’s stage 2 page tables.

egrity of VM data during VM boot and initialization. HypSec keeps its TCB small by delegating complicated boot processes to the untrusted hostvisor, and verifying any loaded VM images in the corevisor before they are run. As shown in Figure 1, when a new VM is created, the hostvisor participates with the corevisor in a verified boot process. The hostvisor calls *VM CREATE* to request the corevisor to allocate VM state in corevisor memory, including an NPT and VCPU state, a per virtual CPU (VCPU) data structure. It then calls *VM BOOT* to request the corevisor to authenticate the loaded VM images. If successful, the hostvisor can then call *VM ENTER* to execute the VM. In other words, the hostvisor stores VM images and loads them to memory, avoiding implementing this complex procedure in the corevisor. The corevisor verifies the cryptographic signatures of VM images using public key cryptography, avoiding any shared secret between the user and HypSec.

Both the public keys and VM image signatures are stored in TEE secure storage prior to any attack, as shown in Figure 1. If the VM kernel binary is detached and can be mapped separately to memory, the hostvisor calls the corevisor to verify the image. If the VM kernel binary is in the VM disk image's boot partition, HypSec-aware virtual firmware bootstraps the VM. The firmware is signed and verified like VM boot images. The firmware then loads the signed kernel binary or a signed bootloader such as GRUB from the cleartext VM disk partition. The firmware then calls the corevisor to verify the VM kernel binary or bootloader. In the latter case, the bootloader verifies VM kernel binaries using the signatures on the virtual disk; GRUB already supports this. GRUB can also use public keys in the signed GRUB binary. The corevisor ensures only images it verified, either a kernel binary, virtual firmware, or a bootloader binary, can be mapped to VM memory. Finally, the corevisor sets the VM program counter to the entry point of the VM image to securely boot the VM.

As discussed in Section 3.5, HypSec expects that VM disk images are encrypted as part of an end-to-end encryption approach. HypSec ensures that any password or secret used to decrypt the VM disk is not exposed to the hostvisor. Common encrypted disk formats [6, 57] use user-provided passwords to protect the decryption keys. HypSec can store the encrypted key files locally or remotely using a cloud provider's key management service (KMS) [5, 58]. The KMS maintains a secret key which is preloaded by administrators into hosts' TEE secure storage. The corevisor decrypts the encrypted key file using the secret key, and maps the resulting password to VM memory, allowing VMs to obtain the password without exposing it to the hostvisor. The same key scheme is used for VM migration; HypSec encrypts and decrypts the VM state using the secret key from the KMS.

## 3.2 CPU

Hypervisors provide CPU virtualization by performing four main functions: handling traps from the VM; emulating

privileged CPU instructions executed by the guest OS to ensure the hypervisor retains control of CPU hardware; saving and restoring VM CPU state, including GPRs and system registers such as page table base registers, as needed when switching among VMs and between a VM and the hypervisor; and scheduling VCPUs on physical CPUs. Hypervisors typically have full access to VM CPU state when performing any of these four functions, which can pose a problem for VM security if the hypervisor is compromised.

HypSec protects VM CPU state from the hostvisor while keeping its TCB small by restricting access to VM CPU state to the corevisor while delegating complex CPU functions that can be done without access to VM CPU state to the hostvisor. This is done by having the corevisor handle all traps from the VM, instruction emulation, and world switches between VMs and the hostvisor, all of which require access to VM CPU state. VCPU scheduling is delegated to the hostvisor as it can be done without access to VM CPU state.

The corevisor configures the hardware to route all traps from the VM, as well as interrupts as discussed in Section 3.4, to go to the corevisor, ensuring that it retains full hardware control. It also deprivileges the hostvisor to ensure that the hostvisor has no access to corevisor state. Since all traps from the VM go to the corevisor, the corevisor can trap and emulate CPU instructions on behalf of the VM. The corevisor multiplexes the CPU execution context between the hostvisor and VMs on the hardware. The corevisor maintains VCPU execution context in the VCPU state in-memory data structure allocated on *VM CREATE*, and maintains the hostvisor's CPU context in a similar *Host state* data structure; both states are only accessible to the corevisor. On VM exits, the corevisor first saves the VM execution context from CPU hardware registers to VCPU state, then restores the hostvisor's execution context from Host state to the CPU hardware registers. When the hostvisor calls to the corevisor to re-enter the VM, the corevisor first saves its execution context to Host state, then restores the VM execution context from VCPU state to the hardware. All saving and restoring of VM CPU state is done by the corevisor, and only the corevisor can run a VM.

The hostvisor handles VCPU scheduling, which can involve complex scheduling mechanisms especially for multiprocessors. For example, the Linux scheduler code alone is over 20K LOC, excluding kernel function dependencies and data structures shared with the rest of the kernel. VCPU scheduling requires no access to VM CPU state, as it simply involves mapping VCPUs to physical CPUs. The hostvisor schedules a VCPU to a physical CPU and calls to the corevisor to run the VCPU. The corevisor then loads the VCPU state to the hardware.

HypSec by default ensures that the hostvisor has no access to any VM CPU state, but sometimes a VM may execute instructions that requiring sharing values with the hostvisor that may be stored in general purpose registers (GPRs). For example, if the VM executes a hypercall that includes some parameters and

the hypercall is handled by the hostvisor, it will be necessary to pass the parameters to the hostvisor, and those parameters may be stored in GPRs. In these cases, the instruction will trap to the corevisor. The corevisor will identify the values that need to be passed to the hostvisor, then copy the values from the GPRs to an in-memory per VCPU intermediate VM state structure that is accessible to the hostvisor. Similarly, hostvisor updates to the intermediate VM state structure can be copied back to GPRs by the corevisor to pass values back to the VM. Only values from the GPRs explicitly identified by the corevisor for parameter passing are copied to and from intermediate VM state; values in other CPU registers are not accessible to the hostvisor.

The corevisor determines if and when to copy values from GPRs, and the GPRs from which to copy, based on the specific CPU instructions executed. The set of instructions are those used to execute hypercalls and special instructions provided by the architecture to access virtual hardware via model-specific registers (MSRs), control registers in the x86 instruction set, or memory-mapped I/O (MMIO). There are typically only a few specific CPU instructions that involve parameter passing to the hostvisor via GPRs, but the specific cases are architecture dependent.

For example, on ARM, HypSec copies selected GPRs to and from intermediate VM state for power management hypercalls to the virtual firmware interface and selected MMIO accesses to virtual hardware. For power management hypercalls, the guest kernel passes input parameters in GPRs, and the corevisor copies only those GPRs to intermediate VM state to make the parameters available to the hostvisor. Upon returning to the VM, the hostvisor provides output data as return values to the power management hypercalls, which the corevisor copies from intermediate VM state back to GPRs to make them available to the VM. As discussed in Sections 3.4 and 3.5, values stored and loaded in GPRs on MMIO accesses to the virtual interrupt controller interface or I/O devices are also copied between the selected GPRs and the intermediate VM state to make them available to the hostvisor.

### 3.3 Memory

Hypervisors provide memory virtualization by performing three main functions: memory protection to ensure VMs cannot access unauthorized physical memory, memory allocation to provide physical memory to VMs, and memory reclamation to reclaim physical memory from VMs. Other advanced memory management features may also be performed that build on these functions. All of these functions rely on NPTs. A guest OS manages the traditional page tables to map guest virtual memory addresses (gVA) to guest physical memory addresses (gPA). The hypervisor manages the NPTs to map from gPAs to host physical memory addresses (hPA) so it can virtualize and restrict a VM's access to physical memory. The hypervisor has full access to physical memory so it can manage VM memory either directly [11] or via a host OS kernel's [23]

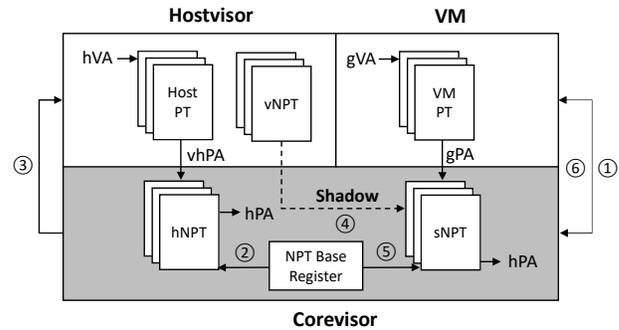

Figure 2: HypSec Memory Virtualization

memory management APIs. A compromised hypervisor or host OS kernel thus has unfettered access to VM memory and can read and write any data stored by VMs in memory.

HypSec protects VM memory from the hostvisor while keeping its TCB small by restricting access to VM memory to the corevisor while delegating complex memory management functions that can be done without access to actual VM data in memory to the hostvisor. The corevisor is responsible for memory protection, including configuring NPT hardware, while memory allocation and reclamation is largely delegated to the hostvisor. HypSec memory protection imposes an additional requirement, which is to also protect corevisor and VM memory from the hostvisor.

**Memory Protection.** The corevisor uses the NPT hardware in the same way as modern hypervisors to virtualize and restrict a VM's access to physical memory, but in addition leverages NPTs to isolate hostvisor memory access. The corevisor configures NPT hardware as shown in Figure 2. The hostvisor is only allowed to manage its own page tables (Host PT) and can only translate from host virtual memory addresses (hVAs) to what we call virtualized host physical memory addresses (vhPAs). vhPAs are then in turn translated to hPAs by the Host Nested Page Table (hNPT) maintained by the corevisor. The corevisor adopts a flat address space mapping; each vhPA is mapped to an identical hPA. The hostvisor, if granted access, is given essentially the same view of physical memory as the corevisor. The corevisor prevents the hostvisor from accessing corevisor and VM memory by simply unmapping the memory from the hNPT to make the physical memory inaccessible to the hostvisor. Any hostvisor accesses to corevisor or VM memory will trap to the corevisor, enabling the corevisor to intercept unauthorized accesses. Physical memory is statically partitioned between the hostvisor and corevisor, but dynamically allocated between the hostvisor and VMs as discussed below. The corevisor allocates NPTs from its own memory pool which is not accessible to the hostvisor. All VCPU state is also stored in corevisor memory.

The corevisor also protects corevisor and VM memory against DMA attacks [75] by retaining control of the IOMMU. The corevisor allocates IOMMU page tables from its memory and exports the *IOMMU OPS* API to device drivers in the

hostvisor to update page table mappings. The corevisor validates requests and ensures that attackers cannot control the IOMMU to access memory owned by itself or the VMs.

**Memory Allocation.** Memory allocation for VMs is largely done by the hostvisor, which can reuse memory allocation functions available in an integrated host OS kernel to dynamically allocate memory from its memory pool to VMs. Traditional hypervisors simply manage one NPT per VM. However, HypSec’s memory model disallows the hostvisor from managing VM memory and therefore NPTs. The hostvisor instead manages an analogous Virtual NPT (vNPT) for each VM, and HypSec introduces a Shadow Nested Page Table (sNPT) managed by the corevisor for each VM as shown in Figure 2. The sNPT is used to manage the hardware by shadowing the vNPT. The corevisor multiplexes the hardware NPT Base Register between hNPT and sNPT when switching between the hostvisor and a VM.

Figure 2 also depicts the steps in HypSec’s memory virtualization strategy. When a guest OS tries to map a gVA to an unmapped gPA, a nested page fault occurs which traps to the corevisor (step 1). If the corevisor finds that the faulted gPA falls within a valid VM memory region, it then points the NPT Base Register to hNPT (step 2) and switches to the hostvisor to allocate a physical page for the gPA (step 3). The hostvisor allocates a virtualized physical page identified by a vhPA and updates the entry in its vNPT corresponding to the faulting gPA with the allocated vhPA. Because the vhPA is mapped to an identical hPA, the hostvisor is able to implicitly manage host physical memory. The hostvisor then traps to the corevisor (step 4), which determines the faulting gPA and identifies the updates made by the hostvisor to the vNPT. The corevisor verifies the resulting vhPA is not owned by itself or other VMs, the latter by tracking ownership of physical memory using a unique VM identifier (VMID), and copies those updates to its sNPT. The corevisor unmaps the vhPA from the hNPT, so that the hostvisor no longer has access to the memory being allocated to the VM. The corevisor updates the NPT Base Register to point to the sNPT (step 5) and returns to the VM (step 6) so that the VM has access to the allocated memory identified by the hPA that is identical to the vhPA. Although possible, HypSec does not scrub pages allocated to VMs by the hostvisor. Guest OSes already scrub memory allocated from their free list before use for security reasons, so the hostvisor cannot allocate pages that contain malicious content to VMs.

HypSec’s use of shadow page tables differs significantly from previous applications of it to collapse multi-level page tables down into what is supported by hardware [2, 11, 16, 52, 82]. In contrast, HypSec uses shadowing to protect hardware page tables, not virtualize them. The corevisor does not shadow guest OS updates in its page tables; it only shadows hostvisor updates to the vNPT. HypSec does not introduce additional traps from the VM for page table synchronization. Overshadow [16] maintains multiple shadow page tables for a given VM that provide different

views (plaintext/encrypted) of physical memory to protect applications from an untrusted guest OS. In contrast, HypSec manages one shadow page table for each VM that provides a plaintext view of gPA to hPA. The shadowing mechanism in HypSec is also orthogonal to recent work [19] that uses shadow page tables to isolate kernel space memory from user space.

**Memory Reclamation.** HypSec supports VM memory reclamation in the hostvisor while preserving the privacy and integrity of VM data in memory in the corevisor. When a VM voluntarily releases memory pages, such as on VM termination, the corevisor returns the pages to the hostvisor by first scrubbing them to ensure the reclaimed memory does not leak VM data, then mapping them back to the hNPT so they are accessible to the hostvisor. To allow the hostvisor to reclaim VM memory pages without accessing VM data in memory, HypSec takes advantage of ballooning [82]. Ballooning is widely supported in common hypervisors, so only modest effort is required in HypSec to support this approach. A paravirtual “balloon” device is installed in the VM. When the host is low on free memory, the hostvisor requests the balloon device to inflate. The balloon driver inflates by getting pages from the free list, thereby increasing the VM’s memory pressure. The guest OS may therefore start to reclaim pages or swap its pages to the virtual disk. The balloon driver notifies the corevisor about the pages in its balloon that are ready to be reclaimed. The corevisor then unmaps these pages from the VM’s sNPT, scrubs the reclaimed pages to ensure they do not leak VM data, and assigns the pages to the hostvisor, which can then treat them as free memory. Deflating the balloon releases memory pressure in the guest, allowing the guest to reclaim pages.

HypSec also safely allows the hostvisor to swap VM memory to disk when it feels memory pressure. The hostvisor uses *GET VM STATE* to get access to the encrypted VM page before swapping it out. Later, when the VM page is swapped in, the corevisor unmaps the swapped-in page from hNPT, decrypts the page, and maps it back to the VM’s sNPT.

**Advanced VM Memory Management.** HypSec by default ensures that the hostvisor has no access to any VM memory, but sometimes a VM may want to share its memory, after encrypting it, with the hostvisor. HypSec provides the *GRANT\_MEM* and *REVOKE\_MEM* hypercalls which can be explicitly used by a guest OS to share its memory with the hostvisor. As described in Section 3.5, this can be used to support paravirtualized I/O of encrypted data in which a memory region owned by the VM has to be shared between the VM and hostvisor for communication and efficient data copying. The VM passes the start of a guest physical frame number (GFN), the size of the memory region, and the specified access permission to the corevisor via the two hypercalls. The corevisor enforces the access control policy by controlling the memory region’s mapping in hNPT. Only VMs can use these two hypercalls, so the hostvisor cannot use it to request access to arbitrary VM pages.

HypSec can support advanced memory virtualization features such as merging similar memory pages, KSM [46]

in Linux, by splitting the work into the simple corevisor functions which require direct access to VM data, and the more complicated hostvisor functions which do not require access to VM data. For example, to support KSM, the hostvisor requests the corevisor for the hash values of a VM's memory pages and maintains the data structure in its address space to support the merging algorithm. The corevisor validates the hostvisor's decision for the pages to be merged, updates the corresponding VM's sNPT, and scrubs the freed page before granting the hostvisor access. While KSM does not provide the hostvisor or other VMs direct access to a VM's memory pages, it can be used to leak some information such as whether the contents of memory pages are the same across different VMs. To avoid this kind of information leakage, HypSec disables KSM support by default.

### 3.4 Interrupts

Hypervisors trap and handle physical interrupts to retain full control of the hardware while virtualizing interrupts for VMs. Accesses to the interrupt controller interface can be done via MSRs or MMIO. Hypervisors provide a virtual interrupt controller interface and trap and emulate VM access to the interface. Virtual devices in the hypervisors can also raise interrupts to the interface. However, giving hypervisors full control of hardware poses a problem for VM security if the hypervisor is compromised.

To protect against a compromised hostvisor, the corevisor configures the hardware to route all physical interrupts and trap all accesses to the interrupt controller to the corevisor, ensuring that it retains full hardware control. However, to simplify its TCB, HypSec delegates almost all interrupt functionality to the hostvisor, including handling physical interrupts and providing the virtual interrupt controller interface. Before entering the hostvisor to handle interrupts, the corevisor protects all VM CPU and memory state, as discussed in Sections 3.2 and 3.3.

The hostvisor has no access to and requires no VM data to handle physical interrupts. However, VM accesses to the virtual interrupt controller interface involve passing parameters between the VM and the hostvisor since the hostvisor provides the interface. On ARM, this is done using only MMIO via the intermediate state structure discussed in Section 3.2. On an MMIO write to interrupt controller interface, the VM passes the value to be stored in a GPR. The write traps to the corevisor, which identifies the instruction and memory address as corresponding to the interrupt controller interface. The corevisor copies the value to be written from the GPR to the intermediate VM state to make the value available to the hostvisor. For example, when the guest OS in the VM sends an IPI to a destination VCPU by doing an MMIO write to the virtual interrupt controller interface, the identifier of the destination VCPU is passed to the hostvisor by copying the value from the respective GPR to the intermediate VM state. Similarly, on an MMIO read from the interrupt controller

interface, the read traps to the corevisor, which identifies the instruction and memory address as corresponding to the interrupt controller interface. The corevisor copies the value from the intermediate VM state updated by the hostvisor to the GPR the VM is using to retrieve the value, updates the PC of the VM to skip the faulting instruction, and returns to the VM.

### 3.5 Input/Output

To ease the burden of supporting a wide range of virtual devices, modern hypervisors often rely on an OS kernel and its existing device drivers to support I/O virtualization, which significantly increase the hypervisor TCB. Similar to previous work [16,33], HypSec assumes an end-to-end I/O security approach, relying on VMs for I/O protection. VMs can leverage secure communication channels such as TLS/SSL for network communications and full disk encryption for storage. This allows the corevisor to relax its I/O protection requirements, simplifying the TCB. HypSec offloads the support of I/O virtualization to the untrusted hostvisor. Since I/O data is already encrypted by VMs, a compromised hostvisor would at most gain access to encrypted I/O data which would not reveal VM data.

HypSec, like other modern hypervisors, supports all three classes of I/O devices: emulated, paravirtualized, and passthrough devices; the latter two provide better I/O performance. Emulated I/O devices are typically supported by hypervisors using trap-and-emulate to handle both port-mapped I/O (PIO) and MMIO operations. In both cases, HypSec configures the hardware to trap the operations to the corevisor which hides all VM data other than actual I/O data and then allows the hostvisor to emulate the operation. For example, to support MMIO, the corevisor zeroes out the mappings for addresses in the VM's sNPT corresponds to virtual device I/O regions. Any subsequent MMIO accesses from the VM result in a memory access fault that traps to the corevisor. The corevisor then securely supports MMIO accesses as discussed in Section 3.4. We assume security aware users disable the use of emulated devices such as the serial port, keyboard, or mouse to avoid leaking private information to a compromised hostvisor.

Paravirtualized devices require that a front-end driver in the VM coordinate with a back-end driver in the hypervisor; the two drivers communicate through shared memory asynchronously. HypSec allows back-end drivers to be installed as part of the untrusted hostvisor. To support shared memory communication, the front-end driver is modified to use `GRANT_MEM` and `REVOKE_MEM` hypercalls to identify the shared data structure and I/O memory buffers as accessible to the hostvisor back-end driver. Since the I/O data is encrypted, hostvisor access to the I/O memory buffers does not risk VM data.

Passthrough devices are assigned to a VM and managed by the guest OS. To support passthrough I/O, HypSec configures the hardware to trap sensitive operations such as Message Signaled Interrupt (MSI) configuration in BAR to trap to the corevisor for secure emulation, while granting VMs

direct access to the non-sensitive device memory region. The corevisor controls the IOMMU to enforce inter-device isolation, and ensures the passthrough device can only access the VM’s own I/O buffer. Since we assume the hardware is not malicious, passthrough I/O can be done securely on HypSec.

## 4 Implementation

We demonstrate how HypSec can improve the security of existing commodity hypervisors by applying our approach to the mainline Linux KVM/ARM [22, 23] hypervisor, given ARM’s increasing popularity in server systems [4, 63, 87]. Table 1 compares commodity hypervisors with the current HypSec implementation, showing that this security improvement comes without compromising on hypervisor features. Since KVM is a hosted hypervisor tightly integrated with a host OS kernel, retrofitting KVM also demonstrates the viability of HypSec in supporting an entire OS kernel as part of the hostvisor.

HypSec requires a higher-privileged CPU mode, nested page tables for memory virtualization, and an IOMMU for DMA protection. These requirements are satisfied by the ARM architecture. ARM VE provides Hyp (EL2) mode for hypervisors that is strictly more privileged than user (EL0) and kernel (EL1) modes. EL2 has its own execution context defined by register and control state, and can therefore switch the execution context of both EL0 and EL1 in software. Thus, the hypervisor can run in an address space that is isolated from EL0 and EL1. ARM VE provides stage 2 page tables

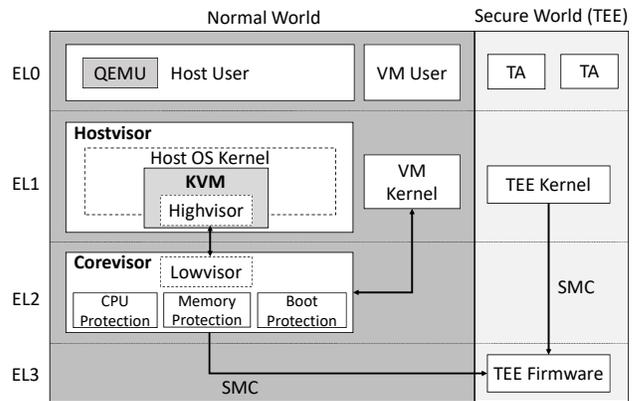

Figure 3: HypSec on KVM/ARM

which are nested level page tables configured in EL2 that affect software in EL0 and EL1. ARM provides the System Memory Management Unit (SMMU) [8] to protect DMA.

HypSec’s corevisor is initialized at machine bootup and runs in EL2 to fully control the hardware. HypSec’s code is embedded in the Linux kernel binary, which is verified and loaded via UEFI. The kernel boots in EL2 and installs a trap handler to later return to EL2. The kernel then enters EL1 so the hostvisor can bootstrap the machine. The hostvisor allocates resources and configures the hardware for the corevisor. The hostvisor then makes a hypercall to the corevisor in EL2 to enable HypSec.

The HypSec ARM implementation leverages KVM/ARM’s split into an EL2 lowvisor and an EL1 highvisor to support the ARM virtualization architecture. This is done because EL2 is necessary for controlling hardware virtualization features, but Linux and KVM are designed to run in kernel mode, EL1. Thus, the lowvisor manages hardware virtualization features and VM-hypervisor switches, while the highvisor contains the rest of the hypervisor and Linux. However, the lowvisor cannot protect VM data if any other part of Linux or KVM are compromised; with KVM/ARM, the Linux host has unfettered access to all VM data.

As shown in Figure 3, the corevisor encapsulates the KVM lowvisor and runs in EL2. The hostvisor, including the KVM highvisor and its integrated Linux OS kernel, runs in EL1. The hostvisor has no access to EL2 registers and cannot compromise the corevisor or disable VM protection. HypSec leverages ARM VE to force VM operations that need hypervisor intervention to trap into EL2. The corevisor either handles the trap directly to protect VM data or world switches the hardware to EL1 to run the hostvisor if more complex handling is necessary. When the hostvisor finishes its work, it makes a hypercall to trap to EL2 so the corevisor can securely restore the VM state to hardware. The corevisor interposes on every switch between the VM and hostvisor, thus protecting the VM’s execution context. Our implementation ensures that the hostvisor cannot invoke arbitrary corevisor functions via hypercalls.

HypSec leverages ARM VE's stage 2 memory translation support to virtualize VM memory and prevent accesses to protected physical memory. The corevisor routes stage 2 page faults to EL2 and rejects illegal hostvisor and VM memory accesses. The corevisor allocates hNPTs and VMs' sNPTs from its protected physical memory and manages the page tables.

To secure DMA, the corevisor uses trap-and-emulate on hostvisor accesses to the SMMU. HypSec ensures only the corevisor has access to the SMMU hardware. The corevisor manages the SMMU page tables in its protected memory to ensure hostvisor devices cannot access corevisor or VM memory, and devices assigned to the VM can only access VM memory.

HypSec leverages the hardware features from VGIC and KVM/ARM's existing support to virtualize interrupts. Our implementation supports ARM GIC 2.0. HypSec relies on QEMU and KVM's virtual device support for I/O virtualization. Our implementation supports emulated devices via MMIO, paravirtualized devices via virtio [67], and passthrough devices. For virtio, we modified front-end drivers to use GRANT/REVOKE\_MEM hypercalls to share memory with the hostvisor back-end drivers. To support passthrough devices, HypSec configures the hardware to grant VMs direct access to them. We modified the front-end virtio-balloon driver to notify the corevisor about the pages allocated for the balloon device. The corevisor scrubs and assigns these pages to the hostvisor, allowing it to safely reclaim memory as needed. Our current implementation does not support page swapping and KSM, which are both left as future work.

HypSec supports secure VM boot using ARM TrustZone-based TEE frameworks such as OP-TEE [61] to store the signatures and keys securely. HypSec tasks QEMU to load the VM boot images to VM memory, but the corevisor requires QEMU to participate with its verified boot process. The corevisor retrieves the VM boot image signatures and the user public key from TrustZone for verifying the VM images remapped to its address space. The corevisor uses Ed25519 [62] to verify the boot images. HypSec builds the VM's stage 2 page table with mappings to the verified VM boot image. If the verification fails, HypSec stops the VM boot process. The same scheme can also verify VM firmware and other binaries. HypSec also retrieves the encrypted password which protects the VM's encrypted disk from either TrustZone or from the cloud provider's key management service. A small AES implementation [45] ported to run in EL2 performs the decryption. We include only two small yet sufficient crypto libraries in EL2 to keep the TCB small. This limits the number of crypto algorithms, but avoids including comprehensive but excessively large crypto libraries such as OpenSSL. HypSec leverages AES to support encrypted VM migration and snapshot, and ensures only encrypted VM data is exposed to the hostvisor.

HypSec's hardware requirements can also be satisfied on Intel's x86 architecture by using Virtual Machine Extensions (VMX) [35] and the IOMMU. Existing x86 hypervisors can be retrofitted to run the corevisor in VMX root operation which

allows control of virtualization features for deprivileging the hostvisor. The hostvisor runs in VMX non-root operation to provide resource management and virtual I/O. The corevisor protects VM execution state by managing a Virtual-Machine Control Structure (VMCS) per CPU, and VM memory by using Extended Page Tables (EPT) and controlling the IOMMU.

## 5 Security Analysis

We present five properties of the HypSec architecture, then discuss how their combination provides a set of security properties regarding HypSec's ability to protect the integrity and confidentiality of VM data.

**Property 1.** *HypSec's corevisor is trusted during the system's lifetime against remote attackers.*

HypSec leverages hardware secure boot to ensure only the signed and trusted HypSec binary can be booted. This prevents an attacker from trying to boot or reboot the system to force it to load a malicious corevisor. The hostvisor securely installs the corevisor during the boot process before network access and serial input service are available. Thus, remote attackers cannot compromise the hostvisor prior to or during the installation of the corevisor. The corevisor protects itself after initialization. It runs in a privileged CPU mode using a separate address space from the hostvisor and the VMs. The corevisor has full control of the hardware including the virtualization features that prevent attackers from disabling its VM protection. The corevisor also protects its page tables so an attacker cannot map executable memory to the corevisor's address space.

**Property 2.** *HypSec ensures only trusted VM images can be booted on VMs.*

Based on Property 1, the trusted corevisor verifies the signatures of the VM images loaded to VM memory before they are booted. The public keys and signatures are stored using TEE APIs for persistent secure storage. A compromised hostvisor therefore cannot replace a verified VM with a malicious one.

**Property 3.** *HypSec isolates a given VM's memory from all other VMs and the hostvisor.*

Based on Property 1, HypSec prevents the hostvisor and a given VM from accessing memory owned by other VMs. The corevisor tracks ownership of physical pages and enforces inter-VM memory isolation using nested paging hardware. A compromised hostvisor could control a DMA capable device to attempt to access VM memory or compromise the corevisor. However, the corevisor controls the IOMMU and its page tables, so the hostvisor cannot access corevisor or VM memory via DMA. VM pages reclaimed by the hostvisor are scrubbed by the corevisor, so they do not leak VM data. HypSec also protects the integrity of VM nested page tables. The corevisor manages shadow page tables for VMs. The MMU can only walk the shadow page tables residing in a protected memory region only accessible to the corevisor. The corevisor manages

and verifies updates to the shadow page tables to protect VM memory mappings.

**Property 4.** *HypSec protects a given VM's CPU registers from the hostvisor and all other VMs.*

HypSec protects VM CPU registers by only granting the trusted corevisor (Property 1) full access to them. The hostvisor cannot access VM registers without permission. Attackers cannot compromise VM execution flow since only the corevisor can update VM registers including program counter (PC), link register (LR), and TTBR.

**Property 5.** *HypSec protects the confidentiality of a given VM's I/O data against the hostvisor and all other VMs assuming the VM employs an end-to-end approach to secure I/O.*

Based on Properties 3 and 4, HypSec protects any I/O encryption keys loaded to VM CPU registers or memory, so a compromised hostvisor cannot steal these keys to decrypt encrypted I/O data. The same protection holds against other VMs.

**Property 6.** *HypSec protects the confidentiality and integrity of a given VM's I/O data against the hostvisor and all other VMs assuming the VM employs an end-to-end approach to secure I/O and the I/O can be verified before it permanently modifies the VM's I/O data.*

Using the reasoning in Property 5 with the additional assumption that I/O can be verified before it permanently modifies I/O data, HypSec also protects the integrity of VM I/O data, as any tampered data will be detected and can be discarded. For example, a network endpoint receiving I/O from a VM over an encrypted channel with authentication can detect modifications of the I/O data by any intermediary such as the hostvisor. If verification is not possible, then HypSec cannot prevent compromises of data availability that result in destruction of I/O data, which can affect data integrity. As an example, HypSec cannot prevent an attacker from arbitrarily destroying a VM's I/O data by blindly overwriting all or parts of a VM's local disk image; both the VM's availability and integrity are compromised since the data is destroyed. Secure disk backups can protect against permanent data loss.

**Property 7.** *Assuming a VM takes an end-to-end approach for securing its I/O, HypSec protects the confidentiality of all of the VM's data against a remote attacker, including if the attacker compromises any other VMs or the hostvisor itself.*

Based on Properties 1, 3, and 4, a remote attacker cannot compromise the corevisor, and any compromise of the hostvisor or another VM cannot allow the attacker to access VM data stored in CPU registers or memory. This combined with Property 5 allows HypSec to ensure the confidentiality of all of the VM's data.

**Property 8.** *Under the assumption that a VM takes an end-to-end approach for securing its I/O and I/O can be verified before it permanently modifies any VM data, HypSec protects the integrity of all of the VM's data against a remote attacker, including if the attacker compromises any other VMs or the hostvisor itself.*

Based on Properties 1, 3, and 4, HypSec ensures a remote attacker cannot compromise the corevisor, and that any compromise of the hostvisor or another VM cannot allow the attacker to access VM data stored in CPU registers or memory, thereby preserving VM CPU and memory data integrity. This combined with Property 6 allows HypSec to ensure the integrity of all of the VM's data.

**Property 9.** *If the hypervisor is benign and responsible for handling I/O, HypSec protects the confidentiality and integrity of all of the VM's data against any compromises of other VMs.*

If both the hostvisor and corevisor are not compromised and the hostvisor is responsible for handling I/O, then the confidentiality and integrity of a VM's I/O data will be protected against other VMs. This combined with Properties 3 and 4 allows HypSec to ensure the confidentiality and integrity of all of the VM's data. This guarantee is equivalent to what is provided by a traditional hypervisor such as KVM.

## 6 Experimental Results

We quantify the performance and TCB of HypSec compared to other approaches, and demonstrate HypSec's ability to protect VM confidentiality and integrity. All of our experiments were run on ARM server hardware with VE support, specifically a 64-bit ARMv8 AMD Seattle (Rev.B0) server with 8 Cortex-A57 CPU cores, 16 GB of RAM, a 512 GB SATA3 HDD for storage, an AMD 10 GbE (AMD XGBE) NIC device, and an IOMMU (SMMU-401) to support control over DMA devices and direct device assignment. The hardware did not support ARM Virtualization Host Extensions [20, 21]. For client-server experiments, the clients ran on an x86 machine with 24 Intel Xeon CPU 2.20 GHz cores and 96 GB RAM. The clients and the server communicated via a 10 GbE unsaturated network connection.

To provide comparable measurements across the approaches, we kept the software environments across all platforms as uniform as possible. We compared KVM with our HypSec modifications versus standard KVM, both in Linux 4.18 with QEMU 2.3.50. In both cases, KVM was configured with its standard VHOST virtio network, and with `cache=none` for its virtual block storage devices [30, 47, 77]. All hosts and VMs used Ubuntu 16.04 with the same Linux 4.18 kernel, except for HypSec changes. All VMs used paravirtualized I/O, typical of cloud infrastructure deployments such as Amazon EC2.

We ran benchmarks both natively on the hardware and in VMs. Each physical or VM instance was configured as a 4-way SMP with 12 GB of RAM to provide a common basis for comparison. This involved two configurations: (1) native Linux capped at 4 cores and 12 GB RAM, and (2) a VM using KVM with 8 cores and 16 GB RAM with the VM capped at 4 virtual CPUs (VCPUs) and 12 GB RAM. We measure multi-core configurations to reflect real-world server deployments. For VMs,

Name	Description
Hypercall	Transition from the VM to the hypervisor and return to the VM without doing any work in the hypervisor. Measures bidirectional base transition cost of hypervisor operations.
I/O Kernel	Trap from the VM to the emulated interrupt controller in the hypervisor OS kernel, and then return to the VM. Measures a frequent operation for many device drivers and baseline for accessing I/O devices supported by the hypervisor OS kernel.
I/O User	Trap from the VM to the emulated UART in QEMU and then return to the VM. Measures base cost of operations that access I/O devices emulated in the hypervisor OS user space.
Virtual IPI	Issue a virtual IPI from a VCPU to another VCPU running on a different PCPU, both PCPUs executing VM code. Measures time between sending the virtual IPI until the receiving VCPU handles it, a frequent operation in multi-core OSes.

Table 2: Microbenchmarks

we pinned each VCPU to a specific physical CPU (PCPU) and ensured that no other work was scheduled on that PCPU. All of the host’s device interrupts and processes were assigned to run on other PCPUs. For client-server benchmarks, the clients ran natively on Linux and used the full hardware available.

## 6.1 Microbenchmark Results

We first ran microbenchmarks to quantify the cost of low-level hypervisor operations. We used the KVM unit test framework [48] listed in Table 2 to measure the cost of transitioning between the VM and the hypervisor, initiating a VM-to-hypervisor OS kernel I/O request, emulating user space I/O with QEMU, and sending virtual IPIs. We slightly modified the test framework to measure the cost of virtual IPIs and to obtain cycle counts on ARM to ensure detailed results by configuring the VM with direct access to the cycle counter.

Microbenchmark	KVM	HypSec
Hypercall	2,896	3,202
I/O Kernel	3,831	4,563
I/O User	9,288	10,704
Virtual IPI	8,816	10,047

Table 3: Microbenchmark Measurements (cycles)

Table 3 shows the microbenchmarks measured in cycles for both standard KVM and HypSec. HypSec introduces roughly 5% to 19% overhead over KVM. HypSec does not increase the number of traps in the operations we measured. The corevisor interposes on existing traps to add additional logic to protect VM data, so the cost is relatively small. The I/O Kernel, I/O User, and Virtual IPI measurements show relatively higher overhead than Hypercall on HypSec because of the cost involved to secure data transfers between the VM and hostvisor for I/O and interrupt virtualization.

Name	Description
Kernbench	Compilation of the Linux 4.9 kernel using <code>allnoconfig</code> for ARM with GCC 5.4.0.
Hackbench	hackbench [66] using Unix domain sockets and 100 process groups running in 500 loops.
Netperf	netperf v2.6.0 [41] running netserver on the server and the client with its default parameters in three modes: TCP_STREAM (throughput), TCP_MAERTS (throughput), and TCP_RR (latency).
Apache	Apache v2.4.18 Web server running ApacheBench [80] v2.3 on the remote client, which measures number of handled requests per second when serving the 41 KB <code>index.html</code> file of the GCC 4.4 manual using 100 concurrent requests.
Memcached	memcached v1.4.25 using the memtier benchmark v1.2.3 with its default parameters.
MySQL	MySQL v14.14 (distrib 5.7.24) running SysBench v.0.4.12 using the default configuration with 200 parallel transactions.

Table 4: Application Benchmarks

## 6.2 Application Workload Results

Next we ran real application workloads to evaluate HypSec compared to standard KVM. Table 4 lists the workloads which are a mix of widely-used CPU and I/O intensive benchmarks. To evaluate VM performance with end-to-end I/O protection, we used five configurations: (1) Native unmodified Linux host kernel without Full Disk Encryption, (2) Unmodified KVM and guest kernel without FDE (KVM), (3) Unmodified KVM and guest kernel with FDE (KVM-FDE), (4) HypSec and paravirtualized guest kernel without FDE (HypSec), (5) HypSec and paravirtualized guest kernel with FDE (HypSec-FDE). For FDE, we use dm-crypt to create a LUKS-encrypted root partition of the VM filesystem. We measure with and without FDE to separately quantify its extra costs. We leveraged the TLS/SSL support in Apache and MySQL and evaluated VM performance on HypSec with end-to-end network encryption.

Figure 4 shows the relative overhead of executing in a VM in our four VM configurations compared to natively. We normalize the results so that a value of 1.00 means the same performance as native hardware. Lower numbers mean less overhead. The performance on real application workloads shows modest overhead overall for HypSec compared to standard KVM. The overhead for HypSec in many cases is less than 10%, even with FDE enabled.

The worst overhead for HypSec occurs for some of the network workloads. Our current implementation of the front-end network virtio driver applies grant/revoke hypercalls on a per transaction basis to make data available to the back-end driver in the hostvisor. Therefore, HypSec’s performance is sub-optimal in workloads where the virtio driver can batch multiple transactions without trapping to the hypervisor, most notably in TCP\_MAERTS. TCP\_MAERTS measures the bandwidth of a VM sending packets to a client. The virtio driver batches multiple sends to avoid traps to hypervisor, while in the implementation measured in the paper, the driver traps additionally

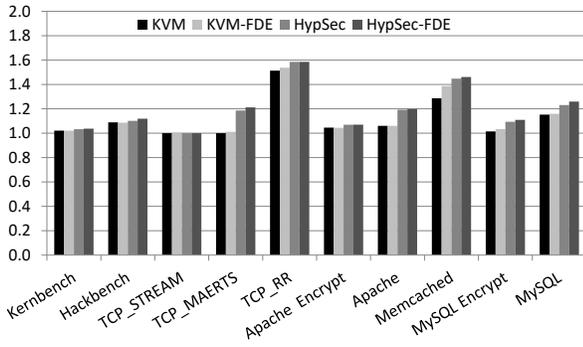

Figure 4: Application Benchmark Performance

on sending network data, resulting in higher overhead. Note that other network workloads such as TCP\_STREAM have negligible overhead as the granularity at which the additional traps happen is large enough that the performance impact is negligible. To avoid extra traps to the hypervisor, our implementation can be optimized by batching the effect of the grant/revoke calls at the same level of granularity as used by the virtio driver to batch multiple transactions. This is an area of future work.

### 6.3 TCB Implementation Complexity

We ran cloc [24] against our implementation’s corevisor to measure the TCB, as shown in Table 5. The total is roughly 8.5K LOC of which just under 4.5K LOC is from the Ed25519 and AES crypto libraries. The rest of the HypSec TCB is less than 4.1K LOC, consisting of mostly CPU/memory protection and existing KVM lowvisor code. Overall, we modified or added a total of 8,695 LOC in the mainline Linux kernel v4.18 across both the corevisor and hostvisor. More than 1.3K LOC were in existing Linux files, and around 7.3K LOC were in new files for HypSec, including around 4.5K LOC in the crypto libraries and slightly less than 2.8K LOC for corevisor functions. Finally, less than 70 LOC were added to QEMU to support secure boot and VM migration. These results demonstrate that HypSec can retrofit existing hypervisors with modest implementation effort.

For comparison purposes, we also used cloc to measure KVM’s TCB in Linux v4.18 and Xen v4.9 for ARM64 support when running Linux v4.18 on Dom0, shown in Table 6. For KVM, we counted its LOC for the specific Linux v4.18 codebase running on the ARM64 server used in our experiments. KVM’s massive TCB with access to VM data consists of more than 1.8M LOC and includes QEMU, the KVM module, core Linux functions such as CPU scheduling, ARM64 architectural support, and the device drivers used on the server.

To provide a fair comparison, we assumed the same threat model for each system and that VMs encrypt their I/O. Even under this assumption, KVM, including its I/O kernel code, must be entirely trusted to protect VM data since a compromised KVM can steal encryption keys from VM CPU and memory

Components	LOC
Ed25519 library	4,074
AES library	403
CPU protection	1,883
Memory protection	1,727
Secure boot	232
Helper	247
HypSec TCB	8,566

Table 5: HypSec TCB

Hypervisor	LOC
HypSec	8,566
KVM	1,857,575
Xen	71,604
Xen + Dom0	2,054,756

Table 6: TCB size comparison with KVM and Xen

state. By retrofitting KVM with HypSec to protect VM CPU and memory against the rest of the KVM codebase, we show that the TCB of KVM can be reduced by more than 200 times.

Using the same assumption, Xen’s TCB should include both its hypervisor code and Dom0, a special privileged VM used to reuse existing Linux drivers to support I/O for user VMs. Although Dom0 is not part of the hypervisor, Xen provides it with a management interface that can request the hypervisor to dump entire VM state, thereby giving a compromised Dom0 full access to encryption keys. Xen’s resulting TCB including Dom0, which has a full copy of Linux, is therefore larger than KVM and hundreds of times larger than HypSec. If we conservatively assume features in Xen’s management stack that expose VM state such as VM dump and migration are disabled, so that we can exclude Dom0 from Xen’s TCB and only count Xen ARM hypervisor code in EL2, Xen’s TCB is then 71K LOC as listed in Table 6. This is roughly an order of magnitude larger than HypSec because Xen still has to do its own bootstrapping, CPU and memory resource management, and completely support memory and interrupt virtualization.

We estimated HypSec’s TCB for an equivalent x86 implementation, assuming HypSec is also applied to KVM Linux v4.18 for x86 hardware with VMX support. We ran cloc against the C files that encapsulate the KVM functions for CPU and memory virtualization to conservatively measure HypSec’s TCB size. The total is less than 27K LOC. Although the TCB size for HypSec on x86 would be larger than HypSec on ARM, we believe the resulting TCB on x86 would still result in a substantial reduction as KVM’s TCB on x86 is also larger than on ARM, at roughly 10M LOC including x86 device drivers; this is an area of future work.

### 6.4 Evaluation of Practical Attacks

We evaluated HypSec’s effectiveness against a compromised hostvisor by analyzing CVEs and identifying the cases where HypSec protects VM data despite any compromise, assuming an equivalent implementation of HypSec for x86 platforms. We analyzed CVEs related to Linux/KVM, which are listed in Tables 7 and 8. The CVEs consider two cases: a malicious VM who exploits KVM functions supported by the hostvisor, and an unprivileged host user who exploits bugs in Linux/KVM. Among the selected CVEs, 16 of them are x86-specific, one is specific to ARM, while the rest are independent of architecture. An attacker’s goal is to exploit these CVEs to obtain

Bug	Description	KVM	HypSec
CVE-2015-4036	Memory Corruption: Array index error in hostvisor.	No	Yes
CVE-2013-0311	Privilege Escalation: Improper handling of descriptors in vhost driver.	No	Yes
CVE-2017-17741	Info Leakage: Stack out-of-bounds read in hostvisor.	No	Yes
CVE-2010-0297	Code Execution: Buffer overflow in I/O virtualization code.	No	Yes
CVE-2014-0049	Code Execution: Buffer overflow in I/O virtualization code.	No	Yes
CVE-2013-1798	Info Leakage: Improper handling of invalid combination of operations for virtual IOAPIC.	No	Yes
CVE-2016-4440	Code Execution: Mishandling of virtual APIC state.	No	Yes
CVE-2016-9777	Privilege Escalation: Out-of-bounds array access using VCPU index in interrupt virtualization code.	No	Yes
CVE-2015-3456	Code Execution: Memory corruption in virtual floppy driver allows VM user to execute arbitrary code in hostvisor.	No	Yes
CVE-2011-2212	Privilege Escalation: Buffer overflow in the virtio subsystem allows guest to gain privileges to the host.	No	Yes
CVE-2011-1750	Privilege Escalation: Buffer overflow in the virtio subsystem allows guest to gain privileges to the host.	No	Yes
CVE-2015-3214	Code Execution: Out-of-bound memory access in QEMU leads to memory corruption.	No	Yes
CVE-2012-0029	Code Execution: Buffer overflow allows VM users to execute arbitrary code in QEMU	No	Yes
CVE-2017-1000407	Denial-of-Service: VMs crash hostvisor by flooding the I/O port with write requests.	No	No
CVE-2017-1000252	Denial-of-Service: Out-of-bounds value causes assertion failure and hypervisor crash.	No	No
CVE-2014-7842	Denial-of-Service: Bug in KVM allows guest users to crash its own OS.	No	No
CVE-2018-1087	Privilege Escalation: Improper handling of exception allows guest users to escalate their privileges to its own OS.	No	No

CVE-2013-4587	Privilege Escalation: Array index error in hostvisor.	No	Yes
CVE-2018-18021	Privilege Escalation: Mishandling of VM register state allows host users to redirect hostvisor execution.	No	Yes
CVE-2016-9756	Info Leakage: Improper initialization in code segment resulting in information leakage in hostvisor stack.	No	Yes
CVE-2013-6368	Privilege Escalation: Mishandling of APIC state in hostvisor.	No	Yes
CVE-2015-4692	Memory Corruption: Mishandling of APIC state in hostvisor.	No	Yes
CVE-2013-4592	Denial-of-Service: Host users cause memory leak in hostvisor.	No	No

Table 8: Selected Set of Analyzed CVEs - from host user

hostvisor privileges and compromise VM data. The CVEs related to our threat model could result in information leakage, privilege escalation, code execution, and memory corruption in Linux/KVM. While KVM does not protect VM data against any of these compromises, HypSec protects against all of them. HypSec does not guarantee availability and cannot protect against CVEs that allow VMs or host users to cause denial of service in the hostvisor. Vulnerabilities that allow unprivileged guest users to attack their own VMs like CVE-2014-7842 and CVE-2018-1087 are unrelated to HypSec’s threat model; protection against CVEs of these types is an area of future work.

We also executed attacks representative of information leakage to show that HypSec protects VM data even if an attacker has full control of the hostvisor. First, we simulated an attacker trying to read or modify VMs’ memory pages. We added a hook to KVM which modifies a page that a targeted gVA maps to. As expected, the compromised KVM (without HypSec) successfully modified the VM page. Using HypSec, the same attack causes a trap to the corevisor which rejects the invalid memory access.

Second, we simulated a host that tries to tamper with a VM’s nested page table by redirecting a gPA’s NPT mapping to host-

owned pages. This is in contrast to the prior attack of modifying VM pages, but shares the same goal of accessing VM data in memory. We added a hook to the nested page fault handler in KVM; the hook allocates a new zero page in the host OS’s address space, which in a real attack could contain arbitrary code data. The hook associates a range of a VM’s gPAs with this zero page. As expected, this attack succeeds in KVM but fails in HypSec. First, the attacker has no access to the sNPT walked by the MMU. Second, the corevisor synchronizes the vNPT to sNPT mapping on the gPA’s initial fault during VM boot, so malicious vNPT modifications do not propagate to sNPT.

## 7 Related Work

The idea of retrofitting a commodity hypervisor with a smaller core was inspired by KVM/ARM’s split-mode virtualization [22, 23], which introduced a thin software layer to enable Linux KVM to make use of ARM hardware virtualization extensions without significant changes to Linux, but did nothing to reduce the hypervisor TCB. HypSec builds on this work to leverage ARM hardware virtualization support to run the corevisor with special hardware privileges to protect VM

data against a compromised hostvisor. More recently, Nested Kernel [25] used the idea of retrofitting a small TCB into a commodity OS kernel, FreeBSD, to intercept MMU updates to enforce kernel code integrity. Both HypSec and Nested Kernel retrofit commodity system software with a small TCB that mediates accesses to critical hardware resources and strengthens system security guarantees with modest implementation and performance costs. Nested Kernel focuses on a different threat model and does not protect against vulnerabilities in existing kernel code in part because both its TCB and untrusted components run at the highest hardware privilege level. In contrast, HypSec deprivileges the hostvisor and uses its TCB to provide data confidentiality and integrity even in the presence of hypervisor vulnerabilities in the hostvisor.

Bare-metal hypervisors often claim a smaller TCB as an advantage over hosted hypervisors, but in practice, the aggregate TCB of the widely-used Xen [11] bare-metal hypervisor includes Dom0 [18, 92] and therefore can be no smaller than hosted hypervisors like KVM. Some work thus focuses on reducing Xen’s attack surface by redesigning Dom0 [15, 18, 59]. Unlike HypSec, these approaches cannot protect a VM against a compromised Xen or Dom0. We believe Xen can be restructured using HypSec by moving resource management, interrupt virtualization, and other hardware-specific dependencies, along with Dom0, into a hostvisor to further reduce Xen’s TCB to protect VM data.

Microhypervisors [32, 74] take a microkernel approach to build clean-slate hypervisors from scratch to reduce the hypervisor TCB. For example, NOVA [74] moves various aspects of virtualization such as CPU and I/O virtualization to user space services. The virtualization services are trusted but instantiated per VM so that compromising them only affects the given VM. Others simplify the hypervisor to reduce its TCB by removing [72] or disabling [60] virtual device I/O support in hypervisors, or partitioning VM resources statically [42, 73]. Although a key motivation for both microhypervisors and HypSec is to reduce the size of the TCB, HypSec does not require a clean-slate redesign, and supports existing full-featured commodity hypervisors without removing important hypervisor features such as I/O support and dynamic resource allocation while preserving confidentiality and integrity of VM data even if the hostvisor is compromised.

HyperLock [86], DeHype [88], and Nexen [70] focus on deconstructing existing monolithic hypervisors by segregating hypervisor functions to per VM instances. While this can isolate an exploit of hypervisor functions to a given VM instance, if a vulnerability is exploitable in one VM instance, it is likely to be exploitable in another as well. Nexen builds on Nested Kernel to retrofit Xen in this manner, though it does not protect against vulnerabilities in its shared hypervisor services. In contrast to HypSec, these systems focus on availability and do not fully protect the confidentiality and integrity of VM data against a compromised hypervisor or host OS.

CloudVisor [92] uses a small, specialized host hypervisor to

support nested virtualization and protect user VMs against an untrusted Xen guest hypervisor, though Xen modifications are required. CloudVisor encrypts VM I/O and memory but does not fully protect CPU state, contrary to its claims of “providing both secrecy and integrity to a VM’s states, including CPU states.” For example, the VM program counter is exposed to Xen to support I/O. As with any nested virtualization approach, performance overhead on application workloads is a problem. Furthermore, CloudVisor does not support widely used paravirtual I/O. CloudVisor has a smaller TCB by not supporting public key cryptography, making key management problematic. In contrast, HypSec protects both CPU and memory state via access control, not encryption, making it possible to support full-featured hypervisor functionality such as paravirtual I/O. HypSec also does not require nested virtualization, avoiding its performance overhead.

To protect user data in virtualization systems, others enable and require VM support for specialized hardware such as Intel SGX [36] or ARM TrustZone. Haven [12] and S-NFV [71] use Intel SGX to protect application data but unlike HypSec, cannot protect the whole VM including the guest OS and applications against an untrusted hypervisor. Although HypSec relies on a TEE to support key management, it fundamentally differs from other approaches which extensively use TEEs for much more than storing keys. Others [34, 96] run a security monitor in ARM TrustZone and rely on ARM IP features such as TrustZone Address Space Controller to protect VMs. vTZ [34] virtualizes TrustZone and protects the guest TEE against an untrusted hypervisor, but does not protect the normal world VM. HA-VMSI [96] protects the normal world VM against a compromised hypervisor but supports limited virtualization features. In contrast, HypSec protects the entire normal world VM against an untrusted hypervisor without requiring VMs to use specialized hardware. HypSec leverages ARM VE to trap VM exceptions to EL2 while retaining hypervisor functionality. Others [40, 78, 90] propose hardware-based approaches to protect VM data in CPU and memory against an untrusted hypervisor. However, without actual hardware implementations, these works implement the proposed changes by modifying either Xen [40] or QEMU [90], or on a simulator [78]. Some of them [40, 78] do not support commodity hypervisors. In contrast, HypSec leverages existing hardware features to protect virtual machine data and supports KVM on ARM server hardware.

Recent architectural extensions [3, 37] proposed hardware support on x86 for encrypted virtual machines. Fidelius [89] leverages AMD’s SEV (Secure Encrypted Virtualization) [3] to protect VMs. Unlike these encryption-based approaches, HypSec primarily uses access control mechanisms.

Some projects focus on hardening the hypervisor to prevent exploitation. They improve hypervisor security by either enforcing control flow integrity [84] or measuring runtime hypervisor integrity [9, 26]. These approaches can be applied to HypSec to further strengthen VM security. XMHF [81]

verifies the memory integrity of its hypervisor codebase but supports single VM with limited virtualization features. Verification of HypSec's TCB is an area of future work.

Various projects extend a trusted hypervisor to protect software within VMs, including protecting applications running on an untrusted guest OS in the VM [16, 17, 33, 55, 91], ensuring kernel integrity and protecting against rootkits and code injection attacks or to isolate I/O channels [64, 69, 83, 85, 95], and dividing applications and system components in VMs then relying on the hypervisor to safeguard interactions among secure and insecure components [27, 54, 76, 79]. Overshadow [16] and Inktag [33] have some similarities with HypSec in that they use a more trusted hypervisor component to protect against untrusted kernel software. Overshadow and Inktag also assume applications use end-to-end encrypted network I/O, though they protect file I/O by replacing it with memory-mapped I/O to encrypted memory. HypSec has three key differences with these approaches. First, instead of memory encryption, HypSec primarily uses access control, which is more lightweight and avoids the need to emulate functions that are problematic when memory is encrypted. Second, instead of instrumenting or emulating complex system calls, HypSec relies on hardware virtualization mechanisms to interpose on hardware events of interest. Finally, instead of protecting against guest OS exploits, HypSec protects against hypervisor and host OS exploits, which none of the other approaches do.

## 8 Conclusions

We have created HypSec, a new approach to hypervisor design that reduces the TCB necessary to protect virtual machines. HypSec decomposes a monolithic hypervisor into a small, trusted corevisor and untrusted hostvisor, the latter containing the vast majority of hypervisor functionality including an entire host operating system kernel. The corevisor leverages hardware virtualization support to execute at a higher privilege level and provide access control mechanisms to restrict hostvisor access to VM data. It can be simple because it only needs to perform basic CPU and memory virtualization. When VMs use secure I/O channels, HypSec can protect the confidentiality and integrity of all VM data. We have demonstrated that HypSec can support existing commodity hypervisors by retrofitting KVM/ARM. The resulting TCB is orders of magnitude less than the original KVM/ARM. HypSec provides strong security guarantees to VMs with only modest performance overhead for real application workloads.

# WAVE: A Decentralized Authorization Framework with Transitive Delegation

Michael P Andersen, Sam Kumar, Moustafa AbdelBaky  
Gabe Fierro, John Kolb, Hyung-Sin Kim, David E. Culler, Raluca Ada Popa  
*University of California, Berkeley*

## Abstract

Most deployed authorization systems rely on a central trusted service whose compromise can lead to the breach of millions of user accounts and permissions. We present WAVE, an authorization framework offering *decentralized trust*: no central services can modify or see permissions and any participant can delegate a portion of their permissions autonomously. To achieve this goal, WAVE adopts an expressive authorization model, enforces it cryptographically, protects permissions via a novel encryption protocol while enabling discovery of permissions, and stores them in an untrusted scalable storage solution. WAVE provides competitive performance to traditional authorization systems relying on central trust. It is an open-source artifact and has been used for two years for controlling 800 IoT devices.

## 1 Introduction

Authorization and authentication are fundamental components of many systems. Most authorization systems today *rely on centralized services* such as centralized credential stores (e.g., [15, 19, 56]), Access Control Lists (ACLs), Active Directory, and OAuth [4]. For example, in a calendar application, a central service stores which users have access to what calendars, and users authenticate to it, e.g. via username and password. In these systems, delegation is critical: for instance, allowing an assistant to edit your calendar, and letting the assistant further delegate restrictive view access to an event organizer. These forms of delegation are typically implemented as changes to a centralized ACL.

However, this approach presents two fundamental problems. First, a centralized service is a central point of attack: a single attack can simultaneously compromise many user accounts and permissions. There have been numerous such breaches [39], and attackers even managed to log in as the victim users. Second, the operator of the central server has a complete view of the private permission data for all users (thus seeing users' social relationships [54]), and can modify permissions [2].

Responding to the weaknesses of centralized systems, recent security systems are increasingly avoiding a trusted central service. This approach has been adopted by end-to-end encryption systems [25], such as WhatsApp and Signal, blockchains (e.g., Bitcoin, Ethereum, Zcash), or ledgers (e.g., IBM's Hyperledger [17], Certificate Transparency [41], Key Transparency [32]). Our goal is to build a scalable decentralized authorization system, permitting delegation under a similar threat model.

We propose a decentralized authorization system that *does not rely on a trusted service*, WAVE (“**W**AVE is an **A**uthorization **V**erification **E**ngine”). WAVE offers decentralized trust: each user's WAVE client manages the permissions of that user and can delegate access to other users. WAVE enforces delegation *cryptographically*, not via a trusted service. It aims to capture a wide range of authorization policies and to provide an alternative to traditional systems, such as OAuth [4] and Active Directory.

Importantly, in providing decentralized transitive delegation, WAVE facilitates applications that span multiple trust domains. For example, IoT orchestration applications like If This Then That (IFTTT) [3] tie together multiple vendors and users, but IFTTT's design relies on several central points of attack: the vendor OAuth servers and the IFTTT token storage servers. The compromise of any one of these servers may affect hundreds of thousands of users. Using WAVE, greater cross-administrative-domain orchestration can be achieved with no central authorization servers, reducing the trust that each domain must place in the others.

### 1.1 Usage Scenarios

While authorization plays a key role in the security of almost any system today, the benefits of decentralized authorization are most pronounced in systems that are inherently distributed, where the prevailing centralized authorization schemes undermine what would otherwise be a resilient system. Our deployment of WAVE over the past two years has focused on securing distributed IoT devices and services used to monitor and control over twenty small to medium-sized commercial and residential buildings; hence, we will use smart buildings as a running example.

Consider a set of campuses, each owned by a property manager. Each campus is composed of multiple buildings, with portions of each building leased out to tenants by the property manager. The property manager within each campus is the authority for the cyberphysical resources associated with the buildings in the campus, but they must *delegate* permission to the individual building managers who must further delegate permissions to the tenants, allowing them to control the portions of the buildings that they rent. Any of these principals may then further delegate permissions to IoT devices, long-running analytics or control services operating on their behalf, perhaps provided by the utility. The building manager and/or tenant will also grant ephemeral permissions on subsets of the building infrastructure to contractors (like HVAC commissioning teams) and, especially in our case, to

researchers.

A similar structure occurs in small residential buildings where a homeowner installs smart devices such as lights and thermostats and needs to delegate permission on those devices to their partner, guest, nanny, or children.

Cross-administrative-domain delegation is present in both examples. In larger buildings, we see the boundary between the property owner and the tenants. In residential buildings, this is most evident when using orchestration tools like IFTTT, where an organization, distinct from the owner of the devices, runs the controller service and needs to obtain permission from the owner.

WAVE is not limited to IoT. It provides general purpose delegable authorization and can, for example, be used in place of OAuth to remove the risk of the centralized token-issuing server and allow for richer delegation semantics.

## 1.2 High-Level Security Goal & Threat Model

At a high level, our objective is to design a system where the compromise of an authorization server does not compromise all the users' permissions. Namely, even if an adversary has compromised any authorization servers and users, it should not be able to:

1. Grant permissions on behalf of uncompromised users.
2. See permissions granted in the system, beyond those potentially relevant to the compromised users. See §4 and §B for our definition of relevant.
3. Undetectably modify the permissions received/granted/revoked by uncompromised users from uncompromised users, or undetectably prevent uncompromised users from granting/receiving/revoking permissions to/from uncompromised users.

## 1.3 Failure Of Existing Systems

Existing authorization systems fall short in two general areas: they do not meet our Security Goals or they do not provide the features required for IoT usage scenarios. More concretely, we summarize the following six requirements that are not simultaneously met by any existing system (as illustrated in Table 4):

**No reliance on central trust.** For example, in the smart buildings scenario, the status quo has certain devices (e.g. LiFx light bulbs) perform their authorization on the vendor's server in the cloud. If that server is compromised, all of those devices in all of the customer buildings are compromised. In this case, the adversary can violate all three Security Goals.

**Transitive delegation.** The smart building scenario illustrates the necessity for transitive delegation and revocation where, for example, a tenant can further delegate their permissions to a control service or guest and have those permissions predicated on the tenant's permissions. If the tenant moves out, all of the permissions they granted should be automatically revoked, even if the building manager is unaware of the grants the tenant has made. This form of transitive delegation is not found in widely-deployed systems like LDAP

or OAuth: where delegation exists, it does not have this transitive predication property. In contrast, this property is well developed in academic work [49, 13, 43, 45, 29, 14, 51, 11].

**Protected permissions.** Parties should be able to see only the permissions that are potentially relevant to them. Even though the property manager is the authority for all the buildings, they must not be able to see the permissions that the tenants grant (Security Goal #2). Existing systems do not offer a solution to this requirement: in many centralized systems, for example, whoever operates the server can see all the permissions. We elaborate further in §9.

**Decentralized verification.** Some existing decentralized systems (e.g. SDSI/SPKI [49] and Macaroons [12]) allow only the authority to verify that an action is authorized. This is adequate in the centralized service case where the authority is the service provider, but it does not work in the IoT case where the root authority (the property manager) has nothing to do with the devices needing to verify an action is authorized (for example a thermostat). Any participant must be able to verify that an action is authorized.

**No ordering constraints.** Delegations must be able to be instantiated in any chronological order. For example, a participant can delegate permissions in anticipation of being granted sufficient ones for the delegation to be useful. We have found this to be critical in our deployments. As a further example, when the building manager's key needed to be replaced (e.g. it expired or was compromised), they created a new key and the property manager had to grant replacement permissions to this new key. In many existing systems (e.g. Macaroons [12]), this necessitates every tenant re-creating their entire permission trees, as all grants must happen in sequence, following the grants to the replacement key. This is not tractable in practice as it requires the coordination of many people and hundreds of devices, leading to extended downtime. Furthermore, when we had such ordering constraints in our prior deployments we observed users choosing insecure long expiry times or broad permissions to avoid this re-issue. As a result, we require that the system enables permission grants to occur out of order, so that permissions grants can be modified (revoked / re-issued) or any key can be "replaced" without re-issuing subsequent delegations. We have also found that this capability leads to safer user practices as "mistakes" like overly narrow permissions and short expiry times are easy to correct.

**Offline participants.** Not all participants have a persistent online presence. A device may be offline at the time that it is granted permissions (e.g. during installation) and it must be able to discover that it received permissions when it comes online. This is trivial to solve with a centralized authorization system, but is not solved in existing decentralized systems (e.g. SDSI/SPKI [49], Macaroons [12] and [13, 43, 45, 29, 27, 44, 59, 18, 57, 50]).

While many existing systems meet some of these require-

ments, no existing work meets all of the requirements concurrently, as shown in §9.

## 1.4 Challenges and Approach

**Compatible authorization model.** The first challenge is identifying a model for authorization that is compatible with these requirements. We examined many authorization models [12, 49, 24, 13, 43, 45, 29, 27, 58, 37, 30, 48, 19, 15, 56, 44, 59, 18, 57, 50], but most of them cannot be enforced without a centralized authority or are incompatible with the other requirements. Nevertheless, we found that representing the authorization model as a graph, such as in SDSI/SPKI [49, 24] where a proof of authorization is a path through a graph, is compatible with our requirements, even though the existing systems implementing it fall short.

Consequently, WAVE maintains a global graph of delegations between entities (Fig. 1a), which are associated with participants. An *entity* is a collection of public and private key pairs and can correspond to a user, service, or group. An edge indicates that an entity grants another entity access according to a *policy*, which is one or more permissions along with a description of the resources for which the permissions are granted, and the expiry of the grant. This enables fine-grained transitive delegation with revocation and expiry.

To enforce the policy cryptographically, each edge, from *issuer* to *subject* entity, is a signed certificate recording the delegation of permissions, which we call an *attestation*. A path from an entity to another entity grants access equal to the *intersection* of the policies on that path. The graph enables entities to *prove* they have some permission  $P$  by revealing a path through the graph from an authority entity to themselves where all the edges of the path grant a superset of  $P$ . This path is called a *proof*. The graph construction allows permissions to be granted in any order, including delegation of permissions one does not yet possess but expects to receive in the future.

While WAVE's authorization graph and proofs are structurally similar to SDSI/SPKI, WAVE differs in three important aspects: (1) while in SDSI/SPKI only a central authority (holding an ACL) can verify a proof, in WAVE anyone can independently (with no communication) verify a proof yielding an authorization policy. (2) WAVE provides a trustworthy, scalable storage solution for attestations that enables discoverability with offline participants and out of order grants, which is out of scope for SDSI/SPKI. (3) Attestations are encrypted in WAVE whereas they are visible in SDSI/SPKI. These differences enable meeting the requirements in §1.3.

**Scalable untrusted storage.** To support granting permissions to offline participants, we use a storage system that enables participants to discover attestations when they later come online. To meet the requirements above, the storage must be able to prove its integrity cryptographically, so as not to compromise Security Goal #3.

Our first design of WAVE [9] was built on Ethereum,

which has these properties. Unfortunately, our experiments showed that a blockchain-based system will not scale to a global size, even though changing permissions is far less common than accessing data.

We present a new type of transparency log, the *Unequivocal Log Derived Map (ULDM)*. Unlike Certificate Transparency [41], which cannot form a proof of nonexistence needed for revocations, or Key Transparency [32], which requires users to audit every object at every epoch, a ULDM is both capable of handling revocations and is efficiently auditable. The ULDM forms the foundation of a horizontally scalable storage tier with cryptographically proven integrity, which could also be useful outside of WAVE. Our current design, described in §5, allows for a shared-nothing architecture of storage servers with independent auditors that need only communicate periodically (e.g., once a day) with clients to verify the correct operation of the storage. The resulting architecture is arbitrarily horizontally scalable with each node having a higher capacity and lower latency than a blockchain, as we show in §8.

**Confidentiality of permissions.** To meet the requirement of protected permissions and Security Goal #2 despite the public ULDM storage tier, there must be a mechanism to prevent the storage servers or the general public from seeing the permissions, while ensuring that parties forming and verifying proofs can see the necessary permissions. The challenge lies in preserving confidentiality while enabling out of order delegation and offline participants. We overcome this challenge with a novel technique called *reverse-discoverable encryption* (RDE, §4) used to encrypt attestations. RDE allows entities to efficiently discover and decrypt the attestations that they can use in a valid proof while using policy-aware encryption to hide most other attestations. Importantly, RDE does not introduce additional constraints on the ordering of delegations or liveness of participants.

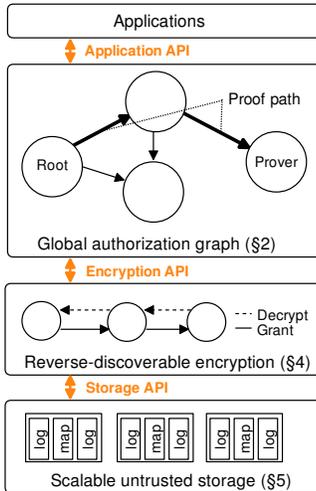

Our implementation of WAVE is a real-world *open-source* artifact [7]. We have deployed and operated various versions of WAVE over the past two years. During this time, WAVE has been used to control more than 20 buildings containing more than 800 IoT devices. We discuss lessons from our deployment in §8.4; in particular, this has allowed us to confirm that the authorization and delegation model presented here is useful in practice. Further, WAVE has offered performance comparable to traditional authorization systems, validating real proofs in 1–4 ms, depending on the depth of delegation.

## 2 WAVE Overview

WAVE runs as a service that can be logically divided into three layers (Fig. 1a) each providing an API (Fig. 1b).

### 2.1 Global Authorization Graph

Recall that the global authorization graph consists of entities, which are bundles of public and private keys, and attestations, which are the permission grants between them. The client (representing a user, device, or service) inter-

(a) The WAVE stack

Subsystem	API
Application	CreateEntity() $\implies$ (privEnt, pubEnt) Delegate(issuer:privEnt, subject:pubEnt, policy) $\implies$ attestation CreateProof(subject:privEnt, policy) $\implies$ (proof) VerifyProof(proof) $\implies$ (subject:pubEnt, policy) NewName(issuer: privEnt, subject:pubEnt, name) $\implies$ (nameDecl) ResolveName(resolver: privEnt, name) $\implies$ (nameDecl) Revoke(issuer:privEnt, object:attestation/pubEnt)
Encryption	EncryptAttest(attestation, partition) $\implies$ attCiphertext DecryptAttest(perspective:privEnt, attCiphertext) $\implies$ attestation
Storage	Put(object, server) $\implies$ hash Get(hash, server) $\implies$ object Enqueue(list:hash, entry:hash, server) lterQueue(list:hash, cursor) $\implies$ (entry:hash, newCursor)

(b) The API provided by WAVE's stack.

Figure 1: An overview of WAVE

acts through the WAVE service with the global authorization graph. Clients can create new entities (e.g., for a service they are deploying).

To grant permissions to other entities, clients use the WAVE service to construct an attestation signed by the granting entity containing a policy describing the permissions. An attestation  $A$  consists of:

- $A$ .issuer: the entity that wishes to grant permissions to another entity,
- $A$ .subject: the entity receiving the permissions,
- $A$ .policy: an expression of permissions, for example, RTree described in §2.4, and
- a revocation commitment described in §6.1
- signature(s) from the issuer.

When accessing a service or controlling a device, clients request a proof from the WAVE service; the WAVE service will search for a path through the global authorization graph from the authority for the service or device in question to the client's entity, where each edge grants a superset of the required permissions. The representation of this path is a self-standing proof of authorization that can be verified without communication with the proving entity. The receiving service or device can use the WAVE service to validate a proof, yielding the authorization policy it permits.

The WAVE service also allows for mapping human readable names to entity public keys to make the system more usable, as we elaborate in §6.2.

## 2.2 Reverse-Discoverable Encryption (RDE)

To ensure the privacy of permissions, the WAVE service uses our protocol, Reverse-Discoverable Encryption (described in §4) to encrypt the attestations. The encryption layer is transparent to clients: the WAVE service will discover and decrypt the portion of the global graph that concerns the client automatically. The only time a client interacts with the encryption layer is when they use RDE to encrypt messages for

application-level end-to-end encryption, which is beyond the scope of this paper.

## 2.3 Scalable Untrusted Storage

When the client instructs the WAVE service to create an entity or an attestation, the WAVE service will place the public keys (for entities) or RDE ciphertext (for attestations) into the scalable untrusted storage (§5). As with RDE, the placement into storage is transparent to clients: clients operate only at the level of granting permissions, creating proofs and verifying proofs. The WAVE client will interact with the storage to discover and decrypt the portion of the global graph necessary for performing those actions without the client manually publishing or retrieving objects.

## 2.4 Resource Tree Authorization Policy

Although WAVE's design is agnostic to the specific mechanism used for expressing the authorization policy (i.e., it is compatible with existing policy languages such as [10, 12]), in our IoT deployments we use a simple yet widely applicable model: a resource tree (*RTree*) modelled roughly after SPKI's pkpfs tags [24].

An RTree policy manages permissions on a hierarchically organized set of resources. A resource is denoted by a URI pattern such as `company-entity/building/device` or `user-entity/albums/holiday/*`. The first element of a URI (e.g. `company-entity`) is called the *namespace authority* or just *namespace*, which specifies the entity who is the *root of authorization* for that resource (the entity who has permission on that policy without having received permission from someone else). The global authorization graph has many different RTrees with namespace authorities, ideally with one per intrinsic authority, e.g. homeowner or company. This lets the system be as decentralized as the naturally occurring authority structure, unlike the single-authority-per-vendor model, used in most systems today, which forces centralization. Depending on the structure of a given resource

hierarchy, there may be a minimum length for the resource URI. This often occurs where the first few elements are used to capture boundaries that exist naturally, such as a department, building or project. These elements that can be relied upon to exist, if present for a given RTree, are called the *resource prefix*. An RTree policy consists of:

- A set of permissions (strings such as “schema::read”)
- A URI pattern describing a set of resources
- A time range describing when the grant is valid
- An *indirections* field, which limits re-delegation

For example, a building manager entity might grant `hvac::actuate on bldgnamespace/floor4/*` over a time range corresponding with the lease terms, allowing further delegation, to a tenant entity.

## 2.5 How WAVE Meets the Requirements

WAVE’s global authorization graph, RDE, and storage layer allow it to achieve the requirements established in §1.3:

**No reliance on central trust.** WAVE achieves decentralization via three design features. First, the permission delegations are cryptographically enforced without a verifying authority. Secondly, any participant can create an RTree namespace, mimicking the natural ownership of resources. Finally, our Unequivocal Log Derived Map §5 allows participants to detect if the untrusted storage servers violate integrity. Although the storage server is centralized for availability, it is not a point of central trust as its behavior is cryptographically enforced.

**Transitive Delegation.** The graph-based authorization model efficiently captures transitive delegation. To delegate permissions, any entity can create an attestation that captures which subset of their permissions they wish to delegate. Since a proof is represented by a path through the graph, if an entity higher up in the delegation tree is revoked, all entities beneath it will no longer be able to prove they have permissions, even though the party revoking the entity may have been unaware of the delegations lower in the tree. This gives us the transitive delegation property.

**Protected permissions.** Through the Reverse-Discoverable Encryption scheme in §4, no party can decrypt attestations that are not potentially relevant to them. In our example, the property manager cannot decrypt attestations that the tenant makes, and the party running the storage servers cannot read any of the attestations.

**Decentralized verification.** WAVE proofs can be verified by anyone, unlike in SDSI/SPKI [49] or Macaroons [12]. This enables an IoT device to verify all messages it receives without communicating with an external service (with the exception of revocation checks, as detailed in §6.1).

**No ordering constraints.** An entity can grant any permissions at any time, including those that it has not yet received (although the recipient won’t be able to form a proof yet). Consequently, attestations can be replaced anywhere in the hierarchy without requiring re-issue of subsequent delega-

tions. Furthermore, our privacy mechanism preserves this property because an attestation can be encrypted under a policy-specific key before the issuer has been granted the permissions corresponding to the policy.

**Offline participants.** Attestations are disseminated through the ULDM storage tier (§5) which allows for entities to discover permissions they have been granted while they were offline and removes the need for any out-of-band online communication between entities.

## 3 Security Guarantees and Roadmap

WAVE must fulfill three security goals (§1.2). Regarding Security Goal #1, WAVE guarantees the following:

**Guarantee 1.** *An attacker Adv can form a proof of authorization on a policy if and only if the authority for that policy is compromised or has delegated access, directly or indirectly, to a compromised entity.*

This guarantee follows directly from the fact that each attestation is signed by its issuer. A WAVE proof can be thought of as a certificate chain. Given that existing systems like SDSI/SPKI [49] use a similar construction, we do not explore this further.

To achieve the other two security goals, WAVE introduces two new techniques: Reverse-Discoverable Encryption (§4) to satisfy Security Goal #2, and Unequivocal Log-Derived Maps (§5) to satisfy Security Goal #3. The following sections introduce these techniques and state formal security guarantees.

## 4 Encrypting Attestations

We encrypt attestations such that entities can decrypt attestations they can use in a valid proof. Entities cannot learn the policy (i.e., what permissions are granted) or the issuer (i.e., who created the attestation) of most other attestations. Our technique, *reverse-discoverable encryption* (RDE), does not require out-of-band communication between entities and works even if attestations are created out of order.

We present our solution incrementally: §4.1 formalizes the problem that RDE solves. §4.2 presents a simplified design of RDE, based on traditional public-key encryption, that provides a weak but useful security guarantee called “structural security.” §4.3 augments the simplified RDE with *policy-aware* encryption to provide a significantly stronger notion of security, at the expense of making discoverability of attestations inefficient. §4.4 presents our final protocol, which provides both efficient discovery of attestations and a significantly stronger guarantee than structural security.

For all the security guarantees stated in this section, we assume that the attacker Adv is computationally-bounded, and that standard cryptographic assumptions hold.

### 4.1 Graph-based Formalization

We formalize the problem in terms of the global authorization graph; an example is shown in Fig. 2. For **correctness**, we require that each entity can decrypt all attestations that

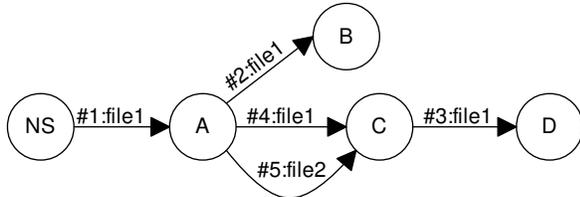

Figure 2: The number to the left of each colon indicates when the attestation was created. The string to the right denotes the resource on which it grants permission.

it can use to form a valid proof where it is the subject. In Fig. 2, entity D should be able to see attestations #1, #4, and #3. Correctness does *not* require D to be able to see attestation #2, as there is no path from B to D granting access to `file1`. Similarly, correctness does *not* require D to be able to see attestation #5, as there is no path from C to D granting access to `file2`. For **security**, we would like each entity to see as few additional attestations as possible.

## 4.2 Structural RDE

This section explains a simplified (yet weaker) version of RDE that is helpful to understand the main idea behind our technique. For this version alone, assume there are no revoked/expired attestations.

Each entity has an additional public-private keypair used only for encrypting/decrypting attestations, separate from the keys used to sign attestations. This keypair is governed by two rules: when an entity grants an attestation, it (1) attaches its private key to the attestation, and (2) encrypts the attestation, including the attached private key, using the public key of the attestation’s subject (recipient). For example, in Fig. 2, #3 contains  $sk_C$  and is encrypted under  $pk_D$  (i.e.,  $Enc(pk_D; \#3 || sk_C)$ ).

This meets the correctness goal; D can decrypt #3 as #3 is encrypted under  $pk_D$ . In decrypting #3, it obtains  $sk_C$ , which it can use to decrypt #4. This works even though attestation #4 was issued after #3. In decrypting #4, it obtains  $sk_A$ , which it can use to decrypt #1. Essentially, each entity can see the attestations it can use in a proof by decrypting them in the reverse order as they would appear in a proof.

This achieves a simple security guarantee called **structural security**, which allows an entity  $e$  to see any attestation  $A$  for which there exists a path from  $A.subject$  to  $e$ . We call it “structural” security because only the structure of the graph, not the policies in attestations, affects whether  $A$  is visible to  $e$ . While structural RDE uses traditional public-key encryption, it differs from systems like PGP in that entities include their long-lived private keys in the attestations they encrypt.

## 4.3 Policy-Aware RDE

Structural security only takes into account the structure of the graph, not the policy of each attestation (i.e., the resources and the expiry). For example, structural RDE allows D to decrypt #5, though this is not necessary to meet the correctness goal; D cannot form a valid proof containing #5 because

its policy differs from #4’s (they delegate access to different files). With policy-aware RDE, we achieve a stronger notion of security that prevents D from decrypting #5 by making two high-level changes to structural RDE.

First, whereas structural RDE encrypts each attestation  $A$  according to only  $A.subject$ , policy-aware RDE encrypts each attestation  $A$  according to both  $A.subject$  and  $A.policy$ . Second, whereas structural RDE includes a key in  $A$  that can decrypt *all* attestations immediately upstream of  $A$ , policy-aware RDE includes a key in  $A$  that can only decrypt upstream attestations with *policies compatible with  $A.policy$* .

**Choosing a suitable encryption scheme.** Because the policy of an attestation determines how it is encrypted, the encryption scheme must be *policy-aware*. In particular, traditional public-key encryption is insufficient for policy-aware encryption (except for a boolean policy). We use the RTree policy type to explain our policy-aware RDE, although the technique applies to other policy types.

We identify Wildcard Identity-Based Encryption (WIBE) [5] as a suitable policy-aware encryption scheme to implement RDE for the RTree policy type. Typically, IBE [16] (or an IBE variant such as WIBE) is instantiated with a single centralized Private Key Generator (PKG) that issues private keys to all participants. This does not meet the goals of WAVE, because the PKG is a central trusted party. In RDE, however, our insight is to *instantiate a WIBE system for every entity, so there is no central PKG*.

A WIBE system consists of a master secret and public key pair (WIBE.msk, WIBE.mpk). A message  $m$  is encrypted using the master public key WIBE.mpk and a fixed-length vector of strings, called an ID:  $WIBE.Enc(WIBE.mpk, ID; m)$ . Using msk, one can generate a secret key for a set of IDs. This set is expressed as an ID with some components replaced by wildcards, denoted  $ID^*$ . The secret key  $sk_{ID^*}$  can decrypt an encrypted message,  $WIBE.Enc(WIBE.mpk, ID; m)$ , if  $ID^*$  and  $ID$  match in all non-wildcard components.

Every policy  $p$  has an associated WIBE ID called a *partition*. The partition corresponding to policy  $p$  is denoted  $P(p)$ . When issuing an attestation  $A$ , an entity encrypts it using  $P(A.policy)$ , in the WIBE system of  $A.subject$ :  $WIBE.Enc(WIBE.mpk_{A.subject}, P(A.policy); A)$ . Furthermore, the issuing entity generates secret keys in its own WIBE system, suitable to decrypt messages encrypted under  $P(A.policy)$ , and includes them in the attestation. Let  $Q(A.policy) = \{ID^*_i\}_i$  represent the set of IDs suitable for decrypting attestations encrypted under  $P(p)$  for  $p$  compatible with  $A.policy$ , then  $A$  includes  $W = \{WIBE.KeyGen(WIBE.msk_{Issuer}, ID^*_i)\}_{ID^*_i \in Q(A.policy)}$ . Below, we develop the *partition map* for RTree, which derives a partition from an RTree policy (i.e., functions  $P$  and  $Q$ ).

**Partition map for RTree.** To define  $P$ , consider that an RTree policy consists of a resource prefix as defined in §2.4 (matching multiple resources) and a time range during which

the permission is valid. To express the start and end of this range as a WIBE ID, we define a time-partitioning tree of depth  $k$  over the entire supported time range; now any time in the supported time range can be represented as a *vector* representing a path in the tree from root to leaf. A WIBE ID is a length- $n$  vector: to represent attestations with a certain time range, we choose  $k$  of those  $n$  components to encode the valid-after time, and another  $k$  components to encode the valid-before time. The remaining  $n - 2k$  components are used for the resource prefix. When granting an attestation for an RTree policy, the issuer encrypts the attestation contents under the resulting WIBE ID  $= P(A.policy)$ . Note that for a time tree of depth  $k$ , and a resource prefix of length  $\ell$ , WIBE must be instantiated with at least  $n = 2k + \ell$ .

The issuer must also include the policy-specific WIBE keys from their own system in the attestations, generated with ID\*s  $Q(A.policy)$ , so that upstream attestations with compatible policies can be discovered. We define  $Q$  for RTree as: let  $E$  be a set of subtrees, each represented as a *prefix* of a time vector (i.e., a vector where unused components are wildcards), that covers the time range from the earliest possible encryption start time to the end of the time range of the attestation's validity. Let  $S$  be a set of subtrees that covers the time range from the start of the attestation's time range to the latest possible encryption time. Attestations have a maximum validity of three years so this limits how long the start and end ranges need to be.  $Q$  returns ID\*s corresponding to the Cartesian product  $S \times E$  with each ID\* also containing the policy's resource prefix. This allows any upstream attestation with an overlapping time range and compatible resource prefix to be decrypted by one of the secret keys in this attestation.

#### 4.4 Efficient Discoverability

In the scheme above, attestations are encrypted under the partition in the subject's WIBE system. Unfortunately, it is subject to two major shortcomings. First, a WIBE ciphertext hides the message that was encrypted, but not the ID used to encrypt it; an attacker who guesses the ID of a ciphertext can efficiently verify that guess. Thus, every encrypted attestation leaks its partition. The second and more serious problem is that attestations are not efficiently discoverable. To understand this, suppose that Bob has issued many attestations  $A_1, \dots, A_n$  for Alice, with different policies. After this, an attestation  $B$  is granted to Bob. Alice might be able to form a proof using  $B$  and one of the  $A_i$ , but she does not know which of the  $A_i$  has a policy that intersects with  $B.policy$ . As a result, she does not know which private key to use to decrypt  $B$ , and has to try *all* of the private keys conveyed by the  $A_i$ . This is infeasible if  $n$  is large, and becomes a vector for denial of service attacks.

If Alice knows  $B$ 's partition, then the problem is solved—Alice can locally index the private keys she has from Bob's system, and efficiently look up a key that can decrypt  $B$ .

However,  $B$  cannot include its own partition in plaintext, because it may leak part of  $B.policy$ .

We solve this by encrypting the partition and storing it in the attestation. For this outer layer of encryption we use a more standard identity-based encryption (denoted IBE) that does not permit extracting the identity from the ciphertext [46, 42] because we do not need wildcards. As with the WIBE scheme, every entity has its own system, removing the centralized PKG. The ID used to encrypt the partition is called the *partition label*, and is denoted  $L(A.policy)$ . For the RTree policy type, it is the RTree namespace of  $A.policy$ . We expect users to have far fewer unique keys for this outer layer, so they can feasibly try all the keys they have.

We also move the WIBE ciphertext under this IBE encryption so that the partition cannot be extracted. Finally, we include IBE keys from the issuer's IBE system, to allow the subject to discover the partition of upstream attestations. We denote the ID\*s corresponding to these keys as  $M(A.policy)$ . Because the partition label is simpler in structure than the partition, defining  $M(A.policy) = \{L(A.policy)\}$  is sufficient. So far, what gets stored in the attestation is:

$$\begin{aligned} & \text{IBE.Enc}(\text{IBE.mpk}_{A.subject}, L(A.policy); P(A.policy)) || \\ & \text{WIBE.Enc}(\text{WIBE.mpk}_{A.subject}, P(A.policy); W || I) \end{aligned} \quad (1)$$

where  $W$  is defined as above, and

$$I = \text{IBE.KeyGen}(\text{IBE.msk}_{\text{Issuer}}; L(A.policy))$$

denotes the IBE secret key from the issuer's system.

#### 4.5 Security Guarantees

We explain here at a high level how the policy-aware RDE restricts the visibility of attestations when used with RTree. Formal guarantees are given in Appendix B. In summary, for each attestation  $A$  granting permission on a namespace: entities who have not been granted permissions in that namespace in a path from  $A.subject$  can only see the subject and revocation commitment. Entities who have been granted some permissions in the namespace in a path from  $A.subject$  can see the partition (in essence the identifier of the key required to decrypt it). An entity  $e$  can decrypt an attestation  $A$  and use it in a proof if there exists a path, from  $A.subject$  to  $e$  where adjacent attestations (including  $A$ ) have intersecting partitions. Issuers can encrypt under IDs before the corresponding private keys exist, so we introduce no ordering requirements and no interactivity requirements.

Thus, even though policy-aware RDE permits some entities to see more attestations than strictly needed to create a proof of authorization, it still provides a significant reduction in visibility when compared to structural security. We formalize the security guarantees of RDE in Appendix B.

A number of potential side channels are out of scope for WAVE, and can be addressed via complementary methods. Our storage layer does not provide any additional confidentiality, so compromised storage servers can see the time of each operation (e.g., when encrypted attestations are stored),

which encrypted attestations are fetched, as well as networking information of the packets arriving at the storage servers (which could be protected via Tor [1], a proxy, or other anonymous/secure messaging methods [21]).

**Revocation.** Although revoked attestations cannot be used in a proof due to the commitment revocation scheme described in §6.1, they still confer the ability to decrypt upstream attestations. Therefore we consider them part of the graph in the formal guarantees (Appendix B). This can be mitigated by keeping expiry times short and reissuing the attestations. As there are no ordering or interactivity requirements, short expiries are easy to implement. For example, if attestation #1 in Fig. 2 were to expire and be reissued, it would not require the reissue of any other attestation.

**Integrity.** Finally, to maintain integrity, the issuer signs the attestation with a single-use ephemeral key ( $pk_e, sk_e$ ):  $s_1 = \text{Sign}(sk_e; A \setminus s_1)$ , where  $A \setminus s_1$  denotes the entire attestation except for  $s_1$ . Then, the issuer includes  $s_1$  in the attestation in plaintext. The use of an ephemeral key ensures the signature does not reveal the issuer’s public key. The issuer includes the outer signature in the plaintext header of the attestation. The issuer signs the ephemeral key  $pk_e$  with their entity private key,  $s_2 = \text{Sign}(sk_{\text{issuer}}; pk_e)$ , creating a short signature chain that ensures the attestation cannot be modified or forged. The issuer includes  $s_2$  in the attestation *encrypted*, to avoid revealing the issuer’s public key. In forming a proof, the verifier is allowed to decrypt  $s_2$ , allowing the verifier to verify  $s_2$  and then  $s_1$ .

#### 4.6 Reducing Leakage in Proofs

The methods discussed above ensure that a prover is able to decrypt all the attestations that it requires to build a proof. However, if a participant simply assembles a list of decrypted attestations into a proof and gives those attestations to a verifier, the verifier learns not only the attestations in that proof, but also the WIBE keys in those attestations, which it can use to decrypt other attestations not in the proof. To solve this, we split the attestation information into two *compartments*, one for the prover (that includes keys it needs to decrypt other attestations) and one for both the prover and the verifier (that includes the policy, issuer, expiry, etc.). We encrypt the prover compartment with  $k_{\text{prover}}$  and the prover/verifier compartment with  $k_{\text{verifier}}$ , both symmetric keys freshly sampled for each attestation.  $k_{\text{prover}}$  and  $k_{\text{verifier}}$  are encrypted with WIBE. This allows the prover to reveal to the verifier the necessary parts of an attestation by sending it the AES verifier key, without allowing the verifier to decrypt other attestations. The final structure of the attestation is in Fig. 3.

#### 4.7 Discovering an Attestation

Each user’s WAVE client maintains a *perspective subgraph* with respect to the user’s entity, which is the portion of the global authorization graph visible to it. For each vertex (entity) in the perspective subgraph, the client “listens” for new attestations whose subject is that vertex (entity), using the

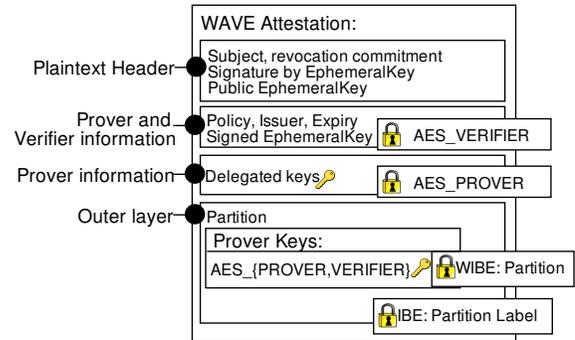

Figure 3: Encrypted WAVE attestation structure. The locks indicate the key used to encrypt the content.

Get and IterQueue API calls to the storage layer. For every attestation  $A$  received, the WAVE client does the following:

1. The client adds edge  $A$  to the perspective subgraph.
2. The client searches its local index for IBE keys received via attestations from  $A.subject$ , and tries to decrypt  $A$ ’s outer layer using each key. If none of the keys work, it marks  $A$  as **interesting** and stops processing it.
3. Having decrypted the outer layer in the previous step, the client can see  $A.partition$ . It searches its index for a WIBE key received via attestations from  $A.subject$  that are at least as general as  $A.partition$ . Unlike the previous step, this lookup is indexed. If the client does not have a suitable key, it marks  $A$  as **partition-known** and stops processing  $A$ .
4. Having completed the previous step, the client marks  $A$  as **useful** and can now see all fields in  $A$ . The client adds WIBE and IBE keys delegated via  $A$  to its index, as keys in the systems of  $A.issuer$ .
5. If the vertex  $A.issuer$  is not part of the perspective subgraph, then the client adds it and requests the storage layer for all attestations whose subject is  $A.issuer$ . They are processed by recursively invoking this algorithm, starting at Step 1 above.
6. If  $A.issuer$  is already in the perspective subgraph:
  - For each IBE key included in  $A$ , the client searches its local index for **interesting** attestations whose subject is  $A.issuer$ , and processes them starting at Step 2 above.
  - For each WIBE key, the client searches its local index for matching **partition-known** attestations whose subject is  $A.issuer$ , and processes them starting at Step 3.

This constitutes a depth-first traversal to discover newly visible parts of the authorization graph revealed by  $A$ .

#### 4.8 Extensions

Our RDE construction for RTree is performant but allows an entity to see attestations not required for correctness (i.e. partition-compatible attestations that are not usable in a proof, as defined in Appendix B). This can be marginally improved by including an additional set of WIBE keys in the attestations to allow for the full resource (not just the prefix) to be captured by  $P$  and  $Q$  but this increases the number

of included keys by a factor of  $\ell$ . Additionally, using KP-ABE [35] instead of WIBE would result in smaller attestations, but higher decryption times.

Aside from different encryption schemes, the RDE technique also generalizes beyond the RTree policy described above. Careful selection of  $P$  and  $Q$ , coupled with the use of a more expressive encryption scheme such as KP-ABE [35] allows for the realization of a more expressive policy (e.g. those discussed in §9) at the cost of decreased performance. While we have not found this trade-off warranted in our setting, this extension is straightforward and still meets our security goals. The formalism in Appendix B largely generalizes to other policy types, but the semantics of compatibility (Note 1) will change depending on the encryption schemes used and on the choice of  $P$ ,  $Q$ ,  $L$ , and  $M$ .

## 5 Scalable Untrusted Storage

To avoid centralized trust when storing attestations, we contribute a storage tier that enforces integrity cryptographically. This tier is physically decentralized: it is spread over multiple servers owned by different parties. Importantly, these individual servers are trusted to maintain availability, but not integrity (in the spirit of Certificate Transparency [41]) or privacy (achieved by RDE, §4). Thus, users and services can interact with storage servers that anybody operates, without trusting the servers' operators, except for availability.

The storage API (Fig. 1b) consists of four functions: Get and Put are used for placing/retrieving entities, attestations, name declarations (§6.2) and revocation secrets (§6.1) in storage; Enqueue places an object hash at the end of a named queue, and lterQueue allows retrieval from a queue. The queue functions facilitate discovery, allowing an entity to notify another entity that a new attestation has been granted to them or a new name declaration has been published.

A blockchain is a natural candidate for such a storage tier. Multiple servers are responsible for maintaining a blockchain, and, due to the underlying Merkle tree data structure, any one server can prove the integrity of its responses to state queries according to a specific Merkle tree root hash, meeting the requirements.

Prior versions of WAVE used an Ethereum blockchain, but extended use and experimentation revealed this solution to be inadequate for three reasons: (1) A blockchain introduces significant latency when adding objects to storage (up to a minute for a confirmed addition in Ethereum). (2) Participating in a blockchain requires constant network bandwidth and CPU time. (3) The blockchain does not scale past a few tens of transactions per second [22], so it could not store attestations for a global authorization system permitting thousands of delegations per second.

Although this problem appears solvable with existing transparency logs such as Certificate Transparency (CT) [41] or Key Transparency (KT) [32], neither of those is appropriate. CT cannot efficiently prove an object does not exist,

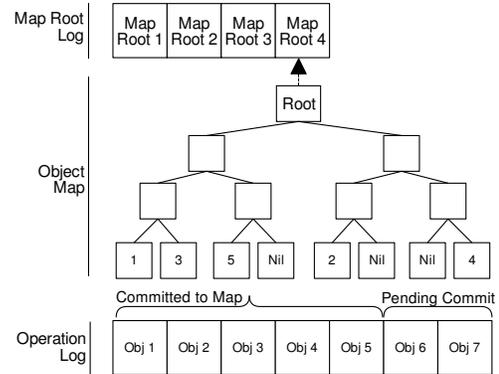

Figure 4: An Unequivocable Log Derived Map (ULDM) built from two Merkle tree logs and a Merkle tree map

needed for revocations, and KT is not efficiently auditable in our context (§9).

Instead, we propose an *Unequivocable Log Derived Map (ULDM)*, a transparency log based on the Verifiable Log Backed Map (VLBM) [23]. A VLBM allows the storage server to form proofs of integrity. The VLBM whitepaper is brief and incomplete: it does not discuss auditing, such as which proofs are exchanged or how they are published, so it is unclear how the VLBM prevents equivocation (i.e., presenting different internally consistent views to different clients). To our knowledge, there is no complete open-source VLBM implementation (the code in the repository [34] only implements a subset of the paper, omitting the log of map roots), so we could not build upon the VLBM or infer its scheme from the code. The ULDM is our approach to filling in the missing pieces, such as an auditing scheme to prevent equivocation and secure batching to increase performance.

A ULDM is constructed using *three* Merkle trees, each serving a different purpose, as shown in Fig. 4. The first tree is the Operation Log, which stores every Put and Enqueue operation and can prove the log is append-only. These operations are then processed in batches into the second tree, the Object Map. This is used to satisfy queries and prove that objects exist or do not exist within the map. The ULDM Object Map is different from [23] as it only stores the hashes of the objects. Finally, every map root created when a batch is processed is inserted into the third Merkle tree, the Map Root Log. This makes the data structure efficiently auditable, as we discuss in §5.4.

In what follows, for every reply that the storage server provides, the storage server provides a signature on the reply along with the relevant version of the Map Root Log.

### 5.1 Inserting Values

To insert a value, the ULDM server: (1) Inserts the value into the Operation Log. (2) Creates a new version of the Object Map that includes the hashes of the new entries. (3) Inserts the new map root into the Map Root Log. Step 1 is batched (multiple values are inserted into the Operation Log together) as is Step 2 (multiple values are inserted into the

Object Map together). Step 3 is synchronous with Step 2.

## 5.2 Merge Promises

Inserts would ideally be performed synchronously, allowing the server to return inclusion proofs for all three trees in response to the insert. Unfortunately, this results in a severe performance penalty as the ratio of new data to overhead (internal nodes in the trees) is poor. This is the same conclusion that Certificate Transparency reaches, and we use a similar solution: batching with promises. When inserting a value, a client receives a *merge promise* (called Signed Certificate Timestamp in CT) which states that the inserted value will be present by a certain point in time. In addition to the absolute timestamp used in CT, ULDM merge promises include the version of the root log as this allows a proof of misbehavior without a trusted source of time. Uncompromised clients must check the value has been merged later. To prove misbehavior when a value is not inserted on time, a client can present a merge promise along with a signed Map Root Log head where the corresponding Object Map does not contain the value and where the version of the head is greater than that in the promise; i.e., a server would need to stop operating completely if it wishes to both avoid merging an object and revealing it is compromised.

## 5.3 Retrieving Values

To retrieve a value, the client sends the storage server the Map Root Log version that it received in a previous request, along with the object identifier it is retrieving (e.g., the hash of an attestation or revocation commitment). If the object exists but has not yet been merged, the merge promise will be returned. There is no guarantee that the storage server will return a value before its merge promise deadline. If the object has been merged or doesn't exist, the server responds with: (1) the object or nil, (2) a proof that the object existed or did not exist in the Object Map at the latest map root, (3) a proof that the latest map root exists in the Map Root Log at the current Map Root Log head, and (4) a consistency proof that the current Map Root Log head is an append-only extension of the version the client passed in its request. This mechanism allows the client to verify that every map satisfying their queries is contained in the Map Root Log, and that the Map Root Log is consistent. Notably, it does not allow the client to verify that the map was correctly derived from the Operation Log. This task is performed by the auditors.

## 5.4 Auditing

An auditor is a party that connects to a storage server and replays the Operation Log to construct replicas of the Object Map and check the Map Root Log. Each client reports the latest Map Root Log head it obtains from the server (signed by the server along with a version number) to the auditors with some frequency. As the entries in the ULDM object map are the hashes of the objects, not the objects themselves, the map constructed by the auditor is several orders of mag-

nitude smaller than the sum of stored objects. For every entry in the Map Root Log, the auditor will read the incremental additions to the map from the Operation Log and apply them to its own copy. It then ensures the hash of the replica Object Map root matches the hash stored in the Map Root Log, proving that the map is correctly derived from the operation log (no objects were modified or removed).

The strength of the ULDM auditing scheme is that a client can report a single value to an auditor (the client's Map Root Log head) and this is sufficient to catch any dishonesty that might have occurred at any point in the client's history. Without the Map Root Log (such as in [34]), any auditing scheme would need to make the client report every Object Map root to the auditor or take the risk that some dishonesty might remain undiscovered. To see how this might occur, imagine that a storage server removes a revocation from the map, answers a query and then re-adds the revocation. Without the Map Root Log, if the client only reports the final map root to an auditor, it would conclude it is valid. In the ULDM case, the client would report the Map Root Log head which covers all prior map versions, enabling the auditor to discover that the previous query was satisfied from an invalid map.

Detecting dishonesty with a single infrequently-reported value has important scalability implications: as we expect there to be many clients, it is important that the load placed on auditors is much less than the query load generated by the clients, otherwise, only large companies could afford to be auditors. In the ULDM model, it is sufficient for a client to contact an auditor rarely (perhaps once a day) to ensure any prior equivocation is discovered.

We expect clients to periodically check in with a random auditor from a public list of auditors. This ensures that the storage server cannot maintain different states for different auditors as it will be discovered when auditor receives a Map Root Log head from a client that is inconsistent with the one received from the storage server directly.

## 5.5 Security Guarantee

We formalize the security guarantee of a ULDM, as follows. By honest client, we denote a client that is neither faulty nor compromised.

**Guarantee 2 (ULDM).** *Let  $C$  be a set of honest clients and  $S$  be a ULDM server. Observe that the Merge Promises following insert requests by these clients and Map Root Log heads sent with retrieval requests by these clients define a partial ordering  $L$  over all requests received by  $S$ . Suppose that there exists a nonempty set  $R$  of requests made by clients in  $C$ , such that there exists no possible history of requests made to  $S$  that is consistent with both  $L$  and all of  $S$ 's responses to requests in  $R$ . If there exists an auditor  $A$  such that each client in  $C$  has sent  $A$  a Map Root Log head it received from  $S$  at least as recent as the one it received for its latest request in  $R$ , then one of the following holds:*

1. One or more clients in  $C$  will be able to detect the in-

consistency by inspecting the responses it received to requests that it made to  $S$ .

2. The auditor  $A$  will be able to detect the inconsistency by inspecting the Map Root Log heads it received from clients in  $C$  and from  $S$ .

We provide a proof sketch in Appendix A.

## 6 Revocation and Naming

With the functionality of RDE and ULDM's, we can easily construct a revocation scheme and a PKI-replacing entity naming scheme.

### 6.1 Commitment-Based Revocation

When a user creates an attestation, it derives a random revocation secret  $s$  from a seed stored with the entity private keys and includes a cryptographic hash of  $s$ ,  $\text{hash}(s)$ , called the *revocation commitment*, in the attestation. The user then inserts the attestation into ULDM storage. Later on, the user can revoke the attestation by publishing the revocation secret  $s$  to the same storage. Revocation of entities works similarly. An entity must have their private key to perform revocation; mechanisms such as [53] can be used to ensure this.

When verifying a proof, the WAVE service ensures that no attestations in the proof have been revoked. To do so, it queries the storage tier for an object matching the revocation commitment  $\text{hash}(s)$  in the attestation. If such an object exists, the verifier knows that the attestation has been revoked. If such an object does not exist, the verifier receives a *proof of nonexistence* for that hash from the storage tier. WAVE ensures revocation only after the Merge promise deadline. The security of this procedure relies on the guarantees of our ULDM transparency log (§5). Alternatively, the entity forming the proof can include proofs of nonexistence, signed by the storage tier with a timestamp, with the attestations, so that the verifier does not have to perform this lookup.

### 6.2 Secure Lookup of Public Keys

To facilitate looking up entity public keys (to be used as the subject in an attestation, and for RDE), without relying on an external PKI, WAVE implements a naming scheme that extends the proposal in SDSI [49]. The base functionality (shared by WAVE and SDSI) allows an entity to name another entity by creating a signed *name declaration*. These name declarations form a web-of-trust global graph, similar to that formed by attestations. By traversing this graph, an entity can resolve hierarchical names. For example, consider when an entity representing a company ACME names an entity representing a department Marketing, which in turn names an entity held by an employee Alice. Then, by verifying the identity of a single entity out of band (the company), an entity can resolve the names of all employees within the company's departments, such as Alice.Marketing.ACME, without having to manually establish the validity of individual employee entities.

The functionality above, proposed by SDSI, does not

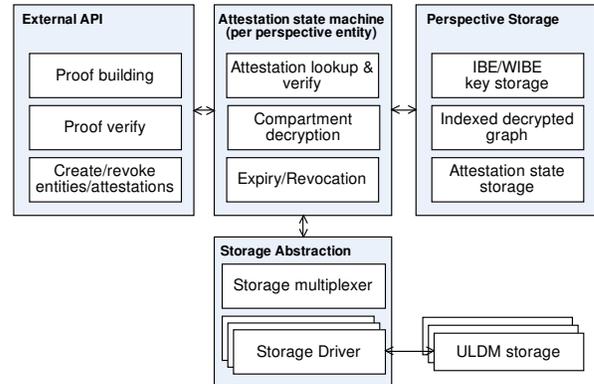

Figure 5: Overview of WAVE's implementation.

provide a distribution mechanism for entities to discover the name declarations required to perform resolution, nor a mechanism to ensure the privacy of declarations so that only authorized parties may read them. WAVE solves both of these problems. Firstly, WAVE stores name declarations in the ULDM storage tier (§5) to ensure name declarations are discoverable without compromising on the goals of the system (especially without requiring on-line participants). Secondly, WAVE uses a variation of the encryption scheme described in §4 to encrypt the name declarations in storage. When creating a name declaration, it is associated with a resource in a namespace (for example, `acme/directory/marketing`) and an entity must be explicitly granted permission on that resource in order to gain the keys required to decrypt the name declaration. In other words, the same attestations that are used to form a proof of authorization are also used to govern which entities can read name declarations, without relying on a central directory server. Resolution of names is done from each entity's cache of decrypted name declarations, stored alongside decrypted attestations.

## 7 Implementation

WAVE is implemented in Go and released as open source [7]. It runs as a background service and applications connect via IPC. The service is composed of four logical parts (Fig. 5).

**The storage abstraction** permits multiple distinct storage providers operating in parallel. As long as the provider implements the API discussed in §5, WAVE can use it. Each storage *driver* is responsible for ensuring the storage is trustworthy, e.g. for a ULDM-based storage it must verify the proofs given by the remote storage server. Attestations can span storage media, i.e., an entity residing on one server can grant permissions to an entity on a different server. We implemented the ULDMs using Merkle trees in Trillian [33] backed by MySQL.

**The perspective storage** keeps track of the decrypted attestations that form the *perspective graph*. This is the portion of the global graph visible from the perspective of the proving entity. WAVE indexes it to allow efficient key retrieval

Operation	AMD64	ARMv8
Create attestation <sup>1</sup>	43.7	445
Create entity	8.9	88.5
Decrypt attestation as verifier	0.48	4.44
Decrypt attestation as subject	3.87	44.0
Decrypt delegated attestation	6.22	67.9

Table 1: Object operation times [ms].

based on a new attestation and efficient attestation retrieval based on a new key. The index also allows for efficient proof building: finding attestations granted from a given issuer that match specific permissions.

**The state machine** is responsible for transitioning the attestation through the states of decryption following the discovery process described in §4.7.

**The external API** is a gRPC [31] API that listens for connections from applications and allows them to use the application API functions given in Fig. 1b. gRPC can generate bindings for multiple languages, so we expect that applications can be written in any language.

**The proof builder**, when asked to build a proof, begins at the namespace authority (the entity that created the RTree namespace) for the resource that permissions are being proved on, and then performs a shortest path discovery through the perspective graph terminating at the proving entity. Note that this is the opposite direction that attestations are traversed during discovery. Only edges granting a superset of the required permissions are traversed and the maximum depth of traversal is limited by the `indirections` parameter in the traversed attestations. These two filters make proof building fast for common cases (see §8.1).

## 8 Evaluation

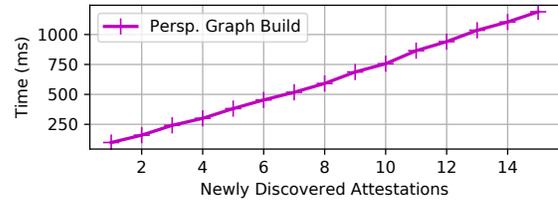

Despite relying on cryptography for its security guarantees, WAVE remains performant, competitive to traditional authentication and authorization systems.

### 8.1 Microbenchmarks

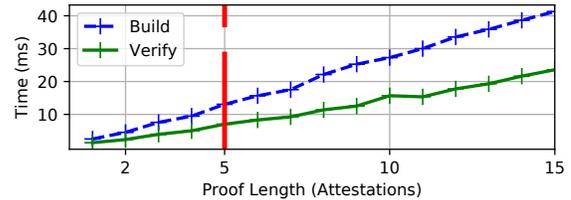

WAVE’s performance is dominated by the cost of the core cryptographic operations, shown in Table 1. These are the times measured by a client using the gRPC application API. The measurement is on an Intel i7-8650U AMD64 CPU representative of a standard modern laptop, and on a Raspberry Pi 3, indicative of a low-cost IoT-class ARMv8 platform.

The verifier does not perform any WIBE decryption, as it has the AES verifier key. The subject entity (the direct recipient of the attestation) can skip the IBE decryption of the partition, but must still perform WIBE decryption. Any other entity that is interested in the attestation because it lies further up the delegation chain must perform IBE decryption, WIBE decryption, and then AES decryption. These decryption operations take place only once—when an attestation is added to the perspective graph—so are a one-off cost of re-

<sup>1</sup>Create attestation uses multiple cores

(a) Perspective graph update/build time

(b) Proof build/verification time

Figure 6: Single core timings for proof operations. Vertical line in Fig. 6b is the expected maximum proof length for common applications.

System	Authentication	Authorization
LDAP+MySQL	6.3ms	0.8ms
OAuth2 JWT	0.3ms	
WAVE 1 attest.	1.2ms	
WAVE 3 attest.	3.6ms	

Table 2: Latency of LDAP+MySQL, OAuth2 vs. WAVE.

ceiving permissions. The verifier decryption happens once per unique proof; after that, it is cached so that subsequent verifications complete in negligible time.

When decrypting attestations and building the perspective graph, we also need to index all the obtained keys and store them on disk. We can see the cost of decryption combined with indexing by measuring the time taken to update a perspective graph, for different sizes of changes to the graph, as shown in Fig. 6a. This includes the time taken to retrieve the encrypted ciphertexts from ULDM-based storage. The dashed vertical line is likely the maximum number of attestations that will be found in a proof as more than five delegations, although supported, is rare in all our deployments.

### 8.2 Traditional Authorization Flow

To compare WAVE against a traditional authorization system, we benchmark the time taken by a representative backend to turn a username and password into an authorization policy using an OpenLDAP server (which authenticates the user and yields the groups they are part of) and a MySQL database (which turns the groups into policy). We also add the time taken to verify an OAuth2 JWT token containing the authorization policy in the form of scopes.

The results are shown in Table 2. For a WAVE proof mirroring the single-delegation structure present in the LDAP/OAuth2 case, the proof verifies in a sixth of the time taken by the traditional LDAP flow. For a case where transitive delegation has been used three times and the proof con-

	PUT 2KB	GET 2KB	En- Queue	Iter- Queue
Latency [ms]	10.7	10.4	10.1	10.0

Table 3: Average storage operation time (ms/op) under 4 uniform loads ( $\approx 100$  requests per second), measured over 30 seconds ( $\approx 3k$  requests per type).

sists of three attestations, the WAVE verification is about half the time of the single-delegation LDAP flow.

As in WAVE, OAuth2 offers a bearer token that can be validated without communicating with the server. In this case, validating a JSON Web Token with a 2048-bit RSA signature takes 0.3ms. WAVE is roughly 4x slower, but completely removes the centralized token-issuing server, leaving the user as the only authority in the system. In OAuth a compromised token issuing server can generate valid tokens without the user’s knowledge.

Note that although OAuth2 has added a form of delegation [36], it requires the OAuth2 server to issue a new token, so is identical to the single-delegation scenario tested here.

This example shows that using WAVE as a replacement for common authorization flows will likely not reduce performance, despite providing transitive delegation and removing all central authorities.

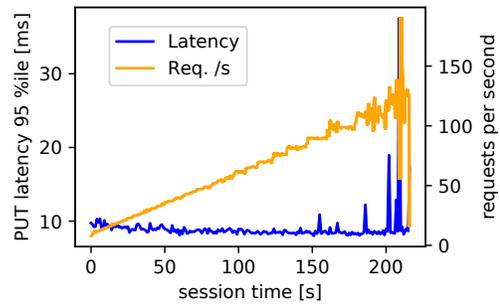

### 8.3 Storage Evaluation

Since an entity in WAVE does not communicate with any other entity, except via the storage, WAVE’s scalability depends on the performance of the global storage. As mentioned in §5, a blockchain is a natural solution, but not scalable enough.

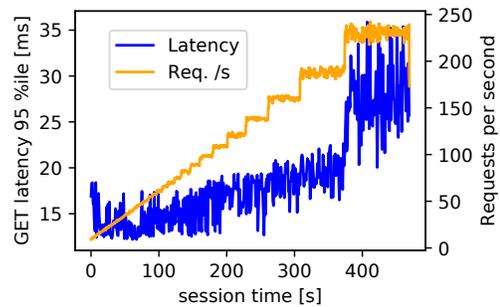

In contrast, the ULDM-based system is shared-nothing and horizontally scalable: the performance of one node does not limit the performance of the overall system. For completeness, we include single-system performance metrics here. Table 3 shows the average latency of the ULDM storage performing single operations at a time (i.e. just GETs or just PUTs). The times for the ULDM-based storage include both the generation of the proofs server-side and the verification of the proofs client-side. Every operation concerns a unique object, so there is no caching.

This ULDM storage was constructed using Trillian backed by MySQL. Fig. 7 shows the limits of a single node, where performance for PUTs degrades at approximately 110 requests per second and performance for GETs degrades at approximately 200 requests per second. We expect that performance could be increased if Trillian were deployed on Spanner [20] as the designers intended, but defer this to future work. Note that in this evaluation, every operation concerns a unique object, so as to benchmark the underlying cost of forming proofs, rather than the cache. Real workloads would likely have more cache hits.

Although our storage implementation is unoptimized and built using an off-the-shelf Merkle tree database, single nodes handle insert loads an order of magnitude higher than

(a) 95th %ile PUT

(b) 95th %ile GET

Figure 7: Latencies for ULDM PUT/GET as the throughput is ramped up to the single-node maximum.

possible on a blockchain system [22]. In addition, every added node scales the capacity of the system linearly. We envision that multiple storage providers, potentially operated by distinct parties, would operate in parallel, similar to Certificate Transparency [41].

### 8.4 Deployment Experiences

WAVE is a real-world artifact and is open source [7]. We operated various versions of WAVE for roughly two years in over 20 buildings, controlling more than 800 devices (thermostats, control processes, motion sensors, and others with little to no existing authorization capabilities) comprising 363 entities, 27 namespaces and 529 attestations (both valid and expired). The global authorization graph in our deployment is visualized in Fig. 8. The median number of delegations in a path is 4 (the maximum is 9). This deployment has given us the opportunity to refine and validate the performance, usability, and expressiveness of WAVE’s authorization model in practice. Applying WAVE to legacy devices whose firmware cannot be modified is done by using an adaptation layer microservice and ensuring all communication with the legacy device flows through that service [8].

**Performance.** In the deployment, most proofs build in under 20ms and validate in under 10ms (as in Fig. 6b). The performance impact of WAVE is imperceptible during normal operation: proofs are cached after processing, accelerating subsequent generation and validation. As mentioned, we built an earlier version of WAVE on top of a blockchain instead of our current ULDM. We conducted extensive bench-

Work	Transitive delegation	Discoverability	No order constraints	Offline participants	No trusted central storage	Protected permissions
Auth. languages [12, 49, 13, 43, 45, 29, 27]	Yes	No	Unknown: no mechanism given			
Hidden credentials [58, 37, 30, 48]	Yes	No	Unknown: no mechanism given			
Centralized authorization [19, 15, 56, 28]	Yes	Yes	Yes	Yes	No	No
Distributed authorization [44, 59, 18, 57, 50]	Yes	Yes	Yes	No	Yes	No
WAVE	Yes	Yes	Yes	Yes	Yes	Yes

Table 4: Related work on decentralized authorization compared to WAVE. We elaborate on these categories in §9.

marks of that version and concluded that it cannot scale past a load roughly equivalent to a city ( $\approx 1$  million buildings). It also incurs significant CPU and bandwidth costs, even when only storing permissions (not data).

**Usability.** In addition to our experience with the deployment, we have also held multiple tutorials with 200+ users. User feedback indicated that WAVE improved most aspects of management (especially administrators having autonomy to grant and revoke permissions). Some aspects of WAVE are harder to manage: no user can enumerate all delegations in the system, which reduces auditability. We were able to mitigate unfamiliarity with WAVE’s authorization model with careful user interface design (which provides secure defaults such as short expiry times) and with teaching users through familiar analogies (e.g., comparing RTree to file paths).

**Expressiveness.** We found that WAVE was able to capture exactly the authorization patterns required in typical cyber-physical usage scenarios. The transitive delegation capability was invaluable in lowering the administrative overhead of deployments. Rather than requiring the building manager to be a part of every commissioning workflow (to create credentials for each new device), permission is granted to the person heading the deployment effort, who then acts with autonomy. For permanent installations, the installing entity can be removed from the permission flow afterwards by granting “around” them directly from the building manager to the devices. For temporary installations, keeping the installing entity in the flow simplifies revocation when the study is over.

## 9 Related Work

Table 4, compares prior authorization and trust management systems with WAVE. Here, we provide additional details.

### 9.1 Trust Management and Authorization

Trust Management (TM) literature over the past two decades has thoroughly researched techniques for transitively delegable authorization. Overviews of TM systems are provided in [14, 51, 11, 6].

Languages used to express authorization policies are summarized in the first row of Table 4 [12, 49, 13, 43, 10, 27]. For example Macaroons [12] provides a mechanism for ex-

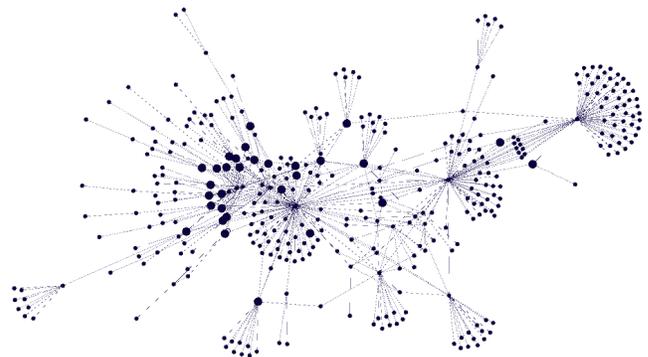

Figure 8: The permission graph for the multi-building deployment. “Bolted” nodes are namespace authorities. Most nodes with a high degree are entities that administer a set of namespaces. Leaf nodes correspond to devices and services that do not perform any delegation.

pressing authorization policy with delegation and context-specific third-party caveats. The goals are quite different, e.g. the authorization is verifiable by the authority only and permissions can only be granted in-order. The system does not specify how cookies are stored and discovered or how it would work with offline participants. In general, authorization language work is complementary to WAVE, as we focus on the layers of the system that lie below the language (how the pieces of policy are stored, disseminated, and discovered). In our deployments we use RTree, based on SPKI’s pkpfs [24], but mechanisms like third-party caveats could be introduced with no changes to the underlying layers.

Hidden credentials (row 2 in Table 4) [58, 37, 30, 48] address a different privacy problem: allowing a prover and verifier to hide their credentials from each other. WAVE solves an orthogonal problem: the privacy of credentials in storage and during discovery.

The remaining literature can be categorized as relying on a centralized credential store for discovery [19, 15, 56], or a distributed credential store [44, 59, 18, 57, 50]. Centralized discovery mechanisms put all credentials in *one place* which makes discovery simple but, as constructed in work thus far, requires this central storage to be trusted. Blockchain work [55, 26] avoids this problem but does not scale, and

thus far has focused on identity, not authorization. Work such as [28] decreases centralization by reducing the trust in cross-administrative-domain applications, such as IFTTT, but still places trust in the central authorization servers belonging to each vendor. In contrast, distributed discovery mechanisms store each credential with its *issuer* and/or *subject*, avoiding the need to trust a central storage system. The resulting discovery mechanisms are more complex and cannot operate if any credential holder is offline. Both the centralized and decentralized credential discovery work thus far have overlooked the privacy of credentials at rest (in the centralized case) or during discovery (in the distributed case); in both cases, there are parties who can read credentials that do not grant them permissions even indirectly.

A concurrent work, Droplet [52], presents a distributed authorization system, but it does not meet the requirements of a general purpose authorization system in §1: Droplet does not provide transitive delegation, it only handles authorization for time series data streams as opposed to the more general policies of WAVE, and it induces a blockchain transaction for every change to an ACL, which scales poorly.

WAVEs attestations and RDE can be used as the key exchange protocol for an end-to-end encryption scheme such as JEDI [38]. JEDI provides resource-oriented message encryption on a tree of resources, which interfaces well with WAVEs RTree authorization policy.

## 9.2 Storage

WAVE's Map Log Root is similar to the approach used by CONIKS [47] and Key Transparency (KT) [32]. There are several differences between a ULDM and the CONIKS/KT data structures. As a ULDM does not need to prevent iteration of the contents, it can be log derived, allowing an efficient verification that it is append-only. In contrast, CONIKS/KT requires every user to check every epoch of the map to ensure the values stored match expectations. This approach would not work for our use case as we expect every user to create hundreds or thousands of objects, and requiring every user to check each of these objects at every map epoch is intractable. The ULDM approach 1) reduces the amount of work as it scales with the number of *additions* to the map rather than the *size* of the map, as in CONIKS, and 2) places the majority of the burden on auditors, rather than users who may be offline.

Revocation Transparency [40] is also similar to a ULDM. It was posted as an informal short note, and to our knowledge, it was never fully developed. It lacks the Operation Log, which requires the client/auditor to request a consistency proof between two versions of the map without knowing the contents (as it cannot construct a replica). We are not aware of any Merkle tree map databases that support this operation. A ULDM is built on simpler operations and can be constructed using an off-the-shelf database, such as Trillian [33], with full auditability.

## 10 Conclusion

WAVE is a *decentralized* authorization framework leveraging an improved graph-based authorization model. It introduces an encryption technique, RDE, for hiding attestation contents, while still allowing efficient discovery of permissions granted out of order to offline participants. WAVE introduces a storage mechanism, the ULDM, that is efficiently auditable. This enables untrusted, horizontally scalable, servers to store the attestations without compromising on the security of the system as a whole.

We used WAVE to manage IoT deployments in 20 buildings for two years, during which we identified six requirements that are critical for IoT deployments. In meeting these requirements, WAVE (1) has no reliance on central trust, (2) provides transitive fine-grained delegation and revocation, (3) protects permissions during discovery and at rest, (4) allows for any party to verify a proof of authorization, (5) allows delegations to occur in any order with no communication between granter and receiver, and finally (6) allows for granting permissions to offline participants. No existing work meets these requirements simultaneously. Our open-source implementation of WAVE offers similar performance to traditional centralized systems while providing stronger security guarantees.

## A Proof of ULDM Security Guarantee

We provide a proof sketch for Guarantee 2.

*Proof Sketch for Guarantee 2.* We show that if neither clients in  $C$  nor the auditor  $A$  detect an attack, then there exists a possible history  $H$  of requests consistent with  $L$  and all responses to requests in  $R$ . Concretely, we show that the Operation Log that the storage server tells the auditor  $A$  is such a valid history  $H$ . Because  $A$  did not detect an inconsistency, we know that, for each client  $c \in C$ , (1) its Map Root Log head, at some point after its last request in  $R$ , is consistent with  $H$ . Because  $c$  did not detect an inconsistency, we know that (2)  $c$ 's sequence of Map Root Log heads is append-only, (3) for each request, the returned object did (or did not, if no object was returned) exist in the Object Map, and (4) for each request, the Map Root Log at the time of the request contains the object map used in (3).

Together, (1) and (2) indicate that (5) the client's entire sequence of Map Root Log heads is consistent with  $H$ . Together, (3) and (4) indicate that (6) the response received for each request in  $R$  is consistent with the current Map Root Log head at the time of the request. Putting together (5) and (6), we can conclude that the response that each client receives to

each request in  $R$  is consistent with  $H$ . Putting together (2) and (6), we can conclude that  $H$  is consistent with the partial ordering imposed by Map Root Log heads for each client  $c$ . Because clients make requests to the server to validate every Merge Promise, this also guarantees that  $H$  is consistent with the partial ordering imposed by Merge Promises. Thus,  $H$  fulfills all desired properties.  $\square$

## B RDE Security Guarantee

Below, we develop definitions to precisely describe the global authorization graph, and then we use them to formalize RDE's security guarantee.

**Definition 1** (Path). *Let  $x$  and  $y$  be entities.  $(A_1, \dots, A_n)$  is a **path** from  $x$  to  $y$  if either  $n > 0$  and  $A_1.\text{issuer} = x$ ,  $A_n.\text{subject} = y$ , and  $A_i.\text{subject} = A_{i+1}.\text{issuer}$  for all  $i \in \{1, \dots, n-1\}$ , or  $n = 0$  and  $x = y$ .*

**Definition 2** (Compatibility). *Let  $A$  and  $B$  be attestations such that  $A.\text{subject} = B.\text{issuer}$ . We write  $A \rightsquigarrow B$  and say " $A$  is **partition-compatible** with  $B$ " if a key corresponding to one of the  $\text{ID}^*$ s in  $Q(A.\text{policy})$  can decrypt a WIBE ciphertext with the  $\text{ID}$   $P(B.\text{policy})$ . We analogously write  $A \mapsto B$  and say " $A$  is **partition-label-compatible** with  $B$ " if a key corresponding to one of the  $\text{ID}^*$ s in  $M(A.\text{policy})$  can decrypt an IBE ciphertext with the  $\text{ID}$   $L(B.\text{policy})$ . We extend this to paths as follows. A path  $(A_1, \dots, A_n)$  is **partition-compatible** if either  $n = 0$ , or  $A_i \rightsquigarrow A_{i+1}$  for all  $i \in \{1, \dots, n-1\}$ . A path  $(A_1, \dots, A_n)$  is **partition-label-compatible** if either  $n = 0$ , or  $A_1 \mapsto A_2$  and  $(A_2, \dots, A_n)$  is partition-compatible.*

Based on our definitions of  $P$ ,  $Q$ ,  $L$ , and  $M$  in §4.3 and §4.4, we can attach semantic meaning to compatibility:

**Note 1** (Compatibility Semantics for RTree).  *$A \rightsquigarrow B$  means that  $A.\text{policy}$  and  $B.\text{policy}$  have overlapping time ranges, URIs with the same namespace, and the same permission string.  $A \mapsto B$  means that  $A.\text{policy}$  and  $B.\text{policy}$  have URIs with the same namespace.*

Now, we formally define the states attached to an attestations during the discovery process (§4.7) so we can later express the leakage of an attestation in each state.

**Definition 3** (Attestation State Machine). *Let  $A$  be an attestation. If there exists a partition-compatible path  $p = (A, P_1, \dots, P_n)$  to an entity compromised by Adv, then we say that  $A$  is **useful** with respect to Adv.*

*Otherwise, if there exists a partition-label-compatible path  $p = (A, P_1, \dots, P_n)$  to an entity compromised by Adv, then we say that  $A$  is **partition-known** with respect to Adv.*

*Otherwise, if there exists a partition-compatible path from  $A.\text{subject}$  to an entity compromised by Adv, then we say that  $A$  is **interesting** with respect to Adv.*

*Otherwise, we say that  $A$  is **unknown** with respect to Adv.*

From  $D$ 's perspective in Fig. 2, for example, #1, #4, and #3 are useful, #5 is partition-known, and #2 is unknown. The components of an RTree policy are described in §2.4.

Based on Definition 3, we can now *informally* state the security guarantee of RDE. Let  $A$  be an attestation such that there does not exist a partition-compatible path from  $A$ .subject to a partition-compatible cycle in the global authorization graph. If  $A$  is **unknown** or **interesting** with respect to Adv, then Adv learns nothing about  $A$  except  $A$ .subject and  $A$ 's revocation commitment. If  $A$  is **partition-known** with respect to Adv, then Adv learns nothing about  $A$  except (1)  $A$ .subject, and (2)  $P(A$ .policy). If  $A$  is useful with respect to Adv, then Adv can decrypt  $A$  and see all of its fields.

We now formalize the security guarantee of RDE as a game played by a challenger Chl and an adversary Adv.

**Guarantee 3 (RDE).** Let  $\lambda$  denote the security parameter. Consider any list of entities in the system, represented as names in  $\{0, 1\}^*$ , any subset of these entities compromised by Adv, and any two authorization graphs  $G_0$  and  $G_1$  each described as a list of attestations in terms of the entity names, subject to the constraints below:

1.  $|G_0| = |G_1|$  and attestations at position  $i$  in the lists of  $G_0$  and  $G_1$  must have the same length. We say that these two attestations **correspond**.
2. Corresponding attestations must have the same state **unknown/interesting/partition-known/useful** w.r.t. Adv.
3. If corresponding attestations are **useful** to Adv, or if either has a partition-compatible path from its subject to a partition-compatible cycle, then they must be identical.
4. If corresponding attestations  $A_0$  and  $A_1$  are **partition-known** to Adv, or if there exists a partition-label-compatible path from  $A_0$ .subject (or  $A_1$ .subject) to a partition-compatible cycle in  $G_0$  (or  $G_1$ ), they must have the same subject and revocation commitment and satisfy  $P(A_0) = P(A_1)$ , but may otherwise differ arbitrarily.
5. If corresponding attestations are **unknown** or **interesting** to Adv (and if there is no partition-label-compatible path from the subject to a partition-compatible cycle) then they must have the same subject and revocation commitment, but may otherwise differ arbitrarily.

Each attestation in the graph is described in terms of the information in §2.1, not RDE ciphertexts. RDE guarantees that Adv's advantage in the following game is negligible in the security parameter  $\lambda$ :

**Initialization.** Chl generates each entity's keypairs. It sends to Adv the public keys (verification key and WIBE/IBE public parameters) corresponding to each entity. For entities corresponding to malicious users, Chl also provides the secret keys (signing key and WIBE/IBE master keys). Furthermore, Chl chooses a random bit  $b \in \{0, 1\}$ , computes the RDE ciphertext for each attestation in  $G_b$ , and gives them to Adv.

**Guess.** Adv outputs a bit  $b' \in \{0, 1\}$ . The adversary's advantage in the game is defined as  $|\Pr[b = b'] - \frac{1}{2}|$ .

The constraints on cycles in Conditions #3, #4, and #5 are due to the lack of KDM-security for the WIBE and IBE used. It may be possible to remove these constraints with KDM-secure variants.

*Proof Sketch for Guarantee 3.* We define a new game in which Adv has no advantage and prove via a hybrid argument that Adv's advantage in the real game differs from its advantage in this new game by at most a negligible amount.

In the hybrid argument, each hybrid represents a game. In the sequence of hybrids, the encrypted graph provided by the challenger if  $b = 0$  is identical to the encrypted graph in the previous hybrid, except that either (1) one of the WIBE or IBE ciphertexts generated by Chl in the Challenge phase is replaced with an encryption of a different string of correct length, or (2) the ID used for IBE encryption is changed to a different ID. Adv cannot distinguish between adjacent hybrids due to CPA-security of WIBE and IBE in case (1), and due to the *anonymity* of IBE in case (2). Because adjacent hybrids are indistinguishable to Adv, the difference in its advantage in adjacent hybrids is negligible. The first game is the real game (Guarantee 3). In the final game, Adv's advantage is 0. By the hybrid argument, we can conclude that Adv's advantage in the real game is negligible.

The order in which ciphertexts are replaced must be chosen carefully. This is because a ciphertext cannot be replaced with an encryption of zero if a secret key to decrypt the ciphertext exists in the graph. We now describe the hybrids.

We identify attestations in the graph in Conditions #4 and #5. Observe that the "partition-compatible" relation defines a directed graph over these attestations in each  $G_0$  and  $G_1$ , where each attestation is a vertex and edges indicate partition-compatibility. We denote these new graphs  $S_0$  and  $S_1$ . Both  $S_0$  and  $S_1$  are directed acyclic graphs, due to the stipulations in Conditions #4 and #5 regarding cycles. Thus,  $S_0$  and  $S_1$  can be linearized. Via a sequence of hybrids, we first replace ciphertexts provided by Chl when it chooses  $b = 0$  with encryptions of a dummy "zero string," following the reverse order of  $S_0$ 's linearization. For attestations in Condition #4, we replace the WIBE ciphertexts in the attestations with encryptions of zero, in a single hybrid game for each attestation. For each attestation in Condition #5, we make two hybrid games; the first replaces its IBE ciphertext with an encryption of zeros, and the second replaces the ID used to encrypt with IBE for that ciphertext with a dummy ID. At the end of this hybrid sequence, the challenger provides a graph containing encryptions of zero in non-useful attestations if  $b = 0$ , and a proper encryption of  $G_1$  if  $b = 1$ .

This is followed by another sequence of hybrids where we similarly transform the encryptions of zero provided by the challenger if  $b = 0$  to proper encryptions of the attestations in  $G_1$ . This is done by transforming attestations in the forward order of  $S_1$ 's linearization. In the final game, the challenger provides a graph containing a proper encryption of  $G_1$ , regardless of the chosen bit  $b$ , so Adv's advantage is 0. This completes the proof sketch.  $\square$

## Abstract

The software development process is quite complex and involves a number of independent actors. Developers check source code into a version control system, the code is compiled into software at a build farm, and CI/CD systems run multiple tests to ensure the software’s quality among a myriad of other operations. Finally, the software is packaged for distribution into a delivered product, to be consumed by end users. An attacker that is able to compromise any single step in the process can maliciously modify the software and harm any of the software’s users.

To address these issues, we designed *in-toto*, a framework that cryptographically ensures the integrity of the software supply chain. *in-toto* grants the end user the ability to verify the software’s supply chain from the project’s inception to its deployment. We demonstrate *in-toto*’s effectiveness on 30 software supply chain compromises that affected hundreds of million of users and showcase *in-toto*’s usage over cloud-native, hybrid-cloud and cloud-agnostic applications. *in-toto* is integrated into products and open source projects that are used by millions of people daily. The project website is available at: <https://in-toto.io>.

## 1 Introduction

Modern software is built through a complex series of steps called a *software supply chain*. These steps are performed as the software is written, tested, built, packaged, localized, obfuscated, optimized, and distributed. In a typical software supply chain, these steps are “chained” together to transform (e.g., compilation) or verify the state (e.g., the code quality) of the project in order to drive it into a *delivered product*, i.e., the finished software that will be installed on a device. Usually, the software supply chain starts with the inclusion of code and other assets (icons, documentation, etc.) in a version control system. The software supply chain ends with the creation, testing and distribution of a delivered product.

Securing the supply chain is crucial to the overall security of a software product. An attacker who is able to control any step in this chain may be able to modify its output for malicious reasons that can range from introducing backdoors in the source code to including vulnerable libraries in the delivered product. Hence, attacks on the software supply chain are an impactful mechanism for an attacker to affect many users at once. Moreover, attacks against steps of the software supply chain are difficult to identify, as they misuse processes that are normally trusted.

Unfortunately, such attacks are common occurrences, have high impact, and have experienced a spike in recent

years [60, 129]. Attackers have been able to infiltrate version control systems, including getting commit access to the Linux kernel [58] and Gentoo Linux [76], stealing Google’s search engine code [22], and putting a backdoor in Juniper routers [48, 96]. Popular build systems, such as Fedora, have been breached when attackers were able to sign backdoored versions of security packages on two different occasions [75, 123]. In another prominent example, attackers infiltrated the build environment of the free computer-cleanup tool CCleaner, and inserted a backdoor into a build that was downloaded over 2 million times [126]. Furthermore, attackers have used software updaters to launch attacks, with Microsoft [108], Adobe [95], Google [50, 74, 140], and Linux distributions [46, 143] all showing significant vulnerabilities. Perhaps most troubling are several attacks in which nation states have used software supply chain compromises to target their own citizens and political enemies [35, 55, 82, 92, 93, 108, 127, 128, 138]. There are dozens of other publicly disclosed instances of such attacks [8, 33, 38, 39, 41, 52, 53, 65, 70, 76, 79, 80, 83, 95, 107, 113, 115, 118, 119, 122, 130–132, 134, 139, 141, 146].

Currently, supply chain security strategies are limited to securing each individual step within it. For example, Git commit signing controls which developers can modify a repository [78], reproducible builds enables multiple parties to build software from source and verify they received the same result [25], and there are a myriad of security systems that protect software delivery [2, 20, 28, 100, 102]. These building blocks help to secure an individual step in the process.

Although the security of each individual step is critical, such efforts can be undone if attackers can modify the output of a step before it is fed to the next one in the chain [22, 47]. These piecemeal measures by themselves can not stop malicious actors because there is no mechanism to verify that: 1) the correct steps were followed and 2) that tampering did not occur in between steps. For example a web server compromise was enough to allow hackers to redirect user downloads to a modified Linux Mint disk image, even though every single package in the image was signed and the image checksums on the site did not match. Though this was a trivial compromise, it allowed attackers to build a hundred-host botnet in a couple of hours [146] due to the lack of verification on the tampered image.

In this paper we introduce *in-toto*, Latin for “as a whole,” the first framework that holistically enforces the integrity of a software supply chain by gathering cryptographically verifiable information about the chain itself. To achieve this, *in-toto* requires a project owner to declare and sign a

*layout* of how the supply chain's steps need to be carried out, and by whom. When these steps are performed, the involved parties will record their actions and create a cryptographically signed statement — called *link metadata* — for the step they performed. The link metadata recorded from each step can be verified to ensure that all steps were carried out appropriately and by the correct party in the manner specified by the layout.

The layout and collection of link metadata tightly connect the inputs and outputs of the steps in such a chain, which ensures that tampering can not occur between steps. The layout file also defines requirements (e.g., Twistlock [30] must not indicate that any included libraries have high severity CVEs) that will be enforced to ensure the quality of the end product. These additions can take the form of either distinct commands that must be executed, or limitations on which files can be altered during that step (e.g., a step that localizes the software's documentation for Mexican Spanish must not alter the source code). Collectively, these requirements can minimize the impact of a malicious actor, drastically limiting the scope and range of actions such an attacker can perform, even if steps in the chain are compromised.

We have built a series of production-ready implementations of `in-toto` that have now been integrated across several vendors. This includes integration into cloud vendors such as Datadog and Control Plane, to protect more than 8,000 cloud deployments. Outside of the cloud, `in-toto` is used in Debian to verify packages were not tampered with as part of the reproducible builds project [25]. These deployments have helped us to refine and validate the flexibility and effectiveness of `in-toto`.

Finally, as shown by our security analysis of three `in-toto` deployments, `in-toto` is not a “lose-one, lose-all” solution, in that its security properties only partially degrade with a key compromise. Depending on which key the attacker has accessed, `in-toto`'s security properties will vary. Our `in-toto` deployments could be used to address most (between 83% - 100%) historical supply chain attacks.

## 2 Definitions and Threat Model

This section defines the terms we use to discuss the software supply chain and details the specific threat model `in-toto` was designed to defend against.

### 2.1 Definitions

The software supply chain refers to the series of *steps* performed in order to create and distribute a *delivered product*. A *step* is an operation within this chain that takes in *materials* (e.g., source code, icons, documentation, binaries, etc.) and creates one or more *products* (e.g., libraries, software packages, file system images, installers, etc.). We refer to both materials and products generically as *artifacts*.

It is common to have the products of one step be used as materials in another step, but this does not mean that a supply chain is a sequential series of operations in practice. Depending on the specifics of a supply chain's workflow, steps may be executed in sequence, in parallel, or as a combination of both. Furthermore, steps may be carried out

by any number of hosts, and many hosts can perform the same step (e.g., to test a step's reproducibility).

In addition to the materials and products, a step in the supply chain produces another key piece of information, *byproducts*. The step's byproducts are things like the `STDOUT`, `STDERR`, and return value that indicate whether a step was successful or had any problems. For example, a step that runs unit tests may return a non-zero code if one of the unit tests fails. Validating byproducts is key to ensuring that steps of the supply chain indicate that the software is ready to use.

As each step executes, information called *link metadata* that describes what occurred, is generated. This contains the materials, products, and byproducts for the step. This information is signed by a key used by the party who performs the action, which we call a *functionary*. Regardless of whether the functionary commits code, builds software, performs QA, localizes documentation, etc., the same link metadata structure is followed. Sometimes a functionary's participation involves repeated human action, such as a developer making a signed git commit for their latest code changes. In other cases, a functionary may participate in the supply chain in a nearly autonomous manner after setup, such as a CI/CD system. Further, many functionaries can be tasked to perform the same step for the sake of redundancy and a minimum threshold of them may be required to agree on the result of a step they all carried out.

To tie all of the pieces together, the *project owner* sets up the rules for the steps that should be performed in a software supply chain. In essence, the project owner serves as the foundation of trust, stating which steps should be performed by which functionaries, along with specifying rules for products, byproducts, and materials in a file called the *layout*. The layout enables a *client* that retrieves the software to cryptographically validate that all actions were performed correctly. In order to make this validation possible, a client is given the *delivered product*, which contains the software, layout, and link metadata. The layout also contains any additional actions besides the standard verification of the artifact rules to be performed by the client. These actions, called *inspections*, are used to validate software by further performing operations on the artifacts inside the delivered product (e.g., verifying no extraneous files are inside a zip file). This way, through standard verification and inspections, a client can assure that the software went through the appropriate software supply chain processes.

### 2.2 Threat Model

The goal of `in-toto` is to minimize the impact of a party that attempts to tamper with the software supply chain. More specifically, the goal is to retain the maximum amount of security that is practical, in any of the following scenarios:

- Interpose between two existing elements of the supply chain to change the input of a step. For example, an attacker may ask a hardware security module to sign a malicious copy of a package before it is added to the repository and signed repository metadata is created to index it [27, 44, 51, 76, 107, 120, 120, 147].

- Act as a step (e.g., compilation), perhaps by compromising or coercing the party that usually performs that step [27, 57, 62, 64, 76, 81, 99, 112, 125]. For example, a hacked compiler could insert malicious code into binaries it produces [126, 136].
- Provide a delivered product for which not all steps have been performed. Note that this can also be a result of an honest mistake [37, 49, 56, 68, 73, 97, 142].
- Include outdated or vulnerable elements in the supply chain [59, 61, 91, 94, 117]. For example, an attacker could bundle an outdated compression library that has many known exploits.
- Provide a counterfeit version of the delivered product to users [8, 35, 66, 70, 71, 95, 118, 134, 135, 146]. This software product can come from any source and be signed by any keys. While *in-toto* will not mandate how trust is bootstrapped, Section 6 will show how other protocols such as TUF [28], as well as popular package managers [2] can be used to bootstrap project owner keys.

**Key Compromise.** We assume that the public keys of project owners are known to the verifiers and that the attacker is not able to compromise the corresponding secret key. In addition, private keys of developers, CI systems and other infrastructure public keys are known to a project owner and their corresponding secret keys are not known to the attacker. In section 5.2, we explore additional threat models that result from different degrees of attacker access to the supply chain, including access to infrastructure and keys (both online and offline).

### 2.3 Security Goals

To build a secure software supply chain that can combat the aforementioned threats, we envision that the following security goals would need to be achieved:

- **supply chain layout integrity:** All of the steps defined in a supply chain are performed in the specified order. This means that no steps can be added or removed, and no steps can be reordered.
- **artifact flow integrity:** All of the artifacts created, transformed, and used by steps must not be altered in-between steps. This means that if step A creates a file `foo.txt` and step B uses it as a material, step B must use the exact file `foo.txt` created by step A. It must not use, for example, an earlier version of the file created in a prior run.
- **step authentication:** Steps can only be performed by the intended parties. No party can perform a step unless it is given explicit permission to do so. Further, no delivered products can be released unless all steps have been performed by the right party (e.g., no releases can be made without a signoff by a release engineer, which would stop accidental development releases [68]).
- **implementation transparency:** *in-toto* should not require existing supply chains to change their practices in order to secure them. However, *in-toto* can be used to represent the existing supply chain configuration and reason about its security practices.

- **graceful degradation of security properties:** *in-toto* should not lose all security properties in the event of key compromise. That is, even if certain supply chain steps are compromised, the security of the system is not completely undermined.

In addition to these security goals, *in-toto* is also geared towards practicality and, as such, it should maintain minimal operational, storage and network overheads.

## 3 System overview

The current landscape of software supply chain security is focused on point-solutions that ensure that an individual step's actions have not been tampered with. This limitation usually leads to attackers compromising a weaker step in the chain (e.g., breaking into a buildfarm [115]), removing steps from the chain [68] or tampering with artifacts while in transit (i.e., adding steps to the chain [66]). As such, we identify two fundamental limitations of current approaches to secure the software supply chain:

1. Point solutions designed to secure individual supply chain steps cannot guarantee the security of the entire chain as a whole.
2. Despite the widespread use of unit testing tools and analysis tools, like fuzzers and static analyzers, software rarely (if ever) includes information about what tools were run or their results. So point solutions, even if used, provide limited protection because information about these tools is not appropriately utilized or even shown to clients who can make decisions about the state of the product they are about to utilize.

We designed *in-toto* to address these limitations by ensuring that all individual measures are applied, and by the right party in a cryptographically verifiable fashion.

In concrete terms, *in-toto* is a framework to gather and verify metadata about different stages of the supply chain, from the first step (e.g., checking-in code on a version control system) to delivered product (e.g., a `.deb` installable package). If used within a software supply chain, *in-toto* ensures that the aforementioned security goals are achieved.

### 3.1 *in-toto* parties and their roles

Similar to other modern security systems [101, 102, 121], *in-toto* uses security concepts like delegations and roles to limit the scope of key compromise and provide a graceful degradation of its security properties.

In the context of *in-toto*, a role is a set of duties and actions that an actor must perform. The use of delegations and roles not only provides an important security function (limiting the impact of compromise and providing separation of privilege), but it also helps the system remain flexible and usable so that behaviors like key sharing are not needed. Given that every project uses a very specific set of tools and practices, flexibility is a necessary requirement for *in-toto*. There are three roles in the framework:

- **Project Owner:** The project owner is the party in charge of defining the software supply chain layout (i.e., define

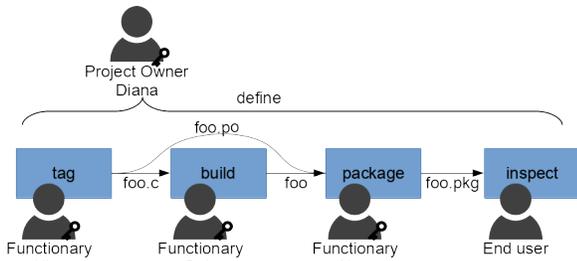

Figure 1: Graphical depiction of the software supply chain with *in-toto* elements added. The project owner creates a layout with three steps, each of which will be performed by a functionary. Notice how the tag step creates `foo.c` and a localization file `foo.po`, which are fed to different steps down the chain.

which steps must be performed and by who). In practice, this would be the maintainer of an open-source project or the dev-ops engineers of a project.

- Functionaries: Functionaries are the parties that perform the steps within the supply chain, and provide an authenticated record of the artifacts used as materials and the resulting products. Functionaries can be humans carrying out a step (e.g., signing off a security audit) or an automated system (e.g., a build farm).
- Client: (e.g., end user): The client is the party that will inspect and afterwards utilize a delivered product.

We will now elaborate on how these three parties interact with the components of *in-toto*.

### 3.2 *in-toto* components

*in-toto* secures the software supply chain by using three different types of information: the software supply chain layout (or layout, for short), link metadata, and the delivered product. Each of these has a unique function within *in-toto*.

#### 3.2.1 The supply chain layout

Laying out the structure of the supply chain allows the developers and maintainers of a project to define requirements for steps involved in source code writing, testing, and distribution within a software product’s lifecycle. In the abstract sense, this supply chain layout is a recipe that identifies which steps will be performed, by whom, and in what order.

The supply chain layout defines a series of *steps* in the supply chain. These definitions are used to enforce measures on what artifacts should be used as *materials*. To ensure that only the intended parties execute the right steps, a public key is associated with each step. In order to ensure that the layout was created by the project owner, it is cryptographically signed with the project owner’s private key.

The project owner will define this supply chain layout by setting different requirements for the project’s steps. These requirements take the form of types of artifacts that can be produced (e.g., a localization step can only produce `.po` files), the expected return values, the type of host that can carry out this step and so forth. When consuming the delivered product, the client (end user) verifies that these requirements are satisfied.

In addition to defining supply chain steps, the layout will also specify a series of *inspection steps* (or inspections). These

inspections will be performed by the verifier on the delivered product to draw further insight about its correctness. This is useful for complex supply chains in which the basic semantics of *in-toto* cannot describe their specific requirements. For example, an inspection step can be used to namespace restrict certain VCS-specific operations to specific functionaries such as making sure that only a QA team member merges code into the develop branch and that all commits are signed.

For example, as seen in Figure 1, a project owner can define a supply chain consisting of three steps: a tag, a build and a package step. With these definitions, the project owner also defines how the artifacts will flow through the supply chain (e.g., `foo.c` is used by build, yet `foo.po` is packaged directly from tag). Afterwards, the project owner can assign functionaries to carry out each of these steps and define an inspection so the end user can verify that `foo` was indeed created during build and that `foo.po` came from the tagged release.

**Layout creation tool.** We provide a web-based layout creation tool [12] to help project owners create *in-toto* layouts. The tool uses an intuitive, graphical interface to define: (1) the steps of the software supply chain (i.e., how is the source code managed? how is the software’s quality verified? how is the software built? how is the software packaged?), (2) the actors (functionaries) who are allowed to perform different steps of the software supply chain. An *in-toto* layout is generated based on this information. In addition, the *in-toto* website [13, 15] provides several examples of layouts, which can serve as starting templates for project owners seeking to integrate *in-toto*.

#### 3.2.2 Link metadata

Verifying the actions carried out in the supply chain, requires information about all steps performed in creating the delivered product. Like a chain in real life, an *in-toto* supply chain consists of conjoined *links*, with each link serving as a statement that a given step was carried out.

Functionaries in charge of executing a step within the supply chain must share information about these links. Sharing such information as what *materials* were fed to the step, and what *product(s)* were created, can ensure no artifacts are altered in transit. To ensure that only the right functionaries performed this step, the piece of link metadata must be signed with the private key that corresponds to this functionary’s key (as defined in the supply chain layout).

There is a one-to-one relationship between the step definitions in the supply chain layout and the link metadata. That is, each piece of link metadata gathered during each step within the supply chain must match what the requirements prescribe for that step. In order to ensure that the link metadata is generated by the intended entity, it must be cryptographically signed with one (or more, if there is a threshold higher than one defined) of the keys indicated in the requirements for that link.

When all the link metadata has been collected, and the supply chain has been properly defined, the supply chain layout and all the links can be shipped, along with the delivered product, to the end user for verification. We show

a minimal software supply chain, along with a graphical representation of an `in-toto` layout in Figure 1.

### 3.2.3 The delivered product

The delivered product is the piece of software that the end user wants to install. In order to verify the delivered product, the end user (or client) will utilize the supply chain layout and its corresponding pieces of link metadata. The end user will use the link metadata to verify that the software provided has not been tampered with, and that all the steps were performed as the project owner intended. In Figure 1 the delivered product consists of the `foo.pkg` file.

### 3.3 `in-toto` usage lifecycle

The `in-toto` usage lifecycle encompasses the following overarching operations:

1. The project owner defines a supply-chain layout.
2. Each step is carried out as specified, and functionaries gather and sign link metadata.
3. A delivered product is shipped to the client, who verifies it upon installation by:
  - ensuring the layout provided was signed by the project owner and is not expired.
  - checking that all the steps defined have enough pieces of link metadata; that such links were signed by the indicated functionaries; and that all artifacts recorded flowed properly between the steps as indicated in the layout.
  - carrying out any inspection steps contained in the layout and making sure that all artifacts recorded match the flow described in the layout.

As seen in Figure 1 a project owner creates the layout to describe an overarching structure of the supply chain that the client can use to verify. Later, functionaries carry out their operations as usual, and submit link metadata to attest for the result of their operation. Finally, a client uses a delivered product, metadata links and a layout to verify the integrity of the delivered product and of the entire chain.

By following the chain of attestations in the link metadata, the client can reconstruct the operations described in Figure 1. Afterwards, the client can verify these attestations against the layout and execute any inspections to make sure everything is in order before consuming the delivered product.

## 4 `in-toto` internals

In order to avoid tampered, incomplete or counterfeit software, `in-toto` ensures the integrity and accuracy of all software supply chain operations. `in-toto` ensures supply chain integrity by the verifying the collected link metadata against a software supply chain layout file. This ensures that all operations were carried out, by the intended party and as the legitimate project owner intended.

Understanding how the system's metadata helps to ensure the integrity of the supply chain is critical to a deeper appreciation of how `in-toto` works. In this section, we will explore the specifics of the link metadata and the layout file to understand how `in-toto` operates.

For the context of this section, we will demonstrate the different features of `in-toto` using Figure 1 as an example. The project owner Diana will create a layout that describes three steps and three functionaries for each step. The first step, `tag`, will produce a file `foo.c` to be input into the build step, as well as a `foo.po` localization file. The second step, `build`, will use the `foo.c` file from the `tag` step and produce a `foo` binary. Finally, the package step will take the `foo.po` and `foo` files and produce a package installable by the end user.

For a more complete and thorough description of all the fields, signature schemes, implementations, a layout editing tool and more, refer to the resources on the project website: <https://in-toto.io>.

### 4.1 The supply chain layout

The supply chain layout explicitly defines the expected layout of the software supply chain. This way, end users can ensure that its integrity is not violated upon verification. To do this, the layout contains the following fields:

```
1 { "_type" : "layout",
2   "expires" : "<EXPIRES>",
3   "readme" : "<README>",
4   "keys" : { "<KEYID>": "<PUBKEY_OBJECT>" ... },
5   "steps" : [ "<STEP>", "... " ],
6   "inspections" : [ "<INSPECTION>", "... " ]
7 }
```

Listing 1: The supply chain layout structure

The overarching architecture of the layout definition includes the following relevant fields:

- An expiration date: this will ensure that the supply chain information is still fresh, and that old delivered products can not be replayed to users.
- A `readme` field: this is intended to provide a human-readable description of the supply chain.
- A list of public keys: these keys belong to each functionary in the supply chain and will be assigned to different steps to ensure that only the right functionary performs a particular step in the supply chain.
- A list of steps: these are the steps to be performed in the supply chain and by who. Step definitions, described in depth in Section 4.1.1, will contain a series of requirements that limit the types of changes that can be done in the pipeline and what functionary can sign link metadata to attest for its existence.
- A list of inspections: these are the inspections to be performed in the supply chain. As described in depth in section 4.1.2, inspections are verification steps to be performed on the delivered product by the client to further probe into its completeness and accuracy.

Though its structure is quite simple, the layout actually provides a detailed description of the supply chain topology. It characterizes each of the steps, and defines any possible requirements for every step. Likewise, it contains instructions for local inspection routines (e.g., verify that every file in a tar archive was created by the right party in the supply chain), which further ensure the delivered product has not been

tampered with. As such the layout allows the project owner to construct the necessary framework for a secure supply chain.

For our example supply chain, Diana would have to list the public keys as described on Listing 2, as well as all the steps.

```

1 { "_type" : "layout",
2   "expires" : "<EXPIRES>",
3   "readme": "foo.pkg supply chain",
4   "keys" : { "<BOBS_KEYID>": "<PUBKEY>",
5             "<ALICES_KEYID>": "<PUBKEY>",
6             "<CLARAS_KEYID>": "<PUBKEY>" },
7   "steps" : [{"name": "tag", "..."},
8             {"name": "build", "..."},
9             {"name": "package", "..."} ],
10  "inspections" : [{"name": "inspect", "..."}]
11 }

```

Listing 2: The supply chain for our example

As described, the layout file already limits all actions to trusted parties (by means of their public keys), defines the steps that are carried out (to limit the scope of any step) and specifies verification routines that are used to dive into the specifics of a particular supply chain. We will describe the latter two fields in depth now.

#### 4.1.1 Step definition

```

1 { "_name": "<NAME>",
2   "threshold": "<THRESHOLD>",
3   "expected_materials": [{"<ARTIFACT_RULE>"}, "..."],
4   "expected_products": [{"<ARTIFACT_RULE>"}, "..."],
5   "pubkeys": ["<KEYID>", "..."],
6   "expected_command": "<COMMAND>"
7 }

```

Listing 3: A supply chain step in the supply chain layout

Every step of the supply chain contains the following fields:

- **name:** A unique identifier that describes a step. This identifier will be used to match this definition with the corresponding pieces of link metadata.
- **expected\_materials:** The materials expected as input `ARTIFACT_RULES` as described in Section 4.1.3. It serves as a master reference for all the artifacts used in a step.
- **expected\_products:** Given the step’s output information, or *evidence*, what should be expected from it? The expected products also contains a list of `ARTIFACT_RULES` as described in section 4.1.3.
- **expected\_command:** The command to execute and any flags that may be passed to it.
- **threshold:** The minimum number of pieces of signed link metadata that must be provided to verify this step. This field is intended for steps that require a higher degree of trust, so multiple functionaries must perform the operation and report the same results. For example, if the threshold is set to  $k$ , then at least  $k$  pieces of signed link metadata need to be present during verification.
- **a list of public keys id’s:** The id’s of the keys that can be used to sign the link metadata for this step.

The fields within this definition list will indicate requirements for the step identified with that name. To verify these requirements, these fields will be matched against the link metadata associated with the step. The

`expected_materials` and `expected_products` fields will be used to compare against the materials and products reported in the link metadata. This ensures that no disallowed artifacts are included, that no required artifacts are missing, and the artifacts used are from allowed steps who created them as products. Listing 4 contains the step definition for the build step for our example Layout above.

```

1 { "_name": "build",
2   "threshold": "1",
3   "expected_materials": [
4     ["MATCH", "foo.c", "WITH",
5      "PRODUCTS", "FROM", "tag"]
6   ],
7   "expected_products": [{"CREATE", "foo"}],
8   "pubkeys": ["<BOBS_PUBKEY>"],
9   "expected_command": "gcc foo.c -o foo"
10 }

```

Listing 4: The build step in our example layout

#### 4.1.2 Inspection definition

Inspection definitions are nearly identical to step definitions. However, since an inspection causes the verifier on the client device to run a command (which can also generate artifacts), there cannot be a threshold of actions. The other fields are identical to the link metadata generated by a step.

#### 4.1.3 Artifact rules

Artifact rules are central to describing the topology of the supply chain by means of its artifacts. These rules behave like firewall rules and describe whether an artifact should be consumed down the chain, or if an artifact can be created or modified at a specific step. As such, they serve two primary roles: to limit the types of artifacts that a step can create and consume; and to describe the flow of artifacts between steps.

For the former, a series of rules describes the operation within the step. A rule, such as `CREATE`, indicates that a material must not exist before the step is carried out and must be reported as a product. Other rules, such as `MODIFY`, `DELETE`, `ALLOW` and `DISALLOW` are used to further limit what a step can register as artifacts within the supply chain. These rules are described in Grammar 5 (full definition in Appendix A). An example of a simple `CREATE` rule can be seen on the step definition in Listing 4.

```
[CREATE|DELETE|MODIFY|ALLOW|DISALLOW] artifact_pattern
```

**Grammar 5:** Grammar for operations within a step. `artifact_pattern` is a regular expression for the paths to artifacts.

For the latter, the `MATCH` rule is used by project owners to describe the flow of artifacts *between steps*. With it, a project owner can mandate that, e.g., a buildfarm must only use the sources that were created during a tag-release step or that only the right localization files are included during a localization step. Compared to the rules above, the `MATCH` rule has a richer syntax, as it needs to account for artifacts relocated during steps (e.g., a packaging step moving `.py` files to `/usr/lib/pythonX.X/site-packages/` or a build step moving artifacts to a build directory) using the `IN` clause. Grammar 6 describes this rule and the `Match` function

describes the algorithm for processing it during verification. An example of a MATCH rule used to match the `foo.c` source from tag into the build step is shown in Listing 4.

```
MATCH source_pattern [IN prefix]
  WITH <MATERIALS|PRODUCTS> [IN prefix] FROM step_name
```

Grammar 6: The match rule grammar. The IN clauses are optional and source\_pattern is a regular expression

---

### function MATCH

**Input:** source\_artifacts; destination\_artifacts, rule

**Output:** result: (SUCCESS/FAIL)

---

```
1: // Filter source and destination materials using the rule's patterns
2: source_artifacts_filtered = filter(rule.source_prefix + rule.source_pattern,
  source_artifacts)
3: destination_artifacts_filtered = filter(rule.destination_prefix +
  rule.destination_pattern, destination_artifacts)
4: // Apply the IN clauses, to the paths, if any
5: for artifact in source_artifacts_filtered do
6:   artifact.path -= rule.source_in_clause
7: for artifact in destination_artifacts_filtered do
8:   artifact.path -= rule.destination_in_clause
9: // compare both sets
10: for artifact in source_artifacts_filtered do
11:   destination_artifact = find_artifact_by_path(destination_artifacts,
  artifact.path)
12: // the artifact with this path does not exist?
13: if destination_artifact == NULL then
14:   return FAIL
15: // are the files not the same?
16: if destination_artifact.hash != artifact.hash then
17:   return FAIL
18: // all of the files filtered by the source materials exist
19: return SUCCESS
```

---

## 4.2 Link metadata files

Link metadata serves as a record that the steps prescribed in the layout actually took place. Its fields show *evidence* that is used for verification by the client. For example, the *materials* and *products* fields of the metadata are used to ensure that no intermediate products were altered in transit before being used in a step.

In order to determine if the executed step complies with its corresponding metadata, several types of information need to be gathered as evidence. A link includes the following fields:

```
1 { "_type" : "link",
2   "_name" : "<NAME>",
3   "command" : "<COMMAND>",
4   "materials": { "<PATH>": "<HASH>", "...": "..." },
5   "products": { "<PATH>": "<HASH>", "...": "..." },
6   "byproducts": { "stdin": "", "stdout": "",
7     "return-value": "" },
8   "environment": { "variables": "<ENV>",

Listing 7: Link metadata format

- Name: This will be used to identify the step and to match it with its corresponding definition inside the layout.
- Material(s): Input file(s) that were used in this step, along with their cryptographic hashes to verify their integrity.
- Command: The command run, along with its arguments.

- Product(s): The output(s) produced and its corresponding cryptographic hash.
- Byproduct(s): Reported information about the step. Elements like the standard error buffer and standard output buffer will be used.
- Signature: A cryptographic signature over the metadata.

Of these fields, the *name*, *materials*, and *products* fields are the counterpart of the fields within the layout definition. This, along with a cryptographic signature used to authenticate the functionary who carried out the step can be used to provide a baseline verification of the supply chain topology (i.e., the steps performed and how do they interrelate via their materials and products). For example, the build step metadata described in Listing 8 shows the file `foo.c` used as a material and the product `foo` as created in the build step.

The *byproducts* field is used to include other meaningful information about a step's execution to further introspect into the specifics of the step that was carried out. Common fields included as byproducts are the standard output, standard error buffers and a return value. For example, if a command exited with non-zero status, then the byproduct field be populated with a value such as `return-value: "126"`. In this case, inspections can be set up to ensure that the return value of this specific command must be 0.

9 }
```

Listing 8: The link for the build step

Having a software supply chain layout along with the matching pieces of link metadata and the delivered product are all the parts needed to perform verification. We will describe verification next.

## 4.3 Verifying the delivered product

Verification occurs when the link metadata and the layout are received by the client and upon installing the delivered product. A standalone or operating-system tool will perform the verification, as described in the function `Verify_Final_Product`. To do this, the user will need an initial public key that corresponds to the supply chain layout, as distributed by a trusted channel or as part of the operating system's installation [106].

The end user starts the verification by ensuring that the supply chain layout provided was signed with a trusted key (lines 2-3) and by checking the layout expiration date to make sure the layout is still valid (lines 5-6). If these checks pass, the public keys of all the functionaries are loaded from the layout (line 8). With the keys loaded, the verification routine will start iterating over all the steps defined in the layout and make sure there are enough pieces of link metadata signed by the right functionaries to match the threshold specified for that role (lines 10-20). If enough pieces of link metadata

---

**function VERIFY\_FINAL\_PRODUCT****Input:** layout; links; project\_owner\_key**Output:** result: (SUCCESS/FAIL)

---

```
1: // verify that the supply chain layout was properly signed
2: if not verify_signature(layout, project_owner_key) then
3:   return FAIL
4: // Check that the layout has not expired
5: if layout.expiration < TODAY then
6:   return FAIL
7: // Load the functionary public keys from the layout
8: functionary_pubkeys = layout.keys
9: // verify link metadata
10: for step in layout.steps do
11:   // Obtain the functionary keys relevant to this step and its corresponding
   metadata
12:   step_links = get_links_for_step(step, links)
13:   step_keys = get_keys_for_step(step, functionary_pubkeys)
14:   // Remove all links with invalid signatures
15:   for link in step_links do
16:     if not verify_signature(link, step_keys) then
17:       step_links.remove(link)
18:   // Check there are enough properly-signed links to meet the threshold
19:   if length(step_links) < step.threshold then
20:     return error("Link metadata is missing!")
21: // Apply artifact rules between all steps
22: if apply_artifact_rules(steps, links) == FAIL then
23:   return FAIL
24: // Execute inspections
25: for inspection in layout.inspections do
26:   inspections.add(Run(inspection))
27: // Verify inspections
28: if apply_artifact_rules(steps + inspections, links) == FAIL then
29:   return FAIL
30: return SUCCESS
```

---

could be loaded for each of the steps and their signatures pass verification, then the verification routine will apply the artifact rules and build a graph of the supply chain using the artifacts recorded in the link metadata (lines 22-23). If no extraneous artifacts were found and all the `MATCH` rules pass, then inspections will be executed<sup>1</sup> (line 25-26). Finally, once all inspections were executed successfully, artifact rules are re-applied to the resulting graph to check that rules on inspection steps match after inspections are executed, because inspections may produce new artifacts or re-create existing artifacts (lines 28-29). If all verifications pass, the function will return `SUCCESS`.

With this verification in place, the user is sure that the integrity of the supply chain is not violated, and that all requirements made by the project's maintainers were met.

#### 4.4 Layout and Key Management

A layout can be revoked in one of two ways, the choice being up to the project owner. One is by revoking the key that was used to sign the layout, the other is by superseding/Updating the layout with a newer one. To update a layout, the project owner needs to replace an existing layout with a newer layout. This can be used to deal with situations when a public key

---

<sup>1</sup>Inspections are executed only after all the steps are verified to avoid executing an inspection on an artifact that a functionary did not create.

of a misbehaving functionary needs to be changed/revoked, because when the project owner publishes a newer layout without that public key, any metadata from such misbehaving functionary is automatically revoked. Updating a layout can also be used to address an improperly designed initial layout. The right expiration date for a layout depends on the operational security practices of the integrator.

## 5 Security Analysis

`in-toto` was designed to protect the software supply chain as a whole by leveraging existing security mechanisms, ensuring that they are properly set up and relaying this information to a client upon verification. This allows the client to make sure that all the operations were properly performed and that no malicious actors tampered with the delivered product.

To analyze the security properties of `in-toto`, we need to revisit the goals described in Section 2. Of these, the relevant goals to consider are *supply chain layout integrity*, *artifact flow integrity*, and *step authentication*. In this section, we explore how these properties hold, and how during partial key compromise the security properties of `in-toto` degrade gracefully.

`in-toto`'s security properties are strictly dependent on an attacker's level of access to a threshold of signing keys for any role. These security properties degrade depending on the type of key compromise and the supply chain configuration.

### 5.1 Security properties with no key compromise

When an attacker is able to compromise infrastructure or communication channels but not functionary keys, `in-toto`'s security properties ensure that the integrity of the supply chain is not violated. Considering our threat model in Section 2, and contrasting it to `in-toto`'s design which stipulates that the supply chain layout and link metadata are signed, we can assert the following:

- An attacker cannot interpose between two consecutive steps of the supply chain because, during verification, the hash on the products field of the link for the first step will not match the hash on the materials field of the link for the subsequent step. Further, a completely counterfeit version of the delivered product will fail validation because its hash will not match the one contained in the corresponding link metadata. Thus, **artifact flow integrity holds**.
- An attacker cannot provide a product that is missing steps or has its steps reordered because the corresponding links will be missing or will not be in the correct order. The user knows exactly which steps and in what order they need to be performed to receive the delivered product. As such, **supply chain layout integrity holds**.
- Finally, an attacker cannot provide link metadata for which he does not have permission to provide (i.e., their key is not listed as one that can sign link metadata for a certain step). Thus, **step authentication holds**.

However, it is important to underline that this threat model requires that the developer's host systems are not compromised. Likewise, it assumes that there are no rogue developers wishing to subvert the supply chain. For practical purposes, we consider a rogue functionary to be equivalent

to a functionary key compromise. Hence this section frames attacks from the standpoint of a key compromise, even when the issue may be executed as a confused deputy problem or a similar issue with equivalent impact.

## 5.2 Security properties if there is a key compromise

`in-toto` is not a “lose-one, lose-all” solution, in that its security properties only partially degrade with a key compromise. Depending on which key the attacker has accessed, `in-toto`’s security properties will vary. To further explore the consequences of key compromise, we outline the following types of attacks in the supply chain:

- Fake-check: a malicious party can provide evidence of a step taking place, but that step generates no products (it can still, however, generate byproducts). For example, an attacker could forge the results of a test suite being executed in order to trick other functionaries into releasing a delivered product with failing tests.
- Product Modification: a malicious party is able to provide a tampered artifact in a step to be used as material in subsequent steps. For example, an attacker could take over a buildfarm and create a backdoored binary that will be packaged into the delivered product.
- Unintended Retention: a malicious party does not destroy artifacts that were intended to be destroyed in a step. For example, an attacker that compromises a cleanup step before packaging can retain exploitable libraries that will be shipped along with the delivered product.
- Arbitrary Supply Chain Control: a malicious party is able to provide a tampered or counterfeit delivered product, effectively creating an alternate supply chain.

### 5.2.1 Functionary compromise

A compromise on a threshold of keys held for any functionary role will only affect a specific step in the supply chain to which that functionary is assigned to. When this happens, the **artifact flow integrity** and **step authentication** security properties may be violated. In this case, the attacker can arbitrarily forge link metadata that corresponds to that step.

The impact of this may vary depending on the specific link compromised. For example, an attacker can fabricate an attestation for a step that does not produce artifacts (i.e., a fake-check), or create malicious products (i.e., a product modification), or pass along artifacts that should have been deleted (i.e., an unintended retention). When an attacker creates malicious products or fails to remove artifacts, the impact is limited by the usage of such products in subsequent steps of the chain. Table 1 describes the impact of these in detail from rows 2 to 5 (row 1 captures the case when the attacker does not compromise enough keys to meet the threshold defined for a step). As a recommended best practice, we assume there is a “DISALLOW \*” rule at the end of the rule list for each step.

It is of note from Table 1 that an attacker who is able to compromise crucial steps (e.g., a build step) will have a greater impact on the client than one which, for example, can only alter localization files. Further, a compromise in functionary keys that do not create a product is restricted

Type of Key Compromise	Compromised Step Rule	Subsequent Step Rule	Impact
Under threshold	Regardless of rule	Regardless of rule	None
Step	None	Regardless of rule	Fake-check
Step	ALLOW pattern1 DELETE pattern2	MATCH pattern*	Unintended Retention
Step	[ALLOW   CREATE   MODIFY] pattern	MATCH pattern	Product Modification
Layout	N/A	N/A	Arbitrary Supply Chain Control

Table 1: Key compromise and impact based on the layout characteristics.

to a fake check attack (row two). To trigger an unintended retention, the first step must also have rules that allow for some artifacts before the `DELETE` rule (e.g., the `ALLOW` rule with a similar artifact pattern). This is because rules behave like artifact rules, and the attacker can leverage the ambiguity of the wildcard patterns to register an artifact that was meant to be deleted. Lastly, note that the effect of product modification and unintended retention is limited by the namespace on such rules (i.e., the `artifact_pattern`).

**Mitigating risk.** As discussed earlier, the bar can be raised against an attacker if a role is required to have a higher threshold. For example, two parties could be in charge of signing the tag for a release, which would require the attacker to compromise two keys to successfully subvert the step.

Finally, further steps and inspections can be added to the supply chain with the intention of limiting the possible transformations on any step. For example, as shown in Section 6, an inspection can be used to dive into a Python’s wheel and ensure that only Python sources in the tag release are contained in the package.

### 5.2.2 Project owner compromise

A compromise of a threshold of keys belonging to the project owner role allows the attacker to redefine the layout, and thereby subvert the supply chain completely. However, like with step-level compromises, an increased threshold setting can be used to ensure an attacker needs to compromise many keys at once. Further, given the way `in-toto` is designed, the layout key is designed to be used rarely, and thus it should be kept offline.

## 5.3 User actions in response to `in-toto` failures

Detecting a failure to validate `in-toto` metadata involves making a decision about whether verification succeeded or whether it failed and, if so, why. The user’s device and the reason for failure are likely to be paramount in the user’s decision about how to respond. If the user is installing in an ephemeral environment on a testing VM, they may choose to ignore the warning and install the package regardless. If the user is installing in a production environment processing PCI data, the failure to validate `in-toto` metadata will be a serious concern. So, we expect users of `in-toto` will respond in much the same way as administrators do today for a package that is not properly signed.

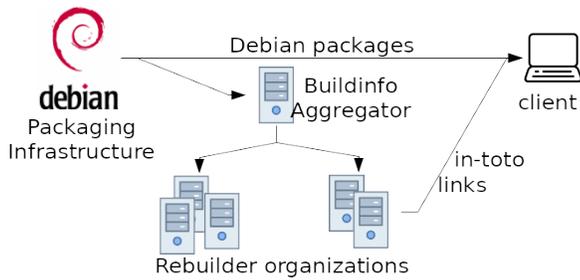

Figure 2: The rebuilder setup.

## 6 Deployment

`in-toto` has about a dozen different integrations that protect software supply chains for millions of end users. This section uses three such integrations to examine how threshold signing, metadata generation, and end-to-end verification function in practical deployments of `in-toto`.

### 6.1 Debian rebuilder constellation

Debian is one of the biggest stakeholders in the reproducible builds project [26], an initiative to ensure bit-by-bit deterministic builds of a source package. One of the main motivations behind reproducible builds is to avoid backdooring compilers [136] or compromised toolchains in the Debian build infrastructure. `in-toto` helps Debian achieve this goal via its step-thresholding mechanism.

The `apt-transport` [16] for `in-toto` verifies the trusted rebuilder metadata upon installing any Debian package. Meanwhile, various institutions (that range from private to non-profit and educational) run rebuilder infrastructure to rebuild Debian packages independently and produce attestations of the resulting builds using `in-toto` link metadata. This way, it is possible to cryptographically assert that a Debian package has been reproducibly built by a set of  $k$  out of  $n$  rebuilders. Figure 2 shows a graphical description of this setup.

By using the `in-toto` verifiable transport, users can make sure that no package was tampered with unless an attacker is also able to compromise at least  $k$  rebuilders and the Debian buildfarm. Throughout this deployment, we were able to test the thresholding mechanism, as well as practical ways to bootstrap project owner signatures through the existing package manager trust infrastructure [32, 34].

**Deployment insight.** Through our interaction with reproducible builds, we were able to better understand how the thresholding mechanism can be used to represent concepts such as a build’s reproducibility and how to build `in-toto` into operating-system tools to facilitate adoption.

### 6.2 Cloud native builds with Jenkins and Kubernetes

“Cloud native” is used to refer to container-based environments [3]. Cloud native ecosystems are characterized by rapid changes and constant re-deployment of the internal components. They are generally distributed systems, and often managed by container orchestration systems such as Kubernetes [23] or Docker Swarm [6]. Thus, their pipelines are mostly automated using pipeline managers such as

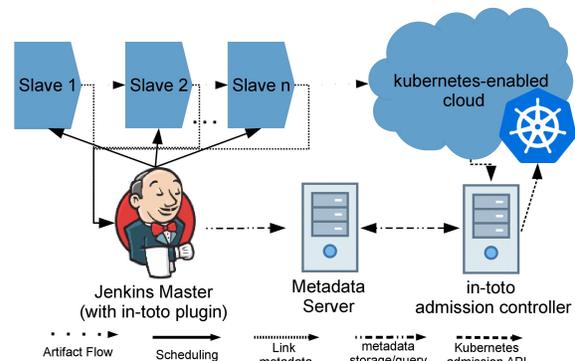

Figure 3: The kubesecc supply chain.

Jenkins [18] or Travis [137]. In this type of ecosystems, a host- and infrastructure-agnostic, automated way to collect supply-chain metadata is necessary not only for security, but also for auditing and analyzing the execution of build processes that led to the creation of the delivered product.

In the context of cloud native applications, `in-toto` is used by Control Plane to track the build and quality-assurance steps on kubesecc [19], a Kubernetes resource and configuration static analyzer. In order to secure the kubesecc supply chain, we developed two `in-toto` components: a Jenkins plugin [11] and a Kubernetes admission controller [7, 17]. These two components allow us to track all operations within a distributed system, both of containers and aggregate `in-toto` link metadata, to verify any container image before it is provisioned. Figure 3 shows a (simplified) graphical depiction of their supply chain.

This deployment exemplifies an architecture for the supply chains of cloud native applications, in which new container images, serverless functions and many types of deployments are quickly updated using highly-automated pipelines. In this case, a pipeline serves as a coordinator, scheduling steps to worker nodes that serve as functionaries. These functionaries then submit their metadata to an `in-toto` metadata store. Once a new artifact is ready to be promoted to a cloud environment, a container orchestration system queries an `in-toto` admission controller. This admission controller ensures that every operation on this delivered product has been performed by allowed nodes and that all the artifacts were acted on according to the specification in the `in-toto` layout.

**Deployment insight.** Our interaction with kubesecc forced us to investigate other artifact identifiers such as container images (in addition to files). While `in-toto` can be used today to track container images, the ability to point to an OCIv2 [21] image manifest can provide a more succinct link metadata representation and will be part of future work.

### 6.3 Datadog: E2E verification of Python packages

Datadog is a monitoring service for cloud-scale applications, providing monitoring of servers, databases, tools, and services, through a software-as-a-service-based data analytics platform [5]. It supports multiple cloud service providers, including Amazon Web Services (AWS), Microsoft Azure,

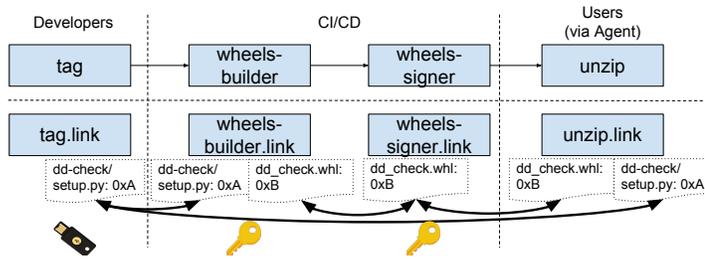

Figure 4: The simplified Datadog agent integrations supply chain. There are three steps (`tag` step, `wheels-builder` step, `wheels-signer` step), and one inspection. Arrows denote `MATCH` rules, the `tag` step is signed using a hardware dongle whereas the CI system uses online keys.

Google Cloud Platform, and Red Hat OpenShift. At the time of writing, it has over 8,000 customers, and collects trillions of monitoring record points per day.

The Datadog *agent* is software that runs on hosts. It collects events and metrics from hosts and sends them to Datadog, where customers can analyze their monitoring and performance data. The agent *integrations* are plug-ins that collect metrics from services running on customer infrastructure. Presently, there are more than one hundred integrations that come installed out-of-the-box with the Agent.

Datadog developers wanted an ability to automatically build and publish new or updated integrations independently of agent releases. This is so interested users can try new or updated integrations as they become available, and test whether they are applicable to their needs.

This section will cover how Datadog built the first tamper-evident pipeline using `in-toto` and how it leveraged TUF to safely bootstrap key distribution and provide replay-protection and freshness guarantees to `in-toto` metadata.

**End-to-end verification with `in-toto`.** The Datadog agent integrations supply chain, shown in Figure 4, has three steps:

1. The first `tag` step outputs Python source code as products. Every integration consists of Python source code and several YAML [133] configuration files. The link for this step is signed using a Yubikey hardware dongle [29]
2. In the second `wheels-builder` step, the pipeline must receive the same source code from the `tag` step and produce a Python wheel [24], as well as its updated Python metadata. Each wheel is a ZIP file and its metadata is an HTML file that points to all the available *versions* of an integration.
3. In the third `wheels-signer` step, the pipeline must receive, as materials, the same products as the `wheels-builder` step. This step signs for all wheels using the system described in the next subsection. It can be dangerous packaging Python source code, because arbitrary code can be executed during the packaging process, which can be inserted by compromising the GitHub repository. Therefore, this step is separate from the `wheels-builder` step, so that a compromise of the former does not yield the signing keys of this step.

Finally, there is one inspection, which first ensures that a given wheel matches the materials of the `wheels-signer`

step. It then extracts files from the wheel and checks that they correspond to exactly the same Python source code and YAML configuration files as the products of the `tag` step. Thus, this layout provides end-to-end verification: it prevents a compromised pipeline from causing users to trust wheels with source code that was never released by Datadog developers.

**Transport with The Update Framework (TUF).** Whereas `in-toto` provides end-to-end verification of the Datadog pipeline, it does not solve a crucial problem that arises in practice: How to securely distribute, revoke, and replace the public keys used to verify the `in-toto` layout. This mechanism must be *compromise-resilient* [100–102, 121], and resistant to a compromise of the software repository or server used to serve files. While SSL / TLS protects users from man-in-the-middle (MitM) attacks, it is not compromise-resilient, because attackers who compromise the repository can simply switch the public keys used to verify `in-toto` layout undetected, and thus defeat end-to-end verification. Likewise, other solutions, such as X509 certificates do not support necessary features such as in-band key revocation and key rotation.

The Update Framework (TUF) [100–102, 121] provides precisely this type of compromise-resilient mechanism, as well as in-band key revocation and key rotation. To do so, TUF adds a higher layer of signed metadata to the repository following two design principles that inspired the `in-toto` design. The first is the use of *roles* in a similar fashion to `in-toto`, so that a key compromise does not necessarily affect all *targets* (i.e., any Python wheels, or even `in-toto` metadata). The second principle is minimizing the risk of a key compromise using *offline* keys, or signing keys that are kept off the repository and pipeline in a cold storage mechanism, such as safe deposit boxes, so that attackers who compromise the infrastructure are unable to find these keys.

TUF is used within the Datadog integrations downloader to distribute, in a compromise-resilient manner, the: (1) root of trust for all wheels, TUF and `in-toto` metadata, (2) `in-toto` layout, and (3) public keys used to verify this layout. TUF also guarantees that MitM attackers cannot tamper with the consistency, authenticity, and integrity of these files, nor rollback or indefinitely replay `in-toto` metadata. This security model is simplified because it ignores some considerations that are out of the scope of this paper.

In summary, the Datadog pipeline uses TUF to appropriately bootstrap the root of the trust for the entire system, and `in-toto` to guarantee that the pipeline packaged exactly the source code signed by one of the Datadog developers inside universal Python wheels. By tightly integrating TUF and `in-toto`, Datadog’s users obtain the compromise resilience of both systems combined.

**Deployment insight.** Through the Datadog deployment, we learned how to use other last-mile systems like TUF to provide not only compromise-resilience, but also replay-protection, freshness guarantees, and mix-and-match protection for `in-toto` metadata.

## 7 Evaluation

We evaluated `in-toto`'s ability to guarantee software supply chain integrity on two fronts: efficiency and security. We set off to answer the following questions:

- Does `in-toto` incur reasonable overheads in terms of bandwidth, storage overhead and verification time?
- Can `in-toto` be used to protect systems against real-life supply chain compromises?

In order to answer the first question, we explored `in-toto` as used in the context of Datadog for two reasons: Datadog offers more than 111 integration packages to verify with `in-toto`, and its data and source code is publicly available. Furthermore, it is a production-ready integration that can be used by Datadog's more than 8,000 clients today [31]. Their clients include major companies like Twitter, NASDAQ and The Washington Post [4].

Then, we surveyed historical supply chain compromises and catalogued them. We evaluated these compromises against the `in-toto` deployments described in Section 6, accounting for their supply chain configuration, and including the actors involved and their possible key assignments. By studying the nature of each compromise, we were able to estimate what degree of key compromise could hypothetically happen and, with it, the consequences of such a compromise on these supply chains when `in-toto` is in place.

### 7.1 `in-toto`'s overhead in the Datadog deployment

In the three major costs that `in-toto` presents are the storage, transfer and verification cost. In order to explore these costs, we set out to use the publicly available Datadog agent integration client and software repository. From this data, we can derive the cost of storing `in-toto` metadata in the repository, the cost of transferring the `in-toto` metadata for any given package and the verification times when installing any package.

**Storage overhead.** In order to understand the storage overhead, we mirrored the existing agent integrations Python package repository. Then, we inspected the package payloads and the repository metadata to show the cost breakdown of the repository as a whole. Table 2 depicts the cost breakdown of the Datadog repository, as mirrored on February 8 of 2019.

Type	total package	Python metadata	TUF	<code>in-toto</code> links	<code>in-toto</code> Layout
RSA 4096	74.02%	0.83%	5.51%	16.75%	2.89%
DSA 1024 & ed25519	74.48%	0.84%	5.54%	16.35%	2.79%
optimized	79.56%	0.90%	5.92%	10.65%	2.97%

Table 2: Storage overhead breakdown for a `in-toto` enabled package repository. All metadata is compressed using `zlib`.

Table 2 shows that `in-toto` takes up about 19% of the total repository size, and thus makes it a feasible solution in terms of storage overhead. In addition, compared to its co-located security system TUF, the cost of using `in-toto` is higher, with almost four times the metadata storage cost. Further, the breakdown also indicates that the governing factor for this storage overhead are the `in-toto` links, rather

than the layout file, with a layout being approximately 6 to 3 times smaller than the links (42 KB in comparison of the 148KB for all the link metadata).

There are two main reasons that drive this cost. First and foremost, is the engineering decision to track all the files within the pipeline (including Python metadata). Although these are not required to be tracked with `in-toto`, for the sake of security (as this type of metadata is being protected by TUF), it eases the implementation at a manageable cost. The second is that of signatures: the signatures used within the Datadog deployment come from either 4096-bit openpgp keys on a Yubikey, or 4096-bit PEM keys. These alone account for almost half of the `in-toto` metadata size.

For this reason, it is possible to further reduce the size of the metadata to 13% of the total repository size. Rows two and three of Table 2 represent the repository overhead when limiting the amount of files tracked to only Python sources and packages and using a DSA1024 as the signing algorithm.

**Network overhead.** Similar to storage overhead, the network overhead incurred by clients when installing any integration is of utmost importance. To explore this cost, we investigate the raw package sizes and contrast it with the size of the package-specific metadata size. It is of note though, that the size of `in-toto` metadata does not scale with the size of the package, but rather the number of files inside of it. This is because most of the metadata cost is taken by pieces of link metadata, of which the biggest three fields are the signature, `expected_materials` and `expected_products`. Figure 5 shows both the distribution of package sizes and the distribution of metadata sizes in increasing order.

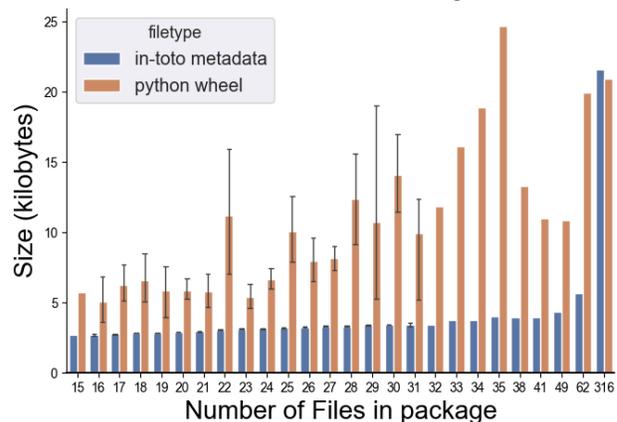

Figure 5: Package and metadata size distribution. Error bars show packages with the same number of files but different sizes.

In Figure 5 we can see that, for most packages, the metadata size cost is below 44% of the package size. In fact for the 90th percentile, the metadata cost approaches a costly 64%, to a worst case of 103%. However, upon inspecting these cases, we found that the issue is that these are cases in which *link metadata is tracking files not contained in the delivered product*. Indeed, `in-toto` is tracking files, such as test suites, fixtures and even iconography that does not get packaged on the integrations Python wheel. The worst case scenario is in fact `cisco_aci`, which only packages 12 files out of 316 contained in the `tag` step metadata.

**Verification overhead.** Finally, to draw insight from the computation time required to verify each package, we ran a series of micro-benchmarks on a laptop with an Intel i7-6500U processor and 8GB of RAM. In this case, we ran an iterated verification routine with the packages already fetched and instrumented the Datadog agent installer to measure the installation time with and without `in-toto` verification.

From this experiment, we conclude that `in-toto` verification adds less than 0.6 seconds on all cases. This is mostly dominated by the signature verification, and is thus bounded by the number of links to verify (i.e., the number of steps times the threshold).

## 7.2 Supply chain data breaches

We surveyed 30 major different supply chain breaches and incidents occurring from January 2010 to January 2019 (this list of historical attacks is included in Appendix B). These historical incidents cover a variety of software products and platforms, such as Apple’s Xcode [113], Android GTK [8], MeDoc financial software [35], Adobe updater [95], PHP PEAR repository [33], and South Korean organizations [138].

Studying these historical attacks identified the type of access that the attacker had (or was speculated to have) and identified three categories: the attacker had control of infrastructure (but not functionary keys), the attacker had control over part of the infrastructure or keys of a specific functionary, and the attacker was able to control the entire supply chain by compromising a project owner’s infrastructure (including their signing key).

For the historical attacks in Appendix B, we determined whether an attack used a compromised key, and then labeled those attacks with “Key Compromise”. We also determined the degree of access in the attack (all the way to the possible step) and labeled each attack with an “Access Level” that indicates the step in the chain where the attack took place.

We now analyze how these compromises could affect the three supply chains where `in-toto` was deployed (as described in Section 6). Our analysis indicates that the majority of attacks (23 out of 30) took place without any key compromise. In those cases, none of the three `in-toto` deployments would have been affected since the client inspection (as described in Sec. 4.3) could detect extraneous artifacts or malicious delivered products.

Out of the 30 studied incidents, 7 involved a key compromise. We summarize our analysis of these attacks in Table 3. One attack, Keydnep [71], used a stolen Apple developer certificate to sign the malicious software package. Therefore, this attack would not have affected any `in-toto` deployments, because `in-toto` would detect that an unauthorized functionary signed the link metadata. Another attack used the developer’s ssh key to upload a malicious Python package on PyPI [52]. All `in-toto` deployments could have detected this attack since files extracted from the malicious package would not exactly match the source code as the products of the first step in the supply chain.

The remaining five attacks involving a key compromise were recent sophisticated incidents that affected many clients

Attack Name	DD	RB	CN
Keydnep [71]	✓	✓	✓
backdoored-pypi [52]	✓	✓	✓
CCleaner Atack [126]	✓	✓	✗
RedHat breach [125]	✓	✓	✗
*NotPetya [35]	✓	✗	✗
Operation Red [138]	✓	✗	✗
KingSlayer [118]	✓	✗	✗

Table 3: The impact of the historical attacks on the three `in-toto` deployments: Datadog (DD), Reproducible Builds (RB), Cloud Native (CN). Out of the 30 historical attacks, 23 did not involve a key compromise, so none of the deployments would have been affected. This table shows the remaining attacks which involved a key compromise. In one attack, marked with a star (\*), it is unknown if a key compromise took place. We assumed that was the case. A ✓ indicates that the deployment could have detected the attack.

and companies. The CCleaner [126] and RedHat [125] attacks are not effective against the Reproducible Builds deployment (RB) and Datadog (DD), as the former implements a threshold mechanism in the build step and the latter does not build binaries in their infrastructure. In a similar flavor, three attacks (Operation Red [138], NotPetya [35], and KingSlayer [118]) would not affect the Datadog deployment, as it implements a threshold mechanism in the packaging step. The Cloud Native deployment, on the other hand, would detect none of these five attacks, as it does not employ thresholds. To conclude, the `in-toto` deployments would detect most of the historical attacks based on the general `in-toto` design principles. For those attacks that involve key compromises, our analysis shows that `in-toto`’s use of thresholds is an effective mechanism.

**Key Takeaway.** Cloud Native (83%) and reproducible builds (90%) integrations of `in-toto` would prevent most historical supply chain attacks. However, integration into a secure update system as was done by Datadog (100%) provides further protection.

## 8 Related Work

To the best of our knowledge, work that attempts to use an automated tool to secure the supply chain is scarce. However, there has been a general push to increase the security of different aspects within the supply chain, as well as to tighten the binding between neighboring processes within that chain. In this section, we mention work relevant to supply chain security, as some of it is crucial for the success of `in-toto` as a framework. We also list work that can further increase the security guarantees offered by `in-toto`.

**Automated supply chain administration systems.** Configuring and automating processes of the supply chain has been widely studied. Works by Bégin et al. [45], Banzai et al., [43] and Andreetto et al. [36] focus on designing supply chains that automatically assign resources and designate parties to take part in different processes to create a product. This work is similar to `in-toto` in that it requires a supply chain topology to carry out the work. However, none of these projects were focused on security. Instead, they deal with adaptability of resources and supply chain automation.

Perhaps most closely related to *in-toto* is the Grafeas API [9] released by Google. However, Grafeas's focus is on tracking and storing supply chain metadata rather than security. Grafeas provides a centralized store for supply chain metadata, which can be later queried by verification tools such as Google's Binary Authorization [84]. Grafeas does not provide a mechanism to describe what steps should be performed, validate performed steps, or even support cryptographic signatures [1]. Finally, *in-toto* is architecture agnostic, while Grafeas is mostly cloud-native; *in-toto* was geared to represent supply chains whether they are cloud-native, off-cloud or hybrid-cloud. We are collaborating with the Grafeas team to natively support *in-toto* link metadata within Grafeas [10].

**Software supply chain security.** In addition, many software engineering practices have been introduced to increase the security of the software development lifecycle [42, 104, 105, 111, 116]. Additional work by Devanbu et al. [67] has explored different techniques to “construct safe software that inspires trust in hosts.” These techniques are similar to *in-toto* in that they suggest releasing supply chain information to the end users for verification.

Though none of these proposals suggest an automated tool to ensure the integrity of the supply chain, they do serve as a helpful first step in designing *in-toto*. As such, their practices could be used as templates for safe supply chain layouts.

Finally, there have been hints by the industry to support features that could be provided by *in-toto* [90, 114, 145]. This includes providing certificates noting the presence of a process within the supply chain and providing software transparency through mechanisms such as reproducible builds.

**Source control security.** The source code repository is usually the first link in the supply chain. Early work in this field has explored the different security properties that must be included in software configuration management tools [63]. Version control systems, such as Git, incorporate protection mechanisms to ensure the integrity of the source code repository, which include commit hash chaining and signed commits [77, 78].

**Buildsystem and verification security.** The field of automated testing and continuous integration has also received attention from researchers. Recently, self-hosted and public automated testing and continuous integration systems have become popular [54, 72, 137]. Work by Gruhn et al. [85] has explored the security implications of malicious code running on CI systems, showing that it is possible for attackers to affect other projects being tested in the same server, or the server itself. This work, and others [69] serve as a motivation for *in-toto*'s threat model.

Further work by Hanawa et al. [87] explores different techniques for automated testing in distributed systems. The work is similar to *in-toto* in that it allocates hosts in the cloud to automatically run tests for different environments and platforms. However, *in-toto* requires such systems to provide certification (in the form of link metadata) that the tests were run and the system was successful.

Subverting the development environment, including subverting the compiler, can have a serious impact on the software supply chain [135]. Techniques such as Wheeler's diverse double-compiling (DDC) [144] can be used to mitigate such “trusting trust” attacks. In the context of reproducible builds project, DDC can also be used for multi-party verification of compiler executables.

**Verifying compilers, applications and kernels.** Ongoing work on verifying compilers, applications and kernels will provide a robust framework for applications that fully comply with their specification [88, 98]. Such work is similar to *in-toto* in that a specification is provided for the compiler to ensure that their products meet stated requirements. However, in contrast to our work, most of this work is not intended to secure the origin of such specification, or to provide any proof of the compilation's results to steps further down the supply chain. Needless to say, verifying compilers could be part of a supply chain protected with *in-toto*.

Furthermore, work by Necula et al. introduces proof-carrying code [109, 110], a concept that relies on the compiler to accompany machine code with proof for verification at runtime. Adding to this, industry standards have included machine code signing [40] to be verified at runtime. This work is similar to *in-toto* in that compilers generate information that will be verified by the end user upon runtime. Although these techniques are more granular than *in-toto*'s (runtime verification vs verification upon installation), they do not aim to secure the totality of the supply chain.

**Package management and software distribution security.** Work by Cappos et al. has been foundational to the design of *in-toto*'s security mechanisms [46, 102, 121]. The mechanisms used to secure package managers are similar to *in-toto* in that they rely on key distribution and role separation to provide security guarantees that degrade with partial key compromise. However, unlike *in-toto*, these systems are restricted to software updates, which limit their scope. Concepts from this line of work could be overlaid on *in-toto* to provide additional “last mile” guarantees for the resulting product, such as package freshness or protection against dependencies that are not packaged with the delivered product.

## 9 Conclusions and future work

In this paper, we have described many aspects of *in-toto*, including its security properties, workflow and metadata. We also explored and described several extensions and implications of using *in-toto* in a number of real-world applications. With this we have shown that protecting the entirety of the supply chain is possible, and that it can be done automatically by *in-toto*. Further, we showed that, in a number of practical applications, *in-toto* is a practical solution to many contemporary supply chain compromises.

Although plenty of work needs to be done in the context of the *in-toto* framework (e.g., decreasing its storage cost), tackling the first major limitations of supply chain security will increase the quality of software products. We expect that, through continued interaction with the industry and

elaborating on the framework, we can provide strong security guarantees for future software users.

## Acknowledgments

We would like to thank the USENIX reviewers and Luke Valenta for reviewing this paper. We would also like to thank Lukas Pühlinger and Lois DeLong from the `in-toto` team; Holger Levsen, Chris Lamb, kpcyrd, and Morten Linderud from Reproducible Builds; the Datadog Agent Integrations (especially Ofek Lev) and Product Security teams; as well as Andrew Martin and Luke Bond from Control Plane for their valuable work towards integrating `in-toto` in all these communities. This research was supported by the NSF under Grants No. CNS 1801430 and DGE 1565478.

## A in-toto artifact rule definition

The following artifact rule definition is taken from the in-toto specification v0.9 [14].

- ALLOW: indicates that artifacts matched by the pattern are allowed as materials or products of this step.

- DISALLOW: indicates that artifacts matched by the pattern are not allowed as materials or products of this step.
- REQUIRE: indicates that a pattern must appear as a material or product of this step.
- CREATE: indicates that products matched by the pattern must not appear as materials of this step.
- DELETE: indicates that materials matched by the pattern must not appear as products of this step.
- MODIFY: indicates that products matched by the pattern must appear as materials of this step, and their hashes must not be the same.
- MATCH: indicates that the artifacts filtered in using source-path-prefix/pattern must be matched to a "MATERIAL" or "PRODUCT" from a destination step with the "destination-path-prefix/pattern".

## B Surveyed Attacks

Attack Name	Key Compromise	Access Level
*NotPetya [35]	✓	PI
CCleaner Attack [126]	✓	BS, PI
Operation Red [138]	✓	PI
KingSlayer [118]	✓	PI
RedHat breach [125]	✓	BS
keydnab [71]	✓	PI

**Abstract.** To be secure, cryptographic algorithms crucially rely on the underlying hardware to avoid inadvertent leakage of secrets through timing side channels. Unfortunately, such timing channels are ubiquitous in modern hardware, due to its labyrinthine fast-paths and optimizations. A promising way to avoid timing vulnerabilities is to devise—and verify—conditions under which a hardware design is free of timing variability, *i.e.*, executes in *constant-time*. In this paper, we present IODINE: a clock-precise, constant-time approach to eliminating timing side channels in hardware. IODINE succeeds in verifying various open source hardware designs in seconds and with little developer effort. IODINE also discovered two constant-time violations: one in a floating-point unit and another one in an RSA encryption module.

## 1 Introduction

Trust in software systems is always rooted in the underlying hardware. This trust is apparent when using hardware security features like enclaves (*e.g.*, SGX and TrustZone), crypto units (*e.g.*, AES-NI and the TPM), or MMUs. But our trust goes deeper. Even for simple ADD or MUL instructions, we expect the processor to avoid leaking any of the operands via *timing side channels*, *e.g.*, by varying the execution time of the operation according to the data. Indeed, even algorithms specifically designed to be resilient to such timing side-channel attacks crucially rely on these assumptions [23–25]. Alas, recently discovered vulnerabilities have shown that the labyrinthine fast-paths and optimizations ubiquitous in modern hardware expose a plethora of side channels that undermine many of our deeply held beliefs [34, 36, 42].

A promising way to ensure that trust in hardware is properly earned is to formally specify our expectations, and then, to *verify*—through mathematical proof—that the units used in security critical contexts do not exhibit

any timing variability, *i.e.*, are *constant-time*. For instance, by verifying that certain parts of an arithmetic logic unit (ALU) are constant-time, we can provide a foundation for implementing secure crypto algorithms in software [16, 20, 22]. Dually, if timing variability is unavoidable, *e.g.*, in SIMD or floating-point units, making this variability *explicit* can better inform mechanisms that attempt to mitigate timing channels at the software level [18, 46, 54] in order to avoid vulnerabilities due to gaps in the hardware-software contract [17, 18].

In this paper, we introduce IODINE: a clock-precise, constant-time approach to eliminating timing side channels in hardware. Given a hardware circuit described in Verilog, a *specification* comprising a set of sources and sinks (*e.g.*, an FPU pipeline start and end) and a set of usage assumptions (*e.g.*, no division is performed), IODINE allows developers to automatically synthesize *proofs* which ensure that the hardware runs in constant-time, *i.e.*, under the given usage assumptions, the time taken to flow from source to sink, is independent of operands, processor flags and interference by concurrent computations.

Using IODINE, a crypto hardware designer can be certain that their encryption core does not leak secret keys or messages by taking a different number of cycles depending on the secret values. Similarly, a CPU designer can guarantee that programs (*e.g.*, cryptographic algorithms, SVG filters) will run in constant-time when properly structured (*e.g.*, when they do not branch or access memory depending on secrets [20]).

IODINE is *clock-precise* in that it enforces constant-time execution directly as a semantic property of the circuit rather than through indirect means like information flow control [55]. As a result, IODINE neither requires the constant-time property to hold unconditionally nor

demands the circuit be partitioned between different security levels (e.g., as in SecVerilog [55]). This makes IODINE particularly suited for verifying existing hardware designs. For example, we envision IODINE to be useful in verifying ARM’s recent set of *data independent timing (DIT)* instructions which should execute in constant-time, if the PSTATE.DIT processor state flag is set [2, 41].

While there have been significant strides in verifying the constant-time execution of software [14–16, 18, 20–22, 53], IODINE unfortunately cannot directly reuse these efforts. Constant time methods for software focus on straight-line, sequential—often cryptographic—code.

Hardware designs, however, are inherently *concurrent* and *long-lived*: circuits can be viewed as collections of processes that run forever, performing parallel computations that update registers and memory in every clock cycle. As a result, in hardware, even the definition of constant-time execution becomes problematic: how can we measure the timing of a hardware design that never stops and performs multiple concurrent computations that mutually influence each other?

In IODINE, we address these challenges through the following contributions.

**1. Definition.** First, we define a notion of constant-time execution for concurrent, long-lived computations. In order to reason about the timing of values flowing between sources and sinks, we introduce the notion of *influence set*. The influence set of a value contains all cycles  $t$ , such that an input (i.e., a source value) at  $t$  was used in its computation. We say that a hardware design is constant time, if all its computation paths (that satisfy usage assumptions) produce the same sequence of influence sets for sinks.

**2. Verification.** To enable its efficient verification, we show how to reduce the problem of checking constant-time execution—as defined through influence sets—to the standard problem of checking assertion validity. For this, we first eschew the complexity of reasoning about several concurrent computations at once, by focusing on a *single* computation starting (i.e., inputs issued) at some cycle  $t$ . We say that a value is *live* for cycle  $t$  ( $t$ -live), if it was influenced by the computation started at  $t$ , i.e.,  $t$  is in the value’s influence set. This allows us to reduce the problem of checking equality of influence sets, to checking the equivalence of membership, for their elements. We say that a hardware design is *liveness equivalent*, if, for any two executions (that satisfy usage assumptions), and any  $t$ ,  $t$ -live values are assigned to sinks in the same

way, i.e., whenever a  $t$ -live value is assigned to a sink in one execution, a  $t$ -live value must also be assigned to a sink in the other.

To check a hardware design for liveness equivalence, we *mark* source data as live in some *arbitrarily chosen* start cycle  $t$ , and track the flow of  $t$ -live values through the circuit using a simple standard taint tracking monitor [44]; the problem of checking liveness equivalence then reduces to checking a simple assertion stating that sinks are always tainted in the same way. Reducing constant-time execution to the standard problem of checking assertion validity allows us to rely on off-the-shelf, mature verification technology, which explains IODINE’s effectiveness.

**3. Evaluation.** Our final contribution is an implementation and evaluation of IODINE on seven open source VERILOG projects—CPU cores, an ALU, crypto-cores, and floating-point units (FPUs). We find that IODINE succeeds in verifying different kinds of hardware designs in a matter of seconds, with modest developer effort (§ 6). Many of our benchmarks are constant-time for intricate reasons (§ 6.3), e.g., whether or not a circuit is constant-time depends on its execution history, circuits are constant-time despite triggering different control flow paths depending on secrets, and require a carefully chosen set of assumptions to be shown constant-time. In our experience, these characteristics—combined with the circuit size—make determining whether a hardware design is constant-time by code inspection near impossible.

IODINE also revealed two constant-time violations: one in the division unit of an FPU designs, another in the modular exponentiation module of an RSA encryption module. The second violation—a classical timing side channel—can be abused to leak secret keys [27, 35].

In summary, this paper makes the following contributions.

- ▶ First, we give a definition for constant-time execution of hardware, based on the notion of *influence sets* (§ 2). We formalize the semantics of VERILOG programs with influence sets (§ 3), and use this formalization to define constant-time execution with respect to usage assumptions (§ 4).
- ▶ Our second contribution is a reduction of constant-time execution to the easy-to-verify problem of liveness equivalence. We formalize this property (§ 4), prove its equivalence to our original notion of constant-time execution (§ 4.3), and show how to verify it using standard methods (§ 5).

```

1 // source(x); source(y); sink(out);
2 // assume(ct = 1);
3
4 reg flp_res, x, y, ct, out, out_ready, ...;
5 wire iszero, isNaN, ...;
6
7 assign iszero = (x == 0) || (y == 0);
8
9 always @(posedge clk) begin
10     ...
11     flp_res <= ... // (2) compute x * y
12 end
13
14 always @(posedge clk) begin
15     if (ct)
16         ...; out <= flp_res; // (4)
17     else
18         if (iszero)
19             out <= 0; // (1)
20         else if (isNaN)
21             ...
22         else out <= flp_res; // (3)
23     end
24 end
25 end

```

**Figure 1:** Floating point multiplier (EX1).

- Our final contribution is an implementation and evaluation of IODINE on several challenging open source hardware designs (§ 6). Our evaluation shows that IODINE can be used to verify constant-time execution of existing hardware designs, rapidly, and with modest user effort.

## 2 Overview

In this section, we give an overview of IODINE and show how our tool can be used to verify that a piece of VERILOG code executes in constant-time. As a running example, we consider a simple implementation of a floating-point multiplication unit.

**Floating Point Multiplier.** Our running example, like most FPUs, is generally *not* constant-time—common operations (*e.g.*, multiplication by zero) are dramatically faster than rare ones (*e.g.*, multiplication by denormal numbers [17,36]). But, like the ARM’s recent support for data independent timing instructions, our FPU contains a processor flag that can be set to ensure that all multiplications are constant-time, at the cost of performance. Fig. 1 gives a simplified fragment of VERILOG code that implements this FPU multiplier. While our benchmarks consist of hundreds of threads with shared variables, pipelining, and contain a myriad of branches and flags which cause dependencies on the execution history (see § 6.3), we

have kept our running example as simple as possible: our multiplier takes two floating-point values—input registers *x* and *y*—and stores the computation result in output register *out*. Recall that VERILOG programs operate on two kinds of data-structures: *registers* which are assigned in *always*-blocks and store values across clock cycles and *wires* which are assigned in *assign*-blocks and hold values only within a cycle. Control register *ct* is used to configure the FPU to run in constant-time (or not). For simplicity, we omit most other control logic (*e.g.*, reset or output-ready bits and processing of inputs). Internally, the multiplier consists of several *fast* paths and a single *slow* path. For example, to implement multiplication by zero, one, NAN, and other special values we, inspect the input registers for these values and produce a result in a single cycle (see (1)). Multiplication by other numbers is more complex, however, and generally takes more than a single cycle. As shown in Fig. 1, this *slow* path consists of multiple intermediate steps, the final result of which is assigned to a temporary register *flp\_res* (see (2)) before *out* (see (3)).<sup>1</sup> Importantly, when the constant-time configuration register *ct* is set, only this *slow* path is taken (see (4)).

**Outline.** In the rest of this section, we show how IODINE verifies that this hardware design runs in constant-time when the *ct* flag is set and violates the constant-time property otherwise. We present our definition of constant-time based on of influence sets in § 2.1, liveness equivalence in § 2.2, and finally show how IODINE formally verifies liveness equivalence by reducing it to a simple safety property that can be handled by standard verification methods § 2.3.

### 2.1 Constant-Time For Hardware

We start by defining *constant-time* execution for hardware.

**Assumptions and Attacker Model.** Like SecVerilog [55], we scope our work to synchronous circuits with a single, fixed-rate clock. We further assume an *external attacker* that can measure the execution time of a piece of hardware (given as influence sets) using a cycle-precise timer. In particular, an attacker can observe the timing of *all* inputs that influenced a given output. These assumptions afford us many benefits. (Though, as we describe in § 7, they are not for free.) For example, assuming a single

<sup>1</sup> For simplicity, we omit the intermediate steps and assume that they implement floating-point multiplication in constant-time. In practice, FPUs may also take different amounts of time depending on such values.

$P ::=$	<b>Program</b>
$[s]_{id}$	<i>process</i>
$P \parallel P$	<i>parallel composition</i>
$\text{repeat } P$	<i>sync. iteration</i>
$\epsilon$	<i>empty process</i>
$s ::=$	<b>Command</b>
$\text{skip}$	<i>no-op</i>
$v = e$	<i>blocking</i>
$v \Leftarrow e$	<i>non-blocking</i>
$v := e$	<i>continuous</i>
$\text{ite}(e, s, s)$	<i>conditional</i>
$s_1 ; \dots ; s_k$	<i>sequence</i>
$\alpha$	<i>annotation</i>
$e ::=$	<b>Expression</b>
$v$	<i>variables</i>
$n$	<i>constants</i>
$f(e_1, \dots, e_k)$	<i>function literal</i>

Figure 2: Syntax for intermediate language VINTER.

```

repeat [iszero := (x == 0 || y == 0)]
|| repeat [...; flp_res <- ...]
|| repeat [
  ite(ct,
    out <- flp_res,
    ite(iszero,
      out <- 0,
      out <- flp_res))
]

```

Figure 3: EX1 written in VINTER

fixed-rate clock, allows us to translate VERILOG programs, such as our FPU multiplier to a more concise representation shown in Figure 3.

**Intermediate Language.** In this language—called VINTER—VERILOG `always`- and `assign`-blocks are represented as concurrent *processes*, wrapped inside an infinite `repeat`-loop. As Fig. 2 shows, each process sequentially executes a series of VERILOG-like statements. (Each process also has a unique identifier  $id \in PIDs$ , which we sometimes omit, for brevity.) Most of these are standard; we only note that VINTER—like VERILOG—supports three types of assignment statements: blocking ( $v = e$ ), non-blocking ( $v \Leftarrow e$ ) and continuous ( $v := e$ ). Blocking assignments take effect immediately, within the current cycle; non-blocking assignments are deferred until the next cycle. Finally, continuous assignments enforce directed equalities between registers or wires: whenever the right-hand side of an equality is changed, the left-hand side is updated by re-running the assignment. Note that VINTER focuses only on the synthesizable fragment of VERILOG, *i.e.*, does not model delays, etc., which are only relevant for simulation.

VINTER processes are composed in parallel using the ( $\parallel$ ) operator. Unlike concurrent software processes, they are, however, synchronized using a single (implicit) fixed-rate clock: each process waits for all other (parallel) processes to finish executing before moving on to the next iteration, *i.e.*, next clock cycle. Moreover, unlike software, these programs are usually data-race free, in order to be synthesizable to hardware.

VINTER processes run forever; they perform computations and update registers (*e.g.*, out in our multiplier) on every clock cycle. For example, pipelined hardware units execute multiple, different computations simultaneously.

**From Software to Hardware.** This execution model, together with the fact that software operates at a higher level of abstraction than hardware, makes it difficult for us to use existing verification tools for constant-time software (*e.g.*, [16, 20]).

First, constant-time verification for software only considers straight-line, sequential code. This makes it ill-suited for the concurrent, long-lived execution model of hardware.

Second, software constant-time models are necessarily conservative. They deliberately abstract over hardware details—*i.e.*, they don't rely on a precise hardware models (*e.g.*, of caches or branch predictors)—and instead use *leakage models* that make control flow and memory access patterns observable to the attacker. This makes constant-time software portable across hardware. But, it also makes the programming model restrictive: the model disallows any branching to protect against hidden microarchitectural state (*e.g.*, the branch predictor).

Since we operate on VERILOG, where all state is explicit and visible, we can instead directly track the influence of secret values on the timing of attacker-observable outputs. This allows us to be more permissive than software constant-time models. For instance, if we can show that the execution of two branches of a hardware design takes the same amount of time, independent of secret inputs, we can safely allow branches on secrets. However, this still leaves the problem of pipelining: hardware ingests inputs and produce outputs at every clock cycle: how then do we know (if and) which secret inputs influenced a particular output?

**Influence Sets.** This motivates our definition for *influence sets*. In order to define a notion of constant-time execution that is suitable for hardware, we first add annotations marking inputs (*i.e.*,  $x$  and  $y$  in our example) as *sources* and outputs (*i.e.*, out) as *sinks*. For a given cycle, we then associate with each register  $x$  its *influence*-

Cycle #	x	y	ct	fr	out	$\theta(x)$	$\theta(y)$	$\theta(ct)$	$\theta(fr)$	$\theta(out)$
0	0	1	F	X	X	{0}	{0}	$\emptyset$	$\emptyset$	$\emptyset$
1	0	1	F	X	0	{1}	{1}	$\emptyset$	$\emptyset$	{0}
⋮										
k-1	0	1	F	0	0	{k-1}	{k-1}	$\emptyset$	{0}	{k-2}
k	0	1	F	0	0	{k}	{k}	$\emptyset$	{1}	{k-1}

**Figure 4:** Execution of EX1, where  $x = 0$  and  $y = 1$ , and  $ct$  is unset. For each variable and cycle, we show its current value and influence set. We assume that it takes  $k$  cycles to compute the output along the slow path, and abbreviate  $flp\_res$  as  $fr$ . **X** denotes an unknown/irrelevant value. Register  $out$  is only influenced by values from the last cycle. Highlighted cells are the difference with Figure 5. Values that stayed the same in the next cycle are shaded.

Cycle #	x	y	ct	fr	out	$\theta(x)$	$\theta(y)$	$\theta(ct)$	$\theta(fr)$	$\theta(out)$
0	1	1	F	X	X	{0}	{0}	$\emptyset$	$\emptyset$	$\emptyset$
1	1	1	F	X	X	{1}	{1}	$\emptyset$	$\emptyset$	{0}
⋮										
k-1	1	1	F	1	X	{k-1}	{k-1}	$\emptyset$	{0}	{k-2}
k	1	1	F	1	1	{k}	{k}	$\emptyset$	{1}	{0, k-1}

**Figure 5:** Execution of EX1, where both  $x = 1$  and  $y = 1$ , and  $ct$  is unset. The execution produces the same influence sets as the execution in Fig. 4, except for cycle  $k$ , where  $out$ 's influence set contains the additional value 0, thereby violating our definition of constant-time execution.

set  $\theta(x)$ . The influence set of a register  $x$  contains all cycles  $t$ , such that an input at  $t$  was used in the computation of  $x$ 's current value. This allows us to define constant-time execution for hardware: we say that a hardware design is constant-time, if any two executions (that satisfy usage assumptions) produce the same sequence of influence sets for their sinks.

**Example.** We now illustrate this definition using our running example EX1 by showing that EX1 violates our definition of constant-time, if the  $ct$  flag is unset. For this, consider Fig. 4 and Fig. 5, which show the state of registers and wires as well as their respective influence sets, for two executions. In both executions, we let  $y = 1$ , but vary the value of the  $x$  register: in Fig. 4, we set  $x$  to 0 to trigger the fast path in Fig. 5 we set it to 1. In both executions, sources  $x$  and  $y$  are only influenced by the current cycle, constant-time flag  $ct$  is set independently of inputs, and temporary register  $flp\_res$  is influenced by the inputs that were issued  $k - 1$  cycles ago, as it takes  $k - 1$  cycles to compute  $flp\_res$  along the slow path.

The two executions differ in the influence sets of  $out$ . In Fig. 4,  $out$  is only influenced by the input issued in the last cycle, through a control dependency on  $iszero$ . In the execution in Fig. 5, its value at cycle  $k$  is however also influenced by the input at 0. This reflects the propagation of the computation result through the slow path. Crucially, it also shows that the multiplier is not constant-

time—the sets  $\theta(out)$  differing between two runs reflects the influence of data on the duration of the computation.

## 2.2 Liveness Equivalence

We now show how to reduce verifying whether a given hardware is constant-time to an easy-to-check, yet equivalent problem called liveness equivalence. Intuitively, liveness equivalence reduces the problem of checking equality of influence sets, to checking the equivalence of membership, for arbitrary elements.

**Liveness Equivalence.** Our reduction focuses on a single computation started at some cycle  $t$ . We say that register  $x$  is *live* for cycle  $t$  ( $t$ -live), if its current value is influenced by an input issued in cycle  $t$ , *i.e.*, if  $t \in \theta(x)$ . Two executions are  $t$ -liveness equivalent, if whenever a  $t$ -live value is assigned to a sink in one execution, a  $t$ -live value must also be assigned in the other. Finally, a hardware design is liveness equivalent, if any two executions that satisfy usage assumptions are  $t$ -liveness equivalent, for any  $t$ .

**Live Value Propagation.** To track  $t$ -liveness for a fixed  $t$ , IODINE internally transforms VINTER programs as follows. For each register or wire (*e.g.*,  $x$  in our multiplier), we introduce a new shadow variable (*e.g.*,  $x^\bullet$ ) that represents its liveness; a shadow variable  $x^\bullet$  is set to L if  $x$  is live and D (dead) otherwise.<sup>2</sup> We then propagate live-

<sup>2</sup> For liveness-bits  $x^\bullet$  and  $y^\bullet$ , we define a join operator  $\vee$ , such that

```

repeat [ iszero := (x == 0 || y == 0);
         iszero* := (x* ∨ y*) ]
|| repeat [ ...; flp_res ← ...;
           ...; flp_res* ← ... // (x* ∨ y*) ]
|| repeat [ ite(ct,
               out ← flp_res;
               out* ← (flp_res* ∨ ct*),
               ite(iszero, out ← 0;
                   out* ← (ct* ∨ iszero*),
                   out ← flp_res;
                   out* ← ( flp_res* ∨
                             (ct* ∨ iszero*) )) ) ]

```

**Figure 6:** EX1, after we propagate liveness using a standard taint-tracking inline monitor.

	x	y	ct	fr	out	x*	y*	ct*	fr*	out*
0	0	1	F	X	X	L	L	D	D	D
1	0	1	F	X	0	D	D	D	D	L
⋮										
k-1	0	1	F	0	0	D	D	D	L	D
k	0	1	F	0	0	D	D	D	D	D

**Figure 7:** Execution of EX1\*, where  $x = 0$  and  $y = 1$ . We show current value and liveness bit for each register and cycle. Register out is live in cycle one, due to the fast path and dead, otherwise. Highlights are the differences with Figure 8. Values that stayed the same in the next cycle are shaded.

ness using a standard taint-tracking inline monitor [44] shown in Figure 6. Intuitively, our monitor ensures that registers and wires that depend on a live value—directly or indirectly, via control flow—are marked live.

**Example.** By tracking liveness, we can again see that our floating-point multiplier is not constant-time when the ct flag is unset. To this end, we “inject” live values at sources ( $x$  and  $y$ ) at time  $t = 0$  for two runs; as before, we set  $y = 1$ , and vary the value of  $x$ : in one execution, we set  $x$  to 0 to trigger the fast path, in the other execution, we set it to 1. Fig. 7 and 8 show the state of the different registers and wires for these runs. In both runs, out is live at cycle 1—due to a control dependency in Fig. 7, due a direct assignment in Fig. 8. But, in the latter, out is *also* live at the  $k$ th cycle. This reflects the fact that the influence sets of out at cycle  $k$  differ in the membership of 0, and therefore witnesses the constant-time violation.

## 2.3 Verifying Liveness Equivalence

Using our reduction to liveness equivalence, we can *verify* that a VERILOG program executes in constant-time using standard methods. For this, we *mark* source data as

$x^* \vee y^*$  is L, if  $x^*$  or  $y^*$  is L and D, otherwise.

	x	y	ct	fr	out	x*	y*	ct*	fr*	out*
0	1	1	F	X	X	L	L	D	D	D
1	1	1	F	X	X	D	D	D	D	L
⋮										
k-1	1	1	F	1	X	D	D	D	L	D
k	1	1	F	1	1	D	D	D	D	L

**Figure 8:** Execution of EX1\*, where both  $x = 1$  and  $y = 1$ . The liveness bits are the same as in 7, except for cycle  $k$ , where out is now live. This reflects the propagation of the output value through the slow path and shows the constant-time violation.

live in some *arbitrarily chosen* start cycle  $t$ . We then verify that any *two* executions that satisfy usage assumptions assign  $t$ -live values to sinks, in the same way.

**Product Programs.** Like previous work on verifying constant-time software [16], IODINE reduced the problem of verifying properties of *two* executions of some program  $P$  by proving a property about a *single* execution of a new program  $Q$ . This program—the so-called *product program* [22]—consists of two disjoint copies of the original program.

**Race-Freedom.** Our product construction exploits the fact that VERILOG programs are *race-free*, *i.e.*, the order in which *always*-blocks are scheduled within a cycle does not matter. While races in software often serve a purpose (*e.g.*, a task distribution service may allow races between equivalent worker threads to increase throughput), races in VERILOG are always artifacts of poorly designed code: any synthesized circuit is, by its nature, race-free, *i.e.*, the scheduling of processes *within* a cycle does not affect the computation outcome. Indeed, races in VERILOG represent an under-specification of the intended design.

**Per-Process Product.** We leverage this insight to compose the two copies of a program in *lock-step*. Specifically, we merge each process of the two program copies and execute the “left” (L) and “right” (R) copies together. For example, IODINE transforms the VINTER multiplier code from Figure 6 into the *per-process product program* shown in Figure 9.

Merging two copies of a program as such is sound: since the program is race-free—any ordering of process transitions *within* a cycle yields the same results—we are free to pick an arbitrary schedule.<sup>3</sup> Hence, IODINE takes a simple ordering approach and schedules the left and right copy of same process at the same time.

**Constant-Time Assertion.** Given such a product program, we can now frame the constant-time verification

<sup>3</sup>To ensure that hardware designs are indeed race-free, our implementation performs a light-weight static analysis to check for races.

$$\begin{array}{l}
\text{repeat} \left[ \begin{array}{l} \text{iszero}_L := (x_L == 0 \parallel y_L == 0); \\ \text{iszero}_R := (x_R == 0 \parallel y_R == 0); \\ \text{iszero}_L^\bullet := (x_L^\bullet \vee y_L^\bullet); \\ \text{iszero}_R^\bullet := (x_R^\bullet \vee y_R^\bullet); \end{array} \right] \\
\parallel \text{repeat} \left[ \begin{array}{l} \dots; \text{flp\_res}_L \leftarrow \dots; \\ \dots; \text{flp\_res}_R \leftarrow \dots; \\ \text{flp\_res}_L^\bullet \leftarrow \dots // (x_L^\bullet \vee y_L^\bullet); \\ \text{flp\_res}_R^\bullet \leftarrow \dots // (x_R^\bullet \vee y_R^\bullet); \end{array} \right] \\
\parallel \text{repeat} \dots
\end{array}$$

Figure 9: Per-process product form of EX1.

challenge as a simple *assertion*: the liveness of the left and right program sink-variables must be the same (regardless of when the computation started). In our example, this assertion is simply  $\text{out}_L^\bullet = \text{out}_R^\bullet$ . This assertion can be verified using standard methods. In particular, IODINE synthesizes process-modular invariants [45] that imply the constant-time assertion (§ 5).

The following two sections formalize the material presented in this overview.

### 3 Syntax and Semantics

Since VERILOG’s execution model can be subtle [12], we formally define syntax and semantics of the VERILOG fragment considered in this paper.

#### 3.1 Preliminaries

For a function  $f$ , we write  $\text{dom } f$  to denote  $f$ ’s domain and  $\text{ran } f$  for its co-domain. For a set  $S \subseteq \text{dom } f$ , we let  $f[S \leftarrow b]$  denote the function that behaves the same as  $f$  except  $S$ , where it returns  $b$ , *i.e.*,  $f[S \leftarrow b](x)$  evaluates to  $b$  if  $x \in S$  and  $f(x)$ , otherwise. We use  $f[a \leftarrow b]$  as a short hand for  $f[\{a\} \leftarrow b]$ . Sometimes, we want to update a function by setting the function values of some subset  $S$  of its domain to a non-deterministically chosen value. For  $S \subseteq \text{dom } f$ , we write  $f[S \leftarrow *](x)$  to denote the function that evaluates to some  $y$  with  $y \in \text{ran } f$ , if  $x \in S$  and  $f(x)$  otherwise.

#### 3.2 Syntax

We restrict ourselves to the *synthesizable* fragment of VERILOG, *i.e.*, we do not include commands like initial blocks that only affect simulation and implement a *normalization step* [32] in which the program is “flattened” by removing module instantiation through in-lining. We provide VERILOG syntax and a translation to VINTER in Appendix A.2, but define semantics in VINTER (Fig. 2).

**Annotations.** We define annotations in Figure 10. Let *Regs* denote the set of registers and *Wires* the set of wires and let  $\text{VARS}$  denote their disjoint union, *i.e.*,

$$\begin{array}{l}
a ::= \quad \quad \quad \text{In/Out} \quad \quad \quad \text{Assump.} \\
| \text{source}(v) \quad \text{source} \quad | \text{init}(\varphi) \quad \text{initially } \varphi \\
| \text{sink}(v) \quad \text{sink} \quad | \square(\varphi) \quad \text{always } \varphi
\end{array}$$

Figure 10: Annotation syntax.

Config	Meaning	Trace	Meaning
$\sigma$	store	$\Sigma$	configuration
$\tau$	liveness map	$\mathbf{l}$	label
$\theta$	influence map	$\mathbf{b}$	liveness bit
$\mu$	assign. buffer	$\pi$	trace
$ev$	event set	$\text{store}(\pi, i)$	$\sigma_i$
$P$	current program	$\text{live}(\pi, i)$	$\tau_i$
$I$	initial program	$\text{inf}(\pi, i)$	$\theta_i$
$c$	clock cycle	$\text{clk}(\pi, i)$	$c_i$
		$\text{reset}(\pi, i)$	$\mathbf{b}_i$

Figure 11: Configuration and trace syntax.

$\text{VARS} \triangleq \text{Regs} \uplus \text{Wires}$ . For a register  $v \in \text{Regs}$ , annotations  $\text{source}(v)$  and  $\text{sink}(v)$  designate  $v$  as source or sink, respectively.<sup>4</sup> We let  $\text{IO} \triangleq (\text{Src}, \text{Sink})$  denote the set of input/output assumptions, where  $\text{Src}$  denotes the set of all sources and  $\text{Sink}$  denote the set of all sinks. Let  $\varphi$  be a first-order formula over some background theory that refers to two disjoint sets of variables  $\text{VARS}_L$  and  $\text{VARS}_R$ . Then, annotations  $\text{init}(\varphi)$  and  $\square(\varphi)$  indicate that formula  $\varphi$  holds initially or throughout the execution. The assumptions are collected in  $\mathbf{A} \triangleq (\text{INIT}, \text{ALL})$ , such that  $\text{INIT}$  contains all formulas under  $\text{init}$  and  $\text{ALL}$  all formulas under  $\square$ .

#### 3.3 Semantics

**Values.** The set of values  $\text{VALS} \triangleq \mathbb{Z} \uplus \{\mathbf{X}\}$  consists of the disjoint union of the integers and special value  $\mathbf{X}$  which represents an irrelevant value. A function application that contains  $\mathbf{X}$  as an argument evaluates to  $\mathbf{X}$ .

**Configurations.** The program state is represented by a *configuration*  $\Sigma \in \text{Configs}$ . Figure 11 shows the components of a configuration. A store  $\sigma \in \text{STORES} \triangleq (\text{VARS} \mapsto \text{VALS})$  is a map from registers and wires to values. A *liveness map*  $\tau \in \text{LIVEMAP} \triangleq (\text{VARS} \mapsto \{\mathbf{L}, \mathbf{D}\})$  is a map from registers and wires to liveness bits. A *influence map*  $\theta \in \text{INFMAPS} \triangleq (\text{VARS} \mapsto \mathcal{P}(\mathbb{Z}))$  is a map from registers and wires to influence sets. *Assignment buffers* serve to model non-blocking assignments. Let  $\text{PIDs}$  denote a set of process identifiers. An assignment buffer  $\mu \in \text{PIDs} \mapsto (\text{VARS} \times \text{VALS} \times \{\mathbf{L}, \mathbf{D}\} \times \mathcal{P}(\mathbb{Z}))^*$  is a map from pro-

<sup>4</sup>To use wires as source/sink, one has to define an auxiliary register.

$$\begin{array}{c}
\text{[VAR]} \\
\hline
v, \sigma, \tau, \theta \dashrightarrow \sigma(v), \tau(v), \theta(v) \\
\\
\text{[FUN]} \\
\hline
\begin{array}{c}
e_1, \sigma, \tau, \theta \dashrightarrow v_1, t_1, i_1 \quad \dots \quad e_k, \sigma, \tau, \theta \dashrightarrow v_k, t_k, i_k \\
t = (t_1 \vee \dots \vee t_k) \quad i = (i_1 \cup \dots \cup i_k) \\
\hline
f(e_1, \dots, e_k), \sigma, \tau, \theta \dashrightarrow f(v_1, \dots, v_k), t, i
\end{array} \\
\\
\text{[CONST]} \\
\hline
n, \sigma, \tau, \theta \dashrightarrow n, D, \emptyset
\end{array}$$

**Figure 12:** Expression evaluation.

cess identifier to a sequence of variable/value/liveness-bit/influence set tuples. An *event set*  $ev \in \mathcal{P}(\text{VARS})$  is a set of variables, where we use  $v \in ev$  to indicate that variable  $v$  has been changed in the current cycle. Finally,  $I \in \text{Progs}$  contains the initial program. Intuitively, the initial program is used to activate all processes when a new clock cycle begins.

**Evaluating Expressions.** We define an evaluation relation  $\dashrightarrow \in (\text{EXPR} \times \text{STORES} \times \text{LIVEMAP} \times \text{INFMAPS}) \mapsto (\text{VALS} \times \{\text{L}, \text{D}\} \times \mathcal{P}(\mathbb{Z}))$  that computes value, liveness-bit, and influence map for an expression. We define the relation through the inference rules shown in Fig. 12. An evaluation step (below the line) can be taken, if the preconditions (above the line) are met. Rule [VAR] evaluates a variable to its current value under the store, its current liveness-bit and influence set. A numerical constant evaluates to itself, is dead and not influenced by any cycle. To evaluate a function literal, we evaluate its arguments and apply the function on the resulting values. A function value is live if any of its arguments are, and its influence set is the union of its influences.

**Transition Relations.** We define our semantics in terms of four separate transition relations of type  $(\text{Configs} \times \text{Labels} \times \text{Configs})$ . We now discuss the individual relations and then describe how to combine them into an overall transition relation  $\rightsquigarrow$ .

**Per-process transition  $\rightsquigarrow_P$ .** The per-process transition relation  $\rightsquigarrow_P$  describes how to step along individual processes. It is defined in Fig. 13. Rules [SEQ-STEP] and [PAR-STEP] are standard and describe sequential and parallel composition. Rule [B-ASN] reduces a blocking update  $x = e$  to *skip*, by first evaluating  $e$  to yield a value  $v$ , liveness bit  $t$  and influence set  $i$ , updating store  $\sigma$ , liveness map  $\tau$  and influence map  $\theta$ , and finally adding  $x$  to the set of modified variables. Rule [NB-ASN] defers a non-blocking assignment. In order to reduce an assignment  $(x \leftarrow e)_{id}$  for process  $id$  to *skip*, the rule evaluates expression  $e$  to value  $v$ , liveness bit  $t$  and influence

set  $i$ , and defers the assignment by appending the tuple  $(x, v, t, i)$  to the back of  $id$ 's buffer. We omit rules for conditionals and structural equivalence. Structural equivalence allows transitions between trivially equivalent programs such as  $P \parallel Q$  and  $Q \parallel P$ .

**Non-blocking Transition  $\rightsquigarrow_N$ .** Transition relation  $\rightsquigarrow_N$  applies deferred non-blocking assignments. It is defined by a single rule [NB-APP] shown in Fig. 13. The rule first picks a tuple  $(x, v, t, i)$  from the front of the buffer of some process  $id$ , and, like [B-ASN], updates store  $\sigma$ , liveness map  $\tau$  and influence map  $\theta$ , and finally adds  $x$  to the set of updated variables.

**Continuous Transition  $\rightsquigarrow_C$ .** Relation  $\rightsquigarrow_C$  specifies how to execute continuous assignments. It is described by rule [C-ASN] in Fig. 13, which reduces a continuous assignment  $x := e$  to *skip* under the condition that some variable  $y$  occurring in  $e$  has changed, *i.e.*,  $y \in ev$ . To apply the assignment, it evaluates  $e$  to value, liveness bit and influence set, and updates store and liveness map and influence map. Importantly, variable  $y$  is not removed from the set of events, *i.e.*, a single assignment can enable several continuous assignments.

**Global Transition  $\rightsquigarrow_G$ .** Finally, global transition relation  $\rightsquigarrow_G$  is defined by rules [NEWCYCLE] and [NEWCYCLE-ISSUE] shown in Fig. 13. [NEWCYCLE] starts a new clock cycle by discarding the current program and event set, emptying the assignment buffer, resetting the wires to some non-deterministically chosen state (as wires only hold their value *within* a cycle), and rescheduling and activating a new set of processes, extracted from initial program  $I$ . For a program  $P$ , let  $\text{REPEAT}(P) \in \mathcal{P}(\text{Progs})$  denote the set of processes that occur under *repeat*. For a set of programs  $S$ , we let  $\square S$  denote their parallel composition. [NEWCYCLE] uses these constructs to reschedule all processes that appear under *repeat* in  $I$ . Both sources and wires are set to  $D$ . The influence map is updated by mapping all wires to the empty set, and each source to the set containing only the current cycle.

[NEWCYCLE-ISSUE] performs the same step, but additionally updates the liveness map by issuing new live bits for the source variables. Both rules increment the cycle counter  $c$ . The rules issue a *label*  $l \in \text{Labels} \triangleq ((\text{STORES} \times \text{LIVEMAP} \times \text{INFMAPS} \times \mathbb{N} \times \{\text{L}, \text{D}\}) \uplus \epsilon)$  which is written above the arrow (all previous rules issue the empty label  $\epsilon$ ). The label contains the current store, liveness map, influence map, clock cycle, and a bit indicating whether new live-bits have been issued. Labels are used to construct the *trace* of an execution, as

we will discuss later.

**Overall Transition**  $\rightsquigarrow$ . We define the overall transition relation  $\rightsquigarrow \in \text{Configs} \times \text{Labels} \times \text{Configs}$  by fixing an order in which to apply the relations. Whenever a *continuous assignment* step (relation  $\rightsquigarrow_C$ ) can be applied, that step is taken. Whenever no continuous assignment step can be applied, however, a *per-process* step (relation  $\rightsquigarrow_P$ ) can be applied, a  $\rightsquigarrow_P$  step is taken. If no continuous assignment and process local steps can be applied, however, an *non-blocking assignment* step (relation  $\rightsquigarrow_N$ ) is applicable, a  $\rightsquigarrow_N$  step is taken. Finally, if neither continuous assignment, per-process, or non-blocking steps can be applied, the program moves to a new clock cycle by applying a *global step* (relation  $\rightsquigarrow_G$ ). Our overall transition relation closely follows the Verilog simulation reference model from Section 11.4 of the standard [12].

**Executions and Traces.** An *execution* is a finite sequence of configurations and transition labels  $\tau \triangleq \Sigma_0 l_0 \Sigma_1 \dots \Sigma_{m-1} l_{m-1} \Sigma_m$  such that  $\Sigma_i \xrightarrow{l_i} \Sigma_{i+1}$  for  $i \in \{1, \dots, m-1\}$ . We call  $\Sigma_0$  *initial state* and require that all taint bits are set to D, the influence map maps each variable to the empty set, the assignment buffer is empty, the current program is the empty program  $\triangleright$ , and the clock is set to 0. The *trace* of an execution is the sequence of its (non-empty) labels. For a trace  $\pi \triangleq (\sigma_0, \tau_0, \theta_0, c_0, b_0) \dots (\sigma_{n-1}, \tau_{n-1}, \theta_{n-1}, c_{n-1}, b_{n-1}) \in \text{Labels}^*$  and for  $i \in \{0, \dots, n-1\}$  we let  $\text{store}(\pi, i) \triangleq \sigma_i$ ,  $\text{live}(\pi, i) \triangleq \tau_i$ ,  $\text{inf}(\pi, i) \triangleq \theta_i$ ,  $\text{clk}(\pi, i) \triangleq c_i$  and  $\text{reset}(\pi, i) = b_i$ , and say the trace has length  $n$ . For a program  $P$  we use  $\text{TRACES}(P) \in \mathcal{P}(\text{Labels}^*)$  to denote the set of its traces, *i.e.*, all traces with initial program  $P$ .

## 4 Constant-Time Execution

We now first define constant-time execution with respect to a set of assumptions. We then define liveness equivalence and show that the two notions are equivalent.

### 4.1 Constant-Time Execution

**Assumptions.** For a formula  $\varphi$  that ranges over two disjoint sets of variables  $\text{VARS}_L$  and  $\text{VARS}_R$  and stores  $\sigma_L$  and  $\sigma_R$  such that  $\text{dom } \sigma_L = \text{VARS}_L$  and  $\text{dom } \sigma_R = \text{VARS}_R$ , we write  $\sigma_L, \sigma_R \models \varphi$  to denote that formula  $\varphi$  holds when evaluated on  $\sigma_L$  and  $\sigma_R$ . For some program  $P$  and a set of assumptions  $A \triangleq (\text{INIT}, \text{ALL})$ , we say that two traces  $\pi_L, \pi_R \in \text{TRACES}(P)$  of length  $n$  *satisfy*  $A$  if *i)* for each formula  $\varphi_I \in \text{INIT}$ ,  $\varphi_I$  holds initially, and *ii)* for each formula  $\varphi_A \in \text{ALL}$ ,  $\varphi_A$  hold throughout, *i.e.*,  $\text{store}(\pi_L, 0), \text{store}(\pi_R, 0) \models \varphi_I$  and

$\text{store}(\pi_L, i), \text{store}(\pi_R, i) \models \varphi_A$ , for  $0 \leq i \leq n-1$ . Intuitively, pairs of traces that satisfy the assumptions are “low” or “input” equivalent.

**Constant Time Execution.** For a program  $P$ , assumptions  $A$  and traces  $\pi_L, \pi_R \in \text{TRACES}(P)$  of length  $n$  that satisfy  $A$ ,  $\pi_L$  and  $\pi_R$  are *constant time* with respect to  $A$ , if they produce the same influence sets for all sinks, *i.e.*,  $\text{inf}(\pi_L, i)(v) = \text{inf}(\pi_R, i)(v)$ , for  $0 \leq i \leq n-1$  and all  $v \in \text{Sink}$ , and where two sets are equal if they contain the same elements. A program is constant time with respect to  $A$ , if all pairs of its traces that satisfy  $A$  are constant time.

### 4.2 Liveness Equivalence

**t-Trace.** For a trace  $\pi$ , we say that  $\pi$  is a *t-trace*, if  $\text{reset}(\pi, t) = L$  and  $\text{reset}(\pi, i) = D$ , for  $i \neq t$ .

**Liveness Equivalence.** For a program  $P$ , let  $\pi_L, \pi_R \in \text{TRACES}(P)$ , such that both  $\pi_L$  and  $\pi_R$  are of length  $n$ . We say that  $\pi_L$  and  $\pi_R$  are *t-liveness equivalent*, if both are *t-traces*, and  $\text{live}(\pi_L, i)(v) = \text{live}(\pi_R, i)(v)$ , for  $0 \leq i \leq n-1$  and all  $v \in \text{Sink}$ . A program is *t-liveness equivalent*, with respect to a set of assumptions  $A$ , if all pairs of *t-traces* that satisfy  $A$  are *t-liveness equivalent*. Finally, a program is *liveness equivalent* with respect to  $A$ , if it is *t-liveness equivalent* with respect to  $A$ , for all  $t$ .

### 4.3 Equivalence

We can now state our equivalence theorem.

**Theorem 1.** *For all programs  $P$  and assumptions  $A$ ,  $P$  executes in constant-time with respect to  $A$  if and only if it is liveness equivalent with respect to  $A$ .*

We first give a lemma which states that, if a register is *t-live*, then  $t$  is in its influence set.

**Lemma 1.** *For any t-trace  $\pi$  of length  $n$ , index  $0 \leq i \leq n-1$ , and variable  $v$ , if  $v$  is *t-live*, *i.e.*,  $\text{live}(\pi, i)(v) = L$ , then  $t$  is in  $v$ 's influence map, *i.e.*,  $t \in \text{inf}(\pi, i)(v)$ .*

We can now state our proof for Theorem 1.

*Proof Theorem 1.* The interesting direction is “right-to-left”, *i.e.*, we want to show that a liveness equivalent program is also constant-time. We prove the contrapositive, *i.e.*, if a program violates constant-time, it must also violate liveness equivalence. For a proof by contradiction, we assume that  $P$  violates constant time execution, but satisfies liveness equivalence. If  $P$  violates constant-time execution, then there must be a sink  $v^*$ , two trace  $\pi_L^*, \pi_R^* \in \text{TRACES}(P)$  that satisfy  $A$ , and some

\end{array}$$

**Figure 13:** Per-thread transition relation  $\rightsquigarrow_P$ , non-blocking transition relation  $\rightsquigarrow_N$ , continuous transition relation  $\rightsquigarrow_C$ , and global restart relation  $\rightsquigarrow_G$ .

index  $i^*$  such that  $\text{inf}(\pi_L^*, i^*)(v^*) \neq \text{inf}(\pi_R^*, i^*)(v^*)$ , and therefore without loss of generality, there is a cycle  $t^*$ , such that  $t^* \in \text{inf}(\pi_L^*, i^*)(v^*)$  and  $t^* \notin \text{inf}(\pi_R^*, i^*)(v^*)$ . We can find two traces  $t^*$ -traces  $\hat{\pi}_L$  and  $\hat{\pi}_R$  that only differ from  $\pi_L^*$  and  $\pi_R^*$  in their liveness maps. But then, since the traces are  $t^*$ -liveness equivalent, by definition, at index  $i^*$  both  $\hat{\pi}_L$  and  $\hat{\pi}_R$  are  $t^*$ -live, i.e.,  $\text{live}(\hat{\pi}_L, i^*)(v^*) = \text{live}(\hat{\pi}_R, i^*)(v^*) = L$  and, by lemma 1,  $t^* \in \text{inf}(\hat{\pi}_R, i^*)(v^*)$ . Since  $\hat{\pi}_R$  and  $\pi_R^*$  only differ in their liveness map, this implies  $t^* \in \text{inf}(\pi_R^*, i^*)(v^*)$ , from which the contradiction follows.  $\square$

## 5 Verifying Constant Time Execution

In this section, we describe how IODINE verifies liveness equivalence by using standard techniques.

**Algorithm IODINE.** Given a VINTER program  $P$ , a set of input/output specifications  $IO$  and a set of assumptions  $A$ , IODINE checks that  $P$  executes in constant time with respect to  $A$ . For this, IODINE first checks for race-freedom. If a race is detected, IODINE returns a witness describing the violation. If no race is detected, IODINE takes the following four steps: **(1)** It builds a set of Horn

clause constraints  $hs$  [26, 33] whose solution characterizes the set of all configurations that are reachable by the per-process product and satisfy  $A$ . **(2)** Next, it builds a set of constraints  $cs$  whose solutions characterize the set of liveness equivalent states. **(3)** It then computes a solution  $Sol$  to  $hs$  and checks whether the solution satisfies  $cs$ . To find a more precise solution, the user can supply additional hints in the form of a set of predicates which we describe later. **(4)** If the check succeeds,  $P$  executes in constant time with respect to  $A$ , otherwise,  $P$  can potentially exhibit timing variations.

**Constraint Solving.** IODINE solves the reachability constraints by using Liquid Fixpoint [10], which computes the *strongest solution* that can be expressed as a conjunction of elements of a set of logical formulas. These formulas are composed of a set of *base predicates*. We use base predicates that track equalities between the liveness bits and values of each variable between the two runs. In addition to these base predicates, we use hints that are defined by the user. We discuss in § 6 which predicates were used in our benchmarks.

## 6 Implementation and Evaluation

In this section, we describe our implementation and evaluate IODINE on several open source VERILOG projects, spanning from RISC processors, to floating-point units and crypto cores. We find that IODINE is able to show that a piece of code is not constant-time and otherwise verify that the hardware is constant-time in a matter of seconds. Except our processor use cases, we found the annotation burden to be light weight—often less than 10 lines of code. All the source code and data are available on GitHub, under an open source license.<sup>5</sup>

### 6.1 Implementation

IODINE consists of a front-end pass, which takes annotated hardware descriptions and compiles them to VINTER, and a back-end that verifies the constant-time execution of these VINTER programs. We think this modular designs will make it easy for IODINE to be extended to support different hardware description languages beyond VERILOG (*e.g.*, VHDL or Chisel [19]).

Our front-end extends the Icarus Verilog parser [9] and consists of 2000 lines of C++. Since VINTER shares many similarities with VERILOG, this pass is relatively straightforward, however, IODINE does not distinguish between clock edges (positive or negative) and, thus, removes them during compilation. Moreover, our prototype does not support the whole VERILOG language (*e.g.*, we do not support assignments to multiple variables).

IODINE’s back-end takes a VINTER program and, following § 5, generates and checks a set of verification conditions. We implement the back-end in 4000 lines of Haskell. Internally, this Haskell back-end generates Horn clauses and solves them using the liquid-fixpoint library that wraps the Z3 [29] SMT solver. Our back-end outputs the generated invariants, which (1) serve as the proof of correctness when the verification succeeds, or (2) helps pinpoint why verification fails.

**Tool Correctness.** The IODINE implementation and Z3 SMT solver [29] are part of our trusted computing base. This is similar to other constant-time and information flow tools (*e.g.*, SecVerilog [55] and ct-verif [16]). As such, the formal guarantees of IODINE can be undermined by implementation bugs. We perform several tests to catch such bugs early—in particular, we validate: (1) our translation into VINTER against the original VERILOG code; (2) our translation from VINTER into Horn clauses against our semantics; and, (3) the generated in-

<sup>5</sup><https://iodine.programming.systems>

variants against both the VINTER and VERILOG code.

### 6.2 Evaluation

Our evaluation seeks to answer three questions: (Q1) Can IODINE be easily applied to existing hardware designs? (Q2) How efficient is IODINE? (Q3) What is the annotation burden on developers?

**(Q1) Applicability.** To evaluate its applicability, we run IODINE on several open source hardware modules from GitHub and OpenCores. We chose VERILOG programs that fit into three categories—processors, crypto-cores, and floating-point units (FPUs)—these have previously been shown to expose timing side channels. In particular, our benchmarks consist of:

- ▶ MIPS- and RISC-V-32I-based pipe-lined CPU cores with a single level memory hierarchy.
- ▶ Crypto cores implementing the SHA 256 hash function and RSA 4096-bit encryption.
- ▶ Two FPUs that implement core operations (+, −, ×, ÷) according to the IEEE-754 standard.
- ▶ An ALU [1] that implements (+, −, ×, <<, ...).

In our benchmarks, following our attacker model from § 2.1, we annotated all the inputs to the computation. For example, this includes the sequence of instructions for the benchmarks with a pipeline (*i.e.*, MIPS, RISC-V, FPU and FPU2) in addition to other control inputs, and all the top level VERILOG inputs for the rest (*i.e.*, SHA-256, ALU and RSA). Similarly, we annotated as sinks, all the outputs of the computation. In the case of benchmarks with a pipeline, this includes the output from the last stage and other results (*e.g.*, whether the result is NaN in FPU), and all the top level VERILOG outputs for the rest. The modifications we had to perform to run IODINE on these benchmarks were minimal and due to parser restrictions (*e.g.*, desugaring assignments to multiple variables into individual assignments, unrolling the code generated by the loop inside the generate blocks).

**(Q2) Efficiency.** To evaluate its efficiency, we run IODINE on the annotated programs. As highlighted in Table 1, IODINE can successfully verify different VERILOG programs of modest size (up to 1.1K lines of code) relatively quickly (<20s). All but the constant-time FPU finished in under 3 seconds. Verifying the constant-time FPU took 12 seconds, despite the complexity of IEEE-754 standard which manifests as a series of case splits in VERILOG. We find these measurements encouraging, especially relative to the time it takes to synthesize VERILOG—verification is orders of magnitude smaller.

Name	#LOC	#Assum		CT	Check (s)
		#flush	#always		
MIPS [5]	434	31	2	✓	1.329
RISC-V [7]	745	50	19	✓	1.787
SHA-256 [8]	651	5	3	✓	2.739
FPU [6]	1182	0	0	✓	12.013
ALU [1]	913	1	5	✓	1.595
FPU2 [3]	272	3	4	✗	0.705
RSA [4]	870	4	0	✗	1.061
<b>Total</b>	5067	94	33	-	21.163

**Table 1:** #LOC is the number of lines of Verilog code, #Assum is the number of assumptions (excluding `source` and `sink`); `flush` and `always` are annotations of the form `init` and `□` respectively, **CT** shows if the program is constant-time, and **Check** is the time IODINE took to check the program. All experiments were run on a Intel Core i7 processor with 16 GB RAM.

**Discovered Timing Variability.** Running IODINE revealed that two of our use cases are not constant-time: one of the FPU implementations and the RSA crypt-core. The division module of the FPU exhibits timing variability depending on the value of the operands. In particular, similar to the example from § 2, the module triggers a fast path if the operands are special values.

The RSA encryption core similarly exhibited time variability. In particular, the internal modular exponentiation algorithm performs a Montgomery multiplication depending on the value of a source bit  $e_i$ : if  $e_i = 1$  then  $\bar{c} := \text{ModPro}(\bar{c}, \bar{m})$ . Since  $e$  is a secret, this timing variability can be exploited to reveal the secret key [27, 35].

**(Q3) Annotation burden.** While IODINE automatically discovers proofs, the user has to provide a set of assumptions  $A$  under which the hardware design executes in constant time. To evaluate the burden this places on developers, we count the number and kinds of assumptions we had to add to each of our use cases. Table 1 summarizes our results: except for the CPU cores, most of our other benchmarks required only a handful of assumptions. Beyond declaring sinks and sources, we rely on two other kinds of annotations. First, we find it useful to specify that the initial state of an input variable  $x$  is equal in any pair of runs, *i.e.*, `init`( $x_L = x_R$ ). This assumption essentially specifies that register  $x$  is flushed, *i.e.*, is set to a constant value, to remove any effects of a previous execution from our initial state. Second, we find it useful to specify that the state of an input variable  $x$  is equal, throughout any pair of runs, *i.e.*, `□`( $x_L = x_R$ ). This assumption is important when certain behavior is expected to be the same in both runs. We now describe these assumptions for our benchmarks.

- ▶ **MIPS:** We specify that the values of the fetched instructions, and the reset bit are the same.
- ▶ **RISC-V:** In addition to the assumptions required by the MIPS core, we also specify that both runs take the same conditional branch, and that the type of memory access (read or write) is the same in both runs (however, the actual values remain unrestricted). This corresponds to the assumption that programs running on the CPU do not branch or access memory based on secret values. Finally, CSR registers must not be accessed illegally (see § 6.3).
- ▶ **ALU:** Both runs execute the same type of operations (*e.g.*, bitwise, arithmetic), operands have the same bit width, instructions are valid, reset pins are the same.
- ▶ **SHA-256 and FPU (division):** We specify that the reset and input-ready bits are the same.

In all cases, we start with no assumptions and add the assumptions incrementally by manually investigating the constant-time “violation” flagged by IODINE.

**Identifying Assumptions.** From our experience, the assumptions that a user needs to specify fall into three categories. The first are straightforward assumptions—*e.g.*, that any two runs execute the same code. The second class of assumptions specify that certain registers need to be flushed, *i.e.*, they need to initially be the same (flushed) for any two runs. To identify these, we first flush large parts of circuits, and then, in a minimization step, we remove all unnecessary assumptions. The last, and most challenging, are implicit invariants on data and control—*e.g.*, the constraints on CSR registers. IODINE performs delta debugging to help pinpoint violations but, ultimately, these assumptions require user intervention to be resolved. Indeed, specifying these assumptions require a deep understanding of the circuit and its intended usage. In our experience, though, only a small fraction of assumptions fall into this third category.

**User Hints.** For one of our benchmarks (FPU), we needed to supply a small number of user hints (<5) to the solver. These hints come in the form of predicates that track additional equalities between liveness bits of the *same* run. This is required, when the two executions can take different control paths, yet execute in constant time. We hope to remove those hints in the future.

### 6.3 Case Studies

We now illustrate how IODINE verifies benchmarks with challenging features and helps explicate conditions under which a hardware design is constant-time, using exam-

```

1  always @(*) begin
2    if (...)
3      Stall = 1; else Stall = 0;
4  end
5  always @(posedge clk) begin
6    if (Stall)
7      ID_instr <= ID_instr;
8    else
9      ID_instr <= IF_instr;
10 end

```

**Figure 14:** Stalling in MIPS [5].

ples from our benchmarks.

**History Dependencies.** In hardware, the result of a computation often depends on inputs from previous cycles, *i.e.*, the computation depends on execution history. For example, when a hardware unit is in use by a previous instruction, the CPU stalls until the unit becomes free.

The code snippet in Fig. 14 contains a simplified version of the stalling logic from our MIPS processor benchmark. On line 3, register `Stall` is set to 1 if instructions in the *execute* and *instruction decode* stages conflict. Its value is then used to update the state of each pipeline stage. In this example, if the pipeline is stalled, the value of the register `ID_instr`, which corresponds to the instruction currently executing in the *instruction decode* stage, stays the same. Otherwise, it is updated with `IF_instr`—the value coming from the *instruction fetch* stage.

Without further assumptions, IODINE flags this behavior as non-constant time, as an instruction can take different times to process, depending on which other instructions are before it in the pipeline. However, after adding the assumption that any two runs execute the *same sequence of instructions*, IODINE is able to prove that `Stall` has the same value in any pair of traces, from which the constant time behavior follows. Importantly, however, we have no assumption on the state of the registers and memory elements that the instructions use.

**Diverging Control Flow.** Methods for enforcing constant time execution of software often require that any two executions take the same control flow path [16]. In hardware, this assumption is too restrictive. Consider the code snippet in Fig. 15 taken from our constant time FPU benchmark (the full logic is shown in Fig. 20 of the Appendix). The first always block calculates the sign bit of the multiplication result (`sign_mul_r`), using inputs `opa` and `opb`. The FPU uses this bit in line 17 (through `sign_mul_final`), to calculate output `out` in line 12. Even though we cannot assume that all exe-

```

1  always @(*)
2    case({opa[31], opb[31]})
3      2'b0_0: sign_mul_r <= 0;
4      2'b0_1: sign_mul_r <= 1;
5      ...
6    endcase
7  ...
8  assign sign_mul_final = (sign_exe_r & ...) ?
9                      !sign_mul_r : sign_mul_r;
10 ...
11 always @(posedge clk)
12 out <= { ( ... ?
13         (f2i_out_sign &
14         !(qnan_d | snan_d) ) :
15         (((fpu_op_r3 == 3'b010)
16         & ... ?
17         sign_mul_final : ...)) } ;

```

**Figure 15:** Diverging control flow in FPU [6].

cutions select the same branches, IODINE can infer that every branch produces the same *influence sets* for the variables assigned under them. Using this information, IODINE can prove that the FPU operates in constant-time, despite diverging control flow paths.

**Assumptions.** IODINE can be used to inform software mechanisms for mitigating timing side-channels by explicating—and verifying—conditions under which a circuit executes in constant time. Consider Figure 16, which shows the logic for updating *Control and Status Registers (CSR)* in our RISC-V benchmark. The wire `de_illegal_csr_access`, defined on line 1 is set by checking whether a CSR instruction is executed in non-privileged mode. For this, the circuit compares the machine status register `csr_mstatus` to the instructions status bit. When `de_illegal_csr_access` is set, the branch instruction on line 8 traps the error and jumps to a predefined handler code. In order to prove that the cycle executes in constant-time, we add an assumption stating that CSR registers are not accessed illegally. This assumption translates into an obligation for software mitigation mechanisms to ensure proper use of CSR registers.

## 7 Limitations and Future Work

We discuss some of IODINE’s limitations.

**Clocks and Assumptions.** For example, IODINE presupposes a single fixed-cycle clock and thus does not allow for checking arbitrary VERILOG programs. We leave an extension to multiple clocks as future work. Similarly, IODINE requires users to add assumptions by hand in somewhat ad-hoc trial-and-error fashion. For large circuits this could prove extremely difficult and poten-

```

1 wire de_illegal_csr_access =
2     de_valid &&
3     de_inst'opcode == 'SYSTEM &&
4     de_inst'funct3 != 'PRIV &&
5     ( csr_mstatus'PRV < de_inst[29:28] ||
6       ... );
7 always @(posedge clk) begin
8     if (de_illegal_csr_access) begin
9         ex_restart <= 1;
10        ex_next_pc <= ...;
11    end
12 end

```

**Figure 16:** Update of CSRs in RISC-V [7].

tially lead to errors where erroneous assumptions may lead IODINE to falsely mark a variable time circuit as constant-time. We leave the inference and validation of assumptions to future work.

**Scale.** We evaluate IODINE on relatively small sized (500-1000 lines) hardware designs. We did not (yet) evaluate the tool on larger circuits, such as modern processors with advanced features like a memory hierarchy, and out-of-order and transient-execution. In principle, these features boil down to the same primitives (always blocks and assignments) that IODINE already handles. But, we anticipate that scaling will require further changes to IODINE, for instance, finding per-module invariants rather than the naive in-lining currently performed by IODINE. We leave the evaluation to larger systems to future work.

## 8 Related Work

**Constant-Time Software.** Almeida et al. [16] verify constant-time execution of cryptographic libraries for LLVM. Their notion of constant-time execution is based on a *leakage model*. This choice allows them to be flexible enough to capture various properties like (timing) variability in memory access patterns and improper use of timing sensitive instructions like DIV. Unfortunately, their notion of constant-time is too restrictive for our setting, as it requires the control flow path of any two runs to be the same. This would, for example, incorrectly flag our FPU multiplier as variable-time. Like IODINE, their tool ct-verif employs a product construction that use the fact that loops can often be completely unrolled in cryptographic code, whereas we rely on race freedom.

Barthe et al. [20] build on the CompCert compiler [39] to enforce constant time execution through an information flow type system.

Reparaz et al. [47] present a method for discovering timing variability in existing systems through a black-box

approach, based on statistical measurements.

All of these approaches address constant-time execution in software and do not translate to the hardware setting (see § 2).

**Self-Composition and Product Programs.** Barthe et al. [22] introduce the notion of self composition to verify information flow. Terauchi and Aiken generalize this construction to arbitrary 2-safety properties [50], *i.e.*, properties that relate two runs, and Clarkson and Schneider [28] generalize to multiple runs. Barthe et al. [21] introduce product programs that, instead of conjoining copies sequentially, compose copies in lock-step; this was later used in other tools like ct-verif. This technique is further developed in [49], which presents an extension of Hoare logic to hyper-properties that computes lock-step compositions on demand, per Hoare-triple.

**Information Flow Safety and Side Channels.** There are many techniques for proving information flow safety (*e.g.*, non-interference) in both hardware and software. Kwon et al. [37] prove information flow safety of hardware for policies that allow explicit declassification and are expressed over streams of input data. They construct relational invariants by using propositional interpolation and implicitly build a full self-composition; by contrast, we leverage race-freedom to create a per-thread product which contains only a subset of behaviors.

SecVerilog [55] proves timing-sensitive non-interference for circuits implemented in an extension of VERILOG that uses value-dependent information flow types. Caisson [40] is a hardware description language that uses information flow types to ensure that generated circuits are secure. GLIF [51, 52] tracks the flow of information at the gate level to eliminate explicit and covert channels. All these approaches have been used to implement information flow secure hardware that do not suffer from (timing) side-channels.

IODINE focuses on clock-precise constant-time execution, not information flow. The two properties are related, but information flow safety does not imply constant-time execution nor the converse (see Appendix A.1 for details). Moreover, SecVerilog, Caisson, and GLIF take a language-design approach whereas we take an analysis-centric view that is more suitable for verifying *existing* hardware designs. Thus, we see our work as largely complementary. Indeed, it may be useful to use IODINE alongside these HDLs to verify constant-time execution for parts of the hardware that handle secret data only, and are thus not checked for timing variability, thereby extending their attacker model.

**Combining Hardware & Software Mitigations.** HyperFlow [31] and GhostRider [43], take hardware/software co-design approach to eliminating timing channels. Zhang et al. [54] present a method for mitigating timing side-channels in software and give conditions on hardware that ensure the validity of mitigations is preserved. Instead of eliminating timing flows all together, they specify quantitative bounds on leakage and offers primitives to mitigate timing leaks through padding. Many other tools [11, 13, 30, 38, 48] automatically quantify leakage through timing and cache side-channels. Our approach is complementary and focuses on clock-precise analysis of existing hardware. However, the explicit assumptions that IODINE needs to verify constant-time behavior can be used to inform software mitigation techniques.

## A Appendix

### A.1 Comparison to Information Flow

In this section, we discuss the relationship between constant time execution and information flow checking. Information flow safety (IFS) and constant time execution (CTE) are *incomparable*, *i.e.*, IFS does not imply CTE, and vice versa. We illustrate this using two examples: one is information flow safe but does not execute in constant time and one executes in constant time but is not information flow safe.

Figure 17 contains example program EX2 which is information flow safe but not constant time. The example contains three registers that are typed high as indicated by the annotation `H`, and one register that is typed low as indicated by the annotation `L`. The program is information flow safe, as there are no flows from high to low. Indeed, SecVerilog [55] type checks this program.

This program, however, is not constant time when  $slow_L \neq slow_R$ . This does not mean that the program leaks high data to low sinks—indeed it does not. Instead, what this means is that the high computation takes a variable amount of time dependent on the secret input values. In cases like crypto cores where the attacker has a stop watch and can measure the duration of the sensitive computation, it’s not enough to be information flow safe: we must ensure the core is constant-time.

Next, consider Figure 18 that contains program EX3 which executes in constant time but is not information flow safe. EX3 violates information flow safety by assigning high input `sec` to low output `out`. The example however executes constant time with source `in` and sink `out` un-

```

1 // source(in_low); source(in_high);
2 // sink(out_low); sink(out_high);
3 module test(input {L} clk,
4             input {L} in_low,
5             input {H} in_high,
6             output {L} out_low,
7             output {H} out_high);
8     reg {H} flp_res;
9     reg {H} slow;
10    reg {L} out_low;
11    reg {H} out_high;
12    always @(posedge clk) begin
13        out_low <= in_low;
14        flp_res <= in_hi;
15        if (slow)
16            out_hi <= flp_res;
17        else
18            out_hi <= in_hi;
19    end
20 endmodule

```

Figure 17: EX2: Non-constant time but info-flow safe.

```

1 // source(in); sink(out);
2 // □ (slow_L = slow_R);
3 reg {L} in;
4 reg {L} out;
5 reg {H} sec;
6 always @(posedge clk) begin
7     out <= in + sec;
8 end

```

Figure 18: EX3: Constant time but not info-flow safe.

der the assumption that `+` does not contain asynchronous assignments.

### A.2 Translation

In Figure 19, we define a relation  $\Rightarrow$  that translates VERILOG programs into VINTER programs. The relation is given in terms of inference rules where a transition step in the rule’s conclusion (below the line) is applicable only if all its preconditions (above the line) are met. Both `always-` and `assign-` blocks are translated into threads that are executed at every clock tick using `withclock`. Each process is given a unique id. Our translation does not distinguish between `posedge` and `negedge` events thereby relaxing the semantics by allowing them to occur in any order. `assign` blocks are transformed into threads executing a continuous assignment. Blocking and non-blocking assignments remain unchanged.

$$\begin{array}{c}
\frac{P \Rightarrow P' \quad Q \Rightarrow Q'}{P \cdot Q \Rightarrow P' \parallel Q'} \quad \frac{s_1 \Rightarrow s'_1 \quad \dots \quad s_n \Rightarrow s'_n}{\text{begin } s_1; \dots; s_n; \text{ end} \Rightarrow s'_1; \dots; s'_n} \\
\\
\frac{s \Rightarrow s' \quad id \text{ fresh}}{\text{always } @(\_) s \Rightarrow \text{repeat } [s']_{id}} \\
\\
\frac{id \text{ fresh}}{\text{assign } v = e \Rightarrow \text{repeat } [v := e]_{id}} \\
\\
\frac{s_1 \Rightarrow s'_1 \quad s_2 \Rightarrow s'_2}{\text{if } (e) s_1 \text{ else } s_2 \text{ end} \Rightarrow \text{ite}(e, s'_1, s'_2)}
\end{array}$$

**Figure 19:** Translation from VERILOG to VINTER.

```

1  always @(*)

## Abstract

Remote Attestation (RA) is a distinct security service that allows a trusted verifier ( $\mathcal{V}_{rf}$ ) to measure the software state of an untrusted remote prover ( $\mathcal{P}_{rv}$ ). If correctly implemented, RA allows  $\mathcal{V}_{rf}$  to remotely detect if  $\mathcal{P}_{rv}$  is in an illegal or compromised state. Although several RA approaches have been explored (including hardware-based, software-based, and hybrid) and many concrete methods have been proposed, comparatively little attention has been devoted to formal verification. In particular, thus far, no RA designs and no implementations have been formally verified with respect to claimed security properties.

In this work, we take the first step towards formal verification of RA by designing and verifying an architecture called *VRASED*: Verifiable Remote Attestation for Simple Embedded Developments. *VRASED* instantiates a hybrid (HW/SW) RA co-design aimed at low-end embedded systems, e.g., simple IoT devices. *VRASED* provides a level of security comparable to HW-based approaches, while relying on SW to minimize additional HW costs. Since security properties must be jointly guaranteed by HW and SW, verification is a challenging task, which has never been attempted before in the context of RA. We believe that *VRASED* is the first formally verified RA scheme. To the best of our knowledge, it is also the first formal verification of a HW/SW co-design implementation of any security service. To demonstrate *VRASED*'s practicality and low overhead, we instantiate and evaluate it on a commodity platform (TI MSP430). *VRASED* was deployed using the Basys3 Artix-7 FPGA and its implementation is publicly available.

## 1 Introduction

The number and variety of special-purpose computing devices is increasing dramatically. This includes all kinds of embedded devices, cyber-physical systems (CPS) and Internet-of-Things (IoT) gadgets, that are utilized in various “smart” settings, such as homes, offices, factories, automotive systems and public venues. As society becomes increasingly accustomed to being surrounded by, and dependent on, such devices, their security becomes extremely important. For actuation-capable devices, malware can impact both security and safety, e.g., as demonstrated by Stuxnet [49]. Whereas, for sensing devices, malware can undermine privacy by obtaining ambient information. Fur-

thermore, clever malware can turn vulnerable IoT devices into zombies that can become sources for DDoS attacks. For example, in 2016, a multitude of compromised “smart” cameras and DVRs formed the Mirai Botnet [2] which was used to mount a massive-scale DDoS attack (the largest in history).

Unfortunately, security is typically not a key priority for low-end device manufacturers, due to cost, size or power constraints. It is thus unrealistic to expect such devices to have the means to prevent current and future malware attacks. The next best thing is detection of malware presence. This typically requires some form of **Remote Attestation** (RA) – a distinct security service for detecting malware on CPS, embedded and IoT devices. RA is especially applicable to low-end embedded devices that are incapable of defending themselves against malware infection. This is in contrast to more powerful devices (both embedded and general-purpose) that can avail themselves of sophisticated anti-malware protection. RA involves verification of current internal state (i.e., RAM and/or flash) of an untrusted remote hardware platform (prover or  $\mathcal{P}_{rv}$ ) by a trusted entity (verifier or  $\mathcal{V}_{rf}$ ). If  $\mathcal{V}_{rf}$  detects malware presence,  $\mathcal{P}_{rv}$ 's software can be re-set or rolled back and out-of-band measures can be taken to prevent similar infections. In general, RA can help  $\mathcal{V}_{rf}$  establish a static or dynamic root of trust in  $\mathcal{P}_{rv}$  and can also be used to construct other security services, such as software updates [43] and secure deletion [40]. Hybrid RA (implemented as a HW/SW co-design) is a particularly promising approach for low-end embedded devices. It aims to provide the same security guarantees as (more expensive) hardware-based approaches, while minimizing modifications to the underlying hardware.

Even though numerous RA techniques with different assumptions, security guarantees, and designs, have been proposed [9, 10, 14–16, 20, 21, 25, 30, 35, 38, 38–40, 43], a major missing aspect of RA is the high-assurance and rigor derivable from utilizing computer-aided formal verification to guarantee security of the design and implementation of RA techniques. Because all aforementioned architectures and their implementations are not systematically designed from abstract models, their soundness and security can not be formally argued. In fact, our RA verification efforts revealed that a previous hybrid RA design – SMART [21] – assumed that disabling interrupts is an atomic operation and hence opened the door to compromise of  $\mathcal{P}_{rv}$ 's secret key in the window between the time of

the invocation of disable interrupts functionality and the time when interrupts are actually disabled. Another low/medium-end architecture – Trustlite [30] – does not achieve our formal definition of RA soundness. As a consequence, this architecture is vulnerable to self-relocating malware (See [13] for details). Formal specification of RA properties and their verification significantly increases our confidence that such subtle issues are not overlooked.

In this paper we take a “verifiable-by-design” approach and develop, from scratch, an architecture for **V**erifiable **R**emote **A**ttestation for **S**imple **E**mbedded **D**eveloped (*VRASED*). *VRASED* is the first formally specified and verified RA architecture accompanied by a formally verified implementation. Verification is carried out for all trusted components, including hardware, software, and the composition of both, all the way up to end-to-end notions for RA soundness and security. The resulting verified implementation – along with its computer proofs – is publicly available [1]. Formally reasoning about, and verifying, *VRASED* involves overcoming major challenges that have not been attempted in the context of RA and, to the best of our knowledge, not attempted for any security service implemented as a HW/SW co-design. These challenges include:

**1** – Formal definitions of: (i) end-to-end notions for RA soundness and security; (ii) a realistic machine model for low-end embedded systems; and (iii) *VRASED*’s guarantees. These definitions must be made in single formal system that is powerful enough to provide a common ground for reasoning about their interplay. In particular, our end goal is to prove that the definitions for RA soundness and security are implied by *VRASED*’s guarantees when applied to our machine model. Our formal system of choice is Linear Temporal Logic (LTL). A background on LTL and our reasons for choosing it are discussed in Section 2.

**2** – Automatic end-to-end verification of complex systems such as *VRASED* is challenging from the computability perspective, as the space of possible states is extremely large. To cope with this challenge, we take a “divide-to-conquer” approach. We start by dividing the end-to-end goal of RA soundness and security into smaller sub-properties that are also defined in LTL. Each HW sub-module, responsible for enforcing a given sub-property, is specified as a Finite State Machine (FSM), and verified using a Model Checker. *VRASED*’s SW relies on an F\* verified implementation (see Section 4.3) which is also specified in LTL. This modular approach allows us to efficiently prove sub-properties enforced by individual building blocks in *VRASED*.

**3** – All proven sub-properties must be composed together in order to reason about RA security and soundness of *VRASED* as one whole system. To this end, we use a theorem prover to show (by using LTL equivalences) that the sub-properties that were proved for each of *VRASED*’s sub-modules, when composed, imply the end-to-end definitions of RA soundness

and security. This modular approach enables efficient system-wide formal verification.

## 1.1 The Scope of Low-End Devices

This work focuses on low-end devices based on low-power single core microcontrollers with a few KBytes of program and data memory. A representative of this class of devices is the Texas Instrument’s MSP430 microcontroller (MCU) family [26]. It has a 16-bit word size, resulting in  $\approx 64$  KBytes of addressable memory. SRAM is used as data memory and its size ranges between 4 and 16KBytes (depending on the specific MSP430 model), while the rest of the address space can be used for program memory, e.g., ROM and Flash. MSP430 is a Von Neumann architecture processor with common data and code address spaces. It can perform multiple memory accesses within a single instruction; its instruction execution time varies from 1 to 6 clock cycles, and instruction length varies from 16 to 48 bits. MSP430 was designed for low-power and low-cost. It is widely used in many application domains, e.g., automotive industry, utility meters, as well as consumer devices and computer peripherals. Our choice is also motivated by availability of a well-maintained open-source MSP430 hardware design from Open Cores [22]. Nevertheless, our machine model is applicable to other low-end MCUs in the same class as MSP430 (e.g., Atmel AVR ATmega).

## 1.2 Organization

Section 2 provides relevant background on RA and formal verification. Section 3 contains the details of the *VRASED* architecture and an overview of the verification approach. Section 4 contains the formal definitions of end-to-end RA soundness and security and the formalization of the necessary sub-properties along with the implementation of verified components to realize such sub-properties. Due to space limitation, the proofs for end-to-end soundness and security derived from the sub-properties are discussed in Appendix A. Section 5 discusses alternative designs to guarantee the same required properties and their trade-offs with the standard design. Section 6 presents experimental results demonstrating the minimal overhead of the formally verified and synthesized components. Section 7 discusses related work. Section 8 concludes with a summary of our results. End-to-end proofs of soundness and security, optional parts of the design, *VRASED*’s API, and discussion on *VRASED*’s prototype can be found in Appendices A to C.

## 2 Background

This section overviews RA and provides some background on computer-aided verification.

## 2.1 RA for Low-end Devices

As mentioned earlier, RA is a security service that facilitates detection of malware presence on a remote device. Specifically, it allows a trusted verifier ( $\mathcal{V}rf$ ) to remotely measure the software state of an untrusted remote device ( $\mathcal{P}rv$ ). As shown in Figure 1, RA is typically obtained via a simple challenge-response protocol:

1.  $\mathcal{V}rf$  sends an attestation request containing a challenge ( $\mathcal{C}hal$ ) to  $\mathcal{P}rv$ . This request might also contain a token derived from a secret that allows  $\mathcal{P}rv$  to authenticate  $\mathcal{V}rf$ .
2.  $\mathcal{P}rv$  receives the attestation request and computes an *authenticated integrity check* over its memory and  $\mathcal{C}hal$ . The memory region might be either pre-defined, or explicitly specified in the request. In the latter case, authentication of  $\mathcal{V}rf$  in step (1) is paramount to the overall security/privacy of  $\mathcal{P}rv$ , as the request can specify arbitrary memory regions.
3.  $\mathcal{P}rv$  returns the result to  $\mathcal{V}rf$ .
4.  $\mathcal{V}rf$  receives the result from  $\mathcal{P}rv$ , and checks whether it corresponds to a valid memory state.

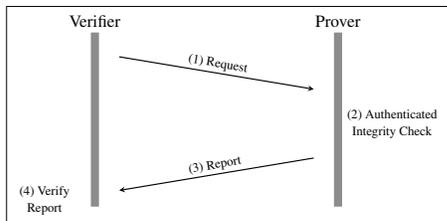

Figure 1: Remote attestation (RA) protocol

The *authenticated integrity check* can be realized as a Message Authentication Code (MAC) over  $\mathcal{P}rv$ 's memory. However, computing a MAC requires  $\mathcal{P}rv$  to have a unique secret key (denoted by  $\mathcal{K}$ ) shared with  $\mathcal{V}rf$ . This  $\mathcal{K}$  must reside in secure storage, where it is **not** accessible to any software running on  $\mathcal{P}rv$ , except for attestation code. Since most RA threat models assume a fully compromised software state on  $\mathcal{P}rv$ , secure storage implies some level of hardware support.

Prior RA approaches can be divided into three groups: software-based, hardware-based, and hybrid. Software-based (or timing-based) RA is the only viable approach for legacy devices with no hardware security features. Without hardware support, it is (currently) impossible to guarantee that  $\mathcal{K}$  is not accessible by malware. Therefore, security of software-based approaches [35, 44] is attained by setting threshold communication delays between  $\mathcal{V}rf$  and  $\mathcal{P}rv$ . Thus, software-based RA is unsuitable for multi-hop and jitter-prone communication, or settings where a compromised  $\mathcal{P}rv$  is aided (during attestation) by a more powerful accomplice device. It also requires strong constraints and assumptions on the hardware platform and attestation usage [31, 34]. On the other extreme, hardware-based approaches require either i)  $\mathcal{P}rv$ 's attestation functionality to be housed entirely within dedicated hardware, e.g., Trusted

Platform Modules (TPMs) [47]; or ii) modifications to the CPU semantics or instruction sets to support the execution of trusted software, e.g., SGX [27] or TrustZone [3]. Such hardware features are too expensive (in terms of physical area, energy consumption, and actual cost) for low-end devices.

While neither hardware- nor software-based approaches are well-suited for settings where low-end devices communicate over the Internet (which is often the case in the IoT), hybrid RA (based on HW/SW co-design) is a more promising approach. Hybrid RA aims at providing the same security guarantees as hardware-based techniques with minimal hardware support. SMART [21] is the first hybrid RA architecture targeting low-end MCUs. In SMART, attestation's integrity check is implemented in software. SMART's small hardware footprint guarantees that the attestation code runs safely and that the attestation key is not leaked. HYDRA [20] is a hybrid RA scheme that relies on a secure boot hardware feature and on a secure micro-kernel. Trustlite [30] modifies Memory Protection Unit (MPU) and CPU exception engine hardware to implement RA. Tytan [9] is built on top of Trustlite, extending its capabilities for applications with real-time requirements.

Despite much progress, a major missing aspect in RA research is high-assurance and rigor obtained by using formal methods to guarantee security of a concrete RA design and its implementation. We believe that verifiability and formal security guarantees are particularly important for hybrid RA designs aimed at low-end embedded and IoT devices, as their proliferation keeps growing. This serves as the main motivation for our efforts to develop the first formally verified RA architecture.

## 2.2 Formal Verification, Model Checking & Linear Temporal Logic

Computer-aided formal verification typically involves three basic steps. First, the system of interest (e.g., hardware, software, communication protocol) must be described using a formal model, e.g., a Finite State Machine (FSM). Second, properties that the model should satisfy must be formally specified. Third, the system model must be checked against formally specified properties to guarantee that the system retains such properties. This checking can be achieved via either Theorem Proving or Model Checking.

In Model Checking, properties are specified as *formulae* using Temporal Logic and system models are represented as FSMs. Hence, a system is represented by a triple  $(S, S_0, T)$ , where  $S$  is a finite set of states,  $S_0 \subseteq S$  is the set of possible initial states, and  $T \subseteq S \times S$  is the transition relation set, i.e., it describes the set of states that can be reached in a single step from each state. The use of Temporal Logic to specify properties allows representation of expected system behavior over time.

We apply the model checker NuSMV [17], which can be

used to verify generic HW or SW models. For digital hardware described at Register Transfer Level (RTL) – which is the case in this work – conversion from Hardware Description Language (HDL) to NuSMV model specification is simple. Furthermore, it can be automated [28]. This is because the standard RTL design already relies on describing hardware as an FSM.

In NuSMV, properties are specified in Linear Temporal Logic (LTL), which is particularly useful for verifying sequential systems. This is because it extends common logic statements with temporal clauses. In addition to propositional connectives, such as conjunction ( $\wedge$ ), disjunction ( $\vee$ ), negation ( $\neg$ ), and implication ( $\rightarrow$ ), LTL includes temporal connectives, thus enabling sequential reasoning. We are interested in the following temporal connectives:

- **X $\phi$**  – **neXt**  $\phi$ : holds if  $\phi$  is true at the next system state.
- **F $\phi$**  – **Future**  $\phi$ : holds if there exists a future state where  $\phi$  is true.
- **G $\phi$**  – **Globally**  $\phi$ : holds if for all future states  $\phi$  is true.
- **$\phi$  U  $\psi$**  –  **$\phi$  Until  $\psi$** : holds if there is a future state where  $\psi$  holds and  $\phi$  holds for all states prior to that.

This set of temporal connectives combined with propositional connectives (with their usual meanings) allows us to specify powerful rules. NuSMV works by checking LTL specifications against the system FSM for all reachable states in such FSM. In particular, all VRASED’s desired security sub-properties are specified using LTL and verified by NuSMV. Finally, a theorem prover [19] is used to show (via LTL equivalences) that the verified sub-properties imply end-to-end definitions of RA soundness and security.

### 3 Overview of VRASED

VRASED is composed of a HW module (HW-Mod) and a SW implementation (SW-Att) of  $\mathcal{P}rv$ ’s behavior according to the RA protocol. HW-Mod enforces access control to  $\mathcal{K}$  in addition to secure and atomic execution of SW-Att (these properties are discussed in detail below). HW-Mod is designed with minimality in mind. The verified FSMs contain a minimal state space, which keeps hardware cost low. SW-Att is responsible for computing an attestation report. As VRASED’s security properties are jointly enforced by HW-Mod and SW-Att, both must be verified to ensure that the overall design conforms to the system specification.

#### 3.1 Adversarial Capabilities & Verification Axioms

We consider an adversary,  $\mathcal{A}$ , that can control the entire software state, code, and data of  $\mathcal{P}rv$ .  $\mathcal{A}$  can modify any writable memory and read any memory that is not explicitly protected by access control rules, i.e., it can read anything (including secrets) that is not explicitly protected by HW-Mod. It can also

re-locate malware from one memory segment to another, in order to hide it from being detected.  $\mathcal{A}$  may also have full control over all Direct Memory Access (DMA) controllers on  $\mathcal{P}rv$ . DMA allows a hardware controller to directly access main memory (e.g., RAM, flash or ROM) without going through the CPU.

We focus on attestation functionality of  $\mathcal{P}rv$ ; verification of the entire MCU architecture is beyond the scope of this paper. Therefore, we assume the MCU architecture strictly adheres to, and correctly implements, its specifications. In particular, our verification approach relies on the following simple axioms:

- **A1 - Program Counter:** The program counter ( $PC$ ) always contains the address of the instruction being executed in a given cycle.
- **A2 - Memory Address:** Whenever memory is read or written, a data-address signal ( $D_{addr}$ ) contains the address of the corresponding memory location. For a read access, a data read-enable bit ( $R_{en}$ ) must be set, and for a write access, a data write-enable bit ( $W_{en}$ ) must be set.
- **A3 - DMA:** Whenever a DMA controller attempts to access main system memory, a DMA-address signal ( $DMA_{addr}$ ) reflects the address of the memory location being accessed and a DMA-enable bit ( $DMA_{en}$ ) must be set. DMA can not access memory when  $DMA_{en}$  is off (logical zero).
- **A4 - MCU reset:** At the end of a successful *reset* routine, all registers (including  $PC$ ) are set to zero before resuming normal software execution flow. Resets are handled by the MCU in hardware; thus, reset handling routine can not be modified.
- **A5 - Interrupts:** When interrupts happen, the corresponding *irq* signal is set.

*Remark:* Note that Axioms A1 to A5 are satisfied by the OpenMSP430 design.

SW-Att uses the HACLS\* [52] HMAC-SHA256 function which is implemented and verified in F\*<sup>1</sup>. F\* can be automatically translated to C and the proof of correctness for the translation is provided in [41]. However, even though efforts have been made to build formally verified C compilers (CompCert [33] is the most prominent example), there are currently no verified compilers targeting lower-end MCUs, such as MSP430. Hence, we assume that the standard compiler can be trusted to semantically preserve its expected behavior, especially with respect to the following:

- **A6 - Callee-Saves-Register:** Any register touched in a function is cleaned by default when the function returns.
- **A7 - Semantic Preservation:** Functional correctness of the verified HMAC implementation in C, when converted to assembly, is semantically preserved.

*Remark:* Axioms A6 and A7 reflect the corresponding compiler specification (e.g., *msp430-gcc*).

Physical hardware attacks are out of scope in this paper.

<sup>1</sup><https://www.fstar-lang.org/>

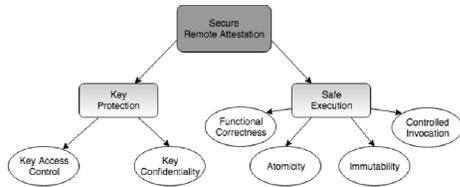

Figure 2: Properties of secure RA.

Specifically,  $\mathcal{A}$  can not modify code stored in ROM, induce hardware faults, or retrieve  $\mathcal{P}rv$  secrets via physical presence side-channels. Protection against physical attacks is considered orthogonal and could be supported via standard tamper-resistance techniques [42].

### 3.2 High-Level Properties of Secure Attestation

We now describe, in high level, the sub-properties required for RA. In section 4, we formalize these sub-properties in LTL and provide single end-to-end definitions for RA soundness and security. Then we prove that *VRASED*'s design satisfies the aforementioned sub-properties and that the end-to-end definitions for soundness and security are implied by them. The properties, shown in Figure 2, fall into two groups: *key protection* and *safe execution*.

#### Key Protection:

As mentioned earlier,  $\mathcal{K}$  must not be accessible by regular software running on  $\mathcal{P}rv$ . To guarantee this, the following features must be correctly implemented:

- **P1- Access Control:**  $\mathcal{K}$  can only be accessed by SW-Att.
- **P2- No Leakage:** Neither  $\mathcal{K}$  (nor any function of  $\mathcal{K}$  other than the correctly computed HMAC) can remain in unprotected memory or registers after execution of SW-Att.
- **P3- Secure Reset:** Any memory tainted by  $\mathcal{K}$  and all registers (including PC) must be erased (or be inaccessible to regular software) after MCU reset. Since a reset might be triggered during SW-Att execution, lack of this property could result in leakage of privileged information about the system state or  $\mathcal{K}$ . Erasure of registers as part of the reset ensures that no state from a previous execution persists. Therefore, the system must return to the default initialization state.

#### Safe Execution:

Safe execution ensures that  $\mathcal{K}$  is properly and securely used by SW-Att for its intended purpose in the RA protocol. Safe execution can be divided into four sub-properties:

- **P4- Functional Correctness:** SW-Att must implement expected behavior of  $\mathcal{P}rv$ 's role in the RA protocol. For instance, if  $\mathcal{V}rf$  expects a response containing an HMAC of memory in address range  $[A, B]$ , SW-Att implementa-

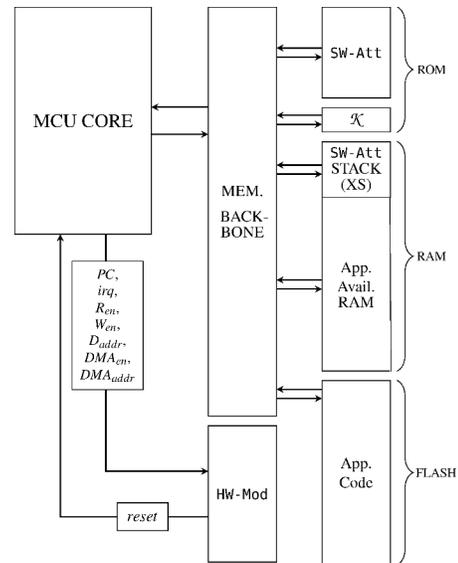

Figure 3: VRASED system architecture

tion should always reply accordingly. Moreover, SW-Att must always finish in finite time, regardless of input size and other parameters.

- **P5- Immutability:** SW-Att executable must be immutable. Otherwise, malware residing in  $\mathcal{P}rv$  could modify SW-Att, e.g., to always generate valid RA measurements or to leak  $\mathcal{K}$ .
- **P6- Atomicity:** SW-Att execution can not be interrupted. The first reason for atomicity is to prevent leakage of intermediate values in registers and SW-Att's data memory (including locations that could leak functions of  $\mathcal{K}$ ) during SW-Att execution. This relates to **P2** above. The second reason is to prevent roving malware from relocating itself to escape being measured by SW-Att.
- **P7- Controlled Invocation:** SW-Att must always start from the first instruction and execute until the last instruction. Even though correct implementation of SW-Att is guaranteed by **P4**, isolated execution of chunks of a correctly implemented code could lead to catastrophic results. Potential ROP attacks could be constructed using gadgets of SW-Att (which, based on **P1**, have access to  $\mathcal{K}$ ) to compute valid attestation results.

Beyond aforementioned core security properties, in some settings,  $\mathcal{P}rv$  might need to authenticate  $\mathcal{V}rf$ 's attestation requests in order to mitigate potential DoS attacks on  $\mathcal{P}rv$ . This functionality is also provided (and verified) as an optional feature in the design of *VRASED*. The differences between the standard design and the one with support for  $\mathcal{V}rf$  authentication are discussed in Appendix B.

### 3.3 System Architecture

*VRASED* architecture is depicted in Figure 3. *VRASED* is implemented by adding HW-Mod to the MCU architecture, e.g., MSP430. MCU memory layout is extended to include Read-Only Memory (ROM) that houses SW-Att code and  $\mathcal{K}$  used in the HMAC computation. Because  $\mathcal{K}$  and SW-Att code are stored in ROM, we have guaranteed immutability, i.e., **P5**. *VRASED* also reserves a fixed part of the memory address space for SW-Att stack. This amounts to  $\approx 3\%$  of the address space, as discussed in Section 6<sup>2</sup>. Access control to dedicated memory regions, as well as SW-Att atomic execution are enforced by HW-Mod. The memory backbone is extended to support multiplexing of the new memory regions. HW-Mod takes 7 input signals from the MCU core:  $PC$ ,  $irq$ ,  $D_{addr}$ ,  $R_{en}$ ,  $W_{en}$ ,  $DMA_{addr}$  and  $DMA_{en}$ . These inputs are used to determine a one-bit *reset* signal output, that, when set to 1, resets the MCU core immediately, i.e., before execution of the next instruction. The *reset* output is triggered when HW-Mod detects any violation of security properties<sup>3</sup>.

### 3.4 Verification Approach

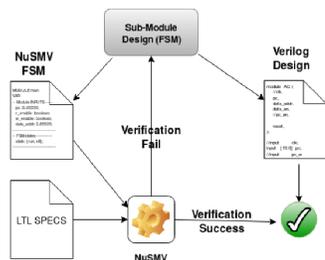

Figure 4: *VRASED*'s submodule verification

An overview of HW-Mod verification is shown in Figures 4 and 5. We start by formalizing RA sub-properties discussed in this section using Linear Temporal Logic (LTL) to define invariants that must hold throughout the entire system execution. HW-Mod is implemented as a composition of sub-modules written in the Verilog hardware description language (HDL). Each sub-module implements the hardware responsible for ensuring a given subset of the LTL specifications. Each sub-module is described as an FSM in: (1) Verilog at Register Transfer Level (RTL); and (2) the Model-Checking language SMV [17]. We then use the NuSMV model checker to verify that the FSM complies with the LTL specifications. If verification fails, the sub-module is re-designed.

Once each sub-module is verified, they are combined into a single Verilog design. The composition is converted to SMV

<sup>2</sup>A separate region in RAM is not strictly required. Alternatives and trade-offs are discussed in Section 5

<sup>3</sup>Resets due to *VRASED* violations do not give malware advantages as malware can always trigger resets on the unmodified MCU by inducing software faults.

using the automatic translation tool Verilog2SMV [28]. The resulting SMV is simultaneously verified against all LTL specifications to prove that the final Verilog design for HW-Mod complies with all secure RA properties.

We clarify that the individual SMV sub-modules' design and verification steps are not strictly required in the verification pipeline. This is because verifying SMV that is automatically translated from the composition of HW-Mod would suffice. Nevertheless, we design FSMs in SMV first so as to facilitate sub-modules' development and reasoning with an early additional check before going into their actual implementation and composition in Verilog.

**Remark:** Automatic conversion of the composition of HW-Mod from Verilog to SMV rules out the possibility of human mistakes in representing Verilog FSMs as SMV.

For the SW-Att part of *VRASED*, we use the HMAC-SHA-256 from the HACL\* library [52] to compute an authenticated integrity check of attested memory and  $Chal$  received from  $\mathcal{V}rf$ . This function is formally verified with respect to memory safety, functional correctness, and cryptographic security. However, key secrecy properties (such as clean-up of memory tainted by the key) are not formally verified in HACL\* and thus must be ensured by HW-Mod.

As the last step, we prove that the conjunction of the LTL properties guaranteed by HW-Mod and SW-Att implies soundness and security of the RA architecture. These are formally specified in Section 4.2.

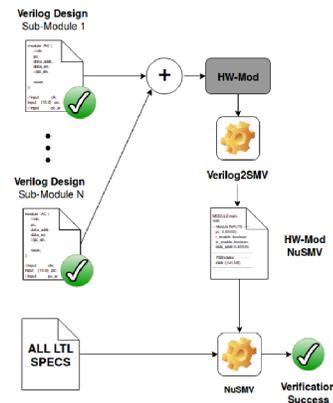

Figure 5: Verification framework for the composition of sub-modules (HW-Mod).

## 4 Verifying VRASED

In this section we formalize RA sub-properties. For each sub-property, we represent it as a set of LTL specifications and construct an FSM that is verified to conform to such specifications. Finally, the conjunction of these FSMs is implemented in Verilog HDL and translated to SMV using Verilog2SMV. The

generated SMV description for the conjunction is proved to simultaneously hold for all specifications. We also define end-to-end soundness and security goals which are derived from the verified sub-properties (See Appendix A for the proof).

## 4.1 Notation

To facilitate generic LTL specifications that represent VRASED’s architecture (see Figure 3) we use the following:

- $AR_{min}$  and  $AR_{max}$ : first and last physical addresses of the memory region to be attested;
- $CR_{min}$  and  $CR_{max}$ : physical addresses of first and last instructions of SW-Att in ROM;
- $K_{min}$  and  $K_{max}$ : first and last physical addresses of the ROM region where  $\mathcal{K}$  is stored;
- $XS_{min}$  and  $XS_{max}$ : first and last physical addresses of the RAM region reserved for SW-Att computation;
- $MAC_{addr}$ : fixed address that stores the result of SW-Att computation (HMAC);
- $MAC_{size}$ : size of HMAC result;

Table 1 uses the above definitions and summarizes the notation used in our LTL specifications throughout the rest of this paper.

To simplify specification of defined security properties, we use  $[A, B]$  to denote a contiguous memory region between  $A$  and  $B$ . Therefore, the following equivalence holds:

$$C \in [A, B] \Leftrightarrow (C \leq B \wedge C \geq A) \quad (1)$$

For example, expression  $PC \in CR$  holds when the current value of  $PC$  signal is within  $CR_{min}$  and  $CR_{max}$ , meaning that the MCU is currently executing an instruction in CR, i.e, a SW-Att instruction. This is because in the notation introduced above:  $PC \in CR \Leftrightarrow PC \in [CR_{min}, CR_{max}] \Leftrightarrow (PC \leq CR_{max} \wedge PC \geq CR_{min})$ .

**FSM Representation.** As discussed in Section 3, HW-Mod sub-modules are represented as FSMs that are verified to hold for LTL specifications. These FSMs correspond to the Verilog hardware design of HW-Mod sub-modules. The FSMs are implemented as Mealy machines, where output changes at any time as a function of both the current state and current input values<sup>4</sup>. Each FSM has as inputs a subset of the following signals and wires:  $\{PC, irq, R_{en}, W_{en}, D_{addr}, DMA_{en}, DMA_{addr}\}$ .

Each FSM has only one output, *reset*, that indicates whether any security property was violated. For the sake of presentation, we do not explicitly represent the value of the *reset* output for each state. Instead, we define the following implicit representation:

1. *reset* output is 1 whenever an FSM transitions to the *Reset* state;
2. *reset* output remains 1 until a transition leaving the *Reset* state is triggered;

<sup>4</sup>This is in contrast with Moore machines where the output is defined solely based on the current state.

Table 1: Notation summary

Notation	Description
$PC$	Current Program Counter value
$R_{en}$	Signal that indicates if the MCU is reading from memory (1-bit)
$W_{en}$	Signal that indicates if the MCU is writing to memory (1-bit)
$D_{addr}$	Address for an MCU memory access
$DMA_{en}$	Signal that indicates if DMA is currently enabled (1-bit)
$DMA_{addr}$	Memory address being accessed by DMA, if any
$irq$	Signal that indicates if an interrupt is occurring (1-bit)
$CR$	(Code ROM) Memory region where SW-Att is stored: $CR = [CR_{min}, CR_{max}]$
$KR$	( $\mathcal{K}$ ROM) Memory region where $\mathcal{K}$ is stored: $KR = [K_{min}, K_{max}]$
$XS$	(eXclusive Stack) secure RAM region reserved for SW-Att computations: $XS = [XS_{min}, XS_{max}]$
$MR$	(MAC RAM) RAM region in which SW-Att computation result is written: $MR = [MAC_{addr}, MAC_{addr} + MAC_{size} - 1]$ . The same region is also used to pass the attestation challenge as input to SW-Att
$AR$	(Attested Region) Memory region to be attested. Can be fixed/predefined or specified in an authenticated request from $\mathcal{V}$ : $AR = [AR_{min}, AR_{max}]$
<i>reset</i>	A 1-bit signal that reboots the MCU when set to logic 1
$A1, A2, \dots, A7$	Verification axioms (outlined in section 3.1)
$P1, P2, \dots, P7$	Properties required for secure RA (outlined in section 3.2)

3. *reset* output is 0 in all other states.

## 4.2 Formalizing RA Soundness and Security

We now define the notions of soundness and security. Intuitively, RA soundness corresponds to computing an integrity ensuring function over memory at time  $t$ . Our integrity ensuring function is an HMAC computed on memory  $AR$  with a one-time key derived from  $\mathcal{K}$  and  $Chal$ . Since SW-Att computation is not instantaneous, RA soundness must ensure that attested memory does not change during computation of the HMAC. This is the notion of temporal consistency in remote attestation [14]. In other words, the result of SW-Att call must reflect the entire state of the attested memory at the time when SW-Att is called. This notion is captured in LTL by Definition 1.

**Definition 1.** End-to-end definition for soundness of RA computation

$$G: \{ PC = CR_{min} \wedge AR = M \wedge MR = Chal \wedge [(-reset) U (PC = CR_{max})] \rightarrow \\ F: [PC = CR_{max} \wedge MR = HMAC(KDF(\mathcal{K}, Chal), M)] \}$$

where  $M$  is any  $AR$  value and  $KDF$  is a secure key derivation function.

In Definition 1,  $PC = CR_{min}$  captures the time when SW-Att is called (execution of its first instruction).  $M$  and  $Chal$  are the values of  $AR$  and  $MR$ . From this pre-condition, Definition 1 asserts that there is a time in the future when SW-Att computation finishes and, at that time,  $MR$  stores the result of  $HMAC(KDF(\mathcal{K}, Chal), M)$ . Note that, to satisfy Definition 1,  $Chal$  and  $M$  in the resulting HMAC must correspond to the values in  $AR$  and  $MR$ , respectively, when SW-Att was called.

RA security is defined using the security game in Figure 6.

It models an adversary  $\mathcal{A}$  (that is a probabilistic polynomial time, ppt, machine) that has full control of the software state of  $\mathcal{P}rv$  (as the one described in Section 3.1). It can modify  $AR$  at will and call  $SW\_Att$  a polynomial number of times in the security parameter ( $\mathcal{K}$  and  $Chal$  bit-lengths). However,  $\mathcal{A}$  can not modify  $SW\_Att$  code, which is stored in immutable memory. The game assumes that  $\mathcal{A}$  does not have direct access to  $\mathcal{K}$ , and only learns  $Chal$  after it receives from  $\mathcal{V}rf$  as part of the attestation request.

**Definition 2.**  
**2.1 RA Security Game (RA-game):**  
**Assumptions:**  
 -  $SW\_Att$  is immutable, and  $\mathcal{K}$  is not known to  $\mathcal{A}$   
 -  $l$  is the security parameter and  $|\mathcal{K}| = |Chal| = |MR| = l$   
 -  $AR(t)$  denotes the content in  $AR$  at time  $t$   
 -  $\mathcal{A}$  can modify  $AR$  and  $MR$  at will; however, it loses its ability to modify them while  $SW\_Att$  is running

---

**RA-game:**  
 1. **Setup:**  $\mathcal{A}$  is given oracle access to  $SW\_Att$ .  
 2. **Challenge:** A random challenge  $Chal \leftarrow \mathcal{S}\{0,1\}^l$  is generated and given to  $\mathcal{A}$ .  $\mathcal{A}$  continues to have oracle access to  $SW\_Att$ .  
 3. **Response:** Eventually,  $\mathcal{A}$  responds with a pair  $(M, \sigma)$ , where  $\sigma$  is either forged by  $\mathcal{A}$ , or the result of calling  $SW\_Att$  at some arbitrary time  $t$ .  
 4.  $\mathcal{A}$  wins if and only if  $\sigma = HMAC(KDF(\mathcal{K}, Chal), M)$  and  $M \neq AR(t)$ .

---

**2.2 RA Security Definition:**  
 An RA protocol is considered secure if there is no ppt  $\mathcal{A}$ , polynomial in  $l$ , capable of winning the game defined in 2.1 with  $Pr[\mathcal{A}, RA\text{-game}] > \text{negl}(l)$

Figure 6: RA security definition for  $VRASED$

In the following sections, we define  $SW\_Att$  functional correctness, LTL specifications 2-10 and formally verify that  $VRASED$ 's design guarantees such LTL specifications. We define LTL specifications from the intuitive properties discussed in Section 3.2 and depicted in Figure 2. In Appendix A we prove that the conjunction of such properties achieves soundness (Definition 1) and security (Definition 2). For the security proof, we first show that  $VRASED$  guarantees that  $\mathcal{A}$  can never learn  $\mathcal{K}$  with more than negligible probability, thus satisfying the assumption in the security game. We then complete the proof of security via reduction, i.e., show that existence of an adversary that wins the game in Definition 2 implies the existence of an adversary that breaks the conjectured existential unforgeability of HMAC.

**Remark:** The rest of this section focuses on conveying the intuition behind the specification of LTL sub-properties. Therefore, our references to the MCU machine model are via Axioms **A1 - A7** which were described in high level. The interested reader can find an LTL machine model formalizing these notions in Appendix A, where we describe how such machine model is used construct computer proofs for Definitions 1 and 2.

### 4.3 $VRASED$ $SW\_Att$

To minimize required hardware features, hybrid RA approaches implement integrity ensuring functions (e.g., HMAC) in software.  $VRASED$ 's  $SW\_Att$  implementation is built on top of

```

1 void HACL_HMAC_SHA2_256_hmac_entry() {
2     uint8_t key[64] = {0};
3     memcpy(key, (uint8_t*) KEY_ADDR, 64);
4     hacl_hmac((uint8_t*) key, (uint8_t*) key, (uint32_t) 64, (uint8_t*)
5             CHALL_ADDR, (uint32_t) 32);
6     hacl_hmac((uint8_t*) MAC_ADDR, (uint8_t*) key, (uint32_t) 32, (uint8_t*)
7             ATTEST_DATA_ADDR, (uint32_t) ATTEST_SIZE);
8     return();
9 }

```

Figure 7:  $SW\_Att$  C Implementation

HACL\*'s HMAC implementation [52]. HACL\* code is verified to be functionally correct, memory safe and secret independent. In addition, all memory is allocated on the stack making it predictable and deterministic.

$SW\_Att$  is simple, as depicted in Figure 7. It first derives a new unique context-specific key ( $key$ ) from the master key ( $\mathcal{K}$ ) by computing an HMAC-based key derivation function, HKDF [32], on  $Chal$ . This key derivation can be extended to incorporate attested memory boundaries if  $\mathcal{V}rf$  specifies the range (see Appendix B). Finally, it calls HACL\*'s HMAC, using  $key$  as the HMAC key.  $ATTEST\_DATA\_ADDR$  and  $ATTEST\_SIZE$  specify the memory range to be attested ( $AR$  in our notation). We emphasize that  $SW\_Att$  resides in ROM, which guarantees **P5** under the assumption of no hardware attacks. Moreover, as discussed below,  $HW\_Mod$  enforces that no other software running on  $\mathcal{P}rv$  can access memory allocated by  $SW\_Att$  code, e.g.,  $key[64]$  buffer allocated in line 2 of Figure 7.

HACL\*'s verified HMAC is the core for guaranteeing **P4** (Functional Correctness) in  $VRASED$ 's design.  $SW\_Att$  functional correctness means that, as long as the memory regions storing values used in  $SW\_Att$  computation ( $CR$ ,  $AR$ , and  $KR$ ) do not change during its computation, the result of such computation is the correct HMAC. This guarantee can be formally expressed in LTL as in Definition 3. We note that since HACL\*'s HMAC functional correctness is specified in  $F^*$ , instead of LTL, we manually convert its guarantees to the LTL expressed by Definition 3. By this definition, the value in  $MR$  does not need to remain the same, as it will eventually be overwritten by the result of  $SW\_Att$  computation.

**Definition 3.**  $SW\_Att$  functional correctness

$$G : \{ PC = CR_{min} \wedge MR = Chal \wedge [(-reset \wedge \neg irq \wedge CR = SW\_Att \wedge KR = \mathcal{K} \wedge AR = M) \cup PC = CR_{max}] \rightarrow F : [PC = CR_{max} \wedge MR = HMAC(KDF(\mathcal{K}, Chal), M)] \}$$

where  $M$  is any arbitrary value for  $AR$ .

In addition, some HACL\* properties, such as stack-based and deterministic memory allocation, are used in alternative designs of  $VRASED$  to ensure **P2** – see Section 5.

Functional correctness implies that the HMAC implementation conforms to its published standard specification on all possible inputs, retaining the specification's cryptographic security. It also implies that HMAC executes in finite time. Secret

independence ensures that there are no branches taken as a function of secrets, i.e.,  $\mathcal{K}$  and  $key$  in Figure 7. This mitigates  $\mathcal{K}$  leakage via timing side-channel attacks. Memory safety guarantees that implemented code is type safe, meaning that it never reads from, or writes to: invalid memory locations, out-of-bounds memory, or unallocated memory. This is particularly important for preventing ROP attacks, as long as **P7** (controlled invocation) is also preserved<sup>5</sup>.

Having all memory allocated on the stack allows us to either: (1) confine SW-Att execution to a fixed size protected memory region inaccessible to regular software (including malware) running on  $\mathcal{P}rv$ ; or (2) ensure that SW-Att stack is erased before the end of execution. Note that HACL\* does not provide stack erasure, in order to improve performance. Therefore, **P2** does not follow from HACL\* implementation. This practice is common because inter-process memory isolation is usually provided by the Operating System (OS). However, erasure before SW-Att terminates must be guaranteed. Recall that *VRASED* targets low-end MCUs that might run applications on bare-metal and thus can not rely on any OS features.

As discussed above, even though HACL\* implementation guarantees **P4** and storage in ROM guarantees **P5**, these must be combined with **P6** and **P7** to provide safe execution. **P6** and **P7** – along with the key protection properties (**P1**, **P2**, and **P3**) – are ensured by HW-Mod and are described next.

## 4.4 Key Access Control (HW-Mod)

If malware manages to read  $\mathcal{K}$  from ROM, it can reply to  $\mathcal{V}rf$  with a forged result. HW-Mod access control (AC) sub-module enforces that  $\mathcal{K}$  can only be accessed by SW-Att (**P1**).

### 4.4.1 LTL Specification

The invariant for key access control (AC) is defined in LTL Specification (2). It stipulates that system must transition to the *Reset* state whenever code from outside  $CR$  tries to read from  $D_{addr}$  within the key space.

$$G : \{ \neg(PC \in CR) \wedge Ren \wedge (D_{addr} \in KR) \rightarrow reset \} \quad (2)$$

### 4.4.2 Verified Model

Figure 8 shows the FSM implemented by the AC sub-module which is verified to hold for LTL Specification 2. This FSM has two states: *Run* and *Reset*. It outputs  $reset = 1$  when the AC sub-module transitions to state *Reset*. This implies a hard-reset of the MCU. Once the reset process completes, the system leaves the *Reset* state.

<sup>5</sup>Otherwise, even though the implementation is memory-safe and correct as a whole, chunks of a memory-safe code could still be used in ROP attacks.

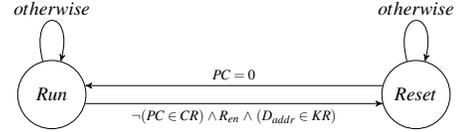

Figure 8: Verified FSM for Key AC

## 4.5 Atomicity and Controlled Invocation (HW-Mod)

In addition to functional correctness, safe execution of attestation code requires immutability (**P5**), atomicity (**P6**), and controlled invocation (**P7**). **P5** is achieved directly by placing SW-Att in ROM. Therefore, we only need to formalize invariants for the other two properties: atomicity and controlled execution.

### 4.5.1 LTL Specification

To guarantee atomic execution and controlled invocation, LTL Specifications (3), (4) and (5) must hold:

$$G : \{ \{ \neg reset \wedge (PC \in CR) \wedge \neg(X(PC) \in CR) \} \rightarrow [PC = CR_{max} \vee X(reset)] \} \quad (3)$$

$$G : \{ \{ \neg reset \wedge \neg(PC \in CR) \wedge (X(PC) \in CR) \} \rightarrow [X(PC) = CR_{min} \vee X(reset)] \} \quad (4)$$

$$G : \{ irq \wedge (PC \in CR) \rightarrow reset \} \quad (5)$$

LTL Specification (3) enforces that the only way for SW-Att execution to terminate is through its last instruction:  $PC = CR_{max}$ . This is specified by checking current and next  $PC$  values using LTL  $neXt$  operator. In particular, if current  $PC$  value is within SW-Att region, and next  $PC$  value is out of SW-Att region, then either current  $PC$  value is the address of the last instruction in SW-Att ( $CR_{max}$ ), or  $reset$  is triggered in the next cycle. Also, LTL Specification (4) enforces that the only way for  $PC$  to enter SW-Att region is through the very first instruction:  $CR_{min}$ . Together, these two invariants imply **P7**: it is impossible to jump into the middle of SW-Att, or to leave SW-Att before reaching the last instruction.

**P6** is satisfied through LTL Specification (5). Atomicity could be violated by interrupts. However, LTL Specification (5) prevents an interrupt to happen while SW-Att is executing. Therefore, if interrupts are not disabled by software running on  $\mathcal{P}rv$  before calling SW-Att, any interrupt that could violate SW-Att atomicity will necessarily cause an MCU *reset*.

### 4.5.2 Verified Model

Figure 9 presents a verified model for atomicity and controlled invocation enforcement. The FSM has five states. Two basic states *notCR* and *midCR* represent moments when  $PC$  points to an address: (1) outside  $CR$ , and (2) within  $CR$ , respectively, not including the first and last instructions of SW-Att. Another

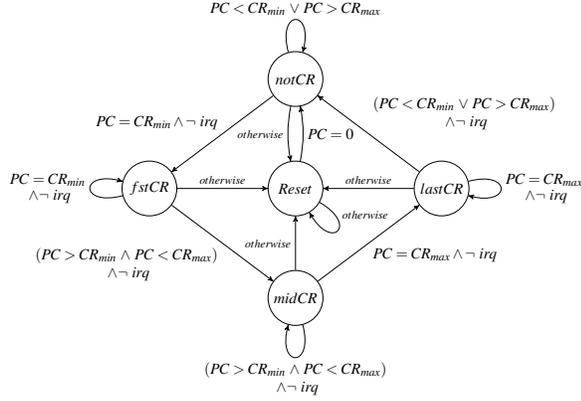

Figure 9: Verified FSM for atomicity and controlled invocation.

two: *fstCR* and *lstCR* represent states when *PC* points to the first and last instructions of SW-Att, respectively. Note that the only possible path from *notCR* to *midCR* is through *fstCR*. Similarly, the only path from *midCR* to *notCR* is through *lstCR*. The FSM transitions to the *Reset* state whenever: (1) any sequence of values for *PC* does not obey the aforementioned conditions; or (2) *irq* is logical 1 while executing SW-Att.

## 4.6 Key Confidentiality (HW-Mod)

To guarantee secrecy of  $\mathcal{K}$  and thus satisfy **P2**, VRASED must enforce the following:

1. No leaks after attestation: any registers and memory accessible to applications must be erased at the end of each attestation instance, i.e., before application execution resumes.
2. No leaks on reset: since a reset can be triggered during attestation execution, any registers and memory accessible to regular applications must be erased upon reset.

Per Axiom **A4**, all registers are zeroed out upon reset and at boot time. Therefore, the only time when register clean-up is necessary is at the end of SW-Att. Such clean-up is guaranteed by the Callee-Saves-Register convention: Axiom **A6**.

Nonetheless, the leakage problem remains because of RAM allocated by SW-Att. Thus, we must guarantee that  $\mathcal{K}$  is not leaked through "dead" memory, which could be accessed by application (possibly, malware) after SW-Att terminates. A simple and effective way of addressing this issue is by reserving a separate secure stack in RAM that is only accessible (i.e., readable and writable) by attestation code. All memory allocations by SW-Att must be done on this stack, and access control to the stack must be enforced by HW-Mod. As discussed in Section 6, the size of this stack is constant – 2.3KBytes. This corresponds to  $\approx 3\%$  of MSP430 16-bit address space. We discuss VRASED variants that do not require a reserved stack and trade-offs between them in Section 5.

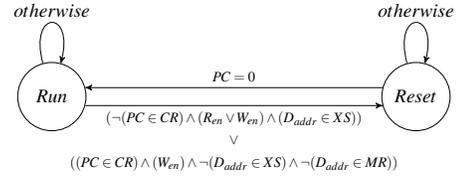

Figure 10: Verified FSM for Key Confidentiality

### 4.6.1 LTL Specification

Recall that *XS* denote a contiguous secure memory region reserved for exclusive access by SW-Att. LTL Specification for the secure stack sub-module is as follows:

$$\mathbf{G} : \{ \neg(PC \in CR) \wedge (Ren \vee W_{en}) \wedge (D_{addr} \in XS) \rightarrow reset \} \quad (6)$$

We also want to prevent attestation code from writing into application memory. Therefore, it is only allowed to write to the designated fixed region for the HMAC result (*MR*).

$$\mathbf{G} : \{ (PC \in CR) \wedge (W_{en}) \wedge \neg(D_{addr} \in XS) \wedge \neg(D_{addr} \in MR) \rightarrow reset \} \quad (7)$$

In summary, invariants (6) and (7) enforce that only attestation code can read from/write to the secure reserved stack and that attestation code can only write to regular memory within the space reserved for the HMAC result. If any of these conditions is violated, the system resets.

### 4.6.2 Verified Model

Figure 10 shows the FSM verified to comply with invariants (6) and (7).

## 4.7 DMA Support

So far, we presented a formalization of HW-Mod sub-modules under the assumption that DMA is either not present or disabled on *Prv*. However, when present, a DMA controller can access arbitrary memory regions. Such memory access is performed concurrently in the memory backbone and without MCU intervention, while the MCU executes regular instructions.

DMA data transfer is performed using dedicated memory buses, e.g.,  $DMA_{en}$  and  $DMA_{addr}$ . Hence, regular memory access control (based on monitoring  $D_{addr}$ ) does not apply to memory access by DMA controller. Thus, if DMA controller is compromised, it may lead to violation of **P1** and **P2** by directly reading  $\mathcal{K}$  and values in the attestation stack, respectively. In addition, it can assist *Prv*-resident malware to escape detection by either copying it out of the measurement range or deleting it, which results in a violation of **P6**.

### 4.7.1 LTL Specification

We introduce three additional LTL Specifications to protect against aforementioned attacks. First, we enforce that DMA

cannot access  $\mathcal{K}$ .

$$\mathbf{G} : \{DMA_{en} \wedge (DMA_{addr} \in KR) \rightarrow reset\} \quad (8)$$

Similarly, LTL Specification for preventing DMA access to the attestation stack is defined as:

$$\mathbf{G} : \{DMA_{en} \wedge (DMA_{addr} \in XS) \rightarrow reset\} \quad (9)$$

Finally, invariant (10) specifies that DMA must be always disabled while  $PC$  is in SW-Att region. This prevents DMA controller from helping malware escape during attestation.

$$\mathbf{G} : \{(PC \in CR) \wedge DMA_{en} \rightarrow reset\} \quad (10)$$

#### 4.7.2 Verified Model

Figure 11 shows the FSM verified to comply with invariants (8) to (10).

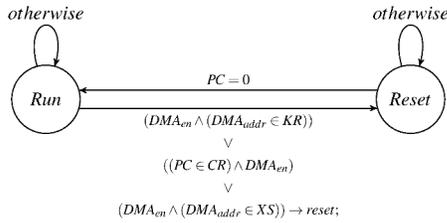

Figure 11: Verified FSM for DMA protection

### 4.8 HW-Mod Composition

Thus far, we designed and verified individual HW-Mod sub-modules according to the methodology in Section 3.4 and illustrated in Figure 4. We now follow the workflow of Figure 5 to combine the sub-modules into a single Verilog module. Since each sub-module individually guarantees a subset of properties **P1–P7**, the composition is simple: the system must reset whenever any sub-module reset is triggered. This is implemented by a logical OR of sub-modules reset signals. The composition is shown in Figure 12.

To verify that all LTL specifications still hold for the composition, we use Verilog2SMV [28] to translate HW-Mod to SMV and verify SMV for all of these specifications simultaneously.

### 4.9 Secure Reset (HW-Mod)

Finally, we define an LTL Specification for secure reset (**P3**). According to Axiom **A4**, all registers (including  $PC$ ) are set to 0 on reset. However, the reset routine implemented by the MCU might take several clock cycles. Ensuring that  $reset = 1$  until the point when registers are wiped is important in order to guarantee that  $\mathcal{K}$  is not leaked through registers after a reset. That is because some part of  $\mathcal{K}$  might remain in some of the registers if a reset happens during SW-Att execution.

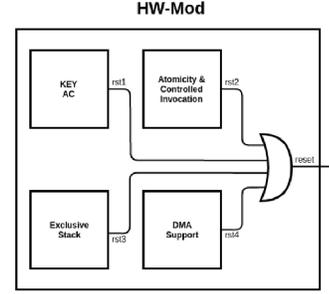

Figure 12: HW-Mod composition from sub-modules

### 4.9.1 LTL Specification

To guarantee that the reset signal is active for long enough so that the MCU reset finishes and all registers are cleaned-up, it must hold that:

$$\mathbf{G} : \{reset \rightarrow [(reset \text{ U } PC = 0) \vee \mathbf{G}(reset)]\} \quad (11)$$

Invariant (11) states: when reset signal is triggered, it can only be released after  $PC = 0$ . Transition from *Reset* state in all sub-modules presented in this section already takes this invariant into account. Thus, HW-Mod composition also verifies LTL Specification (11).

## 5 Alternative Designs

We now discuss alternative designs for *VRASED* that guarantee verified properties without requiring a separate secure stack region for SW-Att operations. Recall that HW-Mod enforces that only SW-Att can access this stack. Since memory usage in HACL\* HMAC is deterministic, the size of the separate stack can be pre-determined – 2,332bytes. Even though resulting in overall (HW and SW) design simplicity, dedicating 3% of addressable memory to secure RA might not be desirable. Therefore, we consider several alternatives. In Section 6 the costs involved with these alternatives are quantified and compared to the standard design of *VRASED*.

### 5.1 Erasure on SW-Att

The most intuitive alternative to a reserved secure stack (which prevents accidental key leakage by SW-Att) is to encode corresponding properties into the HACL\* implementation and proof. Specifically, it would require extending the HACL\* implementation to zero out all allocated memory before every function return. In addition, to retain verification of **P2** (in Section 3.2) and ensure no leakage, HACL\*-verified properties must be extended to incorporate memory erasure. This is not yet supported in HACL\* and doing so would incur a slight performance overhead. However, the trade-off between performance and RAM savings might be worthwhile.

At the same time, we note that, even with verified erasure as a part of SW-Att, **P2** is still not guaranteed if the MCU does not guarantee erasure of the entire RAM upon boot. This is necessary in order to consider the case when *Prv* re-boots in the middle of SW-Att execution. Without a reserved stack,  $\mathcal{K}$  might persist in RAM. Since the memory range for SW-Att execution is not fixed, hardware support is required to bootstrap secure RAM erasure before starting any software execution. In fact, such support is necessary for all approaches without a separate secure stack.

## 5.2 Compiler-Based Clean-Up

While stack erasure in HACL\* would integrate nicely with the overall proof of SW-Att, the assurance would be at the language abstraction level, and not necessarily at the machine level. The latter would require additional assumptions about the compilation tool chain. We could also consider performing stack erasure directly in the compiler. In fact, a recent proposal to do exactly that was made in zerostack [45], an extension to Clang/LLVM. In case of *VRASED*, this feature could be used on unmodified HACL\* (at compilation time), to add instructions to erase the stack before the return of each function enabling **P2**, assuming the existence of a verified RAM erasure routine upon boot. We emphasize that this approach may increase the compiler's trusted code base. Ideally, it should be implemented and formally verified as part of a verified compiler suite, such as CompCert [33].

## 5.3 Double-HMAC Call

Finally, complete stack erasure could also be achieved directly using currently verified HACL\* properties, without any further modifications. This approach involves invoking HACL\* HMAC function a second time, after the computation of the actual HMAC. The second "dummy" call would use the same input data, however, instead of using  $\mathcal{K}$ , an independent constant, such as  $\{0\}^{512}$ , would be used as the HMAC key.

Recall that HACL\* is verified to only allocate memory on the stack in a deterministic manner. Also, due to HACL\*'s verified properties that mitigate side-channels, software flow does not change based on the secret key. Therefore, this deterministic allocation implies that, for inputs of the same size, any variable allocated by the first "real" HMAC call (tainted by  $\mathcal{K}$ ), would be overwritten by the corresponding variable in the second "dummy" call. Note that the same guarantee discussed in Section 5.1 is provided here and secure RAM erasure at boot would still be needed for the same reasons. Admittedly, this double-HMAC approach would consume twice as many CPU cycles. Still, it might be a worthwhile trade-off, especially, if there is memory shortage and lack of previously discussed HACL\* or compiler extension.

# 6 Evaluation

We now discuss implementation details and evaluate *VRASED*'s overhead and performance. Section 6.2 reports on verification complexity. Section 6.3 discusses performance in terms of time and space complexity as well as its hardware overhead. We also provide a comparison between *VRASED* and other RA architectures targeting low-end devices, namely SANCUS [38] and SMART [21], in Section 6.4.

## 6.1 Implementation

As mentioned earlier, we use OpenMSP430 [22] as an open core implementation of the MSP430 architecture. OpenMSP430 is written in the Verilog hardware description language (HDL) and can execute software generated by any MSP430 toolchain with near cycle accuracy. We modified the standard OpenMSP430 to implement the hardware architecture presented in Section 3.3, as shown in Figure 3. This includes adding ROM to store  $\mathcal{K}$  and SW-Att, adding HW-Mod, and adapting the memory backbone accordingly. We use Xilinx Vivado [50] – a popular logic synthesis tool – to synthesize an RTL description of HW-Mod into hardware in FPGA. FPGA synthesized hardware consists of a number of logic cells. Each consists of Look-Up Tables (LUTs) and registers; LUTs are used to implement combinatorial boolean logic while registers are used for sequential logic elements, i.e., FSM states and data storage. We compiled SW-Att using the native msp430-gcc [46] and used Linker scripts to generate software images compatible with the memory layout of Figure 3. Finally, we evaluated *VRASED* on the FPGA platform targeting Artix-7 [51] class of devices.

## 6.2 Verification Results

As discussed in Section 3.2, *VRASED*'s verification consists of properties **P1–P7**. **P5** is achieved directly by executing SW-Att from ROM. Meanwhile, HACL\* HMAC verification implies **P4**. All other properties are automatically verified using NuSMV model checker. Table 2 shows the verification results of *VRASED*'s HW-Mod composition as well as results for individual sub-modules. It shows that *VRASED* successfully achieves all the required security properties. These results also demonstrate feasibility of our verification approach, since the verification process – running on a commodity desktop computer – consumes only small amount of memory and time: < 14MB and 0.3sec, respectively, for all properties.

Table 3: Evaluation of cost, overhead, and performance of RA

Method	RAM Erasure Required Upon Boot?	FPGA Hardware			Verilog LoC	Memory (byte)		Time to attest 4KB	
		LUT	Reg	Cell		ROM	Sec. RAM	CPU cycles	ms (at 8MHz)
Core (Baseline)	N/A	1842	684	3044	4034	0	0	N/A	N/A

	VRASED	SMART	SANCUS
Design Type	Hybrid (HW/SW)	Hybrid (HW/SW)	Pure HW
RA function	HMAC-SHA256	HMAC-SHA1	SPONGENT-128/128/8
ROM for RA code	Yes	Yes	No
DMA Support	Yes	No	No
Formally Verified	Yes	No	No

### 6.3 Performance and Hardware Cost

We now report on *VRASED*'s performance considering the standard design (described in Section 4) and alternatives discussed in Section 5. We evaluate the hardware footprint, memory (ROM and secure RAM), and run-time. Table 3 summarizes the results.

**Hardware Footprint.** The secure stack approach adds around 587 lines of code in Verilog HDL. This corresponds to around 15% of the code in the original OpenMSP430 core. In terms of synthesized hardware, it requires 122 (6.6%) and 37 (5.4%) additional LUTs and registers respectively. Overall, *VRASED* contains 193 logic cells more than the unmodified OpenMSP430 core, corresponding to a 6.3% increase.

**Memory.** *VRASED* requires ~4.5KB of ROM; most of which (96%) is for storing HACLS\* HMAC-SHA256 code. The secure stack approach has the smallest ROM size, as it does not need to perform a memory clean-up in software. However, this advantage is attained at the price of requiring 2.3KBytes of reserved RAM. This overhead corresponds to 3.5% of MSP430 16-bit address space.

**Attestation Run-time.** Attestation run-time is dominated by the time it takes to compute the HMAC of *Prv*'s memory. The secure stack, erasure on SW-Att and compiler-based clean-up approaches take roughly .45s to attest 4KB of RAM on an MSP430 device with a clock frequency at 8MHz. Whereas, the

<sup>6</sup>As mentioned in Section 5.2, there is no formally verified msp430 compiler capable of performing stack erasure. Thus, we estimate overhead of this approach by manually inserting code required for erasing the stack in SW-Att.

double MAC approach requires invoking the HMAC function twice, leading its run-time to be roughly two times slower.

**Discussion.** We consider *VRASED*'s overhead to be affordable. The additional hardware, including registers, logic gates and exclusive memory, resulted in only a 3-6% increase. The number of cycles required by SW-Att exhibits a linear increase with the size of attested memory. As MSP430 typically runs at 8-25MHz, attestation of the entire RAM on a typical MSP430 can be computed in less than a second. *VRASED*'s RA is relatively cheap to the *Prv*. As a point of comparison we can consider a common cryptographic primitive such as the Curve25519 Elliptic-Curve Diffie-Hellman (ECDH) key exchange. A single execution of an optimized version of such protocol on MSP430 has been reported to take  $\approx 9$  million cycles [24]. As Table 3 shows, attestation of 4KBytes (typical size of RAM in some MSP430 models) can be computed three times faster.

### 6.4 Comparison with Other Low-End RA Architectures

We here compare *VRASED*'s overhead with two widely known RA architectures targeting low-end embedded systems: SMART [21] and SANCUS [38]. We emphasize, however, that both SMART and SANCUS were designed in an ad hoc manner. Thus, they can not be formally verified and do not provide any guarantees offered by *VRASED*'s verified architecture. Nevertheless, it is considered important to contrast *VRASED*'s cost with such architectures to demonstrate its affordability.

Table 4 presents a comparison between features offered and required by aforementioned architectures. SANCUS is, to the best of our knowledge, the cheapest pure HW-based architecture, while SMART is a minimal HW/SW RA co-design. Since SANCUS's RA routine is implemented entirely in HW, it does not require ROM to store the SW implementation of the integrity ensuring function. *VRASED* implements a MAC with digest sizes of 256-bits. SMART and SANCUS, on the other hand, use SHA1-based MAC and SPONGENT-128/128/8 [7], respectively. Such MACs do not offer strong collision resistance due to the small digest sizes (and known collisions). Of the three architectures, *VRASED* is the only one secure in the presence of DMA and the only one to be rigorously specified and formally verified.

Figure 13 presents a quantitative comparison between the RA architectures. It considers additional overhead in relation to the latest version of the unmodified OpenMSP430 (Available

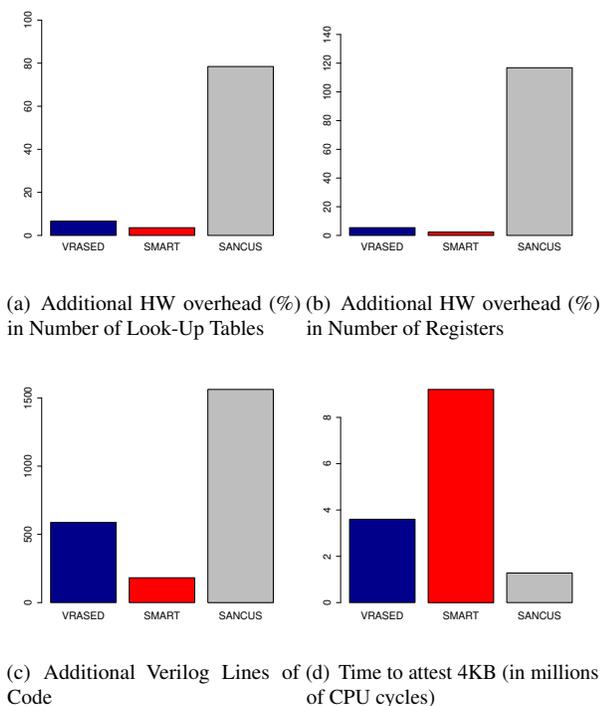

Figure 13: Comparison between RA architectures targeting low-end devices

at [22]). Compared to *VRASED*, *SANCUS* requires  $12\times$  more Look-Up Tables,  $22\times$  more registers, and its (unverified) TCB is 2.5 times larger in lines of Verilog code. This comparison demonstrates the cost of relying on a HW-only approach even when designed for minimality. *SMART*'s overhead is slightly smaller than that of *VRASED* due to lack of DMA support. In terms of attestation execution time, *SMART* is the slowest, requiring 9.2M clock cycles to attest 4KB of memory. *SANCUS* achieves the fastest attestation time (1.3M cycles) due to the HW implementation of SPONGENT-128/128/8. *VRASED* sits in between the two with a total attestation time of 3.6M cycles.

## 7 Related Work

We are unaware of any previous work that yielded a formally verified RA design (RA architectures are overviewed in Section 2.1). To the best of our knowledge, *VRASED* is the first verification of a security service implemented as HW/SW co-design. Nevertheless, formal verification has been widely used as the *de facto* means to guarantee that a system is free of implementation errors and bugs. In recent years, several efforts focused on verifying security-critical systems.

In terms of cryptographic primitives, Hawblitzel et al. [23] verified new implementations of SHA, HMAC, and RSA. Beringer et al. [4] verified the Open-SSL SHA-256 implementation. Bond et al. [8] verified an assembly implementation of

SHA-256, Poly1305, AES and ECDSA. More recently, Zinzindohoué, et al. [52] developed *HACL\**, a verified cryptographic library containing the entire cryptographic API of NaCl [5]. As discussed earlier, *HACL\**'s verified HMAC forms the core of *VRASED*'s software component.

Larger security-critical systems have also been successfully verified. For example, Bhargavan [6] implemented the TLS protocol with verified cryptographic security. CompCert [33] is a C compiler that is formally verified to preserve C code semantics in generated assembly code. Klein et al. [29] designed and proved functional correctness of *seL4* – the first verified general-purpose microkernel. More recently, Tuncay et al. verified a design for Android OS App permissions model [48].

The importance of verifying RA has been recently acknowledged by Lugou et al. [36], which discussed methodologies for specifically verifying HW/SW RA co-designs. A follow-on result proposed the *SMASH-UP* tool [37]. By modeling a hardware abstraction, *SMASH-UP* allows automatic conversion of assembly instructions to the effects on hardware representation. Similarly, Cabodi et al. [11, 12] discussed the first steps towards formalizing hybrid RA properties. However, none of these results yielded a fully verified (and publicly available) RA architecture, such as *VRASED*.

## 8 Conclusion

This paper presents *VRASED* – the first formally verified RA method that uses a verified cryptographic software implementation and combines it with a verified hardware design to guarantee correct implementation of RA security properties. *VRASED* is also the first verified security service implemented as a HW/SW co-design. *VRASED* was designed with simplicity and minimality in mind. It results in efficient computation and low hardware cost, realistic even for low-end embedded systems. *VRASED*'s practicality is demonstrated via publicly available implementation using the low-end MSP430 platform. The design and verification methodology presented in this paper can be extended to other MCU architectures. We believe that this work represents an important and timely advance in embedded systems security, especially, with the rise of heterogeneous ecosystems of (inter-)connected IoT devices.

The most natural direction for future work is to adapt *VRASED* to other MCU architectures. Such an effort could follow the same verification methodology presented in this paper. It would involve: (1) mapping MCUs specifications to a set of axioms (as we did for MSP430 in Section 3), and (2) adapting the proofs by modifying the LTL Specifications and hardware design (as in Section 4) accordingly. A second direction is to extend *VRASED*'s capabilities to include and verify other trusted computing services such as secure updates, secure deletion, and remote code execution. It would also be interesting to verify and implement other RA designs with different requirements and trade-offs, such as software- and hardware-based techniques. In the same vein, one promising

direction would be to verify HYDRA RA architecture [20], which builds on top of the formally verified `seL4` [29] microkernel. Finally, the optimization of `VRASED`'s HMAC, with respect to computation and memory allocation, while retaining its verified properties, is an interesting open problem.

## APPENDIX

### A RA Soundness and Security Proofs

#### A.1 Proof Strategy

We present the proofs for RA soundness (Definition 1) and RA security (Definition 2). Soundness is proved entirely via LTL equivalences. In the proof of security we first show, via LTL equivalences, that *VRASED* guarantees that adversary  $\mathcal{A}$  can never learn  $\mathcal{K}$  with more than negligible probability. We then prove security by showing a reduction of HMAC’s existential unforgeability to *VRASED*’s security. In other words, we show that existence of  $\mathcal{A}$  that breaks *VRASED* implies existence of HMAC- $\mathcal{A}$  able to break conjectured existential unforgeability of HMAC. The full machine-checked proofs for the LTL equivalences (using Spot 2.0 [19] proof assistant) discussed in the remainder of this section are available in [1].

#### A.2 Machine Model

To prove that *VRASED*’s design satisfies end-to-end definitions of soundness and security for RA, we start by formally defining (in LTL) memory and execution models corresponding to the architecture introduced in Section 3.

**Definition 4** (Memory model).

1.  $\mathcal{K}$  is stored in ROM  $\leftrightarrow G : \{KR = \mathcal{K}\}$
2. *SW-Att* is stored in ROM  $\leftrightarrow G : \{CR = SW-Att\}$
3. *MR*, *CR*, *AR*, *KR*, and *XS* are non-overlapping memory regions

The memory model in Definition 4 captures that *KR* and *CR* are ROM regions, and are thus immutable. Hence, the values stored in those regions always correspond to  $\mathcal{K}$  and *SW-Att* code, respectively. Finally, the memory model states that *MR*, *CR*, *AR*, *KR*, and *XS* are disjoint regions in the memory layout, corresponding to the architecture in Figure 3.

**Definition 5** (Execution model).

1.  $Modify\_Mem(i) \rightarrow (W_{en} \wedge D_{addr} = i) \vee (DMA_{en} \wedge DMA_{addr} = i)$
2.  $Read\_Mem(i) \rightarrow (R_{en} \wedge D_{addr} = i) \vee (DMA_{en} \wedge DMA_{addr} = i)$
3.  $Interrupt \rightarrow irq$

Our execution model, in Definition 5, translates MSP430 behavior by capturing the effects on the processor signals when reading and writing from/to memory. We do not model the effects of instructions that only modify register values (e.g., ALU operations, such as *add* and *mul*) because they are not necessary in our proofs.

The execution model defines that a given memory address can be modified in two cases: by a CPU instruction or by DMA. In the first case, the  $W_{en}$  signal must be on and  $D_{addr}$  must contain the memory address being accessed. In the second case,  $DMA_{en}$  signal must be on and  $DMA_{addr}$  must contain the address being modified by DMA. The requirements for reading from a given address are similar, except that instead of  $W_{en}$ ,  $R_{en}$  must be on. Finally, the execution model also captures the fact that an interrupt implies setting the *irq* signal to 1.

#### A.3 RA Soundness Proof

The proof follows from *SW-Att* functional correctness (expressed by Definition 3) and LTL specifications 3, 5, 7, and 10

**Theorem 1.** *VRASED* is sound according to Definition 1.

*Proof.*

$$Definition\ 3 \wedge LTL_3 \wedge LTL_5 \wedge LTL_7 \wedge LTL_{10} \rightarrow Theorem\ 1$$

□

The formal computer proof for Theorem 1 can be found in [1]. Due to space limitations, we only provide some intuition, by splitting the proof into two parts. First, SW-Att functional correctness (Definition 3) would imply Theorem 1 if  $AR$ ,  $CR$ ,  $KR$  never change and an interrupt does not happen during SW-Att computation. However, memory model Definitions 4.1 and 4.2 already guarantee that  $CR$  and  $KR$  never change. Also, LTL 5 states that an interrupt cannot happen during SW-Att computation, otherwise the device resets. Therefore, it remains for us to show that  $AR$  does not change during SW-Att computation. This is stated in Lemma 1.

**Lemma 1.** *Temporal Consistency – Attested memory does not change during SW-Att computation*

$$G : \{ \\ PC = CR_{min} \wedge AR = M \wedge \neg reset \ U (PC = CR_{max}) \rightarrow \\ (AR = M) \ U (PC = CR_{max}) \}$$

In turn, Lemma 1 can be proved by:

$$LTL_3 \wedge LTL_7 \wedge LTL_{10} \rightarrow Lemma\ 1 \quad (12)$$

The reasoning for Equation 12 is as follows:

- $LTL_3$  prevents the CPU from stopping execution of SW-Att before its last instruction.
- $LTL_7$  guarantees that the only memory regions written by the CPU during SW-Att execution are  $XS$  and  $MR$ , which do not overlap with  $AR$ .
- $LTL_{10}$  prevents DMA from writing to memory during SW-Att execution.

Therefore, there are no means for modifying  $AR$  during SW-Att execution, implying Lemma 1. As discussed above, it is easy to see that:

$$Lemma\ 1 \wedge LTL_5 \wedge Definition\ 3 \rightarrow Theorem\ 1 \quad (13)$$

## A.4 RA Security Proof

Recall the definition of RA security in the game in Figure 6. The game makes two key assumptions:

1. SW-Att call results in a temporally consistent HMAC of  $AR$  using a key derived from  $\mathcal{K}$  and  $Chal$ . This is already proved by VRASED’s soundness.
2.  $\mathcal{A}$  never learns  $\mathcal{K}$  with more than negligible probability.

By proving that VRASED’s design satisfies assumptions 1 and 2, we show that the capabilities of untrusted software (any DMA or CPU software other than SW-Att) on  $\mathcal{P}rv$  are equivalent to the capabilities of  $\mathcal{A}$  in RA-game. Therefore, we still need to prove item 2 before we can use such game to prove VRASED’s security. The proof of  $\mathcal{A}$ ’s inability to learn  $\mathcal{K}$  with

**Lemma 2.** *Key confidentiality –  $\mathcal{K}$  can not be accessed directly by untrusted software ( $\neg(PC \in CR)$ ) and any memory written to by SW-Att can never be read by untrusted software.*

$$G : \{ \\ \neg(PC \in CR) \wedge Read\_Mem(i) \wedge i \in KR \rightarrow reset \wedge \\ (DMA_{en} \wedge DMA_{addr} = i \wedge i \in KR \rightarrow reset) \wedge \\ [\neg reset \wedge PC \in CR \wedge Modify\_Mem(i) \wedge \neg(i \in MR) \rightarrow \\ G : \{ \neg(PC \in CR) \wedge Read\_Mem(i) \vee DMA_{en} \wedge DMA_{addr} = i \\ \rightarrow reset \}] \\ \}$$

more than negligible probability is facilitated by A6 - Callee-Saves-Register convention stated in Section 3. A6 directly implies no leakage of information through registers on the return of SW-Att. This is because, before the return of a function, registers must be restored to their state prior to the function call. Thus, untrusted software can only learn  $\mathcal{K}$  (or any function of  $\mathcal{K}$ ) through memory. However, if untrusted software can never read memory written by SW-Att, it never learns anything about  $\mathcal{K}$  (the secret-independence of SW-Att at the HACl\* level even implies a lack of timing side-channels, subject to our assumption that this property is preserved by msp430-gcc and the MCU implementation). Now, it suffices to prove that untrusted software can not access  $\mathcal{K}$  directly and that it can never read memory written by SW-Att. These conditions are stated in LTL in Lemma 2. We prove that VRASED satisfies Lemma 2 by writing a computer proof (available in [1]) for Equation 14. The reasoning for this proof is similar to that of RA soundness and omitted due to space constraints.

$$LTL_2 \wedge LTL_6 \wedge LTL_7 \wedge LTL_8 \wedge LTL_9 \wedge LTL_{10} \rightarrow Lemma\ 2 \quad (14)$$

We emphasize that Lemma 2 does not restrict reads and writes to  $MR$ , since this memory is used for inputting  $Chal$  and receiving SW-Att result. Nonetheless, the already proved RA soundness and LTL 4 (which makes it impossible to execute fractions of SW-Att) guarantee that  $MR$  will not leak anything, because at the end of SW-Att computation it will always contain an HMAC result, which does not leak information about  $\mathcal{K}$ . After proving Lemma 2, the capabilities of untrusted software on  $\mathcal{P}rv$  are equivalent to those of adversary  $\mathcal{A}$  in RA-game of Definition 2. Therefore, in order to prove VRASED’s security, it remains to show a reduction from HMAC security according to the game in Definition 2. VRASED’s security is stated and proved in Theorem 2.

**Theorem 2.** *VRASED is secure according to Definition 2 as long as HMAC is a secure MAC.*

*Proof.* A MAC is defined as tuple of algorithms  $\{Gen, Mac, Vrf\}$ . For the reduction we construct a slightly modified  $HMAC'$ , which has the same  $Mac$  and  $Vrf$  algorithms as standard HMAC but  $Gen \leftarrow KDF(\mathcal{K}, Chal)$  where  $Chal \leftarrow \mathcal{S}\{0, 1\}^l$ . Since KDF function itself is implemented as a  $Mac$  call, it is easy to see that the outputs of

*Gen* are indistinguishable from random. In other words, the security of this slightly modified construction follows from the security of HMAC itself. Assuming that there exists  $\mathcal{A}$  such that  $\Pr[\mathcal{A}, \text{RA}_{\text{game}}] > \text{negl}(l)$ , we show that such adversary can be used to construct HMAC- $\mathcal{A}$  that breaks existential unforgeability of HMAC' with probability  $\Pr[\text{HMAC-}\mathcal{A}, \text{MAC-game}] > \text{negl}(l)$ . To that purpose HMAC- $\mathcal{A}$  behaves as follows:

1. HMAC- $\mathcal{A}$  selects *msg* to be the same  $M \neq AR$  as in RA-game and asks  $\mathcal{A}$  to produce the same output used to win RA-game.
2. HMAC- $\mathcal{A}$  outputs the pair  $(\text{msg}, \sigma)$  as a response for the challenge in the standard existential unforgeability game, where  $\sigma$  is the output produced by  $\mathcal{A}$  in step 1.

By construction,  $(\text{msg}, \sigma)$  is a valid response to a challenge in the existential unforgeability MAC game considering HMAC' as defined above. Therefore, HMAC- $\mathcal{A}$  is able to win the existential unforgeability game with the same  $> \text{negl}(l)$  probability that  $\mathcal{A}$  has of winning RA-game in Definition 2.  $\square$

## B Optional Verifier Authentication

```

1 void HACL_HMAC_SHA2_256_hmac_entry() {
2   uint8_t key[64] = {0};
3   uint8_t verification[32] = {0};
4   if (memcmp(CHALL_ADDR, CTR_ADDR, 32) > 0)
5   {
6     memcpy(key, KEY_ADDR, 64);
7
8     hacl_hmac((uint8_t*) verification, (uint8_t*) key,
9              (uint32_t) 64, *((uint8_t*)CHALL_ADDR),
10             (uint32_t) 32);
11
12     if (!memcmp(VRF_AUTH, verification, 32)
13         {
14       hacl_hmac((uint8_t*) key, (uint8_t*) key,
15                (uint32_t) 64, (uint8_t*) verification,
16                (uint32_t) 32);
17       hacl_hmac((uint8_t*) MAC_ADDR, (uint8_t*) key,
18                (uint32_t) 32, (uint8_t*) ATTEST_DATA_ADDR,
19                (uint32_t) ATTEST_SIZE);
20       memcpy(CTR_ADDR, CHALL_ADDR, 32);
21     }
22   }
23
24   return();
25 }

```

Figure 14: SW-Att Implementation with  $\mathcal{V}_{rf}$  authentication

Depending on the setting where  $\mathcal{P}_{rv}$  is deployed, authenticating the attestation request before executing SW-Att may be required. For example, if  $\mathcal{P}_{rv}$  is in a public network, the adversary may try to communicate with it. In particular, the adversary can impersonate  $\mathcal{V}_{rf}$  and send fake attestation requests to  $\mathcal{P}_{rv}$ , attempting to cause denial-of-service. This is particularly relevant if  $\mathcal{P}_{rv}$  is a safety-critical device. If  $\mathcal{P}_{rv}$  receives too many attestation requests, regular (and likely honest) software running on  $\mathcal{P}_{rv}$  would not execute because SW-Att would run all the time. Thus, we now discuss an optional part of VRASED's design suitable for such settings. It supports

authentication of  $\mathcal{V}_{rf}$  as part of SW-Att execution. Our implementation is based on the protocol in [10].

Figure 14 presents an implementation of SW-Att that includes  $\mathcal{V}_{rf}$  authentication. It also builds upon HACL\* verified HMAC to authenticate  $\mathcal{V}_{rf}$ , in addition to computing the authenticated integrity check. In this case,  $\mathcal{V}_{rf}$ 's request additionally contains an HMAC of the challenge computed using  $\mathcal{K}$ . Before calling SW-Att, software running on  $\mathcal{P}_{rv}$  is expected to store the received challenge on a fixed address *CHALL\_ADDR* and the corresponding received HMAC on *VRF\_AUTH*. SW-Att discards the attestation request if (1) the received challenge is less than or equal to the latest challenge, or (2) HMAC of the received challenge is mismatched. After that, it derives a new unique key using HKDF [32] from  $\mathcal{K}$  and the received HMAC and uses it as the attestation key.

HW-Mod must also be slightly modified to ensure security of  $\mathcal{V}_{rf}$ 's authentication. In particular, regular software must not be able to modify the memory region that stores  $\mathcal{P}_{rv}$ 's counter. Notably, the counter requires persistent and writable storage, because SW-Att needs to modify it at the end of each attestation execution. Therefore, *CTR* region resides on FLASH. We denote this region as:

- $CTR = [CTR_{min}, CTR_{max}]$ ;

LTl Specifications (15) and (16) must hold (in addition to the ones discussed in Section 4).

$$\mathbf{G} : \{ \neg(PC \in CR) \wedge W_{en} \wedge (D_{addr} \in CTR) \rightarrow reset \} \quad (15)$$

$$\mathbf{G} : \{ DMA_{en} \wedge (DMA_{addr} \in CTR) \rightarrow reset \} \quad (16)$$

LTl Specification (15) ensures that regular software does not modify  $\mathcal{P}_{rv}$ 's counter, while (16) ensures that the same is not possible via the DMA controller. FSMs in Figures 8 and 11, corresponding to HW-Mod access control and DMA sub-modules, must be modified to transition into *Reset* state according to these new conditions. In addition, LTl Specification (7) must be relaxed to allow SW-Att to write to *CTR*. Implementation and verification of the modified version of these sub-modules are publicly available at VRASED's repository [1] as an optional part of the design.

## C API & Sample Application

VRASED ensures that any violation of secure RA properties is detected and causes the system to reset. However, benign applications running on the MCU must also comply with VRASED rules to execute successfully. To ease the process of setting up the system for a call to SW-Att, VRASED provides an API that takes care of necessary configuration on the application's behalf. This API and a sample application deployed using FPGAs are described in the extended version of this paper, available at [18].

# Mobile Private Contact Discovery at Scale

## Abstract

Mobile messengers like WhatsApp perform contact discovery by uploading the user's entire address book to the service provider. This allows the service provider to determine which of the user's contacts are registered to the messaging service. However, such a procedure poses significant privacy risks and legal challenges. As we find, even messengers with privacy in mind currently do not deploy proper mechanisms to perform contact discovery privately.

The most promising approaches addressing this problem revolve around private set intersection (PSI) protocols. Unfortunately, even in a weak security model where clients are assumed to follow the protocol honestly, previous protocols and implementations turned out to be far from practical when used at scale. This is due to their high computation and/or communication complexity as well as lacking optimization for mobile devices. In our work, we remove most obstacles for large-scale global deployment by significantly improving two promising protocols by Kiss et al. (PoPETS'17) while also allowing for malicious clients.

Concretely, we present novel precomputation techniques for correlated oblivious transfers (reducing the online communication by factor 2x), Cuckoo filter compression (with a compression ratio of  $\approx 70\%$ ), as well as 4.3x smaller Cuckoo filter updates. In a protocol performing oblivious PRF evaluations via garbled circuits, we replace AES as the evaluated PRF with a variant of LowMC (Albrecht et al., EUROCRYPT'15) for which we determine optimal parameters, thereby reducing the communication by factor 8.2x. Furthermore, we implement both protocols with security against malicious clients in C/C++ and utilize the ARM Cryptography Extensions available in most recent smartphones. Compared to previous smartphone implementations, this yields a performance improvement of factor 1,000x for circuit evaluations. The online phase of our fastest protocol takes only 2.92s measured on a real WiFi connection (6.53s on LTE) to check 1,024 client contacts against a large-scale database with  $2^{28}$  entries. As a proof-of-concept, we integrate our protocols in the client application of the open-source messenger Signal.

## 1 Introduction

After installation, mobile messaging applications first perform a so-called *contact discovery*. This allows new users to automatically connect with all other users of the messaging service whose phone numbers are stored in their address book. There exist various ways to perform contact discovery. For example, WhatsApp simply uploads the user's entire address book on a regular basis to match contacts [1].

However, revealing all personal contacts to a service provider poses significant privacy risks: from the social graph of users a variety of personal information can be inferred and journalists, for example, may need to cover the identity of some of their informants to protect whistleblowers from potential consequences. When installing a mobile messaging application, users also jeopardize the privacy of people who are not even connected to the particular service by transmitting their contact information without consent. An illustrative example of a severe breach of privacy can be seen in the case of WhatsApp, which was acquired by Facebook in 2014 and shared its database with the parent company: Facebook users received friend recommendations of strangers who happened to see the same psychiatrists [33].

Unfortunately, applying simple protection mechanisms like hashing the phone numbers of contacts locally before the upload to the service provider is not helpful since these hashes are vulnerable to brute-force and dictionary attacks due to the relatively small range of possible pre-images. Furthermore, the service provider can still tell whether two users share a contact even a long time after running the discovery routine by storing the received hash values. Custom wrappers<sup>1</sup> for messaging applications can somewhat circumvent these problems by allowing users to manually select contacts to expose to the messaging application. However, this approach only protects the contacts of users actually using such custom wrappers. Furthermore, manually selecting the contacts to match is a usability problem.

<sup>1</sup>e.g., <https://www.backes-srt.com/en/solutions-2/whatsbox>

One possible solution to this dilemma is to apply a particular form of secure two-party computation. In general, secure two-party computation allows parties  $P_1$  and  $P_2$  to jointly compute a publicly known function  $f$  on their respective inputs  $X_1$  and  $X_2$  s.t. the parties learn no information from the protocol execution but the result. The research area of *private set intersection* (PSI) focuses on optimized protocols for the case where  $X_1$  and  $X_2$  are sets of elements, and  $f$  is the intersection function. PSI has been studied in great depth in the past years, yielding very efficient protocols (e.g., [41, 51]) based on oblivious transfer extensions (OTe, cf. [4, 36, 39]). However, while these protocols are very efficient in many scenarios, they turn out to be impractical for use-cases like private contact discovery on mobile devices, where the input set of the service provider is much larger (sometimes by a factor of a few million) than the input set of the user. This is because the online phase of these protocols (which depends on the actual inputs) has a computation and communication complexity that is linear in the size of the larger set.

Therefore, other PSI protocols for the case of *unbalanced* set sizes were developed (e.g., [19, 21, 40, 59]). However, only [40] actually provides an implementation on real mobile smartphone clients. The experiments performed by the authors of [40] show a rather large discrepancy between protocol execution on x86-based PC hardware and Android smartphones where performance-critical cryptographic operations are implemented in Java. In fact, their performance results do not encourage real-world deployment. For example, their fastest protocol that can easily be made secure against malicious clients requires more than 52s on a smartphone with WiFi connection to check a single client contact against a database with only  $2^{20}$  entries.

The developers of Signal, a mobile messaging service similar to WhatsApp but with focus on privacy, considered the use of PSI protocols for contact discovery. However, they refrained from actually implementing PSI since the academic research in PSI and the related private information retrieval (PIR) protocols “is quite a disappointment” [44]. Instead, they presented a technology preview that protects the contact discovery task on the server side with Intel Software Guard Extensions (SGX), a trusted execution environment that can be attested by remote users [45]. In theory, this yields a secure contact discovery service with negligible performance overhead compared to plain computation. However, Intel SGX is a proprietary engineering-driven solution with no cryptographic security guarantees and vulnerable to severe attacks, e.g., the recent Foreshadow attack [16] managed to reliably extract confidential data from enclaves. Moreover, some fixes for hardware security designs such as Intel SGX require hardware changes that can take years to enter the market and result in repeated acquisition costs. In contrast, fixes for flawed implementations of provably secure cryptographic protocols can be deployed quickly via software updates.

Thus, we revisit state-of-the-art unbalanced PSI protocols which provide cryptographic security and show that using new optimizations and native implementations they turn out to be practical on modern smartphones. Furthermore, we achieve security against malicious clients: since every user could run a manipulated version of the messaging application, deviations from the protocol may lead to revealing information about the server’s database. On the other hand, we assume that the server behaves semi-honestly, i.e., it follows the protocol but tries to learn as much information as possible. This is a reasonable assumption since there are legal requirements and financial incentives to behave correctly: once misconduct gets known publicly, users will abandon the misbehaving service and switch to a more trustworthy alternative.

## 1.1 Our Contributions

As a motivation, we investigate how contact discovery is handled in widely used mobile messaging applications. For this, we conduct a survey where we analyze privacy policies, source code, and network traffic. Our results show that in practice none of these applications protect the users’ privacy during contact discovery.

We optimize two protocols for unbalanced PSI that can easily be made secure against malicious clients and are suitable for private contact discovery: one that uses oblivious evaluations of the Naor-Reingold PRF (NR-PSI, cf. [31, 40, 47]) and one that uses Yao’s garbled circuits (GC-PSI, cf. [40, 52, 56]) to run oblivious AES evaluations. For both protocols we apply new forms of correlated random OT precomputation (reducing the online communication by factor 2x, which is of independent interest) and introduce a method for Cuckoo filter compression (with a compression ratio of  $\approx 70\%$  and negligible computational overhead) as well as 4.3x smaller Cuckoo filter updates to reduce the required network communication. Moreover, we improve the GC-PSI protocol by instantiating the PRF with LowMC [2], a cipher specifically designed for efficient evaluation in secure protocols, instead of the default choice AES. While this was already proposed in [40], we find optimal parameter sets for LowMC and provide implementations. Compared to AES, we thereby reduce the communication by factor 8.2x.

We provide C/C++ implementations for both protocols with security against malicious clients that make use of the Cryptography Extensions (CE) in the ARMv8 architecture available in most recent smartphones for hardware-accelerated execution. Thereby, we improve the runtime of the online phase of the GC-PSI protocol by more than a factor of 1,000x compared to the previous work of [40] that only implements security against semi-honest clients. We overcome further shortcomings of previous works w.r.t security and scalability by evaluating the implementations using recommended security parameters, reasonable false positive probabilities, and considering large-scale set sizes on the server side.

Our fastest protocol takes only 2.92s measured on a real WiFi connection (6.53 s on LTE) and 6.07 MiB of communication in the online phase to check 1,024 client contacts against a database with  $2^{28}$  entries (more than the number of monthly active users for popular messengers like Telegram [61]). For the setup phase it is required to transfer a compressed Cuckoo filter once whose size is linear in the number of the database entries ( $\approx 1$  GiB for  $2^{28}$  entries); since the filter is identical for all clients, service providers can handle the resulting traffic efficiently via CDNs. To remain practical for even larger set sizes (the market leader WhatsApp currently has more than 1.6 billion users [61]), we suggest multiple extensions, e.g., combining our protocols with multi-server PIR s.t. the overall client-server communication complexity becomes logarithmic in the size of the server database.

As a proof-of-concept, we integrate both of our protocols in the Signal Android client, thereby positioning our secure cryptographic approach as a practical alternative to vulnerable trusted execution environments like Intel SGX.

## 1.2 Motivating Survey

To determine how contact discovery is currently being done in practice, we conducted a survey on a comprehensive selection of mobile messengers that are “secure” in the sense that they offer end-to-end encryption. Each application was analyzed by evaluating the mandatory privacy policy, which is supposed to state exactly which data the application transmits to its server and how the server processes and stores that data. Unfortunately, these policies are not always precise enough to determine the employed contact discovery method. In these cases, we inspected the source code (if publicly available) or the network communication by means of the man-in-the-middle proxy *mitmproxy*<sup>2</sup>. We circumvented certificate pinning by using the *Xposed*<sup>3</sup> framework together with the *JustTrustMe*<sup>4</sup> plugin that can disable certificate checking routines in several commonly used security libraries.

Our results are summarized in Tab. 1. All surveyed messengers upload contact information (at least the contact’s phone number) either in the clear or in hashed form. While this form of contact discovery is very efficient (requiring only a few bytes of communication per element), it threatens the privacy of users directly or indirectly via brute-force or dictionary attacks. Furthermore, even if the server cannot determine the actual contact data, it can still tell whether two users share a contact by comparing uploaded hash values.

This can be somewhat mitigated by using salted hashing s.t. the hashes received by the server are different whenever a client triggers contact discovery. However, only one of the surveyed messengers employs this approach as it requires to

hash the entire server database for each fresh salt received by a client. Furthermore, brute-force attacks are still feasible.

## 2 Related Work

In this section, we discuss existing unbalanced PSI protocols and other works that focus on PSI in the smartphone setting.

**Unbalanced PSI.** Kiss et al. [40] discuss multiple unbalanced PSI protocols with precomputation (cf. §3.5) and security against semi-honest adversaries. Their NR-PSI and GC-PSI protocols (based on [31] and [52], respectively) are the foundation of our work. We augment these protocols with new OT precomputation techniques, efficient Cuckoo filters [27, 59], a specialized cipher [2] for the GC-PSI protocol, and security against malicious clients. The authors of [40] also evaluate their protocols on smartphones, but based on less efficient Java implementations. In our work, we present C/C++ implementations that make use of the hardware-accelerated cryptography available in most recent smartphones.

Resende and de Freitas Aranha [59] use techniques similar to [40], but replace Bloom filters [12] with the more efficient and versatile Cuckoo filters [27] to efficiently represent the encrypted server database (cf. §3.4) in a Diffie-Hellman style PSI protocol [7] with security against semi-honest adversaries. In our work, we optimize communication by proposing methods for Cuckoo filter compression and updates, and perform evaluations with reasonable parameters: while in [59] the authors settle with an error probability of  $\approx 2^{-13}$ , which results, on average, in one false positive when 10 clients match  $2^{10}$  contacts each, we propose realistic Cuckoo filter parameters for error probabilities  $\approx 2^{-29}$  and  $\approx 2^{-39}$ .

Demmler et al. [21] present a different approach assuming multiple non-colluding servers. Their idea is to first perform a variant of private information retrieval (PIR) to reduce the

<sup>2</sup><https://mitmproxy.org>

<sup>3</sup><https://repo.xposed.info>

<sup>4</sup><https://github.com/Fuzion24/JustTrustMe>

server’s input set and then perform a traditional PSI protocol on the reduced sets. While this approach is very performant, the requirement of non-colluding servers presents challenges for the data-owners: they not only need to guarantee that these servers do not collude, but also need to ensure that their client data is not leaked to other parties. This leads to the difficult situation where the server party needs to trust a second server but simultaneously is assumed to not collude with it. However, even if servers are malicious and/or collude, they cannot learn more about client inputs than in currently deployed naive hashing-based contact discovery methods.

Chen et al. [19] give a PSI protocol based on fully homomorphic encryption. The authors present multiple optimizations that make the protocol practically viable. Their work was improved and extended to the special use case of *labeled* PSI [18], where for intersecting items an associated label is transferred and security is not only guaranteed in case of malicious clients but also malicious servers (with some controlled leakage). The advantage of the protocols of [18, 19] is that their communication complexity is sublinear instead of linear in the size of the server set. However, this comes at the cost of repeated high computational overhead, whereas the online phase of our protocols is very efficient and requires no cryptographic operations on the server side.

**Mobile PSI.** Huang et al. [34] provided first performance results for secure computation on smartphones with security against semi-honest adversaries. They implemented a circuit-based PSI protocol on Android. Their implementation managed to evaluate  $\approx 100$  AND gates per second, taking about 10 min to intersect two sets of 256 items each.

Asokan et al. [6] implemented an RSA-based PSI protocol with security against semi-honest adversaries on smartphones for secure mobile resource sharing.

Carter et al. [17] presented a maliciously secure system for secure outsourced garbled circuit evaluation on mobile devices. Subsequently, Mood et al. [46] showed how to further optimize outsourced evaluation. They also point out how their framework can be used to implement a secure friend finder.

“PROUD” [49] is a decentralized approach for private contact discovery based on the DNS system. It enables users to privately discover the current network addresses of friends, which differs from the scenario of a centralized messaging service we consider. Moreover, friendship bootstrapping requires an out-of-band communication channel between users.

Compared to these works, we optimize protocols for unbalanced PSI with a central service provider and provide native implementations for maximum performance on smartphones.

### 3 Background

In the following, we introduce cryptographic building blocks that are required for the remainder of this work.

#### 3.1 Oblivious Transfer (Extensions)

Oblivious transfer (OT) [57] is a cryptographic protocol that in its most basic form allows a sender  $P_1$  to obliviously transfer one out of two messages  $(m_0, m_1)$  to a receiver  $P_2$  based on a selection bit  $b$  chosen by  $P_2$  s.t.  $P_1$  learns nothing about  $b$  and  $P_2$  learns only  $m_b$  but nothing about  $m_{1-b}$ .

It was shown in [35] that performing OTs always requires some form of public key cryptography. However, with OT extension (OTe) protocols [9, 36], a small number (e.g., 128) of “base OTs” can be extended to a large number of OTs using only efficient symmetric cryptographic operations.

There exist flavors of OTe with reduced communication complexity [5]: In random OT (R-OT), neither party inputs any values, but the inputs of sender and receiver are randomly chosen by the protocol. In correlated OT (C-OT),  $m_0$  is chosen at random, whereas  $m_1$  is computed as a function  $f$  of  $m_0$ :  $m_1 = f(m_0)$ , where  $f$  is privately known to  $P_1$  only.

It is possible to precompute OTs s.t. all computationally expensive operations are performed via R-OTs in advance [8]. Later, the random values obtained via R-OTs are used to mask the actual inputs, requiring only cheap XOR operations in the style of one-time-pad encryption.

#### 3.2 Garbled Circuits

Yao’s garbled circuits (GC) [62] is one of the most prominent techniques for secure two-party computation. (In the following the two parties are called *garbler* and *evaluator*.) The idea is to represent the function that is evaluated as a Boolean circuit and to replace each logical two-input gate by a *garbled gate*. Each wire of the garbled gate is given two random wire labels, representing 0 and 1. To garble a gate, the garbler uses all four combinations of the gate’s two input wire labels to encrypt the corresponding output wire label, based on the truth table of the original gate, and sends the resulting ciphertexts, the so-called *garbled table*, to the evaluator. The evaluator can then use the two input wire labels it possesses to decrypt one of the four ciphertexts and receive the output wire label, which is then used as input for subsequent gates.

We now describe how the evaluator obtains the wire labels corresponding to the inputs of the two parties: Since the garbler knows all wire labels, it can send the wire labels corresponding to its input bits to the evaluator. However, to ensure input privacy for the evaluator, the wire labels corresponding to the evaluator’s input bits are retrieved via OTs. The garbler also sends information that allows the evaluator to decode the final output wire labels to 0 or 1.

Several optimizations for Yao’s original scheme have been presented s.t. today it is most efficient to combine the following techniques: Point-and-Permute [10], Free-XOR [42], fixed-key AES garbling [11], and Half-Gates [63].

### 3.3 OPRF Evaluation

An oblivious pseudorandom function (OPRF) is a protocol between two parties: sender  $P_1$  holding key  $k$  and receiver  $P_2$  holding input  $x$ . After the invocation of the protocol,  $P_2$  learns the output  $f_k(x)$  of a keyed pseudorandom function (PRF)  $f$ . Additionally, it is guaranteed that  $P_1$  does not learn anything about  $x$  and  $P_2$  does not learn anything about  $k$ .

OPRF evaluations can be used to build PSI protocols as proposed in [28, 30, 40, 52]: The server samples a key  $k$  uniformly at random, evaluates the PRF  $f_k(x_i)$  on each of its items  $x_i \in X$ , and sends the results to the client. Server and client now engage in the OPRF protocol, where the server inputs key  $k$  and the client inputs elements  $y_j \in Y$ . After this step, the client obtains  $f_k(y_j)$  for each item  $y_j \in Y$  and can perform a plain intersection between the items  $f_k(x_i)$  and  $f_k(y_j)$ . The client then outputs the elements  $y_j$  corresponding to the values in the intersection.

In this work, we instantiate the PRF either using the Naor-Reingold PRF [47] (NR-PSI) or a garbled circuit-based evaluation of a block cipher (GC-PSI). In [37], the authors describe an alternative algebraic OPRF construction based on a PRF by Dodis-Yampolskiy [25]. However, due to the use of Paillier encryption, this construction is likely slower than the Naor-Reingold PRF and their follow-up work [38], the basis for [59] (cf. §6.2). Moreover, it requires a common reference string in the form of an RSA modulus with unknown factorization.

### 3.4 Cuckoo Filters

Cuckoo filters [27] are an alternative to the more popular Bloom filters [12]. Like Bloom filters, they are a data structure for compact set representation that allows for fast membership testing with controllable *false positive probability* (FPP). Cuckoo filters employ a hashing technique similar to Cuckoo hashing [48], which has been used in the past as a building block in PSI protocols (e.g., [41, 51, 53–56]).

Resende and de Freitas Aranha [59] first used Cuckoo filters in a PSI protocol. This is due to several advantages over Bloom filters when representing the server’s database, namely they (i) support inserting and deleting items subsequently, whereas standard Bloom filters only support inserting items, and variants that do support deletion such as counting Bloom filters have much higher storage costs; (ii) have better lookup performance; and (iii) use less space in many scenarios while having the same false positive probability.

Cuckoo filters consist of a table of buckets with fixed bucket size  $b$ . Inside the buckets, so-called tags are stored. Tags are small bitstrings obtained by hashing items. More precisely, to represent an item  $x$  in a Cuckoo filter, we first calculate its tag  $t_x = H_l(x)$ , where  $H_l$  is a hash function with output bitlength  $v$ . This tag is stored in one out of two possible buckets. The position of the first possible bucket is calculated as  $p_1 = H(x)$ , where  $H$  is another hash function that maps the

input to a position in the table of buckets. In case this bucket is already full, the tag is stored in the second possible bucket at position  $p_2 = p_1 \oplus H(t_x)$ . Note that it is always possible to determine the other candidate bucket  $p_j$  just from knowing its tag  $t_x$  and the current position  $p_i$ :  $p_j = p_i \oplus H(t_x)$ . If both buckets are full, one tag in one of the buckets is chosen at random, removed from that bucket, and moved to its other possible bucket. This procedure is repeated recursively until no more relocations are necessary.

To check whether an item is contained in the Cuckoo filter, one computes its tag and both possible bucket locations and compares the tags stored there for equality. For deleting the item, the matching tag is removed from the filter.

Due to hash collisions, two items may produce equal tags. As a consequence, lookups can lead to false positives. The false positive probability  $\epsilon_{max}$  is mainly dependent on the tag size  $v$  and also slightly on the bucket size  $b$  since larger buckets result in more possible collisions within each bucket.

### 3.5 Unbalanced PSI with Precomputation

For private contact discovery, the following properties are desired: (i) the server performs the computationally expensive tasks; (ii) all computationally expensive and communication intensive tasks are performed only once; and (iii) the actual intersection computation is very fast and also allows for efficient updates. Therefore, [40] suggest to use PSI protocols with precomputation, where most time consuming tasks are performed ahead of the actual intersection.

Our PSI protocols for unbalanced set sizes share a common structure. Following the precomputation approach of [40], they are divided into the following four phases: (i) The *base phase* is completely independent of any input data and consists, e.g., of OT precomputation. Its complexity is linear in the maximum number of contacts a client expects to match in future protocol executions before the base phase is re-run. (ii) The complexity of the *setup phase* is linear in the size of the large set held by the server. It involves encrypting all elements in the server database via PRF evaluations as described in §3.3 and inserting them into a Cuckoo filter for compact representation, which is transferred to the client. (iii) During the *online phase* client and server jointly perform OPRF evaluations on all elements of the client. The client then looks up all received encryptions in the Cuckoo filter to determine the intersection. Thus, the complexity of the online phase is only linear in the size of the small client set. (iv) Changes in the server database trigger the *update phase*, where the Cuckoo filter on the client side is updated by sending a small delta for each inserted or deleted database entry.

## 4 Optimizing OPRF-based PSI Protocols

We propose more efficient database representations and PRFs, give the full descriptions for our optimized NR- and GC-

PSI protocols, enable security against malicious clients, and suggest multiple extensions to further increase practicality.

## 4.1 More Efficient Database Representations

**Realistic Cuckoo Filter Parameters.** Resende and de Freitas Aranha [59] propose using Cuckoo filters as an extension to the DH-based PSI protocol of [7] and they perform experiments to find optimal Cuckoo filter parameters based on the number of server items and the desired error probability. While their findings are directly applicable to our use case, they set very aggressive Cuckoo filter parameters (tag size  $v = 16$ , bucket size  $b = 3$ ) and settle for a maximum *false positive probability* (FPP) of  $\epsilon_{max} \approx 2^{-13}$ . We find this FPP not practical since it implies that about one in 10 clients performing PSI for  $2^{10}$  elements receives a false positive.

Instead, we propose to use tag size  $v = 32$  to reach a FPP of  $\epsilon_{max} \approx 2^{-29}$  or tag size  $v = 42$  to reach a FPP of  $\epsilon_{max} \approx 2^{-39}$  while still maintaining a bucket size of  $b = 3$ . For our experiments, we choose the parameter set  $v = 32, b = 3$ , and choose the size of the Cuckoo filter to have a load factor of  $\approx 66\%$ , leading to a Cuckoo filter size of 6 MiB per  $2^{20}$  items.

**Novel Cuckoo Filter Compression.** The size of Cuckoo filters can be reduced by applying a simple but effective compression technique that to the best of our knowledge was not considered before: For each entry of a Cuckoo filter, an additional bit is transmitted that indicates whether this entry is empty or holds a tag. The entry itself is only transmitted if it is not empty. This way, the filter is represented as a bit map and a list of tags. For a Cuckoo filter storing  $n$  items with tag size  $v$ , bucket size  $b$ , and load factor  $l$ , this reduces the size from  $\frac{n}{l} \cdot v$  bits to  $\frac{n}{l} + n \cdot v$  bits. In the example above, the size of the Cuckoo filter is reduced from 6 MiB to 4.19 MiB, i.e., by  $\approx 30\%$ . An advanced version of the compression technique presented above encodes the number of tags (0 to  $b$ ) in each bucket with  $\log_2(b + 1)$  bits instead of sending  $b$  bits per bucket. This is possible since the actual position of each tag within a bucket is not important.

This compression technique is especially useful for very sparse Cuckoo filters, which appear in use cases where the set of items is expected to grow fast (e.g., during the release phase of a new messaging application). For example, if only 10% of a Cuckoo filter storing a maximum of  $2^{20}$  items is occupied, it can be compressed by a factor of 8.3x.

In concurrent and independent work, Breslow and Jayasena [15] proposed *Morton filters*, which combine these compression techniques with cache-optimized layouts and further optimizations. Morton filters provide higher insertion, lookup, and deletion throughput than traditional Cuckoo filters, while usually having equal or slightly lower storage costs. We leave the evaluation and usage of Morton filters in our protocols for future work.

**Better Cuckoo Filter Updates.** In [59], when performing an update after new elements are inserted into or deleted from the server's set, each encrypted element to be updated is sent to the client where it is inserted into the existing Cuckoo filter. However, for Cuckoo filters, all information required to insert a new item is its tag and the index of one of its candidate buckets. From this information, it is possible to calculate the second candidate bucket in case relocations are necessary. The same information is also sufficient to delete an item. For example, the bucket index in a Cuckoo filter storing  $n = 2^{28}$  items with bucket size  $b = 3$  and load factor  $\approx 66\%$  can be represented with 27 bits. This results in sending 59 bits per updated element for tag size  $v = 32$ . In comparison, in [59] an encrypted element is represented by one point on the GLS-254 binary elliptic curve, which results in 256 bits of communication when using point compression with two trace bits, which needs 4.3x more communication than our approach.

## 4.2 More Efficient PRF for GC-PSI

During the online phase of the GC-PSI protocol, both parties interactively evaluate an OPRF on the client's items using garbled circuits. For each of the client's items, the server prepares a garbled circuit  $\widehat{PRF}_k$  that evaluates the chosen PRF under the server's key  $k$ . The choice of this PRF has a significant impact on both the runtime and the communication complexity of the overall protocol. Several improvements for Yao's GC protocol [62] have appeared in recent years that changed the desired properties of the functions to be evaluated. Most notably is the Free-XOR [42] optimization, which allows XOR gates to be evaluated securely "for free", meaning all necessary operations can be performed locally without any communication between the parties. This optimization has led to research in the area of ciphers with a low number of AND and instead many free XOR gates.

In previous GC-PSI implementations, the choice of the PRF was AES-128. Using the optimized S-Box implementation of [13], an AES-128 circuit (without key schedule) has 5,120 AND gates [32], serving as a baseline for comparison.

In this section, we focus on variants of LowMC [2], a highly parameterizable block cipher designed for use cases in multi-party computation (MPC) and fully-homomorphic encryption (FHE). [40] mentioned the possibility of using LowMC instead of AES for GC-PSI. We look at several instantiations of LowMC and present optimized parameter sets specifically for the use case of GC-PSI and mobile contact discovery. In the following, we give a short description of LowMC and highlight the different parameter choices.

LowMC [2] is a block cipher where block size  $n$ , key size  $k$ , number of S-Boxes per substitution layer  $m$ , and allowed data complexity  $d$  can be chosen freely up to some sanity constraints. The required number of rounds  $r$  to reach the security claims is then derived from these parameters.

**Data Complexity.** The data complexity of a cipher is the number of plaintext-ciphertext pairs allowed to be released before the security claims no longer hold. In the GC-PSI protocol, we can exactly control the maximum number of published plaintext-ciphertext pairs by limiting the number of client queries, and therefore can reduce the number of LowMC rounds required for security. We set the allowed data complexity to be  $d = 2^{64}$ , allowing for  $2^{20}$  contact discoveries of  $2^{10}$  items for each of the  $2^{28}$  clients, while still being below the security margin by a factor of over 100x. For smaller-scale applications, we also give a parameter set for  $2^{32}$  total data complexity, which suffices to run  $2^{20}$  queries of  $2^{10}$  items each. While we could also use this parameter set for larger-scale applications, the system needs to be re-keyed after the data complexity has been reached.

**Key Schedule.** In many MPC applications using OPRF evaluations, one party knows the entire secret key and can, therefore, perform any key-scheduling algorithm (e.g., for AES or LowMC) offline. The circuit is then modified to take the expanded key as an input. In many cases, this can be a performance improvement since the key-schedule algorithm does not have to be computed using the MPC protocol. However, when performing OPRF evaluations using garbled circuits, the party holding the secret key needs to send wire labels for each input bit, increasing the communication. While for AES-128, only 11x more wire labels need to be transferred for the expanded key, some instantiations of LowMC require several hundreds of rounds. Sending labels for the expanded key essentially removes the advantage of the lower AND count that comes with such a large number of rounds. However, we observe that in the GC-PSI protocol the OPRF evaluation is always performed with the same key. Thus, we can bundle all of the client’s circuits together into one large circuit and evaluate the key-schedule only once. This means that we only need to send the wire labels corresponding to the non-expanded key once, and therefore save  $\approx 2$  KiB for each subsequent client item when using a 128-bit key. It is also possible to only evaluate parts of the garbled circuit if the number of client items is lower than the number of precomputed circuits.

**LowMC Instances.** For use in our GC-PSI protocol, we highlight several LowMC instances, exploring different parameter choices. In Tab. 2, we give the parameters and compare the number of AND gates to AES-128. The number of rounds is calculated according to the LowMCv3 round formula<sup>5</sup>, which was updated by the LowMC team to take new cryptanalysis of LowMC (cf. [23, 24, 58]) into consideration. We can observe some interesting properties: LowMC instances (1) and (2) require the same number of rounds to be secure, but instance (1) has the maximum number of possi-

<sup>5</sup>[https://github.com/LowMC/lowmc/blob/master/determine\\_rounds.py](https://github.com/LowMC/lowmc/blob/master/determine_rounds.py)

Table 2: Comparison of PRF instances for use in the GC-PSI protocol. The recommended instance is highlighted in bold.

ble S-Boxes, while (2) does not. Since instance (2) provides the same security as (1) while requiring fewer S-Boxes, and therefore a lower amount of AND gates, it should always be preferred. LowMC instance (3) has the smallest possible S-Box layer with only one S-Box per round and also the lowest number of AND gates. While its 208 rounds can be a drawback in some protocols, Yao’s GC protocol [62] has a constant number of communication rounds and therefore the large number of LowMC rounds does not decrease performance in high-latency networks. Additionally, using the optimizations presented by [22], the large number of linear layer computations can be reduced, bringing the evaluation time of (3) close to (1) and (2). For these reasons, we recommend the use of instance (3) for GC-PSI, which requires 8.2x fewer AND gates than standard AES-128 (6). Thus, we perform all performance evaluations using instance (3). For use cases with small data complexity requirements, we recommend LowMC instance (4), which is a small improvement of 8.3 % in runtime and communication compared to (3). For completeness and direct comparison to AES-128, we also give a variant of LowMC with data complexity of  $2^{128}$  in (5).

### 4.3 Optimized GC-PSI Protocol

The idea of using Yao’s GC protocol for OPRF evaluations was first proposed in [52] and used to construct a PSI protocol in the precomputation setting in [40].

The full protocol description is given in Fig. 1. We propose an optimization that halves the online communication for the OTs (which is the only communication in the online phase). This optimization is of independent interest as it improves the practicality of Yao’s GC protocol in arbitrary use cases with precomputation. It is based on the observation that with the Free-XOR technique [42] for Yao’s GC protocol [62], the client receives one of the two labels  $l^0$  and  $l^1 = l^0 \oplus \Delta$  via OT depending on its input bit, where  $l^0$  is chosen at random and  $\Delta$  is a random global constant only known by the garbler. A natural consideration would be to replace the real OTs, as used in [40], with correlated OTs (C-OTs) (cf. §3.1). Unfortunately, since the client input is unknown in the base phase, this prevents either the precomputation of the garbled circuits or the OTs. This is because in the online phase when using OT precomputation [8], the random messages  $r^0$  and  $r^1$  obtained by the sender in the base phase need to be swapped

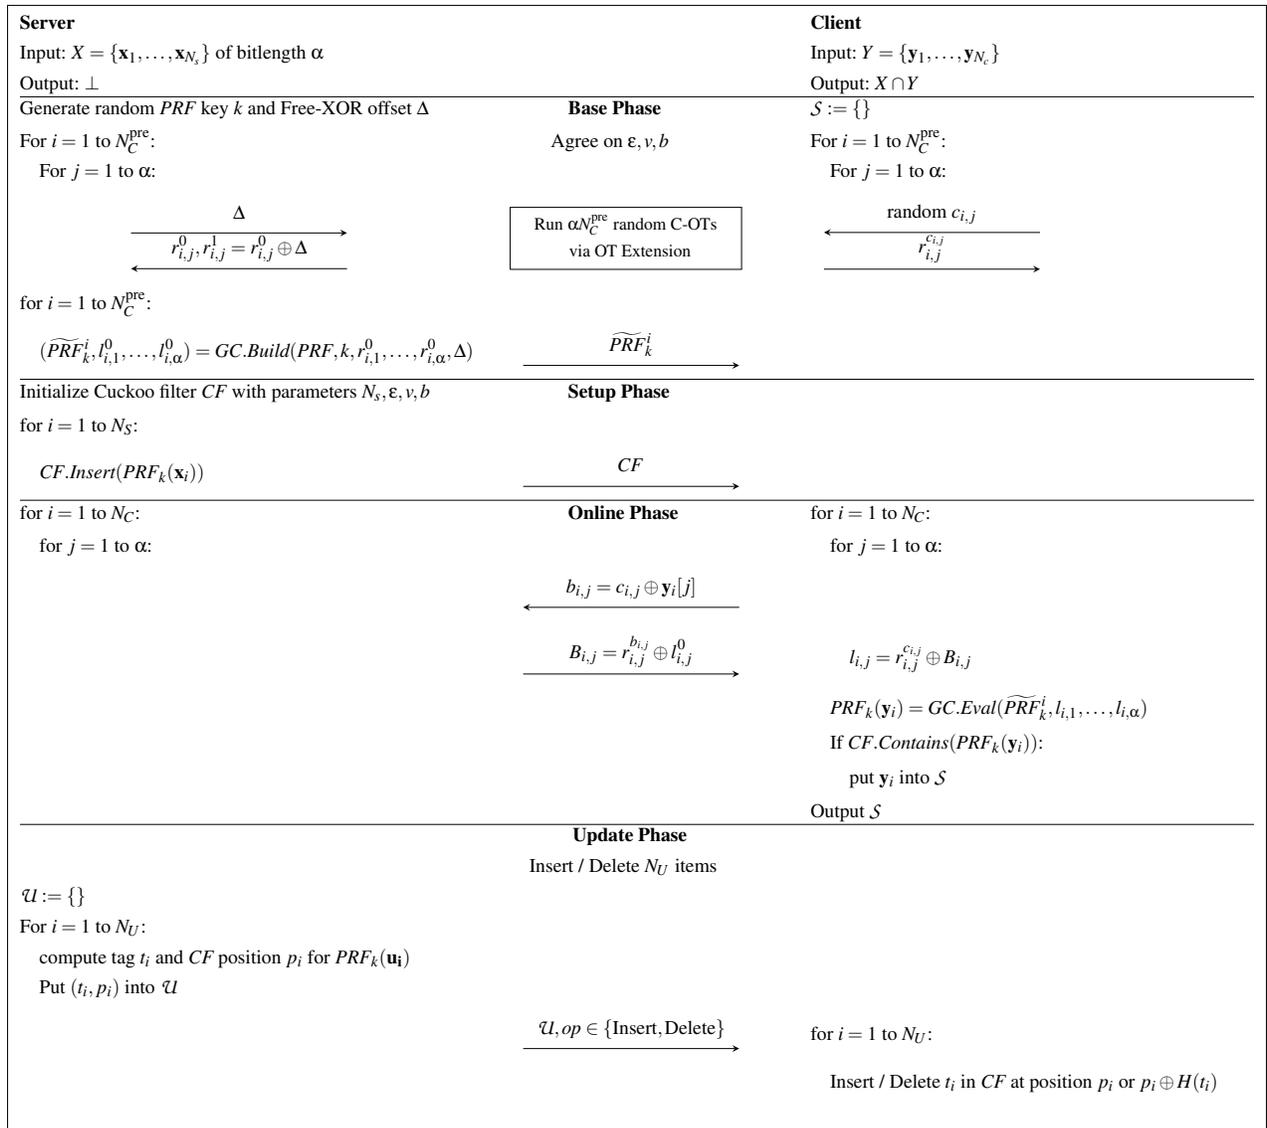

Figure 1: Our optimized GC-PSI protocol (based on [40, 52, 59]). Wire labels are computed as  $l_{i,j}^0 = r_{i,j}^0 \oplus \delta_{i,j}$  and  $l_{i,j}^1 = l_{i,j}^0 \oplus \Delta$ , where the values  $\delta_{i,j}$  are chosen at random while building the garbled circuit.  $N_C^{pre} \geq N_C$  denotes the number of precomputed OTs and garbled circuits; the base phase must be repeated before further online phase executions once  $N_C^{pre}$  queries are exceeded.

in case the random choice made by the receiver differs from its actual input. Thus, it would be necessary to swap input wire labels in the garbled circuits, which requires recomputing and resending at least the first layer of those circuits.

Our novel precomputation method circumvents this dilemma: In the base phase we run C-OTs via OT extension s.t. the garbler on input  $\Delta$  learns the random but correlated values  $r^0$  and  $r^1 = r^0 \oplus \Delta$ , whereas the evaluator upon random choice  $c$  learns  $r^c$ . For garbling we choose the labels for the input wires of the circuit as  $l^0 = r^0 \oplus \delta$  and  $l^1 = l^0 \oplus \Delta$ . Here,  $\delta$  is a newly introduced random value that in contrast to  $\Delta$  is not global but chosen individually for each label pair. In the online phase of the protocol, the evaluator sends a correction

bit  $b = c \oplus y$  stating whether its random choice  $c$  differs from the actual input  $y$ . The garbler responds with  $B = r^b \oplus l^0$ . This way, the evaluator learns either  $\delta$  or  $\delta \oplus \Delta$ . It then sets the label for its input to  $l = r^c \oplus B$ . As one can easily verify for the four possible combinations of random choices  $c$  and correction bits  $b$ , the evaluator always retrieves the correct label.

The security of the C-OT precomputation is based on the same arguments as standard OT precomputation [8] and since we use a fresh uniformly random  $\delta$  for each wire label, the resulting wire label is also uniformly random. In other words, we resolve the problem by fixing the wire labels but if necessary swapping the masks required to retrieve the correct label from the initial C-OT result.

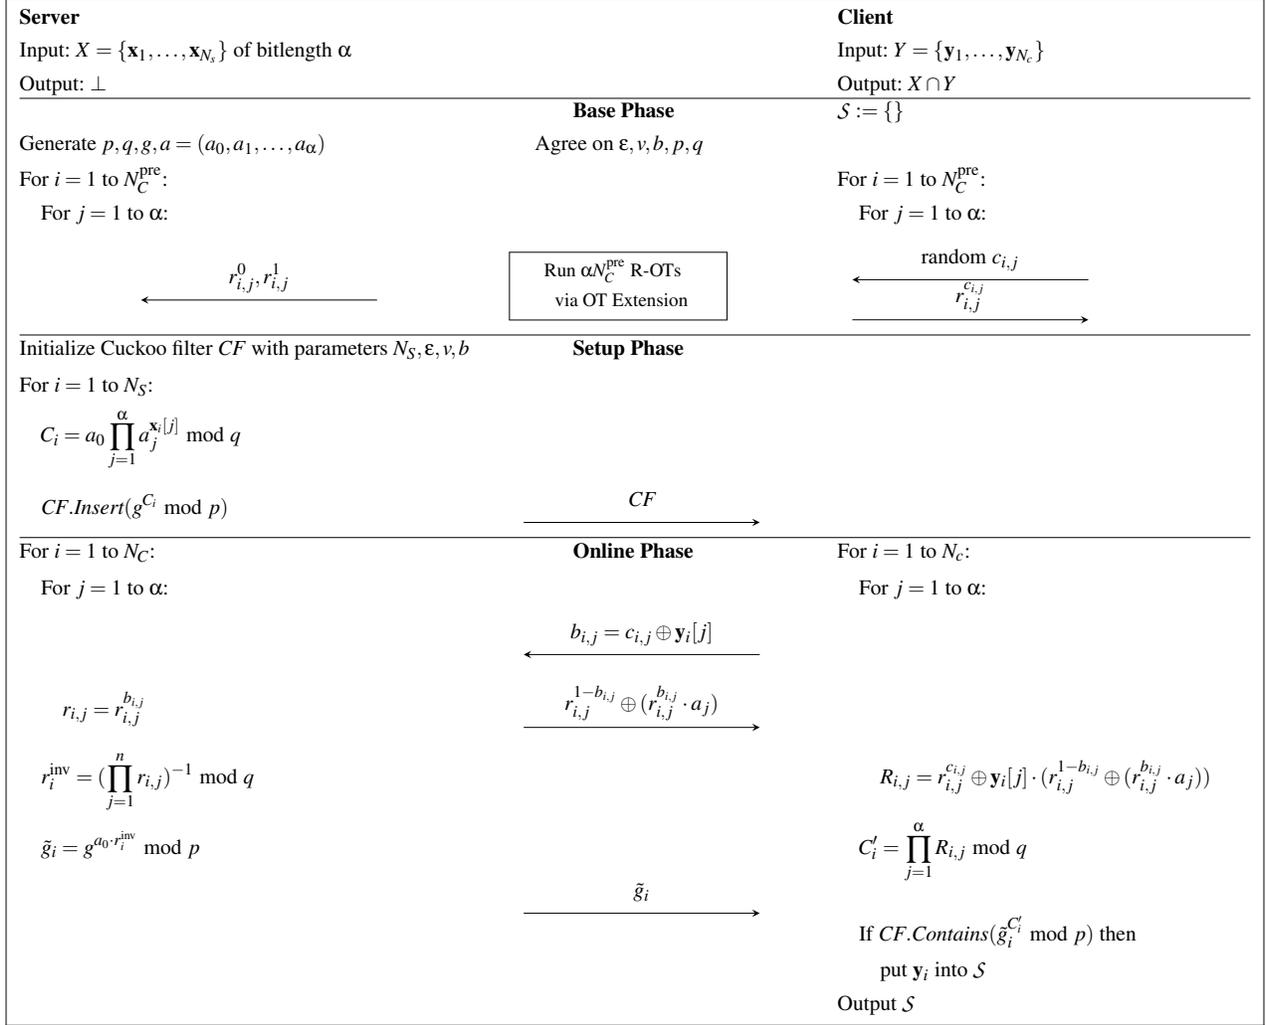

Figure 2: Our optimized NR-PSI protocol (based on [31, 40, 59]). When using a plain finite field, the modulus  $p$  is prime,  $q$  is a prime divisor of  $p - 1$ ,  $g \in \mathbb{Z}_p^*$  is of order  $q$ , and  $a_0, a_1, \dots, a_\alpha$  as well as  $r_{i,j}^0, r_{i,j}^1$  are random numbers in  $\mathbb{Z}_q^*$ . The update phase is omitted since it is similar to the GC-PSI protocol (cf. Fig. 1), except using the NR-PRF to compute tag  $t_i$  and CF position  $p_i$ .

#### 4.4 Optimized NR-PSI Protocol

The usage of the Naor-Reingold PRF (NR-PRF) [47] for PSI was first proposed in [31] and the resulting PSI protocol transformed into the precomputation setting in [40]. The NR-PRF for key  $k$  and element  $x_i$  is defined as

$$f_k(x_i) = g^{a_0 \cdot \prod_{j=1}^{\alpha} a_j^{x_{i,j}}} \bmod p, \quad (1)$$

where, when using a plain finite field,  $p$  is a prime,  $q$  is a prime divisor of  $p - 1$ ,  $g \in \mathbb{Z}_p^*$  is a generator of order  $q$ ,  $a_0, a_1, \dots, a_\alpha$  are random numbers in  $\mathbb{Z}_q^*$  forming key  $k$ , and  $\alpha$  is the bitlength of element  $x_i$ .

Among all protocols for mobile contact discovery evaluated in [40], NR-PSI is the only protocol besides GC-PSI that can easily be made secure against malicious clients by employing malicious secure OT extensions (cf. §4.5). Furthermore, according to the empirical performance comparison in [40], the

NR-PSI protocol causes  $\approx 30x$  less communication overhead than GC-PSI without our optimizations. This is why we also consider the NR-PSI protocol in this work and compare it to our optimized GC-PSI implementation in §6.

The full protocol description is given in Fig. 2. We propose an optimization that improves the online communication for OTs by factor 2x. The optimization is based on the observation that in the definitions of [31] the client chooses between a random  $r$  and  $r \cdot a$  depending on the current bit of its input element. This implies that C-OTs (cf. §3.1) can be used instead of real OTs, thereby sending only one message in the size of the symmetric security parameter instead of the two messages when using the OTe protocols of [3].

Since we use the precomputation form of [40], we propose a novel combination of OT precomputation [8] and C-OT [3]. As in OT precomputation, the client sends a correction bit  $b$  stating whether its random choice  $c$  in the precomputation

phase equals its real input. Depending on  $b$ , the server then decides which of the two random messages obtained during OT precomputation is chosen as  $r$  and which is used to mask the correlated message  $r \cdot a$  that is sent to the client. Likewise, the client either proceeds with the message obtained during OT precomputation as  $r$  or uses this message to unmask the received correlated message.

## 4.5 Malicious Security

As observed already in [40], the only messages sent by the client in the GC-PSI and NR-PSI protocols are those in the base OT and OT extension protocols as well as the correction bits during the online phase when applying OT precomputation [8]. Therefore, both protocols can easily be made secure against a malicious client by using a maliciously secure OTe protocol such as [4] or [39], together with maliciously secure base OTs such as [50]. As the OT extension contributes only a small percentage to the total runtime of the PSI protocols and today's maliciously secure OTe protocols are only slightly less efficient than the passively secure OT extension of [3], the total runtime of the PSI protocols does not increase by a noticeable amount when replacing the OTe protocols. Please note that enumeration attacks (i.e., querying the server repeatedly with different inputs) are still possible when using our protocols. However, even an ideal functionality for PSI (e.g., a trusted third party) and currently deployed non-private contact discovery methods cannot prevent this. We recommend to employ well-established measures like rate limiting to mitigate such attacks.

The case of a malicious server is different: it could, for example, send wrong wire labels, use wrong circuit descriptions, or send a wrong server set. In general, the client does not reveal the intersection result to the server, so a malicious server can only influence the correctness of the client's computation, but cannot learn any information about the client's items when using maliciously secure OTs. Unfortunately, in most mobile messaging applications, the client sends information about the intersection (most likely even the entire intersection) to the server. This allows a malicious server to learn information about the client's items that are not part of the intersection of the two actual input sets. Therefore, we need to assume a semi-honest server in such scenarios. Preventing malicious behavior on the server side could be done by combining our protocols with a trusted execution environment for hardware-enforced code and remote attestation capabilities s.t. the server's protocol deviation possibilities are restricted to wrong inputs for the Cuckoo filter construction. However, assuming a semi-honest server is reasonable since there are legal requirements and financial incentives for a service provider to behave correctly: once misconduct gets known publicly, users will abandon the malicious service and switch to a more trustworthy alternative.

## 4.6 Further Extensions

The bottleneck for very large server sets is the communication required to send the Cuckoo filter to the client. For example, a compressed Cuckoo filter for  $2^{28}$  server items with false positive probability  $\epsilon_{max} \approx 2^{-29}$  has a size of  $\approx 1$  GiB, which is prohibitively large for transmission on mobile network speeds and data plans. For even larger server databases, the protocols eventually become impractical. For example, for a server database with  $2^{31}$  entries, it would be necessary to download a Cuckoo filter of size  $\approx 8$  GiB. Therefore, we describe how to reduce the overall client-server communication to be logarithmic in the size of the server database. We propose further extensions to increase practicality in App. A.

### Combination with Private Information Retrieval (PIR).

In their PIR-PSI protocol, Demmler et al. [21] propose the use of multiple non-colluding servers together with a multi-server PIR protocol. Applied to our PSI protocols, the extension works as follows: After the server prepared the Cuckoo filter, it is not transmitted to the client, but to a second non-colluding server instead. Since the Cuckoo filter only contains the results of PRF evaluations, the second server does not learn anything about the items in the main server's set. The client then performs the OPRF evaluation for each of its items with the first server and then runs a multi-server PIR protocol to retrieve the fingerprints stored in the Cuckoo filter.

The communication complexity for the multi-server PIR lookup is  $O(\kappa \log n)$ , where  $\kappa$  is the symmetric security parameter and  $n$  the size of the server database [14, 21]. Since the overall client-server communication therefore is logarithmic and not linear in the size of the server database, our protocols are expected to remain practical even for server databases with more than a billion items. In practice, the remaining challenge for messaging services is to find a trustworthy partner operating the second PIR server while at the same time making it credible to users that no collusion is happening.

## 5 Android Implementation

To demonstrate the feasibility of our optimized PSI protocols for performing private contact discovery on mobile devices, we provide implementations for smartphones running on Android.<sup>6</sup> Previous works [34, 40] presented experiments on dedicated mobile devices, but the performance of these implementations was not sufficient for real-world usage. For example, the Java implementation of [40], which is based on the OblivM framework [43], takes more than a second to evaluate a single garbled AES-128 circuit. In our implementation, we make use of native C/C++ code support in Android and also use hardware acceleration for cryptographic operations available in modern smartphones. More precisely, native

<sup>6</sup><https://contact-discovery.github.io>

AES-128 instructions are used both as a PRNG and during the creation and evaluation of the garbled circuit. These features allow our implementation to reach truly practical performance. Compared to the Java-based implementation of [40], we evaluate a garbled AES-128 circuit more than 1,000x faster.

## 5.1 Base OTs and OT Extension

For performing base OTs, we use the OT protocol of Chou and Orlandi [20] with the additional verification step proposed by Doerner et al. [26]. Together with the (C-)OT extension protocol of Keller, Orsini, and Scholl [39], this results in a maliciously secure protocol (cf. [26]).

Our OT implementation is based on `libOTe` by Rindal [60], which is heavily optimized for the x86 architecture. Thus, we ported large parts of the library to the ARMv8 architecture to achieve high performance on mobile devices. At the same time, we kept the library compatible with its x86 counterpart to facilitate natural development of client-server applications.

## 5.2 GC-PSI Implementation

For the GC-PSI protocol, we implement Yao’s GC protocol (cf. §3.2) with Free-XOR [42] and Half-Gates [63], resulting in no communication for XOR-gates and two wire labels of  $\kappa$  bits each per AND gate, where  $\kappa = 128$  is the symmetric security parameter.

For creating and evaluating the garbled tables, the most efficient choice today is fixed-key AES [11], mainly due to the hardware support for AES that is widespread in modern x86 CPUs. The ARM Cryptography Extensions (CE) introduced in the ARMv8 architecture similarly provide hardware instructions for AES, SHA-1, and SHA-2 variants, resulting in AES speedups of factor 35x compared to a standard AES software implementation. This allows us to also use fixed-key AES [11] for garbling in our implementation.<sup>7</sup> Additionally, the ARMv8 architecture provides instructions for vector operations on 128-bit registers (the so-called NEON instruction set), which we use to efficiently work with 128-bit wire labels. In Tab. 7 in App. B, we demonstrate the wide availability of ARM CE in most recent smartphone processors.

## 5.3 NR-PSI Implementation

For implementing the NR-PSI protocol, we use the modified `libOTe` version described in §5.1 for C-OT precomputation as well as the GNU `GMP`<sup>8</sup> library for modular arithmetic operations and the `MIRACL`<sup>9</sup> library for instantiating the protocol

<sup>7</sup>As recently reported by [29], many secure computation implementations use fixed-key AES incorrectly. However, according to [29], our instantiation for garbling following the definitions of [63] is not affected. In contrast, `libOTe` [60] is currently vulnerable. The suggested fixes however are not expected to result in a significant negative performance impact [29].

<sup>8</sup><https://gmplib.org>

<sup>9</sup><https://github.com/miracl/MIRACL>

with elliptic curve P-256. The advantage of instantiating the NR-PSI protocol with ECC instead of using a plain finite field with comparable security parameters is that the size of the values  $\tilde{g}_i$  transferred during the online phase (cf. Fig. 2) is reduced by factor 8x. Also, computationally expensive modular exponentiations are replaced with point multiplications. We refer to this variant as ECC-NR-PSI in the following. All libraries are compiled specifically for the ARMv8 architecture.

## 6 Performance Evaluation

We empirically evaluate the performance of our optimized GC-PSI and NR-PSI protocols and compare them to other unbalanced PSI protocols from the literature.

**Benchmark Settings.** For easy comparison to related work, we choose similar sizes for the server’s and the client’s set:  $N_s \in \{2^{20}, 2^{24}, 2^{26}, 2^{28}\}$  and  $N_c \in \{1, 2^8, 2^{10}\}$ . Here,  $N_c = 1$  represents the case where a client wants to check a new contact. All items have a bitlength of  $\alpha = 128$ . We instantiate all primitives and protocols with 128-bit security.

In all of our experiments, the sever is equipped with an Intel Core™ i7-4600U CPU @ 2.6GHz and 16GiB of RAM. The client is a Google Pixel XL 2 smartphone with a Snapdragon 835 CPU @ 2.45GHz and 4GiB of RAM. We consider two network settings: (i) an IEEE 802.11ac WiFi connection with  $\approx 230$ Mbit/s down-/upload and 70ms RTT and (ii) a mobile LTE connection with 42Mbit/s download ( $S \rightarrow C$ ), 4Mbit/s upload ( $S \leftarrow C$ ), and 80ms RTT.

Note that the LTE network speeds are real-world parameters and exhibit a significant difference in the down- and upload rates. This is common in commercially available data plans and often not taken into account in previous evaluations.

### 6.1 GC-PSI and NR-PSI Protocol

The runtime and communication costs for the base, setup, and online phase of our protocols are shown in Tab. 3, Tab. 4, and Tab. 5, respectively, and are averaged over 100 executions (except for the setup phase, where we chose 10 or less executions due to the larger runtime). We use LowMC instance (3) from Tab. 2 for the evaluation. In all tests, only a single thread was used for both the server and the client. Since all phases of our protocols can be parallelized trivially, we expect a near-linear speedup when using multiple threads, except in situations where the bottleneck is network bandwidth. Furthermore, note that in the base and online phases of the GC-PSI protocol, only one party actually performs the computationally expensive task of garbling or evaluating the circuit. Therefore, if both parties are ready, the base and online phases of the GC-PSI protocol can be interleaved in a pipelined fashion, where the server sends the garbled circuits and the client evaluates them as soon as parts of them are available. This

Parameters $N_c^{\text{pre}}$	Protocol	Time [s]		Comm. [MiB]

	LowMC-GC-PSI	7.27	0.25	0.63	4.19
	ECC-NR-PSI	241.54			

Table 4: Setup phase of our PSI protocols. Server setup run once for *all* clients. The Cuckoo filter parameters are set as described in §4.1 ( $\epsilon_{\max} = 2^{-29.4}$ ,  $v = 32$ ,  $b = 3$ ). Best results marked in bold. Note that the size of the client set does not influence the runtime of the setup phase and the client does not send any data during the setup phase in any protocol.

method can reduce the runtime of the combined base and online phase to the runtime of the slower phase.

We observe that using LowMC instead of AES in the GC-PSI protocol leads to 7.4x less communication and thus to a much smaller runtime in the base phase, while the online phase of both protocol versions is very comparable. Only during the one-time setup phase, the AES version is more efficient due to AES-NI instructions. Using a hardware-accelerated implementation of LowMC could reduce this runtime close to the one of AES, but we again stress that the setup phase is a one-time cost. This confirms our choice of LowMC over AES as the PRF in GC-PSI.

ECC-NR-PSI is the most efficient protocol during the base phase since it does not send garbled circuits to the client: compared to the LowMC version of GC-PSI, it requires 12x less communication. The ECC-NR-PSI online phase is slightly slower than both GC-PSI protocols, while being the fastest for a single item. The one-time setup phase of the ECC-NR-PSI protocol is much slower than both GC-PSI protocol versions due to elliptic curve operations.

## 6.2 Comparison with Related Work

We now highlight differences to other works in the literature and compare our optimized GC- and NR-PSI protocols and implementations to other unbalanced PSI implementations available for Android in Tab. 6. Comparisons with implementations for the x86 architecture are given in App. D.

Parameters $N_c$	Protocol	Time [s]		Comm. [KiB]	
		WiFi	LTE	$S \rightarrow C$	$S \leftarrow C$
$2^{10}$	AES-GC-PSI	<b>1.43</b>	<b>1.86</b>	<b>2,048</b>	<b>16.00</b>
	LowMC-GC-PSI	1.71	2.02	<b>2,048</b>	<b>16.00</b>

Table 5: Online phase of our PSI protocols. Best results marked in bold. The influence of the server set size on runtime and communication is negligible and therefore not listed.

Chen et al. [18, 19]. The protocols of [18, 19] for unbalanced PSI are based on leveled fully homomorphic encryption (FHE). They both work as follows: the client encrypts all its items and sends them to the server, which then computes the intersection under encryption with all of its own items and returns the result in encrypted form. The client can then decrypt the received ciphertexts to find the intersection.

The protocol in [19] is only defined for 32bit strings, a limitation that stems from the parameter choice of the FHE scheme. Since the universe of possible items is larger than  $2^{32}$  in the use case of contact discovery, we exclude this protocol from further comparisons. However, this limitation was lifted in the subsequent work [18] where arbitrary length items are supported. The benefits of [18] compared to our protocols are that the client is not required to store any data and that the total communication is sublinear in the size of the server database. For example, for  $N_s = 2^{28}$ , the total communication in the protocol of [18] is only 18.4MB.

However, there is a huge computational overhead during the online phase of the protocol: even on a high-end server it takes more than 12s on 32 threads to compute the intersection with  $N_c = 1024$  client elements. Unfortunately, the online phase needs to be repeated whenever there are updates on client or server side. Also, due to the employed FHE batching optimizations, the runtime for a single item is almost equal to the runtime for thousands of items. Assuming that each of the  $N_s = 2^{28}$  registered clients runs one update per day, this would require the service provider to pay for  $2^{28} \cdot 12.1 \cdot 32 \approx 28.9$  million core hours every day. In contrast, the online phases of our protocols run in  $\approx 2$ s for  $N_c = 1024$  in the WiFi setting on a single-threaded smartphone and require no cryptographic operations on server side. The evaluation of [18] was performed on two servers with Intel Xeon CPUs in a 10Gbit/s local network. Therefore, it is also unclear how the FHE encryption and decryption routines perform in a mobile setting on real smartphones.

Resende and de Freitas Aranha [59]. In [59], the authors present implementation improvements for the PSI protocol of [7]. For each element in the client’s set, they perform 3

point multiplications and transmit 2 group elements. This results in a lower communication than our approaches (64 B for 2 group elements vs. 22 KiB per garbled circuit vs. 6 KiB per item in NR-PSI). However, one major contribution of [59] is a significant optimization of the GLS-254 curve for x86 CPUs. It is therefore unclear how their protocol performs on smartphones with ARMv8-A hardware. Furthermore, their Cuckoo filters parameters allow for a false positive probability that is too high for real-world deployment (cf. §4.1). Finally, their protocol assumes semi-honest adversaries, and while a maliciously secure variant [38] of their basic protocol exists, its performance has not yet been evaluated.

**Kiss et al. [40].** In [40], the authors consider various semi-honest PSI protocols, from which their GC-PSI and NR-PSI protocols are the foundation of our work. Their Android implementation (in pure Java) takes about 1.5 s for a single oblivious AES evaluation in their GC-PSI protocol. The authors therefore conclude that instead their ECC-DH-PSI protocol is most suited for the mobile use case since the evaluation time for a single item is 23 ms. However, both of our optimized protocols with security against malicious clients are more than competitive with an evaluation time of less than 2 ms for a single item. For  $N_c = 1024$  client elements, the combined base and online time of our optimized GC- and NR-PSI protocols improves by more than a factor of 300x and 30x, respectively, compared to the unoptimized semi-honest implementations of [40] in both the WiFi and the LTE network setting. Also, the total communication during the base and

online phase improves by factors 7.5x and 10.9x compared to the respective GC- and NR-PSI protocols of [40].

## 7 Conclusion

Our native implementations of our optimized NR- and GC-PSI protocols are two almost equivalently outstanding solutions for large-scale mobile private contact discovery with security against malicious clients. The Signal developers stated that to actually deploy PSI-based contact discovery, it would need to be able to handle a server database with 1 billion users while address books are assumed to contain up to 10,000 contacts. In terms of latency, lookups are required to take less than 2 s, while in terms of throughput a single core should be able to handle 1,600 contacts per second. Clearly, we cannot meet these demanding requirements yet. Therefore, as part of future work, we suggest to implement and evaluate our proposed extensions (especially the combination with PIR) to take the next important steps towards real-world deployment.

## Acknowledgments

This work was co-funded by the DFG as part of project E4 within the CRC 1119 CROSSING and project A.1 within the RTG 2050 “Privacy and Trust for Mobile Users”, by the BMBF and the HMWK within CRISP, and by the European Union’s Horizon 2020 research and innovation programme under grant agreement No 644052 (HECTOR). ## A Protocol Extensions

We propose further extensions for improving practicality.

**Combination with FHE Protocols.** Protocols for unbalanced PSI based on fully homomorphic encryption (FHE), e.g., [18], are computationally expensive and thus much slower during the online phase than our protocols (cf. §6.2). However, their advantage is that the total amount of communication is sublinear in the size of the server database. When clients install a new messaging application and are not connected to a high-speed WiFi network, such FHE-based protocols likely produce faster contact discovery results, which leads to higher user satisfaction. Thus, we recommend the following hybrid use of contact discovery protocols: Directly after installation of a mobile messaging application, a FHE-based protocol (e.g., [18]) is used to perform the initial contact discovery. Then, while the phone is charging overnight and is connected to a WiFi network, the base and setup phase of one of our protocols is performed. This leads to very efficient online phases for future protocol runs, which are performed regularly when updates on client or server side happen (potentially over mobile data plans where communication matters). See also §6.2 for a more detailed comparison between FHE-based unbalanced PSI protocols and our work.

### Dedicated Server for Cuckoo Filter Membership Tests.

In many scenarios, a large number of clients is part of a single organization. For example, consider the mobile malware detection scenario discussed in [40], where all applications installed on a client’s smartphone are checked against a database of malicious applications. When employing such a malware detection service in an enterprise context, a company usually buys a volume license for all of its employees.

To reduce the overall data communication, the company could host a dedicated server which would receive the large encrypted database of server items represented as a compressed Cuckoo filter once. If a client then wants to compute the intersection between installed and malicious applications, it only communicates with the malware detection service provider to

perform OPRF evaluations and then hands off the encrypted items to the trusted company server, which performs the set intersection on behalf of the clients and reports back the result. Since this trusted server does not have knowledge of the PRF key, it cannot directly deduce which items the client holds.

However, since the OPRF result is deterministic when using the same secret key, the trusted server can learn when multiple clients request the same item. Furthermore, it could interact with the malware detection service provider itself to obtain encryptions of known items, which it can compare to the encrypted items of the clients. However, this kind of leakage can be argued to be acceptable in many settings, such as the company-internal setting mentioned above.

**Partitioning the Database.** A simple solution to reduce the required communication during the setup phase is to partition the server database s.t. clients only download Cuckoo filters relevant for the contacts in their address book (for example w.r.t. number prefixes, states, countries, or regions).

Assuming that the majority of users has contacts in only very few such partitions, this approach leads to practical data transmission sizes even for services with billions of users. In the worst case (i.e., a user has contacts in all partitions or prefers to leak no information at all), multiple runs of our protocols can cover the worldwide user base.

However, this solution presents a significant performance / privacy trade-off since clients leak information about their social graph. For example, intelligence agencies might find it suspicious if US citizens evidently have contacts in middle eastern countries. How severe the privacy of users is threatened also depends on how fine-grained the chosen partitions are: if they are too small, it might even be possible to identify an individual just by observing Cuckoo filter downloads.

## B ARM Cryptography Extensions (CE)

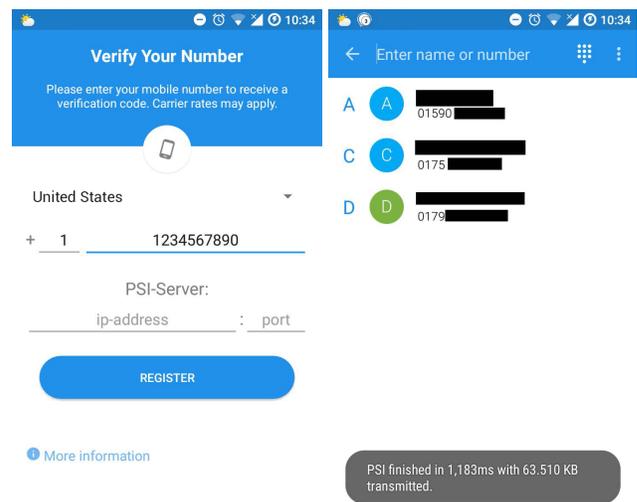

The wide availability of the ARM Cryptography Extensions (CE) in modern smartphone processors is highlighted in Tab. 7.

System-on-a-Chip (SoC)	Example Smartphones and Tablets	CE
Apple A4, A5, A6	iPhone 4, iPad, iPad 2, iPhone 5	✗
Apple A7, A8, A9	iPhone (5s,6), iPad Air, iPad mini 2	✓
Apple A10, A11, A12	iPhone (7,8,X,Xs), iPad (2018), iPad Pro	✓
Snapdragon 801	HTC One (E8), OnePlus One	✗
Snapdragon 805	Galaxy S5+, Nexus 6	✗
Snapdragon 808	Nexus 5X, LG G4, Moto X Style	✓
Snapdragon 810	OnePlus 2, Nexus 6P, Sony Xperia Z5	✓
Snapdragon 820	OnePlus 3, Galaxy S7, LG G5	✓
Snapdragon 821	Google Pixel (XL), LG G6	✓
Snapdragon 835	Google Pixel 2 (XL), Galaxy S8	✓
Snapdragon 845	OnePlus 6, Galaxy S9, Sony Xperia Z2	✓

Table 7: Availability of ARM Cryptography Extensions (CE) in modern smartphone and tablet systems-on-a-chip (SoCs).

## C Signal Integration Demonstrator

As a proof-of-concept, we modified the client application of the open-source messenger Signal to perform contact discovery using our PSI protocols. To be able to run the modified client with the official servers, the integration works as follows: Whenever Signal triggers the contact discovery routine, we run one of the PSI protocols with our own PSI server<sup>10</sup>. The resulting matches are then used as input for the unmodified Signal contact discovery routine. This way, the official Signal server only learns the hashes of phone numbers which are already registered to the service. Our changes to the user interface of the Android version of the Signal application are depicted in Fig. 3.

(a) Signal registration.

(b) Contact discovery result.

Figure 3: Screenshots of our prototype integration into the open-source messenger Signal.

## D Comparison of Unbalanced PSI Protocols on the x86 Architecture

The goal of our paper is to provide efficient private contact discovery for mobile messaging applications via improved unbalanced PSI protocols with implementations optimized for smartphones. Therefore, we focus our implementation and evaluation efforts on the mobile use case and perform our experiments on real smartphones with ARMv8 architecture. However, to present the complete picture, we give a comparison to protocols for unbalanced PSI running on x86 hardware and communicating in a local network in Tab. 8.

<sup>10</sup>In practice, this PSI server would be run by Signal and use the actual database of Signal users.

## Abstract

We present EverParse, a framework for generating parsers and serializers from tag-length-value binary message format descriptions. The resulting code is verified to be safe (no overflow, no use after free), correct (parsing is the inverse of serialization) and non-malleable (each message has a unique binary representation). These guarantees underpin the security of cryptographic message authentication, and they enable testing to focus on interoperability and performance issues.

EverParse consists of two parts: LowParse, a library of parser combinators and their formal properties written in F\*; and QuackyDucky, a compiler from a domain-specific language of RFC message formats down to low-level F\* code that calls LowParse. While LowParse is fully verified, we do not formalize the semantics of the input language and keep QuackyDucky outside our trusted computing base. Instead, it also outputs a formal message specification, and F\* automatically verifies our implementation against this specification.

EverParse yields efficient zero-copy implementations, usable both in F\* and in C. We evaluate it in practice by fully implementing the message formats of the Transport Layer Security standard and its extensions (TLS 1.0–1.3, 293 datatypes) and by integrating them into miTLS, an F\* implementation of TLS. We illustrate its generality by implementing the Bitcoin block and transaction formats, and the ASN.1 DER payload of PKCS #1 RSA signatures. We integrate them into C applications and measure their runtime performance, showing significant improvements over prior handwritten libraries.

## 1 Introduction

Because they are directly exposed to adversarial inputs, parsers are often among the most vulnerable components of security applications, and techniques to simplify their construction while ensuring their safety and correctness are valuable. Hence, developers prefer self-describing formats like JSON or XML (with universal implementations) or use automated tools and libraries to generate parsers from structured

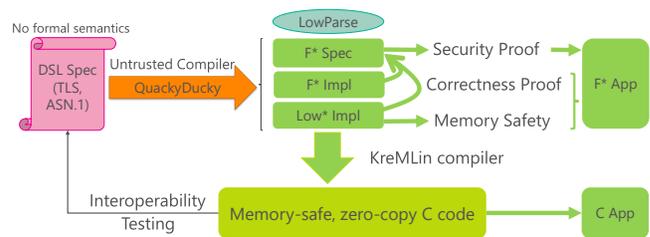

Figure 1: EverParse architecture

format specifications, or even from type declarations in Java or C++. However, when parsing is on the critical path of an application’s performance, or because of requirements of the message format (such as compliance with a standard), developers may be forced to write and maintain their own parsers and serializers in low-level unsafe languages like C, increasing the risk of attacks triggered by malicious inputs.

More specifically, when the application authenticates messages in some way—using for instance cryptographic hashes, MACs, encryptions, or signatures—it is critical for security to ensure that the messages are verified, parsed, and interpreted by the receiver exactly as intended by the sender before serialization. This is often at odds with general-purpose formats and tools that may not provide such non-malleability guarantees.

This paper presents EverParse, a new framework to automatically generate efficient, low-level parsers and serializers in C from declarative descriptions of tag-length-value (TLV) binary message formats. The generated parsers and serializers are formally verified to be *safe* (no use-after-free, no buffer overruns, no integer overflows, ...), *functionally correct* (parsers and serializers are inverse of one another), and *non-malleable* (valid messages have unique representations). With EverParse, developers of low-level protocols can enjoy the ease of programming and maintenance expected from parser generators, and stop worrying about details of the message format and trade-offs between security and performance.

**Architecture Overview.** Figure 1 depicts the overall architecture of EverParse and its two main components: a simple, untrusted frontend (named QuackyDucky) for compiling message format descriptions; and a library of verified parsers and serializers (named LowParse).

Verification is based on F\* [48], a programming language and proof assistant. Whereas F\* is a high-level functional language, whose code extracts by default to OCaml or F#, it also embeds a language named Low\* for writing verified low-level code that extracts to C using a tool named KReMLin [38]. EverParse uses Low\* to program efficient, low-level parsers and serializers, proving them safe, correct and non-malleable in F\*, and then extracting them to C. The resulting C code can be compiled using several off-the-shelf C compilers, including CompCert [28] for highest assurance, or more mainstream compilers like Clang or GCC.

The input of EverParse is a message format description for a collection of types, in the C-like language commonly used in RFCs and similar specifications. QuackyDucky translates this description into a collection of F\* modules, one for each input type, and F\* typechecks each of these modules to verify their safety and security. The modules produced by QuackyDucky include a formal parser specification (using high-level F\* datatypes) and two correct implementations of this specification: one high-level and the other in Low\*, suitable for extraction to safe C code. This lower-level implementation enables efficient message processing; it automatically performs the same input validation as the high-level parser, but it operates in-place using interior pointers to binary representations within messages. Its performance is similar to handwritten C code—but its safety, correctness, and security are automatically verified. Hence, rather than verifying existing, ad hoc C code by hand, which would require much effort and expertise even for small protocols, our toolchain automatically yields C code verified by construction.

The code generated by QuackyDucky consists of applications of *combinators* in LowParse, which are higher-order functions on parsers. For instance, given an integer parser, one can build a parser for pairs of integers by applying the concatenation combinator to two copies of the integer parser. While parser combinators are widely used in functional languages [22, 27], they are usually more difficult to apply in languages that do not easily support higher-order programming with closures, like C. However, by employing partial evaluation within F\*, we specialize higher-order code to efficient, ad hoc, first-order C code.

We carry out all proofs on combinators once and for all within LowParse. Only the conditions for composing them must be checked (by typing) in the code produced by QuackyDucky. LowParse is split into three layers: one for *specifications*, where we prove non-malleability, one for *high-level functional implementations*, which are proved functionally correct with respect to specifications, and one for *low-level implementations*, which operate on positions within buffers

and are proved functionally correct and memory safe.

EverParse code can be used in two ways. A verified F\* application can use the formal specification for its security proof, and either the high-level or low-level implementation—this is the approach adopted for verifying protocols as part of the Everest project [6], and notably the MITLS [7] implementation of the TLS secure channel protocol. Alternatively, a native C/C++ application can use the interface extracted from the Low\* implementation by the KReMLin compiler—this is the approach taken in this paper for performance evaluation.

**Our contributions** We present the following contributions:

- A definition of message-format security, motivated by a discussion of several vulnerabilities whose root cause is malleability (§2).
- QuackyDucky, a compiler from tag-length-value message format descriptions to their high-level datatype specifications and low-level implementations. It provides the first implemented zero-copy and secure message format language that captures several existing protocols and standards, including TLS, PKCS #1 signature payloads, and Bitcoin (§4).
- LowParse, a library of verified parser and formatter combinators, with support for non-malleability proofs (§5).
- A qualitative evaluation of EverParse: we present a complete case study of applying EverParse to the message formats of all TLS versions, featuring many improvements and corrections over the standard’s descriptions. We integrate the generated high-level implementation into MITLS, an implementation of the TLS protocol in F\*. For a few select types, we also replace the high-level implementation with the Low\* one (§3).
- A quantitative evaluation of EverParse: we compare the performance of our extracted low-level parsers for Bitcoin blocks and the ASN.1 payload of PKCS #1 signatures with their counterparts in Bitcoin Core and mbedTLS. We find that our automatically generated code meets, and in some cases significantly exceeds, the performance of hand-written C/C++ reference code (§6).

All the components of EverParse and its dependencies are open-source and publicly available at <https://github.com/project-everest/everparse>

## 2 Parsing Security: Definitions & Attacks

In this paper, we focus on applications that authenticate the contents of serialized messages in some way. Cryptographic mechanisms provide (serialized) bytestring authentication, whereas applications rely on (parsed) message authentication. Hence, correctness and runtime safety are not sufficient to preserve authentication: a correct parser may accept inputs outside the range of the serializer, or multiple serializations of the same message, which may lead to subtle, and sometimes

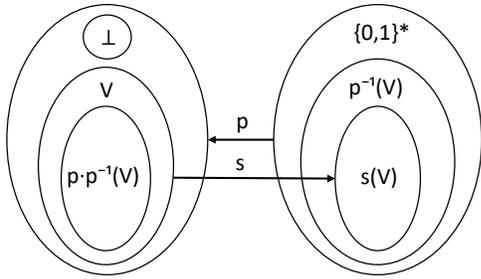

Figure 2: Parsing and serialization functions

devastating, vulnerabilities. We propose a security definition for authenticated message formats to prevent such vulnerabilities, and illustrate it using known high-impact attacks against popular applications.

## 2.1 What is a Secure Message Format?

We first set up notations for parsers and serializers, illustrated in Figure 2, and define their properties of interest. Given a set  $\mathcal{V}$  of valid messages,

- a *parser* is a function  $p : \{0, 1\}^* \rightarrow \mathcal{V} \cup \{\perp\}$  that returns either a message  $m \in \mathcal{V}$  or a parsing error  $\perp$ ;
- a *serializer*, or *formatter*, is a function  $s : \mathcal{V} \rightarrow \{0, 1\}^*$ .

Informally, parsers and formatters are inverse of one another. A parser is *correct* with respect to a serializer when it yields back any formatted message:  $\forall m \in \mathcal{V}, p(s(m)) = m$ , and *exact* when it accepts only serialized messages:  $p^{-1}(\mathcal{V}) = s(\mathcal{V})$ .

Parsers may also be considered on their own. A parser is *non-malleable* (or *injective*) when it accepts at most one binary representation of each message:  $\forall x, y \in \{0, 1\}^*, p(x) = p(y) \Rightarrow (x = y \vee p(x) = \perp)$ , and *complete* (or *surjective*) when it accepts at least one binary representation of each message:  $p(\{0, 1\}^* \setminus \{\perp\}) = \mathcal{V}$ . If  $p$  is a non-malleable parser for  $\mathcal{V}$ , then  $p^{-1}$  is a serializer over  $p(\{0, 1\}^* \setminus \{\perp\})$ .

We say that  $p$  is a *secure parser* for  $\mathcal{V}$  if  $p$  is non-malleable and complete. If  $p$  is secure, then it is also correct and exact with respect to the (unique) serializer  $p^{-1}$ . We say a serializer  $s$  is secure if there exists a secure parser  $p$  such that  $s = p^{-1}$ . (§5 provides more general definitions that account for parsers that do not consume their whole input.)

In the rest of the paper, we only consider parsers that operate on strings of bytes  $\mathcal{B} = \{0, 1\}^8$ .

## 2.2 Attacks on Parsers

**Heartbleed** Unsurprisingly, the most common type of parser vulnerability is simply memory safety bugs. Indeed, one of the most impactful attacks in the past decade, Heartbleed (which is estimated to have affected up to 55% of the top internet websites [17]) is a simple buffer overrun caused by improper validation of the length field in the TLS messages defined in OpenSSL’s implementation of the heartbeat protocol extension (shown in Figure 3). Interestingly, the spec-

```
struct {
    HeartbeatMessageType type;
    uint16 payload_length;
    opaque payload[payload_length];
    opaque padding[padding_length];
} HeartbeatMessage;
The total length of a HeartbeatMessage MUST NOT exceed
2^14 or max_fragment_length when negotiated [RFC6066].
The padding is random content that MUST be ignored by
the receiver. The padding_length MUST be at least 16,
and equal to TLSPlaintext.length-payload_length-3 for
TLS and DTLSPlaintext.length-payload_length-3 for DTLS
The sender of a HeartbeatMessage MUST use a random
padding of at least 16 bytes. The padding of a
received HeartbeatMessage message MUST be ignored.
```

Figure 3: Specification of the Heartbeat message (fragment)

ification of `HeartbeatMessage` is very unusual among TLS types (explained in detail in §3), because it contains a variable length field (`padding`) that is not prefixed by an explicit length (`padding_length` is not defined in the struct, but its value is defined semantically). Indeed, as specified, this type is not expressible in QuackyDucky because the padding length depends on a field of the parent `TLSPlaintext` type, and we only capture dependencies between fields that are concatenated. This forces applications to verify the `padding_length` semantically, increasing the risk of error. The Heartbleed disaster would likely have been averted if the format was specified using standard TLS constructors for variable length fields:

```
struct {
    HeartbeatMessageType type;
    opaque payload<0..2^14-21>;
    opaque padding<16..2^14-3>;
} HeartbeatMessage;
```

This example illustrates the benefits of writing message format descriptions in a constrained language: it encourages uniform patterns and enables automated analysis.

**PKCS #1 signature forgery** The PKCS #1 v1.5 signature format illustrates the risks of applying message parsing after a cryptographic operation (in this case, modular exponentiation). Given a public key  $(N = pq, e)$  where  $p$  and  $q$  are large secret primes, the raw RSA signature  $\sigma$  over a message  $m$  is computed as  $\sigma = m^d \bmod N$  where the secret exponent  $d = e^{-1} \bmod (p-1)(q-1)$  is hard to compute without knowing  $p$  and  $q$ . As written, this scheme is not usable because  $m$  must be smaller than  $N$ , and it has the undesirable homomorphic property that the signature of the product of 2 messages is equal (modulo  $N$ ) to the product of the signature of each message (thus, it is easy to forge new valid signatures from existing ones). To fix these shortcomings, PKCS #1 v1.5 defines a standard for hashing and padding the message to sign: given an arbitrary message  $m$ , it is first

hashed into a digest  $h$ , then stored together with the identifier  $a$  of the hash algorithm into an ASN.1 DER [36] structure. The distinguished encoding rules are supposed to ensure that the serializer  $\rho$  for this structure is secure. The final signature is obtained by applying raw RSA to  $\rho(a, h)$  left-padded to the size of  $N$  with padding of the form  $\backslashx00\backslashx01(\backslashxFF)^*\backslashx00$ .

The security of the scheme relies heavily on (the integer interpretation of) the padding: it is computationally hard to forge a valid signature  $\sigma$  because  $\sigma^e \bmod N$  must be of the form  $2^{\lceil \log_2(N) \rceil - 15} - 2^{\lceil \log_2(\rho(a, h)) \rceil + 1} + \rho(a, h)$  for some digest  $h$  and hash identifier  $a$ . It is hard to find such a value by brute force because all but the  $\lceil \log_2(\rho(a, h)) \rceil$  last bits are fixed, and inverting the modular exponentiation by  $e$  is hard without knowing  $d$ . However, if the ASN.1 parser  $\pi$  used after exponentiation is malleable (or non exact), there may exist a large class of inputs  $x$  such that  $\pi(x) = (a, h)$ . If this class contains inputs that fill most of the  $\lceil \log_2(N) \rceil$  bits of the message, the padding may be reduced to  $\backslashx00\backslashx01\backslashx00$ . When  $e$  is small ( $e = 3$  is commonly used by legacy public keys), it may be easy to find a value  $\sigma$  such that  $\sigma^e \bmod N = 2^{\lceil \log_2(N) \rceil - 15} + x$  with  $\pi(x) = (a, h)$  for any  $h$ . For instance, in Bleichenbacher's original description of the attack (retold by Finney [18]), the parser ignores the bytes that appear after the encoded ASN.1 structure, i.e. if  $\pi(x) \neq \perp$ ,  $\pi(x|z) = \pi(x)$  for all  $z$ . To forge a valid signature for  $h$ , one can simply compute the cubic root of  $2^{\lceil \log_2(N) \rceil - \lceil \log_2(\rho(a, h)) \rceil - 16}(\backslashx0100||\rho(a, h))$ .

Ever since its publication, this attack has reappeared in dozens of implementations, including several recent examples (e.g. [9, 13, 37, 49]). Interestingly, the parser malleability bugs that cause the attack are diverse: unparsed extra bytes are tolerated at the end of the message [18, 49]; the parser accepts arbitrary parameters in the algorithm identifier [9]; and a length overflow causes only its last 4 bytes to be counted [13]. This diversity illustrates how difficult it is to write secure parsers and to detect malleability vulnerabilities—some of the attacks above have existed for years in popular libraries. All variants lead to universal signature forgery: an attacker can freely impersonate any client or server, sign malicious code updates, etc.

**Bitcoin transaction malleability** Another well-documented case of parser security attacks occurred against Bitcoin [34] transactions, which are signed by the sender, then hashed (after serialization) and stored in Merkle trees. Transactions are identified by their hash, which covers more data than what the sender signs (in particular, the hash includes the signature itself). The format of transactions is malleable in several ways: one example is the encoding of this signature, which originally did not mandate the ASN.1 DER rules for non-malleability. Another source comes from the ECDSA signing algorithm, which is a randomized scheme (hence, there are many valid signatures for the same message) that always has two valid representations: if  $(r, s)$  is a valid signature, then  $(r, -s)$  also is, and can be trivially computed without knowl-

edge of the private key. Other sources of malleability are related to the `scriptSig` construct of the Bitcoin Script language,<sup>1</sup> inasmuch as the signature is passed to a stack-based script to authorize spending. In total, BIP62 [50] lists 9 different sources of malleability. Each of them allows an attacker to alter a valid transaction  $t$  into a semantically-equivalent valid transaction  $t'$  such that  $h(t) \neq h(t')$ . One way to exploit this is to try to fool someone into believing that a transaction they submitted was rejected by the network, although in reality, it was accepted under a different transaction hash. The Mt. Gox bitcoin exchange blamed this attack for the loss of over 850,000 bitcoins (worth \$473M at the time of bankruptcy) and although this claim is heavily disputed, later forensic examination of the blockchain by Decker et al. [12] revealed that in total, 300,000 bitcoins were spent over 30,000 transactions confirmed under a different identifier than originally submitted between Feb 1, 2014 and Feb 28, 2014.

**Ambiguous TLS message** Sometimes, the message specifications themselves are ambiguous, and cannot be implemented by a secure parser. This is the case of the `ServerKeyExchange` message in TLS:

```
enum {dh_anon, dhe, ecdhe, rsa, (255)} KeyExchange;
struct {
    select (KeyExchange) {
        case dh_anon: DHAnonServerKeyExchange;
        case dhe: SignedDHKeyExchange;
        case ecdhe: SignedECDHKeyExchange;
        case rsa: Fail; /* Force error: no SKE in RSA */
    } key_exchange;
} ServerKeyExchange;
```

This message represents an untagged union: the struct is missing a field of type `KeyExchange` that clarifies which case to use in the union. A parser for an untagged union can only be secure if the format of all cases share no common prefix. The specification of TLS assumes that the key exchange algorithm is available from the context (in this case, it is part of the negotiation process). However, it turns out that the security of the TLS negotiation depends itself on the `ServerKeyExchange` message. This leads to a real practical attack reported by Mavrogiannopoulos et al. [32], where a `SignedDHKeyExchange` is interpreted as a bogus `SignedECDHKeyExchange`. Worryingly, two other TLS types use untagged unions: `ClientKeyExchange` (in TLS 1.2) and `CertificateEntry` (in TLS 1.3).

### 3 Case Study: the TLS Message Format

We choose the TLS message format as our main case study for several reasons: the message format description of TLS is reasonably specified; it is designed to be secure and extensible; it defines hundreds of types that exercise the full range

<sup>1</sup><https://en.bitcoin.it/wiki/Script>

```

uint32 word; /* Type declaration */
word digest[16]; /* Fixed-length array of 4 words */
word phrase<0..2^8-1>; /* List of 0 to 16 words */
struct {
    opaque id[32]; /* Array of 32 bytes */
    uint16 payload<2..8>; /* List of 1 to 4 uint16 */
    digest payload_digest;
} body; /* Struct with 3 fields */
enum {
    request (0x2300), /* Constant tag */
    response (0x2301),
    (65535) /* Indicates 16 bit representation */
} header; /* Enum with 2 defined cases */
struct {
    header tag;
    select(tag) { /* Tagged union */
        case request: body;
        case response: phrase;
    } x; /* Enum-dependent field type */
} message;
struct {
    uint24 len; /* Explicit length */
    message data[len]; /* Ensures length(data)=len */
} batch; /* Length encapsulation */

```

Figure 4: Sample type descriptions in TLS message format.

of available combinators in LowParse; and there exists a verified F\* implementation of TLS that we can use to test the integration of the generated parsers (including the integration of parser security lemmas into the protocol security proof).

**Language Description** IETF’s RFC 2246 [14] specification of TLS 1.0, published in 1999, includes a section that describes the presentation language of its message format, inspired by C and XDR [46], and illustrated in Figure 4. A description consists of a sequence of type declarations. The base types are unsigned fixed-length integers `uint8`, `uint16`, `uint24`, and `uint32`, with `opaque` being used instead of `uint8` to indicate raw bytes. The type constructors are fixed-length arrays, variable-length lists, structs, enums, and tagged unions. The length boundaries of arrays and lists are all counted in bytes rather than in elements: for instance, type `digest` in Figure 4 is an array of elements of type `word` whose binary representation takes 16 bytes in total; since each `word` takes 4 bytes, this array holds exactly 4 elements. Arrays can be constructed only from fixed-length types, whereas lists can be defined for any types: as illustrated by `answer` and `payload`, their format declares the range of their length; and their binary representation embeds their actual length within that range.

Following the convention of RFCs, we interpret types in terms of the byte sequences that represent their elements. The representation of a struct is the concatenation of the representations of each of its fields in sequence, without any padding. Arrays are the concatenation of elements whose total length in bytes is the array’s annotated size. Lists are represented by

a length field encoded in a fixed number of bytes (determined by the maximum length of the list, encoded in big endian), followed by a concatenation of the elements. A special case of structs are length-dependent fields, e.g., the `batch` type in Figure 4. In these types the first field describes the length of a single (variable-length) element of the specified type of the second field represented adjacently. The interpretation of enumerations contains the big endian encodings of its elements in a constant number of bytes determined by the size descriptor of the enum type. Tagged unions (like `message` in the figure) are encoded as the concatenation of the tag’s enum representation followed by the encoding of the corresponding case’s type. TLS messages are more compact than many TLV formats: explicit tags only appear for tagged unions, and lengths only for lists (or when ascribed). All structural information is erased, in contrast with BSON [33] (which encodes field names) or Protocol Buffers [20] (which encodes field numbers).

We automatically extracted the data format descriptions from the RFCs for TLS 1.2 [15] (including descriptions also for TLS 1.0 and TLS 1.1), for TLS 1.3 [40], for TLS extensions (RFC 6066), and from the TLS IANA parameter assignments, which defines additional constants for enumerations. We then merged them together by hand, and edited some of them to fix minor mistakes, avoid name clashes in the original descriptions, and gain precision (e.g. by adding length dependencies documented in the RFC text).

**Extensibility** A difficult issue for any format description languages is extensibility: as new versions of the protocol are defined, it is often necessary to extend messages with new fields and cases while maintaining compatibility with older implementations. To address this problem, TLS was designed with extensibility through open enumerations. As a simple example, TLS has an enum type that defines the possible cipher suites to negotiate. Receiving a value that doesn’t match any of the defined cases of the enum is not a parsing error—instead, the value should be treated as unknown but valid, and the receiver should ignore it in the rest of the negotiation. This also applies to enums that act as a tag for unions. For instance, the hello messages contain a list of extensions tagged with an extension type. Although this is implicit in the standard, it is possible to define a default type for unknown values in a `select`. The protocol is extended by defining new values for enums (such as new cipher suites or new group names), and new defined cases for tagged unions (for instance, new extensions). Interestingly, many TLS implementations fail to understand this concept, and incorrectly reject unknown values. To fight this problem, Google recently introduced GREASE [4], which causes Chrome to randomly include undefined values in all extensible fields of the protocol, thereby enforcing that implementations that interoperate with Chrome be extensible.

Unfortunately, the TLS standard does not clearly say which

```

/* All TLS versions*/
struct {
    ExtensionType extension_type;
    opaque extension_data<0..2^16-1>;
} Extension;

/* From RFC 5246, section 7.4.2 */
opaque ASN.1Cert<1..2^24-1>;
struct {
    ASN.1Cert certificate_list<0..2^24-1>;
} Certificate;

/* From RFC 8446, section 4.4.2 */
enum { X509(0), RawPublicKey(2), (255)} CertType;
opaque ASN1_subjectPublicKeyInfo<1..2^24-1>;
struct {
    select (certificate_type) {
        case RawPublicKey: ASN1_subjectPublicKeyInfo;
        case X509: ASN.1Cert; } cert;
    Extension extensions<0..2^16-1>;
} CertificateEntry;
struct {
    opaque certificate_request_context<0..2^8-1>;
    CertificateEntry certificate_list<0..2^24-1>;
} Certificate;

```

Figure 5: The Certificate type for TLS 1.2 vs TLS 1.3.

enums and which tagged unions are extensible in the message format, and instead explain their intended semantics in text. In QuackyDucky, we add an explicit annotation to mark which enums are extensible, and we extend the syntax of `select` to support `default` cases. For instance, we mark the tag of extensions `ExtensionType` with the `/*@open*/` attribute, but not the tag of messages `HandshakeType`, as the RFC states that receiving any unknown message is an error.

**Protocol versions** Another complication stems from version differences not captured by extensibility. Consider the `Certificate` message in TLS 1.2 [15] and TLS 1.3 [40]. Its format, listed in Figure 5, illustrates several problems with the TLS specification. First, the two definitions of the `Certificate` type are mutually incompatible, even though the `Certificate` message is defined in both versions using the same `handshakeType` tag. Second, the `CertificateEntry` type of TLS 1.3 uses an untagged union, where the value of the tag depends on the context rather than on a value sent over the network (as in `ServerKeyExchange` and `ClientKeyExchange` where the key exchange algorithm is omitted). Third, the `Extension` type is under-specified: there are complex rules and tables about which extension may appear in which message (see [40, §4.2]), and the type of each extension contents depends on which message it appears in. None of these constraints are currently captured in type definitions.

To address the issue of conflicting definitions across versions, we split the definitions of incompatible types such as

TLS 1.2	TLS 1.3
<pre> struct {     HandshakeType type;     uint24 length;     select (type) {         case hello_request:             Empty;         case certificate:             Certificate12;         /* ... */         case finished:             Finished;     } m[length]; } Handshake12; </pre>	<pre> struct {     HandshakeType type;     uint24 length;     select (msg_type) {         case eoad:             Empty;         case certificate:             Certificate13;         /* ... */         case key_update:             KeyUpdate;     } m[length]; } Handshake13; </pre>

Figure 6: Specialized Handshake types for TLS 1.2 and 1.3

`Certificate` and we define version-specific variants of the handshake message type, shown in Figure 6. Before version negotiation, hello messages are parsed using a third, version-agnostic `Handshake` type. We then switch to parsers for the negotiated version, thus ensuring that the following messages are parsed using precise, version-specific types.

To address the problem of untagged unions, we introduce an `/*@implicit*/` attribute for tags, which instructs QuackyDucky to generate an interface where the value of the tag is passed as an additional argument to the parser and formatter. This approach is not compositional, and comes with a restriction: if a type that contains an implicit tag appears in another type, it must appear at a location that includes an explicit length. The parsing will be *staged*: when it reaches the surrounding length, it skips its contents, leaving it uninterpreted. The application needs to manually call the parser for the untagged union by providing the tag value. The presence of untagged unions is a clear mistake in message formats, as the application is responsible for providing the correct tag when it calls the parser, and thus, we only provide a conditional security guarantee in this case.

Similarly to what we did with message types, we split and specialize the definition of extension types for each message that may include them (hellos, hello retry, encrypted extensions, certificate, certificate request, new session ticket). This also reveals some interesting mistakes in RFCs. For instance, in [41, Appendix A], the authors fail to understand the purpose of the explicit length around extensions, and incorrectly believe it is redundant with the length of the list in the extension contents. They claim merging the two lengths makes the extension less ambiguous; in reality, their change makes the format *more ambiguous*: it is no longer possible to distinguish between receiving no ticket and receiving an empty ticket. To handle such corner cases, we add support in QuackyDucky to coerce `opaque` arrays with explicit lengths to `opaque` lists after parsing.

## 4 Compiling Message Format Descriptions

We now present our compiler from the message formats of §3 to parsers and serializers for processing these messages in  $\text{Low}^*$  [38]. We briefly review  $\text{F}^*$  and  $\text{Low}^*$  (§4.1), then explain the code generated by QuackyDucky in three parts: datatypes and parser specifications for verification purposes (§4.2); high-level functional parsers and serializers (§4.3); and lower-level code for reading (§4.4) and writing (§4.5) messages.

QuackyDucky recursively descends through the structure of the format description, generating parsers and serializers for compound types from those previously generated, while keeping track of their properties (notably their length boundaries). QuackyDucky mostly composes the combinators provided by  $\text{LowParse}$ , described in §5. In contrast with this library, which involves complex proofs for a few generic combinators, the generated code is verbose but shallow, enabling us to automatically verify its safety, correctness, and non-malleability using the properties verified in  $\text{LowParse}$ .

### 4.1 Verified Programming in $\text{Low}^*$ (Review)

**The  $\text{F}^*$  language and proof assistant** We carry out our specification, implementation and proofs using  $\text{F}^*$  [48], a functional language and proof assistant based on dependent types. A simple form of dependent types supported in  $\text{F}^*$  is *refinement types*, to represent types of values satisfying additional properties: whereas  $\text{int}$  is the  $\text{F}^*$  type of mathematical integers, the type  $\text{nat}$  of non-negative mathematical integers is defined as the refinement type  $(x: \text{int} \{ x \geq 0 \})$ .  $\text{F}^*$  supports types that depend on other types and values. It also supports functions where argument types can depend on the values of the previous arguments and the type of the return value of a function can depend on the values of its arguments. For instance, the integer division function, which would have a simple type  $\text{int} \rightarrow \text{int} \rightarrow \text{int}$  in a functional language such as OCaml, can be given a more precise type, such as  $(a: \text{int}) \rightarrow (b: \text{int} \{ b > 0 \}) \rightarrow (q: \text{int} \{ 0 \leq a - b * q < b \})$  meaning that  $\text{F}^*$  will reject, at typechecking time, any call to such a function if it cannot prove the second argument is strictly positive ( $b > 0$ ). Conversely, the caller can use the postcondition on its return value  $0 \leq a - b * q < b$  to prove further goals.

$\text{F}^*$  is not just a proof assistant: it is also a programming language enjoying automatic translation (*extraction*) into executable languages such as OCaml or C; in this extraction process, the user can mark some of their  $\text{F}^*$  functions as *ghost*, to have them erased at extraction time, such as lemmas and proofs, but also auxiliary functions that need not, or cannot, be executed at run time. To this end,  $\text{F}^*$  equips its function types with an *effect* system. By default, given two types  $t$  and  $u$ , all functions from type  $t$  to  $u$ , in the type  $t \rightarrow u$ , will be extracted, one says that they are in the  $\text{Tot}$  effect, so their type can be written as  $t \rightarrow \text{Tot } u$ ; to mark a function ghost, the user needs

to use the  $\text{GTot}$  effect, hence using the function type  $t \rightarrow \text{GTot } u$  instead. Stateful functions that operate on mutable objects (such as a mutable array of bytes, i.e. `uint8_t*` in C) live in the  $\text{ST}$  effect and are extracted to stateful OCaml or C code.

All  $\text{F}^*$  proofs rely on automatic encoding of proof obligations to first-order logic, which are then solved by automatic theorem provers such as Z3, leading to reduced overall proof effort.  $\text{F}^*$  also has a tactic system [31] that can be used in cooperation with, or in replacement of, Z3-based proofs.

**The  $\text{Low}^*$  subset of  $\text{F}^*$  and its extraction to C code** Users who wish to use our parsers and serializers not only demand performance, but also the ability to integrate our code into their codebases. Therefore, OCaml is oftentimes not a viable option; instead, we compile our  $\text{F}^*$  code to C.

As shown in Figure 1, specifications are first implemented in  $\text{F}^*$ . This implementation can already be compiled to C using a dedicated compiler,  $\text{KReMLin}$ . However, lacking further restrictions, this  $\text{F}^*$  implementation relies on lists and bytes as values, meaning that compiling the  $\text{F}^*$  implementation through  $\text{KReMLin}$  generates code that (i) is inefficient, because it uses functional byte copies and linked lists; (ii) is not idiomatic: no C programmer would write such code; and (iii) requires a garbage collector, since lists and bytes are persistent values with no lifetime (as in, say, OCaml).

To avoid these shortcomings, the  $\text{Low}^*$  [38] subset of  $\text{F}^*$  defines a C-like memory model that talks about the stack and the heap, along with corresponding abstractions and libraries, e.g. for mutable arrays, machine integers and in-place loops. Using  $\text{Low}^*$  requires the programmer to rewrite their code and reason about spatial and temporal safety; in exchange for these added constraints, the  $\text{F}^*$  code is compiled by  $\text{KReMLin}$  to idiomatic, readable, efficient C code that does not require a garbage collector. The  $\text{Low}^*$  restrictions only apply to executable code; computationally-irrelevant portions of the program, such as proofs and ghost code, retain the full power of  $\text{F}^*$ , since they are eliminated when compiled to C.

### 4.2 Datatypes and Parser Specifications

Continuing from §2.1, we use  $\text{F}^*$  types to represent sets of parsed values. Hence, QuackyDucky generates a parsed type  $t$  for each named format description in its input.

Our  $\text{F}^*$  types for parser and serializer specifications are listed below.

```
type parser (t:Type) (k:meta) =
  p: (input: seq uint8 → GTot (option (t * l: nat{! ≤ length input})))
  { parser_prop k p }

type serializer (#t:Type) (#k:meta) (p: parser t k) =
  s: (t → GTot (seq uint8))
  { ∀ (x:t) . p (s x) == Some (v, length (s v)) }
```

The parser type definition is parameterized by a parsed type  $t$  and some metadata  $k$  (explained below) that records verified properties of the parser. It states that a parser is a pure function

that takes as input a sequence of bytes (of arbitrary length) and returns an optional result that consists of some parsed value of type  $t$  and the number of input bytes consumed.  $\text{GTot}$  states that this parser is ghost, that is, used only for verification; option indicates that it may return nothing in case parsing fails; the refinement  $l \leq \text{length input}$  ensures that it consumes at most a prefix of its input; the refinement  $\text{parser\_prop } k \ p$  states that  $p$  is *non-malleable* (see formal definition in §5) and that it satisfies the properties recorded in  $k$ .

The metadata  $k$  includes a verified range of lengths of input that the parser may consume. This range provides useful bounds for programming with this parser, for instance to wait for a minimal number of input bytes before parsing, or to allocate I/O buffers of adequate sizes. Internally, QuackyDucky also relies on this information to select more efficient implementations (for example when the input length is fixed) and to require that some parsers consume at least one byte (for example to compute the length of a list from its binary format). The metadata may include additional properties, indicating for instance that the parser always fails; or that it always succeeds given enough input bytes; or that it is no-lookahead (see §5).

The serializer type definition is indexed by a *parser* for  $t$ , not just by  $t$  (the # makes this parameter an implicit argument, as it can be inferred from  $p$ ). It states that a serializer specification is a pure, total, ghost function from values of type  $t$  to sequences of bytes, such that parsing its output for any value  $v$  of type  $t$  succeeds and yields back  $v$  and its binary length.

**Running Example** Consider the following excerpt of the TLS 1.3 wire format description [40] for the body of its first ClientHello message.

```
struct {
  ProtocolVersion version;
  opaque random[32];
  opaque session_id<0..32>;
  CipherSuite cipher_suites<2..2^16-2>;
  Compression compressions<1..2^8-1>;
  ClientHelloExtension extensions<0..2^16-1>;
} ClientHello;
```

This message includes a 2-byte protocol version, a 32-byte random nonce, a variable-length session identifier for resumption, and variable-length list of proposed cipher suites, compression methods, and extensions. QuackyDucky translates it to a corresponding F\* record type:

```
let in_range x min max = min ≤ x ∧ x ≤ max
type clientHello = {
  version : protocolVersion;
  random : (b:bytes {Bytes.length b == 32});
  session_id : (b:bytes{in_range (Bytes.length b) 0 32});
  cipher_suites : (l:list cipherSuite{in_range (List.length x) 1 32767});
  compressions : (l: list compression{in_range (List.length l) 1 255});
  extensions : (l: list extension{in_range (extensions_bytesize l) 0 65535});}
```

This high-level type includes precise length information, coded as refinements. Since the elements of the first three

lists have constant binary lengths, QuackyDucky computes precise bounds on their numbers of elements. Conversely, the extensions in the last list are themselves of variable lengths, hence QuackyDucky captures the bounds on its total binary size using an auxiliary function `extension_list_bytesize` previously defined from the `extension` serializer. The main benefit of capturing these constraints is to ensure that *all* messages of type `clientHello` can be serialized to a standard-compliant bytestring.

QuackyDucky also generates the corresponding metadata, parser and serializer specifications.

```
let clientHello_meta = {low=43;high=131396; ...}
val clientHello_parser: parser clientHello_meta clientHello
val clientHello_serializer: serializer clientHello_parser
```

The parser metadata is exposed in the generated interface (indicating, e.g., that the shortest TLS `clientHello` body message takes 43 bytes) whereas the parser and serializer specs are kept abstract—the interface gives their types, but hides the details of their wire format. Thus, the three lines above state the abstract, joint properties of our generated parser and serializer specs (including non-malleability and round-trip properties) and typechecking these specs ensures these properties hold.

Anticipating on the combinators defined in §5, we give below an outline of the generated definition of `clientHello_parser`, which parses our sample message by successively calling the parsers corresponding to each of its fields:

```
let clientHello_parser =
  ((protocolVersion_parser × clientHello_random_parser) × ...)
  synth (fun ((pv, r), ...) → { protocolVersion = pv; random = r; ... })
```

These definitions are used only as reference implementations and are not extracted to C. In a second stage, QuackyDucky generates actual parsers and serializers, and typechecking their code ensures they safely implement these specs.

### 4.3 Functional Parsers and Serializers

QuackyDucky generates high-level functional parsers and serializers, with the following interface. (The “32” suffix indicates that their code uses 32-bit machine integers instead of the unbounded integers in their specs.)

```
val clientHello_parser32: parser32 clientHello_parser
val clientHello_serializer32: serializer32 clientHello_serializer
```

We systematically index our implementations by their specifications. Here, for instance, the type definition `parser32`  $p$  used above simply states that a high-level parser for the parser-specification  $p$  is a pure function that takes a (bounded, immutable) F\* bytestring and returns the same result as  $p$  on the corresponding sequence of bytes except that the consumed length is an unsigned 32-bit integer.

We give below an F\* code sample illustrating their use: a ‘reader’ function that counts the number of cipher suites in a given ClientHello message in wire format, and a ‘writer’ function that builds a message given a configuration.

```

let count_ciphersuites (input: bytes): UInt32.t =
  match clientHello_parser32 input with
  | None → 0ul
  | Some ch → List.length ch.ciphersuites

let compute_extensions config: (l: list extension {...}) = ...

let hello (cfg: config) : bytes =
  clientHello_serializer32 {
    version = TLS_1p3;
    random = config.random;
    ...;
    extensions = compute_extensions config; }

```

This code and its supporting parsers and formatters operate on immutable bytestrings. Although it can be safely extracted to C, it is inefficient, and the implicit allocations and copies mandate the use of a garbage-collector. For example, `clientHello_parser32` allocates 4 lists and briefly uses only one.

#### 4.4 Low-Level Accessors and Readers

To provide more efficient implementations, QuackyDucky also generates code for a lower-level API that enables in-place processing of messages in their binary formats.

We begin with a low-level alternative to parsing. For each parser specification  $p$ , QuackyDucky provides functions that operate on an input buffer. A *validator* reads the input buffer and returns either the number of bytes that  $p$  would consume by successfully parsing its contents, or an error code. Thus, successful validation ensures the existence of a high-level message in binary format, but does not construct it. Assuming the input buffer is valid, then, for each field of the message, an *accessor* computes the position of the first byte in its binary representation. This guarantees in particular that this representation of this element of the message is also valid. Accessor computations are similar to pointer arithmetic in C, or “get element pointer” computations in LLVM, but they sometimes require reading the lengths of intermediate parts in order to skip them. For each base type (e.g. 16-byte unsigned integers), a *reader* takes an input buffer and position and actually parses and returns a value of that type.

Continuing with our example, QuackyDucky produces a validator for `clientHello` and an accessor for every field (shown below only for its `cipherSuites`).

```

val clientHello_validator : validator clientHello_parser
val accessor_clientHello_cipherSuites :
  accessor
  clientHello_parser
  clientHello_cipherSuites
  clientHello_cipherSuites_parser

```

The type definitions `validator` and `accessor` are still parameterized by parser specifications, but they are more complex, since they describe functions that operate on pointers to mutable buffers. We represent their input as a *slice*, that is, a Low\* buffer (§4.1) and its length, and a *position* within this slice.

(Experimentally, computations on integer positions based on a single pointer are simpler to verify, and better optimized by C compilers.) Accordingly, our validators return either the final position in the slice after successful validation, or an error coded as a large integer. We illustrate their use by re-implementing the `count_cipherSuites` example of §4.3 in Low\*.

```

let count_ciphersuites_inplace (input:slice) (pos:UInt32.t) =
  let pos_final = clientHello_validator input pos in
  if max_length < pos_final then 0ul (* invalid input *)
  else
    let pos_ciphersuites = accessor_clientHello_cipherSuites input pos in
    clientHello_cipherSuites_count input pos_ciphersuites

```

The last line calls another QuackyDucky-generated function that returns the length of a list of cipher suites in wire format. In this case, since each cipher suite takes exactly two bytes, this length is computed without actually reading the list content, by dividing its binary length by two.

Unsurprisingly, this function yields C code of the form:

```

// A slice is the pair of a byte array and its size
typedef struct {uint8_t * base; uint32_t len; } slice;
uint32 count_ciphersuites_inplace(slice input, uint32 pos) {
  uint32 pos_final = clientHello_validator(input,pos);
  if (max_length < pos_final) return 0;
  else {
    uint32 pos_ciphersuites = accessor_clientHello_cipherSuites(input,pos);
    return clientHello_cipherSuites_count(input,pos_ciphersuites);
  }
}

```

Once compiled by Clang, we can check on the resulting machine code that the ‘else’ branch eventually boils down to (1) adding 34 to `pos` to skip the first two fields; (2) reading and adding the one-byte length of the third field; (3) reading the two-byte length of the fourth field and shifting it by one.

Validators, accessors, jumpers and readers are specified using a *validity* predicate,  $\text{valid}(p, m, b, i)$  stating that the parser  $p$  succeeds when provided the bytes in buffer  $b$  starting from offset  $i$  in memory state  $m$ . If this predicate holds, then, thanks to the injectivity property of  $p$ , there is a unique value  $\text{contents}(p, m, b, i)$  returned by the parser, and an offset  $\text{getpos}(p, m, b, i)$  within  $b$  one past the end of the representation of that value. This validity predicate is the post-condition of validators when they succeed, and is the precondition of jumpers and readers; accessors for struct fields have the validity predicate for the struct (resp. field) parser as a precondition (resp. postcondition). We give below the type definitions for validators and readers:

```

type validator (#k: meta) (#t: Type) (p: parser k t) =
  (input: slice) → (pos: U32.t) → ST U32.t
  (requires (fun m → live_slice input pos ∧ input.len ≤ max_length))
  (ensures (fun m pos m' → m ≡ m' ∧
    (valid(p, m, input, pos) ⇔ pos' ≤ max_length) ∧
    (pos' ≤ max_length ⇒ pos' == getpos(p, m, input, pos))))

type reader (#k: meta) (#t: Type) (p: parser k t) =
  (input: slice) → (pos: U32.t) → ST t
  (requires (fun m → valid(p, m, input, pos)))
  (ensures (fun m res m' → m ≡ m' ∧ res == contents(p, m, input, pos)))

```

## 4.5 Low-Level Writers

We finally describe our low-level API for serializing a message in an output buffer. Our goal is to avoid intermediate allocations and copies; for example, our high-level `hello` function constructs the whole message before serializing. To this end, QuackyDucky generates families of low-level writers and auxiliary functions that take as parameter an output slice (that is, a buffer and a length) and a write position, modify the buffer between this position and the end of the buffer, and return a new write position. These functions either require that the output buffer is large enough (based on parser metadata) or may also return an error in case the buffer is too small.

In contrast to accessors, which enable random access to validated input in binary format, it is not generally possible to know in advance where to write data before writing any preceding variable-length data. Thus, our API assumes that data will be written sequentially, with the flexibility for the programmer to use an intermediate buffer whenever they choose to write data out of order. A notable exception is for encoding the lengths of variable-length data, which is usually known only after writing the raw data itself. To this end, QuackyDucky provides a *finalizer* that takes two positions in the output buffer, requires as a precondition that the buffer contain a placeholder for the length followed by a valid binary representation of the raw data, computes and writes its length, and ensures as a post-condition that the buffer now contains a valid variable-length representation of this data.

We illustrate these different cases on a low-level variant of the `hello` function, whose Low\* and extracted C code are shown in Figure 7. The first field, `version`, is an enumeration formatted in a fixed two-byte format: it is directly written using the QuackyDucky writer for `protocolVersions`. The second field, `random`, is a fixed-length, previously-allocated bytestring that can be copied from the configuration. Omitting intermediate fields, which may be handled similarly, the last field is a complex list of extensions. The list itself is written by repeatedly calling the extension writer on each element, after skipping the 2 bytes required for their total length. The computed length of the list is finally written by calling a QuackyDucky finalizer.

As a cumulative post-condition of all these steps, we know that the output buffer now contains the concatenation of a valid binary format for each of its fields, and we can conclude that it thus also contains a valid representation of a `clientHello` message by calling the *validity lemma* `clientHello_valid` also generated by QuackyDucky and verified by F\*. The call to this lemma is erased before extraction to C code.

As an important simplification, our sample code requires as static precondition that the output buffer be large enough to hold any valid `clientHello` message. In more realistic code, one would need to dynamically check this length. (Each of these writer functions are fail-safe, but their errors still need to be propagated.)

```
let write_extension_list cfg output pos = ...
  (* write a list of extensions computed from the configuration *)

let write_hello cfg output pos =
  (* write 2 bytes of protocol version *)
  let pos_after_protocol_version =
    write_protocolVersion output pos TLS_1p3 in
  (* copy 32 bytes from the configuration *)
  memcpy cfg.random 0ul out.base pos_after_protocol_version 32ul;
  let pos_after_random = pos_after_protocol_version + 32ul in
  (* similarly write or copy the other fields *)
  let pos_after_session_id = ... in
  let pos_after_ciphersuites = ... in
  let pos_after_compressions = ... in
  (* leave two bytes for the total length of the extension list *)
  let pos_list = pos_after_compressions in
  (* calls an auxiliary function to write the extension list in-place *)
  let pos_after_extensions =
    write_extension_list cfg output pos_list in
  (* computes and writes the extensions length at pos_after_compressions *)
  finalize_clientHelloExtensions
  output pos_after_compressions pos_after_extensions;
  (* call the validity lemma for the clientHello message *)
  let m = get () in clientHello_valid m output pos;
  (* return the final position *)
  pos_after_extensions
```

```
uint32_t write_extension_list(config cfg, slice output, uint32_t pos);
uint32_t write_hello(config cfg, slice output, uint32_t pos)
{
  uint32_t pos_after_protocol_version =
    write_protocolVersion(output, pos0, TLS_1p3);
  memcpy(cfg.random + 0, output.base + pos_after_protocol_version, 32);
  uint32_t pos_after_random = pos_after_protocol_version + 32;
  ...
  uint32_t pos_list = pos_after_compressions + 2;
  uint32_t pos_after_extensions =
    write_extension_list(cfg, output, pos_after_compressions);
  finalize_clientHelloExtensions
  (output, pos_after_compressions, pos_after_extensions);
  return(pos_after_extensions);
}
```

Figure 7: Sample Low\* code for writing a TLS client hello (above) and its translation to C (below).

## 5 LowParse: Secure Parser Combinators

As we have seen in §4.2, QuackyDucky produces parser implementations by composing basic parsers using *combinators*, which are higher-order functions on parsers. For example, a combinator for pairs may take parsers for types  $t$  and  $u$  and yield a parser for type  $t \times u$ . Its implementation may first parse a message of type  $t$ , then parse a message of type  $u$ .

LowParse is our library of parser combinators, based on the long tradition of *monadic* parser combinators [22] in the functional programming community. However, LowParse is unique in that it is tailored to support the verification of non-malleable, correct parsers. We focus on combinators at the

QuackyDucky Syntax	Data Type	Parser Combinator
<code>uintN</code> , $N \in \{8, 16, 32, 64\}$	Unsigned integer within $0..2^N - 1$	<code>parse_uN</code>
<code>t[N]</code> , $N \in \mathbb{N}$	Fixed-size array of $ts$ of length $N$	<code>plist[p] truncN</code>
<code>t&lt;M..N&gt;</code>	List of $ts$ , of variable length $M..N$	<code>vldata(plist[p], M, N)</code>
<code>t{M..N}</code>	List of $ts$ of variable element count $M..N$	$(\text{parse\_uk filter } (n \mapsto M \leq n \leq N)) \triangleright (n \mapsto p^n)$ where $k = 8 \times \log_{256} N$
<code>struct</code> { $t_1$ $x_1$ ; ...; $t_n$ $x_n$ ;	Record with $n$ fields named $(x_i)$ of type $(t_i)$	$(p_1 \times \dots \times p_n)$ <code>synth</code> $((v_1, \dots, v_n) \mapsto \{x_1 = v_1; \dots; x_n = v_n\})$
<code>struct</code> { ...; <code>uintN</code> $x$ ; $t$ $y[x]$ ; ... }	Variable-length field $y$ prefixed by its length $x$	<code>vldata</code> ( $p, 0, 256^{N/8} - 1$ )
<code>enum</code> { $E_1(N_1)$ , ..., $E_n(N_n)$ , ( $M$ )}	Constant integer enumeration (with maximal value $M = 2^N - 1$ )	<code>penum</code> ( <code>parse_uN</code> , $\{(E_1, N_1); \dots; (E_n, N_n)\}$ )
<code>struct</code> { $t$ $x$ ; <code>select</code> ( $x$ ) { <code>case</code> $E_1$ : $t_1$ ; ...; <code>case</code> $E_n$ : $t_n$ } $y$ }	Tagged union ( $t$ must be an enum type)	$p \triangleright_f q$ where $f(E_i, x) = E_i$ and $q(E_i) = p_i$ <code>synth</code> ( $y \mapsto (E_i, y)$ )

Figure 8: The QuackyDucky input language and the corresponding LowParse combinators: everywhere in this table,  $p_i$  is the parser for type  $t_i$ . All lengths are counted in bytes except otherwise mentioned.

specification level and their security properties, then discuss more briefly their implementations. For each specification combinator, we prove non-malleability and inverse properties; for each implementation combinator, we prove both safety and correctness. All properties are verified by typing the library.

Figure 8 summarizes the QuackyDucky input language and the corresponding LowParse combinators. We designed QuackyDucky and LowParse in a modular way, making it easy to extend the surface syntax of QuackyDucky by providing additional combinators. For instance, the `t x{M..N}` syntax for variable-size lists prefixed with their number of elements is a late addition to support the Bitcoin application in §6.2 but is not required for TLS.

We first define the properties attached to the specifications of §4.2. We prove a stronger version of non-malleability than the one given in §2.1, extending the definition there to handle parsers that may not consume all their input.

**Definition 1** A parser  $p$  for type  $t$  is non-malleable if, whenever it succeeds and returns the same parsed value on two inputs, it also returns the same number of consumed bytes, and the two inputs coincide on these bytes.

We also rely on the following no-lookahead property:

**Definition 2** A parser  $p$  has the strong prefix property when, if it succeeds on an input and consumes  $\ell$  bytes, then it returns the same result on any inputs with the same first  $\ell$  bytes.

For a serializer to exist for a format that requires concatenating two value representations valid with respect to two parsers  $p_1, p_2$  (such as pairs, lists, tagged unions, or variable-length data),  $p_1$  is required to have the strong prefix property. Consider for instance serializing a pair of two pieces of data  $x_1, x_2$  using serializers  $s_1, s_2$  correct with respect to parsers  $p_1, p_2$ . We would like to prove that the serialization  $s(x_1, x_2) = s_1(x_1) \cdot s_2(x_2)$  obtained by concatenating the two serializations, is correct with respect to the parser for pairs. By correctness of  $s_1$ ,  $p_1(s_1(x_1))$  succeeds and

returns  $(x_1, |s_1(x_1)|)$ , but this is not enough to know that  $p_1(s_1(x_1) \cdot s_2(x_2))$  succeeds and also returns  $(x_1, |s_1(x_1)|)$  (so that we can cut the input after  $|s_1(x_1)|$  and apply  $p_2$  on the remainder,  $s_2(x_2)$ ), unless  $p_1$  has the strong prefix property.

These properties are included in the definition of `parser_prop` on the metadata generated by QuackyDucky, hence enforced by typing for all its parser specifications.

## 5.1 Specification Combinators

LowParse is an extensible library of combinators. For each parser specification combinator, we attach a corresponding metadata combinator; then, we define, when possible, a serializer combinator.

**Parser combinators** We define primitive parser combinators below. For each of them, we prove injectivity and any relevant additional properties indicated in their metadata, such as the strong prefix property. We also define derived combinators; in contrast, all their properties are established automatically as the result of their definitions (by type unification and matching on their metadata). The code produced by QuackyDucky only inserts annotations to prove their composability conditions, for instance, by computing the length boundaries of the derived metadata, which are then verified by  $F^*$ .

We start by defining primitive parser combinators: `fail`, which consumes no input and fails; `ret[x]`, which consumes no input and succeeds returning  $x$ ; `read_byte`, which consumes and returns a single byte of input; and `and_then`, which sequentially composes two parsers where the second parser depends on the value parsed by the first parser (i.e., monadic composition). For each of these basic combinators, we prove non-malleability and/or the strong prefix property under suitable conditions. For instance, `p and_then q` has the strong prefix property provided that  $p$  has it,  $q[x]$  has it for all  $x$ , and, moreover, if  $q[x_1]$  and  $q[x_2]$  succeed on inputs  $b_1$  and  $b_2$ , respectively, and return the same value, then  $x_1 = x_2$ . (Otherwise, consider for example  $p = \text{read\_byte}$  and  $q = \text{ret}[0]$ .)

Using those primitive combinators, we define derived combinators, for which verification of non-malleability and meta-data correctness automatically follows by typing. Given parsers  $p_0$  and  $p_1$  for  $t_0$  and  $t_1$ , respectively, we can derive a parser for pairs of type  $t_0 \times t_1$  using  $p \times q$ ; mapping functions over parsed results using  $p$  synth  $f$ ; filtering parsed results by some predicate using  $p$  filter  $f$ ; etc. proving non-malleability and the strong prefix property for them under suitable conditions.

More specifically, we derive parsers for fixed-length machine integers, and we prove their non-malleability for both endiannesses. For instance, we define little-endian 16-bit parsing as  $(\text{read\_byte} \times \text{read\_byte}) \text{ synth } ((x, y) \mapsto x + 256 \times y)$ .

Our next combinators support variable-length data and lists:

- Given a parser  $p$  for type  $t$ , the parser  $\text{plist}[p]$  is defined by repeatedly applying  $p$  to its input. It fails as soon as  $p$  fails or consumes zero bytes. If succeeds when  $p$  eventually consumes its whole input and then returns the resulting list of values.
- Given a parser  $p$  for type  $t$  and  $n > 0$ , the parser  $p \text{ trunc } n$  succeeds when  $p$  succeeds on its input truncated to its first  $n$  bytes and consumes exactly  $n$  bytes.

The parser  $\text{plist}[p]$  does not have the strong prefix property, but it consumes all its input. The parser  $p \text{ trunc } n$  always has the strong prefix property, even if  $p$  does not. If  $s$  is a correct serializer for  $p$  at type  $t$ , then  $p \text{ trunc } n$  is a parser for type  $x : t\{|s(x)| = n\}$  and  $s$  is its correct serializer at that type.

We finally present further derived combinators, whose properties are automatically verified by construction:

*Tagged unions:* if  $p$  is a parser for type  $t$  and  $f : u \rightarrow t$  and  $q[x]$  is a parser for type  $(y : u\{f(y) = x\})$  for every  $x : t$ , then:

$$p \triangleright_f q = p \text{ and\_then } (x \mapsto q[x] \text{ synth } (y \mapsto y))$$

is a parser for type  $u$ . This combinator is a strengthening of  $\text{and\_then}$  that enforces non-malleability of  $q$  by making its codomain dependent:  $u$  is the union type, and  $t$  is the tag type, and  $f$  gives the tag of an element of the union type. From there, we define a combinator for *sum types*, which can be used for tagged unions.

*Enum types:* if  $l$  is a list of key-value pairs where each key and each value only appear once, then it defines both a closed enum type (whose elements are the keys that appear in  $l$ ) and an open enum type (whose elements are the known keys that appear in  $l$  and the unknown values that do not appear in  $l$ ). We define parsers for both variants  $\text{penum}(p, l)$  (where  $p$  is the value parser), using  $\text{filter}$ ,  $\text{synth}$  and the dictionary function on key-value pair lists.

*Variable-sized data:* formats such as TLS often specify variable-length data as a payload prefixed by its size in bytes. If  $p$  is a parser for the payload, and if  $s$  is a serializer correct with respect to  $p$ , then we define

$$\begin{aligned} \text{vldata}(p, l, h) = & \text{parse\_u}_\ell \circ \text{filter}(n \mapsto l \leq n \leq h) \\ & \triangleright_f(n \mapsto p \text{ trunc } n) \end{aligned}$$

as a parser for the refined type  $(x : t\{l \leq |s(x)| \leq h\})$ , where  $\ell = 8 \times \lceil \log_{256}(h) \rceil$ , is the bit size of the size integer prefix, and  $f(x) = |s(x)|$ . Such parsers inherit the strong prefix property from the parser for the prefix size, regardless of whether it holds for  $p$ .

**Correct Serializers** Not all parser specifications have correct serializers. For instance,  $\text{ret}[x]$  and  $\text{and\_then}$  do not have a generic serializer. So, in `LowParse`, we provide serializer combinators for  $\text{read\_byte}$ ,  $\text{fail}$ ,  $\text{plist}$ ,  $\text{synth}$ , and  $\triangleright$ , for each of which we prove correctness with respect to its corresponding parser combinator (i.e., that they are inverse of one another). We also easily prove that a correct serializer for  $p$  is also correct for  $p \text{ trunc } n$  and  $p$  filter  $f$  (once its domain is restricted accordingly). From there, we derive correct serializers for  $\times$ ,  $\text{nlist}$ ,  $\text{vldata}$ , etc. for which the correctness proof automatically follows by typing.

## 5.2 Implementation Combinators

For each parser-specification combinator, `LowParse` provides combinators for its high-level parser and for its low-level validators and jumpers (and similarly for serializers). For primitive combinators, we implement their corresponding validators jumpers and serializers; for each of them we prove memory safety and functional correctness with respect to their specification. We implement most derived combinators by following the same construction as for their specs, by assembling the corresponding implementation combinators. Thus, their memory safety and functional correctness automatically follow by typing. We also define accessor combinators for  $\text{synth}$  and tagged unions, and accessors for pair elements, from which `QuackyDucky` derives accessors for struct fields and sum types.

By design, our combinators are inherently higher-order and so they cannot directly be extracted to C. Instead, we rely on meta-programming features of `F*` and `KReMLin`, based on source code annotations, to ensure that all combinator code is inlined and specialized before extraction. In most cases, this is achieved by annotating our source code. In other cases, we extend `LowParse` with `F*` tactics [31], pieces of `F*` metaprograms written once and for all and evaluated at typechecking time to automatically generate `Low*` validators from some type definitions. For example, our validators for enum values and tagged unions are specified using constant key-value lists. Instead of programming a loop on these lists, we meta-program their unrolling at compile-time, which yields a cascade of `ifs` automatically turned into a `switch` by many C compilers. In rare cases, such as unions tagged with an enum value, we write additional validator combinators to more precisely control their inlining by `F*` and `KReMLin`.

In addition, metadata allow us to provide some generic validator combinators that apply regardless of the actual parser combinator. For example, if we know that a parser consumes a constant  $n$  bytes and always succeeds, then we can use a

	QD	F* LoC	Verify	Extract	C LoC	Obj.

validator that just jumps  $n$  bytes. QuackyDucky selects these combinators based on the metadata it computes.

## 6 Integration and Evaluation

We evaluate the integration of EverParse-generated parsers for three applications: the TLS message format, integrated into mITLS; the Bitcoin block and transaction format, integrated into the Bitcoin Core benchmark; and the ASN.1 payload of PKCS #1 signatures, integrated into mbedTLS.

Table 1 shows for each application the lines of QuackyDucky input specification, the amount of F\* code generated, the time required for verification and KReMLin extraction, and the size of the C code and compiled objects. The Bitcoin evaluation was performed on a 28-core Xeon E5-2680 v4 CPU with 128GB of RAM, running with turbo boost and all but one core disabled. The rest of the figures were collected on a 10-core Xeon W-2155 CPU with 128GB of RAM, running F\* commit 7b6d77 with Z3 4.5.1 and GCC 7.4.

### 6.1 TLS Message Format

As described in §3, we have specified the TLS message format for all versions of TLS from 1.0 to 1.3. However, integrating the generated parsers presents some major challenges: implementations tend to define their own representations of messages, with field and tag names that differ from the RFC, and some of them like mbedTLS interleave the parsing and processing of messages. mITLS [7] uses functional, high-level parser implementations and types, operating on values. Most of the basic data types (such as cipher suite names) are defined in a module called `TLSCONSTANTS`, while some specialized ones scattered in other modules (e.g. group names in `CommonDH`). Extension types and parsers are in the `Extensions` module, while message types and parsers are in `HandshakeMessage`. We noticed that these files contain many assumptions and incomplete proofs, many of which have been completed for earlier drafts of TLS 1.3, but not updated as the formats changed (with EverParse, such updates and extensions only require a few changes to the format description).

In total, in order to switch to the high-level implementation produced by QuackyDucky, we update or rename over 200 types (and propagate these changes), which requires 2,865 additions and 3,266 deletions over 38 files (according to our Github pull request). Unlike LowParse, mITLS individually proves the non-malleability of each parser as a lemma separate from parser definitions instead of a refinement; the mITLS

proofs for such lemmas are lengthy and intricate. So, we define a `LowParseWrappers` module to replace such proofs with a uniform call to LowParse parser property lemmas. Our changes do not break other existing proofs, but several generated types are more precise than the handwritten ones (notably, all lists are refined to ensure they can be serialized), which leads to additional conditions to prove in many functions. The generated parsers are also a lot stricter: for instance, we now check at parsing which extensions can appear in a message, and which messages can appear for the negotiated version.

To test the impact of EverParse parsers, we run the simple HTTP client and server tool distributed with mITLS to compare how many requests can be served, using the default algorithm choices. This tool is not optimized for production and processes requests sequentially. We compare the time to process 500 requests between the original mITLS parsers and EverParse high-level parser implementations.

	mITLS	mITLS-EverParse
HTTP requests	49.8 req/s	53.3 req/s

Integrating the low-level Low\* implementations into mITLS requires a large effort, as many functions that are currently pure (operating on values such as lists) become stateful (the buffer that contains the valid positions matching each value must be live). To anticipate the benefits of this effort, we run a synthetic benchmark that validates all messages from a public dataset of TLS handshakes published by Lumen [39]. This dataset contains handshake produced by a wide range of clients and servers, and contains over 13GB of data (including the BSON overhead). As a baseline, we compare in-place validation time with the cost of checking the message length, allocating a buffer of the message size, and copying the contents of the message in the buffer.

Memcpy		EverParse	
1,864 MB/s	1.761 cy/B	2,684 MB/s	1.177 cy/B

### 6.2 Bitcoin Blocks and Transactions

To show that EverParse is extensible and evaluate the performance of its low-level parsers, we implement the Bitcoin block and transaction format, listed in Figure 9. We do not implement Segregated Witness (“segwit”), an extension that overloads the semantics of a length in the block format to conditionally add a new field to the block structure, because it requires a very ad-hoc combinator. Bitcoin requires two LowParse extensions: one for the encoding of “compact integers” (`bitcoin_varint`), and one for lists prefixed by their size in elements rather than in bytes.

For compact integers, the representation may either use 1, 3, 5, or 9 bytes depending on whether the value of the first byte is respectively less than 252, 253, 254, or 255. It is not clear from the Bitcoin documentation and wiki that the format of compact integer is not malleable (e.g. 4636

```
opaque sha256[32];
struct {
    sha256 prev_hash; uint32_le prev_idx;
    opaque scriptSig<0..10000 : bitcoin_varint>;
    uint32_le seq_no;
} txin;
struct {
    uint64_le value;
    opaque scriptPubKey<0..10000 : bitcoin_varint>;
} txout;
struct {
    uint32_le version;
    txin inputs{0..1000 : bitcoin_varint};
    txout outputs{0..11110 : bitcoin_varint};
    uint32_le lock_time;
} transaction;
struct {
    uint32_le version;
    sha256 prev_block; sha256 merkle_root;
    uint32_le timestamp;
    uint32_le bits; uint32_le nonce;
    transaction tx{0..2^16 : bitcoin_varint};
} block;
```

Figure 9: QuackyDucky specification of Bitcoin blocks

could be represented as `fd121c`, or `fe0000121c`). However, we checked that the Core implementation enforces the shortest representation in the `ReadCompactSize` function. Additionally, we allow list types to specify in their range the type of integer used to encode the prefix length or size (e.g. `txin inputs{0..2^14 : bitcoin_varint}`). A drawback of prefixing lists by their number of elements is that the theoretical maximum length of the formatted list can get extremely large. For instance, the maximal size of a well-formed Bitcoin block is over  $2^{320}$  bytes (in practice, it is well-known that non-segwit blocks are at most 1MB). To avoid overflowing OCaml’s 63-bit arithmetic in the parser metadata length computations in QuackyDucky, we must write more conservative boundaries. Scripts are known to be at most 10,000 bytes. Historically, all non-segwit blocks in the main chain contain less than  $2^{16}$  transactions (although the maximum is higher). It is more difficult to bound the number of inputs and outputs of a transaction. If we assume a transaction is standard (at most 100,000 bytes) and all inputs are signed (their script is at least 64 bytes), there are less than 1000 inputs. Since outputs can be as short as 9 bytes, a transaction can have over 11000. Our test data is blocks 100,000 to 110,000 of the Bitcoin blockchain, totaling 21MB. To experimentally check those assumptions, we parsed all of these blocks and confirmed they are accepted by our validator.

For benchmarking, we measure: first, the performance of our zero-copy block validator compared with the built-in deserialization function of the Bitcoin Core client (`commit`

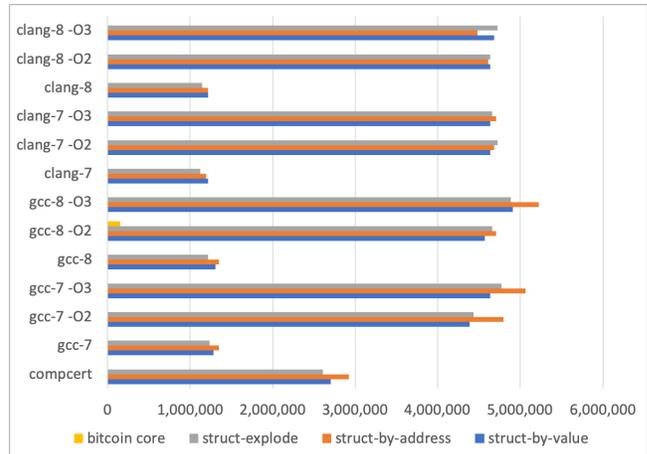

Figure 10: Synthetic performance comparison for validating 10,001 Bitcoin blocks. Throughput in kiB/s, higher is better.

`cbe7efe`); second, the performance variations of our zero-copy block validator across compilers and optimization levels; third, the performance impact of fine-grained code-generation options passed to KReMLin (Figure 10). For each one of those benchmarks, we report numbers in kiB/s, i.e. the throughput; we only occasionally report cycles per byte since most of our validators run at less than 1 cy/B.

The first measurement compares the performance of our code against a reference implementation, namely, Bitcoin Core. Bitcoin uses a custom template for serializing C++ objects. This template is well-optimized and tries to rely on casts and the in-memory representation of base types as much as possible. However, it is not zero-copy: parsing relies on the memory allocated for the C++ object, and serialization requires a copy to the output buffer. The benefit is that the data can be accessed using standard data structure libraries such as `std::vector` for lists. Bitcoin provides a built-in benchmarking tool for many of its features, including block deserialization and validation in `src/bench/checkblock.cpp`.

We modify this benchmark to use our test data of 10,001 blocks and deserialize all of them in each run. The benchmark deserializes 130 times, and reports the median over 5 runs. We keep the default compiler options (`gcc-8, O2` optimization level). The measured throughput is 152,786 kiB/s, which translates to 15 cy/B on the test machine used for the Bitcoin measurements. We then validate the same 21MB of data using our validators, with the same compiler and optimization levels. We obtain a throughput of 4,568,632 kiB/s, which is less than a cycle per byte, for the default KReMLin configuration.

While the validation performance of our code is excellent, we do not claim that this benchmark is representative of real application usage, as it doesn’t account for the overhead of accessor functions to read the block and transaction contents. Nevertheless, this shows that our verified low-level implementation is competitive with hand-optimized formatters.

Second, we measure performance variations across compiler versions. The performance is comparable between the two most recent versions of Clang and GCC, for optimization levels O2 and O3. Unsurprisingly, the default setting without optimization yields much slower code, but even then, we remain considerably faster than the original Bitcoin code. We also measure the performance of our code compiled with CompCert [28]. We find that CompCert is consistently 42% slower than GCC and Clang with optimizations, but still more than twice as fast as GCC or Clang without optimizations. We conclude that our code lends itself well to optimizations by modern compilers, and that users do not need to enable the (risky) O3 performance level to get maximum performance out of Clang or GCC.

Third, we experiment with various compilation schemes of the KReMLin compiler for the core type `LowParse.slice.slice`, a two-field C struct (representing a byte buffer through its base pointer and length) which in the default configuration is passed by value (§4.4). Two alternate compilation schemes are considered. First, passing both the base pointer and length as separate arguments to functions; this is the “struct-explode” category, and yields no performance improvement. Second, we pass those structures by address, relying on an unverified transformation in the KReMLin compiler, similar to CompCert’s `-fstruct-passing` feature. This yields modest performance improvements for GCC 7 and GCC 8 at the higher optimization levels (3% to 9%). We conclude that our generated C code is satisfactory and that we don’t need to either rewrite our code to pass slices by address (a substantial proof burden) or instruct KReMLin to perform this transformation (which would increase the trusted computing base).

Finally, we perform fuzz testing on the X64 machine code of our generated bitcoin-block validator as compiled with `gcc-8 -O2`. (Although our verification results ensure memory safety for all inputs, fuzzing may still, in principle, detect bugs in our toolchain and the C compilers we use.) We use SAGE [19], a fuzzer specialized to parsers, which generates random input, valid or not, and feeds them to the validator which SAGE automatically instruments to check for buffer overflows. As expected, SAGE reported no bugs after 21,664,448 inputs tested at an average rate of 599 inputs per minute.

### 6.3 ASN.1 Payload of PKCS #1 Signatures

Our last example is the payload of PKCS #1 signatures introduced in § 2.2. We extend `LowParse` with a combinator for the encoding of ASN.1 DER lengths. This encoding is particularly convoluted: if a length is less than 127, it is represented over a single byte. Otherwise, the 7 least significant bits of the first byte encode the length in byte of the shortest big endian representation of the length. This means the length can be at most  $2^{2^{1016}} - 1$ . To avoid overflows, we only support values of the first byte less than 132 (i.e. 32-bit lengths). An issue with

the specification is the lack of dependency between the object identifier of the hash algorithm and the octet string of the actual digest: the application is required to check the digest is of the correct length if it tries to parse the signature contents. We capture this dependency by only making the outermost sequence variable length, and by parsing the object identifier as a constant tag of an union of fixed-length arrays. (Note that this is for illustration only, the recommended approach is to serialize the computed hash, and use a constant time comparison with the un-padded signature contents instead).

We integrate our code into `pkcs1_v15_verify` function of `mbedtls`, and modify the built-in benchmarking tool to measure the PKCS #1 signature verification time instead of the raw public key and private key operation time measured by default. In addition, we also export the internal function to format the ASN.1 payload of the signature (`pkcs1_v15_encode`), and compare it with our extracted formatter functions. The following table compares the amount of operations per second and cycles per operation for complete signature verification, and for the encoding of the ASN.1 payload:

Operation	mbedtls		EverParse	
Verify	79K op/s	5,700 cy/op	79K op/s	5,649 cy/op
Encode	31M op/s	14 cy/op	134M op/s	3 cy/op

As expected, the verification time is dominated by the cost of the RSA exponentiation: even though our validator is over 4 times faster and avoids the allocation of a modulus-sized intermediate buffer to compare the expected and computed digests, the impact on overall validation performance is negligible. For signing and encoding, the constant constant parts of the signature payload must be written manually, and separate finalizers must be called for to write the bytes we depend on for the algorithm choice and the outermost ASN.1 length.

We tested our implementation against all variants of the Bleichenbacher’s attack listed in §2.2 and confirmed they are properly rejected.

## 7 Related work

Parsing combinators are widely used in functional programming languages, and there exist several libraries for network protocols [29], including TLS and X.509 [30].

For well-behaved language classes (e.g. regular, context-free), there is a long history on verification of parser correctness with respect to simple specifications (regular expressions, grammars). Jourdan et al. [25] propose a certifying compiler for LR(1) grammars, which translates the grammar into a pushdown automaton and a certificate of language equivalence between the grammar and the automaton. The certificate is checked by a validator verified in Coq [1], while the automaton is interpreted by a verified interpreter. Barthwal et al. [3] propose a verified grammar compiler and automaton interpreter for the simpler class of SLR languages, verified in HOL [42]. For regular languages, Koprowski et al.

introduced TRX [26], an interpreter for regular expressions verified in Coq. All of these works require runtime interpretation, which greatly degrades the performance compared to compilation. Furthermore, they target garbage-collected functional language runtimes like OCaml, which cannot easily be integrated into high-performance, native C applications.

For TLV languages, there have been some attempts [2] to create context-free or even regular specifications for X.509. However, due to the context-sensitive nature of ASN.1, these efforts rely on discretizations of some fields (such as variable-length integers) and drastic simplifications of the format (such as limiting the choice of extensions to a known subset). The combinatorial explosion required to achieve interoperability makes these approaches impractical for real implementations, although some authors claim otherwise [21].

For runtime safety, fuzzing techniques [19, 43] are widely deployed and often included into test suites for cryptographic libraries. Although best practice, fuzzing is by nature incomplete, and may be difficult to apply to authenticated messages (as fuzzing invalidates hashes, signatures and MACs). Dynamic analysis tools like Valgrind [35] or AddressSanitizer [44] are widely used but also incomplete, while static analysis tools like Frama-C [11] require higher expertise, a significant time investment, and tend to scale poorly with large codebases. Because of past attacks, specific tools have been created for TLS and cryptographic libraries, including TLS-Attacker [45], FlexTLS [5], and Wycheproof [8], but their focus is to uncover known vulnerability patterns in protocol implementations rather than prove formal guarantees on their message formats.

Another related line of work [10, 16] applies abstract interpretation and symbolic execution to study the properties of parsers, such as whether two implementations of a format accept the same message. These techniques can be applied to existing implementations, but cannot generate new ones.

Narcissus [47] also constructs correct binary parsers from a verified library of combinators written in Coq. There are two major differences with EverParse: first, Narcissus only proves the correctness of its parsers, while we also prove parser security; second, Narcissus only generates higher-order, functional implementations while our compiled approach means that our parsers are entirely specialized at  $F^*$  extraction, and can be compiled in zero-copy mode. Building on Narcissus, Ye and Delaware [51] build a verified compiler in Coq for parsers and formatters described using Protocol Buffers [20]. Like EverParse, their parsers and formatters are proven to be correct. Their library produces high-level functional code, which is memory-safe by construction—in contrast, EverParse produces low-level C code, together with memory safety proofs. Further, due to the inherent structure of the Protocol Buffers format, their work does not consider non-malleability.

Jim and Mandelbaum [23, 24] have formalized and developed parser generators for a wide class of context-free grammars extended with data dependency, including tag-length-

value encodings, tagged unions, and other forms of dependence supported by QuackyDucky. They also provide tooling, like QuackyDucky, to automatically extract message format descriptions from RFCs and have applied their work to network message formats like IMAP, the popular mail protocol. While the input language of their framework is significantly more expressive than ours, EverParse, in contrast, produces provably safe, secure and functionally correct parsers. Jim and Mandelbaum also do not address message formatting.

## 8 Limitations and Future Work

**Trusted computing base:** we statically guarantee at the  $F^*$  source level memory safety, functional correctness, and non-malleability for all code generated by QuackyDucky. Preserving non-malleability down to machine code requires only preserving functional correctness, since non-malleability is a specification-level guarantee. All our verification results, including preservation of memory safety and functional correctness down to machine code, relies on a trusted computing base (TCB) that includes:

- the  $F^*$  proof assistant and the Z3 theorem prover, although work by Swamy et al. [48] provides a model of a subset of  $F^*$  and proves its soundness;
- the KReMLin compiler from  $Low^*$  to C, although work by Protzenko et al. [38] provides a model of a subset of  $Low^*$ , its compilation to CompCert Clight, and proofs (on paper) that compilation to C preserves memory safety and functional correctness;
- the C compiler, although one can use the CompCert [28] verified C compiler, which ensures the preservation of memory safety and functional correctness, at the expense of some performance.

This trusted base is comparable to Coq-based verified implementations, which trust Coq, the Coq extraction to OCaml, and the OCaml compiler and runtime. Ongoing research aims to reduce this TCB by verifying Coq extraction; similar efforts could, in principle, be applied to  $F^*$  and KReMLin.

Conversely, neither LowParse nor QuackyDucky are in the TCB. LowParse is fully verified. The input format specification of QuackyDucky is trusted for liveness, but not for security: if there is a mistake in the format specification, the worse that can happen is that the generated messages are incompatible with implementations of the correct format. We rely on interoperability testing to detect such mistakes. Conversely, EverParse can be used during the standardization of a new message format, as it can prove that the specification is secure regardless of the generated implementation.

**Expressiveness** QuackyDucky currently focuses on supporting tag-length-value encodings of non-malleable data formats. We show that the message formats of several important protocols and standards, including TLS, PKCS #1 signature payloads and Bitcoin, fall into this class. LowParse,

being the target language of QuackyDucky’s translation, is also currently restricted to supporting non-malleable data formats. However, it would be straightforward to make non-malleability conditional on a flag set in the parser metadata in order to define combinators for zero-copy malleable formats, including MessagePack, CBOR, Apache Arrow, Cap’n proto, and Protocol Buffers which are malleable at least by default (some have canonical representation rules). Generalized to support malleable formats, LowParse, being a library of verified monadic parser combinators, would support parsing with arbitrary data dependence and lookahead, beyond the class of context-free languages—however, coming up with *efficient* verified implementations of parsers for such language classes is an open question. In the future, we will also consider generalizing QuackyDucky to target the class of languages supported by LowParse.

**Side-channel attacks:** the implementation produced by EverParse branches on values read from the input buffer, which may leak (through timing side-channels) information when used on confidential data. We may in principle verify properties such as constant-time execution for the processing of simple message formats, reusing F\* and KReMLin techniques and libraries for side-channel protection of cryptographic algorithms. For example, we may provide constant-time combinators for fixed-length secret bytestrings. We leave such extensions for future work.

**Fuzzing:** since we expect our extracted C code to be compiled by unverified toolchains (such as GCC and LLVM, with optimizations), fuzz testing can provide additional assurance that the compilation from F\* to binary does not break our verified safety properties. We started using fuzzers optimized for parsers, such as SAGE [19], to fuzz the generated bitcoin block validator; we plan to extend their use to fuzz application code that uses generated validators and accessors.

**Integration:** we have integrated the high-level implementation of EverParse TLS parsers into miTLS, but our goal is to transition to the low-level implementation, thus avoiding many unnecessary heap allocations and copies. This is a major step towards making miTLS practical in performance-sensitive deployments.

## 9 Conclusion

Developers should prefer the convenience and robustness of writing high-level format specifications compiled by parser generation tools to programming tedious and error-prone custom parsers, although the latter is sometimes required for performance reasons. EverParse offers a unique combination of high performance, zero-copy implementations and high-assurance formal verification of the generated parsers.

**Acknowledgments** We thank the anonymous reviewers and Prateek Saxena for their helpful comments, which improved the writing of this paper. We thank Barry Bond, Christoph

Wintersteiger and the Everest team for their help in testing EverParse. We thank Clément Pit-Claudel and Benjamin Delaware for insightful discussions on the goals of verified parsing. Tej Chajed and Nadim Kobeissi completed their work during internships at Microsoft Research.

# Blind Bernoulli Trials: A Noninteractive Protocol For Hidden-Weight Coin Flips

Emma Connor and Max Schuchard

University of Tennessee

## Abstract

We introduce the concept of a “Blind Bernoulli Trial,” a noninteractive protocol that allows a set of remote, disconnected users to individually compute one random bit each with probability  $p$  defined by the sender, such that no receiver learns any more information about  $p$  than strictly necessary. We motivate the problem by discussing several possible applications in secure distributed systems. We then formally define the problem in terms of correctness and security definitions and explore possible solutions using existing cryptographic primitives. We prove the security of an efficient solution in the standard model. Finally, we implement the solution and give performance results that show it is practical with current hardware.

## 1 Introduction

Distributed systems sometimes require users to make random choices to drive network behavior. For example, peer-to-peer anonymous systems such as Freenet [12], AP3 [26], and DiscountANODR [36] employ a random “coin flip” in routing decisions to help obscure information about the path of a request from an observer. Opportunistic routing protocols may use a random decision on whether to forward or cache certain content or not. Systems that do rely on users making coin flips usually model the coin flip as a random trial that produces a single bit with a fixed probability. They distribute the probability of the trial’s two possible outcomes either as a static, pre-defined parameter known to the whole network, or as a dynamic parameter distributed to users as cleartext.

However, in some instances the trial probability itself may be sensitive information. For example, if we use dynamic trial probabilities to prioritize certain content in a network (i.e., have some content forwarded with higher probability than others), then observers can distinguish and target higher-priority content. If an anonymous communication system varied the probability of forwarding to fine-tune the

trade-off between performance and anonymity for individual messages, then a malicious node could selectively attempt to deanonymize easier traffic.

For such applications we can envision a cryptographic solution that allows each user to carry out only a single trial and obtain a random bit with some weighted probability, while learning as little as possible about the overall probability of each outcome. The user should not be able to repeat the trial for a different result, since users can easily approximate the probability using multiple results. Nor should they be able to use the trial parameters to learn anything more about the actual probability of the outcomes. Users should be able to perform a trial noninteractively, as they would if the probability were distributed in cleartext. In other words, we want a way to distribute a weighted coin that each user can flip once, while revealing *as little information as possible* about the weight of the coin. We call this construction a “Blind Bernoulli Trial, or *BBT*.”

Specifically, we propose a definition where an authority generates and distributes unique keys to individual users. For each trial, the authority generates an encrypted *tag* that corresponds to the desired probability for that trial. Given a user key and a tag, one can noninteractively compute the outcome of exactly one trial without learning the overall probability.

We formalize the security of this system with a simulation-based definition inspired by the usual definition of semantic security for a cipher. Informally, the definition states that any function that can efficiently be computed by some number of identities and trial parameters could also be computed only knowing the trial results. The definition also includes a “leakage function” to allow schemes that leak some information but still have near-ideal security. The leakage function formally quantifies and places an upper bound on the amount of information an attacker can gain.

This paper evaluates three BBT schemes. First we develop a very simple protocol that meets our definitions and is based on a semantically secure cipher. This scheme essentially encrypts one trial result per user. We discuss why this trivial solution is unsatisfactory and then show an alterna-

tive construction from a general functional encryption primitive. Finally, since no practical functional encryption scheme for general functions is known, we examine more specific functional encryption schemes that support only a limited class of functions. We show how to construct a near-ideal BBT scheme from functional encryption supporting only inner product predicate functions, for which practical schemes currently exist.

In section 6, we compare the security of the ideal BBT schemes with the inner product construction using a quantitative attack analysis, discussing what an attacker can learn about the trial probability given a certain number of trial results. We design and evaluate a simulation of an attacker’s perspective on both possible schemes, using the different information available to the adversary in each case. The attack simulations show that the information gained by an attacker for the inner product scheme, on average, is very similar to the information gained in the ideal case.

Since efficiency is a major concern, we discuss both the running time and storage requirements for the inner product scheme. To evaluate the feasibility of current inner product functional encryption schemes, we implement a recently proposed scheme in software (to our knowledge, the first implementation of this scheme) and provide benchmarks for each algorithm involved in a Blind Bernoulli trial scheme. The benchmarks show that a Blind Bernoulli Trial scheme based on inner product encryption can run in a reasonable amount of time on current hardware.

Finally, we explore in more detail some potential applications of this new cryptographic concept. We discuss two possible distributed-systems scenarios where random behavior is used and the probability of that random behavior is sensitive information. In these cases, Blind Bernoulli trials can enhance privacy in the distributed system by hiding the weighted probabilities from users.

## 1.1 Related Work

Protocols for remote parties to agree on a random bit in a way that is fair and verifiable go back decades in cryptography [6]. These protocols differ from BBT in that their goal is to prevent either party from biasing the result. BBT is almost the opposite: here we explicitly want one party to be able to bias the result and for the other party to be unable to determine the bias.

More generally, secure multi-party computation (MPC) encompasses a wide body of related work that deals with allowing remote parties to interactively perform arbitrary computations together. MPC focuses on protocols that enable distrusting parties to jointly compute a function on private inputs, without revealing the inputs to each other. It allows for private inputs from both parties, and protocols are interactive, proceeding in multiple rounds. Existing MPC schemes can be practical [31]. Our formulation of BBT does not allow

interactive protocols, and the only private input is the probability of the trial. Therefore BBT is not compatible with MPC solutions.

While BBT does not fall under the area of MPC, it does fit squarely within the functional encryption model. Section 4 gives additional background on functional encryption and shows how BBT can be instantiated using general functional encryption.

In contrast with MPC, no practical general functional encryption is known. Recent works have proposed general functional encryption schemes, although these are not yet practical [15]. Other works have focused on implementing efficient functional encryption for specific classes of functions such as inner products and polynomials [18]. This paper primarily focuses on building an efficient construction specifically for BBTs.

## 2 Blind Bernoulli Trials

A Bernoulli trial models a random process with two possible results, where each result occurs with a fixed probability. This has applications in some distributed systems. For example, it provides a very simple means for one user to direct the behavior of a certain percentage of others without knowing exactly how many there are and without needing direct communication. An authority can distribute the parameters for a trial, and users can run a Bernoulli trial with the given parameters to self-organize into groups of approximately the desired proportions.

However, in some cases it may be important to the security goals of the system that individual users do not learn the overall probability of success. In these cases it is not acceptable for an authority to distribute the parameters for a trial, since this directly reveals the overall probability of success to all users. In response to this need, we formulate the concept of a *Blind Bernoulli Trial*, or *BBT*, which allows each user to obtain a single pseudo-random trial result without revealing additional information about the overall probability of success.

At first glance, it might appear that trivial solution would be for the authority to run the trials on a trusted computer and individually send a different trial result to each user. Since a user sees only their result, this scheme is secure. However, this scheme does not meet the requirement that a BBT be noninteractive. This leaves it with an important drawback compared to an unencrypted Bernoulli trial (publishing the probability parameter in plaintext). For an unencrypted Bernoulli trial, the authority can publish the probability parameter once, and any number of users can run a trial or forward the trial parameters to other users. Instead, the trivial interactive solution forces the authority to open an individual communication channel for each user. As a result, this interactive solution presents scalability concerns for systems

where communication between the authority and users may be intermittent or costly.

Ideally, a BBT scheme should more closely mirror the properties we get with a noninteractive unencrypted Bernoulli trial. The authority should be able to publish an encrypted object that represents the trial parameters and any number of users should be able to use this object to obtain a trial result without further interaction with the authority. Therefore, a Blind Bernoulli Trial scheme will try to construct “tags” that represent encrypted trial parameters of varying probabilities. Users will be able to use these tags to conduct trials without interaction with the authority.

In order to hide the overall probability of success for a trial, users must be able to obtain only one trial result per tag. If users could run multiple pseudo-random trials with the same tag they could quickly approximate the probability of success. To avoid this, we require that trial results are deterministic on a per user basis. In other words, the same user will always compute the same result for a given tag. Since Blind Bernoulli Trials must be deterministic, they are not true Bernoulli trials and do not have a “probability” of success in the same sense. Instead, when using a BBT, we are more interested in the overall probability of a trial’s success across a distribution of users. Accordingly, when we speak of the “probability” of an outcome of a Blind Bernoulli Trial, we are referring to the probability of that outcome when a trial is performed with a user key that is selected at random from the set of users. For schemes that require the authority to store key material for each user, the “set of users” refers to the set of user keys kept by the authority. Otherwise, it refers to the set of all possible user keys.

Just as a single user must always get the same result for the same tag, it is also necessary to prevent one entity from controlling many user identities and utilizing them to perform multiple trials on a tag. For this reason, it must be impractical for an adversary to create multiple working user identities. We avoid this by introducing a master key that is required to generate new user identities. These identities take the form of a user key, which is combined with the tag to conduct a single trial. In general, an adversary should not be able to create a user key without the master key. The impact of collusion is discussed at length in Section 6.

Taking into account these properties, we can arrive at a clearer picture for what our scheme must look like: in a cryptographic Blind Bernoulli Trial scheme, an *authority* uses a private *master key* to generate and distribute *user keys* representing individual user identities and *tags*, each representing a Bernoulli trial with a fixed probability of success prescribed by the authority. Given a user key and a tag, there exists a public, deterministic procedure to compute the result of a single Bernoulli trial (either “success” or “failure”) without revealing to the user the probability of success associated with the trial.

Formally, a Blind Bernoulli Trial encryption scheme con-

sists of the following algorithms:

- $\text{Setup}(1^\lambda)$ : Accepts a security parameter  $\lambda$  and returns a master key  $sk$  and public parameters  $pk$ .
- $\text{KeyGen}(sk)$ : returns a user key  $uk$ .
- $\text{TagGen}(x)$ : takes a probability parameter  $x$  and returns a tag  $t$ ; the exact form of the probability parameter can vary depending on the construction. In order to be useful, there must be at least two possible probability parameters that create tags with different probabilities of success.
- $\text{Trial}(uk, t)$ : returns a single bit  $b$  indicating success or failure.

This definition does not allow the trivial interactive solution mentioned earlier, where the authority carries out trials and directly communicates results to each user individually. This reflects a key design goal: that users must be able to obtain trial results without online communication with a centralized infrastructure. Users must be able to transfer tags to each other and each tag must be usable by all users. This allows individuals in a disconnected distributed system to obtain trial results without needing a direct intermediary.

## 2.1 Security Definition

Inherently, a BBT must reveal some information about the underlying probability. For example, an adversary that seeks to distinguish high-probability trials from low-probability ones could, after generating a trial result for a tag with their user key, guess “high-probability” for successful trials and “low-probability” for unsuccessful ones. Such a trivial adversary could already achieve non-negligible advantage in distinguishing between two types of tags.

Since each trial result unavoidably reveals *some* information about the underlying probability of success (a single successful trial means that the trial is more likely to have a higher probability of success), our security definition must take into account this inherent information leakage. Also, our definition must take into account collusion, so that the scheme remains as secure as possible even when a single adversary controls multiple user identities. Therefore, we compare the information an adversary learns from some number of user keys to that learned by an adversary that learns only the trial results corresponding to those keys.

Informally, a Blind Bernoulli Trial scheme is secure if an adversary with access to  $x$  user keys and  $y$  tags learns no more about the probabilities of success of any tags than he would by being given only the results of  $x$  trials for each tag. Since a BBT scheme intends to reveal the outcome of 1 trial per key, clearly this is the best any scheme could hope to do. In Section 6 we discuss some possible attacks when an

adversary controls multiple keys and quantify the amount of information gained by such an adversary.

Formally, we use a simulation-based definition to capture the idea that any function which is efficiently computable from a trial tag and a set of user keys must also be efficiently computable using only the trial results. We also include some allowance for additional information leaked, as this will be useful later in constructing a scheme that achieves near-ideal security with much greater efficiency compared to other schemes.

**Definition 2.1** (Security with leakage). *A Blind Bernoulli trial scheme is secure with respect to a leakage function  $\mathcal{L}$  if for all probabilistic polynomial time (PPT) algorithms  $\mathcal{A}$ , there exists a PPT algorithm  $\mathcal{B}$  such that for all polynomially-bounded functions  $f, h$ , the advantage of  $\mathcal{A}$ , defined as:*

$$\Pr[\mathcal{A}(1^\lambda, uk_1, uk_2, \dots, uk_n, t, h(1^\lambda, x))] = f(1^\lambda, x) - \Pr[\mathcal{B}(1^\lambda, uk_1, uk_2, \dots, uk_n, \text{Trial}(uk_1, t), \text{Trial}(uk_2, t), \dots, \text{Trial}(uk_n, t), \mathcal{L}(t), h(1^\lambda, x))] = f(1^\lambda, x) \quad (1)$$

*is negligible in the security parameter, where  $x$  is the probability parameter and  $t = \text{TagGen}(x)$ .*

This definition is closely-related to the usual definition of semantic security for private-key encryption and formalizes the idea that an adversary should learn as little as possible about a tag beyond the results of the trials of all keys known to the adversary. The leakage function places an upper bound on the amount of information that an adversary can learn from a tag because the definition states that any function that can be efficiently computed with the tag  $t$  can also be efficiently computed with only the trial results (which are intentionally revealed) and  $\mathcal{L}(t)$ .

Implicit in this security definition is the design requirement that an adversary can not forge additional user keys. If a BBT system allowed an adversary to forge a non-zero number of additional keys, that adversary would gain access to an extra set of trial results beyond those generated from their originally controlled keys. Such a system fails to meet our security definition.

## 2.2 Other Design Goals

Security is a necessary property, but it is not the only design goal. To be usable, a BBT scheme must be efficient, both in terms of the running times of the algorithms and the space complexity of keys and tags. As stated previously, we also require that the protocol is noninteractive; that is, that tags can be freely transmitted from user to user and that users can obtain trial results from a tag without direct communication with the authority.

Each algorithm must be efficient enough to run in a reasonable amount of time. The running time of the Trial algorithm is particularly important, as we expect this algorithm to be run most frequently. Each user must run a trial for each tag received. Also, several applications of BBT feature users with lower computing resources compared to the authority. The other algorithms that comprise a BBT scheme are likely to be run less often: Setup is run only once, or only when the system needs to be re-keyed. And if  $n$  tags are created and  $m$  users then we expect the number of trials run to be on the order of  $nm$  if most users receive most tags.

The size of objects in the scheme must also be efficient. “Efficient” tags and user keys should require space logarithmic or at least sublinear in the number of users. In order to minimize storage requirements for the authority, we would also prefer that the tag generation algorithm does not depend on the current state of users. This eliminates the need for the authority to keep a database of users, and also allows user keys to be used even with tags that were generated before the key. This is particularly important in distributed systems applications that are disconnected or high churn, where new users may regularly encounter tags that were generated before the user key.

Another potentially desirable property would be the ability for users to generate tags. We consider this property desirable because if it is not wanted it can easily be removed by composing tags with any cryptographic signature scheme. Users can then simply reject tags that do not have a valid signature from the authority. On the other hand, it is not clear how to add this property to a scheme that does not support it, so we consider a scheme that does allow user tag generation to be more flexible.

A less-obvious but important property of a BBT scheme is the possible probability values for a tag. There is no requirement that a scheme support an arbitrary probability, but only that TagGen accepts some parameter that increases or decreases the probability of success for trials resulting from the generated tag. A scheme that allows more fine-grained control of the probability level is preferable over one that supports more limited probability levels.

## 3 Construction from Semantically-Secure Encryption

A simple BBT scheme can be trivially constructed from any symmetric or asymmetric encryption scheme that is semantically secure. In short, the authority can simply generate and store a random key for each user and send a tag consisting of a different ciphertext for each user, which that user can decrypt to obtain a trial result with the corresponding user key. To run a trial, users simply decrypt the ciphertext corresponding to their key. The security of this scheme follows immediately from the semantic security of the underlying en-

ryption system.

Either a public-key or symmetric system can be used here, as long as it meets the definition for semantic security. A symmetric-key system will be especially efficient, but a public-key system has the advantage that users can generate tags themselves. On the other hand, if a symmetric-key system is used, then the same keys that create tags can also decrypt them, which means that only the authority can hold the keys needed to create tags.

The individual algorithms are described as follows:

### Setup

The authority initializes  $sk$  as an empty list of encryption keys.

### Generating User Keys

The authority generates a decryption key  $uk$  for the underlying cryptosystem, gives it to the user, and appends its corresponding encryption key to  $sk$  (in the case of a symmetric system, the encryption key may be the same as the decryption key).

### Generating Tags

A single tag consists of a set of ciphertexts, with one ciphertext per user. The authority generates it as follows:

1. The authority randomly selects a subset  $S$  containing  $x$  of  $|sk|$  users.
2. For each  $uk_i$  in  $sk$ , the authority computes  $ct_i \leftarrow \text{Encrypt}_{uk_i}(m_{\text{success}})$  if  $uk_i \in S$ , otherwise  $ct_i \leftarrow \text{Encrypt}_{uk_i}(m_{\text{fail}})$
3. The tag is a tuple of all  $ct_i$ :  $t \leftarrow (ct_1, ct_2, \dots, ct_{|sk|})$
4. The probability of success for the tag is  $x/|sk|$ .

### Trials

To perform a trial, a user selects the ciphertext corresponding to that user's key from the set of ciphertexts that forms the tag. The user then decrypts that ciphertext to obtain the trial result:

1.  $m \leftarrow \text{Decrypt}_{uk_i}(ct_i)$ .
2. Return 1 if  $m = m_{\text{success}}$ .
3. Otherwise, return 0.

## 3.1 Discussion

Since a trial consists only of a single decryption, trials are very efficient. User key generation is likewise extremely efficient as it requires only choosing a random key. Trials and user key generation are both  $O(1)$ . However, generating a tag is linear in the number of users, requiring  $l$  encryptions for  $l$  users. The space complexity of tags is also  $O(l)$ . When the number of users is known to be small, this may be acceptable. However, especially because BBT schemes are designed for applications where network resources are extremely limited, the linear space complexity of tags may quickly become a concern as the number of users increases.

This type of BBT scheme also allows for the most fine-grained possible control of probability. The tag generator can select any subset of users of any size for a successful trial. This is contrast to the schemes proposed in Sections 4 and 5, which are both limited in the possible subsets of users that observe a successful trial.

This scheme does not meet the design goal that tag generation does not depend on user state. The authority must maintain a central database of all user keys. If an asymmetric key system is used to allow tag generation by users, this key storage burden is also placed on each user. Each tag will be valid only for the user keys that existed in the authority's database at the time the tag was generated, so it will not be possible for newly-created users to run older tags.

## 4 Construction From Functional Encryption

A BBT scheme with ideal security can be constructed from any functional encryption scheme that supports arbitrary functions. In functional encryption, given a key  $k$  and ciphertext  $ct$ , one can learn the output of a function of the plaintext  $f_k(m)$  without learning anything else about the plaintext [8, 30, 2]. To construct a BBT scheme from a functional encryption primitive, we define the user key functions using a pseudorandom function family (PRF) and a comparison. The tag plaintext consists of a random seed and a threshold value which determines the tag's likelihood of success. The authority encrypts tags under the functional encryption scheme and distributes the ciphertexts to users. Each user key corresponds to a function  $f$  that is defined as:

$$f(s, t) = 1 \text{ if } h(s) < t \quad (2) \\ = 0 \text{ otherwise}$$

where  $h$  is a function selected at random from a PRF for each user key. Although the domain and range of functions in PRFs are typically viewed as bit strings, for our purposes it is more convenient to view them as integers in binary representation.

## Setup

The authority initializes the functional encryption scheme and retains the master key  $sk$  which allows the creation of function keys.

## Generating User Keys

The authority selects  $h$  at random from a PRF and generates the user key  $uk$  as the function key for  $f$ , as described above.

## Generating Tags

The authority selects a seed  $s$  at random from the domain of each function in the PRF. The threshold  $t$  controls the probability  $p$  of the tag and is computed as  $p * \max(\text{range}(h))$ . The authority then encrypts the tuple  $(s, t)$  under the functional encryption scheme to obtain the  $ct$ .

## Trials

To perform a trial, a user computes  $f(s, t)$  using the tag  $ct$  and the user key  $uk$ . The trial result is the function output.

## 4.1 Discussion

Although this construction achieves best-case security and allows fine-grained choice of success probabilities, its description relies on functional encryption for arbitrary functions. While such schemes do exist, they in turn rely on other heavy-handed approaches such as fully homomorphic encryption for which practical implementations are not yet available [15]. Therefore, a more practical solution is needed.

## 5 Construction from Inner Product Encryption

In this section we show how to use any fully attribute-hiding inner product encryption (IPE) scheme to construct a BBT scheme that is secure with respect to the leakage function  $\mathcal{L}(t) = pk$ , where  $pk$  is the public key of the IPE scheme used.

### 5.1 Background

The term “inner product encryption” has been applied to multiple related but distinct cryptographic concepts [21, 5, 28, 29, 27, 19, 3]. In this context, we use it to refer to a specific form of predicate encryption where ciphertexts and keys are each associated with vectors, and the associated predicate is the inner product function. Predicate encryption is a generalized form of public key encryption where each key  $k$  is associated with a predicate function  $f_k$ , and each ciphertext

is associated with an attribute  $y$  [18]. A ciphertext with attribute  $y$  can be decrypted with key  $k$  if and only if  $f_k(y)$  is true.

In general, an IPE scheme operates on  $n$ -dimensional vectors of integers modulo a prime  $p$ . In an IPE scheme, each key  $sk_{\vec{k}}$  is associated with a vector  $\vec{k} \in \mathbb{Z}_p^n$ , and each ciphertext  $ct_{\vec{y}}$  is associated with an attribute vector  $\vec{y} \in \mathbb{Z}_p^n$ . The associated predicate is  $f_{\vec{k}}(ct_{\vec{y}}) = \vec{k} \cdot \vec{y} \stackrel{?}{=} 0$ . In other words, given  $sk_{\vec{k}}$  and a ciphertext  $ct_{\vec{y}}$ , one can compute the plaintext  $m$  if and only if  $\vec{k} \cdot \vec{y} = 0$ . An IPE scheme consists of the following functions:

- $\text{Setup}(1^\lambda)$  outputs public key  $pk$  and secret key  $sk$ .
- $\text{KeyGen}(\vec{k}, sk)$  accepts the secret key  $sk$  and a vector  $\vec{k} \in \mathbb{Z}_p^n$  and outputs  $sk_{\vec{k}}$ .
- $\text{Encrypt}(m, \vec{y}, pk)$  outputs  $ct_{\vec{y}}$ .
- $\text{Decrypt}(ct_{\vec{y}}, sk_{\vec{k}}, pk)$  outputs  $m$  if  $\vec{k} \cdot \vec{y} = 0$ , otherwise outputs  $\perp$ .

*Attribute-hiding IPE* additionally requires that the vector  $\vec{y}$  associated with each ciphertext is hidden. Partially attribute hiding schemes hide  $\vec{y}$  from users who are not authorized to decrypt the associated ciphertext, while fully attribute-hiding schemes hide  $\vec{y}$  even in the case where  $\vec{k} \cdot \vec{y} = 0$ .

IPE security is defined by a game between a challenger and an adversary [28].

**Definition 5.1** (Attribute-hiding IPE Security). *The security of a fully attribute-hiding IPE scheme is defined by the following game between the challenger and an admissible adversary  $\mathcal{A}$*

1. The challenger runs  $\text{Setup}_{\text{IPE}}$  and gives  $pk$  to  $\mathcal{A}$ , retaining  $sk$ .
2.  $\mathcal{A}$  adaptively makes any polynomial number of key queries for key vectors  $\vec{k}_i$ . The challenger gives  $\mathcal{A}$   $sk_{\vec{k}_i} \leftarrow \text{KeyGen}(\vec{k}_i, sk)$
3.  $\mathcal{A}$  chooses challenge attribute vectors  $(\vec{y}_0, \vec{y}_1)$  and challenge plaintexts  $(m_0, m_1)$ .
4. The challenger randomly selects a bit  $b = 0$  or  $b = 1$ .
5. The challenger gives  $\mathcal{A}$   $\text{Encrypt}(m_b, \vec{y}_b, pk)$
6.  $\mathcal{A}$  can again adaptively make a polynomial of key queries for additional key vectors  $\vec{k}_i$ .
7.  $\mathcal{A}$  outputs a guess  $b'$  and wins the game if  $b' = b$ .

Here, an admissible adversary is defined as one whose queries adhere to at least one of the following conditions:

1.  $\vec{k}_i \cdot \vec{y}_0 \neq 0$  and  $\vec{k}_i \cdot \vec{y}_1 \neq 0$  for all  $\vec{k}_i$

2.  $m_0 = m_1$  and either  $(\vec{k}_i \cdot \vec{y}_1 \neq 0 \text{ and } \vec{k}_i \cdot \vec{y}_0 \neq 0)$  or  $(\vec{k}_i \cdot \vec{y}_0 = 0 \text{ and } \vec{k}_i \cdot \vec{y}_1 = 0)$  for all  $\vec{k}_i$ .

Without these restrictions an adversary can trivially infer  $b$  by submitting a challenge attribute pair that will be possible to decrypt for one value of  $b$  and not possible to decrypt for another, or a challenge message pair that can be decrypted to a different value depending on  $b$ .

## 5.2 Construction

With attribute-hiding IPE and its security now defined, we can show how to construct a BBT scheme using it. Intuitively, we will construct user keys and tags from randomly sampled vectors. Tags will correspond to IPE ciphertexts, user keys correspond to IPE user keys, and trials correspond to IPE decryptions. A successful decryption means a successful trial, while a failed decryption indicates a failed trial. We will vary the number of nonzero components in a tag's associated vector to control the probability that a randomly-selected user key will be able to decrypt it. Because the IPE scheme is fully attribute-hiding, the vector associated with tags is hidden from users, regardless of trial result.

### Setup

The Setup function for IPE-based BBT additionally accepts a parameter  $a$  that determines the number of nonzero components in each user key. The authority runs the following procedure:

1. Run  $\text{Setup}_{\text{IPE}}(1^\lambda, n)$  to obtain the private key  $sk$  and public key  $pk$ .
2. Store  $a$  as a public parameter.
3. Select  $m_{\text{success}}$  randomly from the message space of the underlying IPE scheme, and store it as a public parameter.

### Generating User Keys

Every user key has the same number of nonzero components, which is parameterized as  $a$ .

1.  $\vec{k}$  is randomly selected from the set of all vectors with  $a$  nonzero entries.
2.  $uk$  is computed as  $\text{KeyGen}_{\text{IPE}}(\vec{k}, sk)$

### Generating Tags

In this scheme, TagGen accepts the integer probability parameter  $0 < x < n$ , which represents the number of nonzero components in the tag vector:

1.  $\vec{t}$  is randomly selected from the set of all vectors with  $x$  nonzero entries.
2.  $t$  is computed as  $\text{Enc}_{\text{IPE}}(m_{\text{success}}, \vec{t}, pk)$ .

### Trials

1.  $m \leftarrow \text{Dec}_{\text{IPE}}(t, uk, pk)$ .
2. Return 1 if  $m = m_{\text{success}}$ .
3. Otherwise, return 0.

## 5.3 Security

**Theorem 1.** *The IPE-based BBT scheme is secure with respect to the leakage function  $\mathcal{L}(t) = pk$ .*

*Proof.* The proof is simulation-based. For all PPT adversaries  $\mathcal{A}(1^\lambda, uk_1, uk_2, \dots, uk_n, t, h(1^\lambda, \vec{t})) = f(1^\lambda, \vec{t})$  there exists a PPT simulator that achieves the same advantage using only the trial results and the public key:

$$\mathcal{B}(1^\lambda, uk_1, uk_2, \dots, uk_n, \text{Trial}(uk_1, t), \text{Trial}(uk_2, t), \dots, \text{Trial}(uk_n, t), pk, h(1^\lambda, \vec{t})) = f(1^\lambda, \vec{t})$$

The simulator  $\mathcal{B}$  produces an output that is computationally indistinguishable from that of  $\mathcal{A}$ . The algorithm for  $\mathcal{B}$  proceeds as follows:

```

 $\vec{s} \leftarrow \langle 1, 1, \dots, 1, 1 \rangle$ 
for  $1 \leq j \leq n$  do
   $\vec{v}_j \leftarrow \langle 0, 0, \dots, 1, \dots, 0, 0 \rangle$  where only the  $j$ th element is 1.
   $t_j \leftarrow \text{Encrypt}(\vec{v}_j, pk)$ 
end for
for all  $uk_i$  do
  if  $\text{Trial}(uk_i, t)$  is success then
    for  $1 \leq j \leq n$  do
      if  $\text{Trial}(uk_i, t_j)$  is not success then
         $\vec{s}_j \leftarrow 0$ 
      end if
    end for
  end if
end for
 $s \leftarrow \text{Encrypt}(\vec{s}, pk)$ 
Run  $\mathcal{A}(1^\lambda, uk_1, uk_2, \dots, uk_n, s, h(1^\lambda, \vec{t}))$  and output the result.

```

The output of algorithm  $\mathcal{B}$  described above must be computationally indistinguishable from the output of  $\mathcal{A}$ ; otherwise, an adversary could leverage the difference in the two to break the security of the underlying IPE scheme as follows:

1. Choose  $\vec{t}$  as an arbitrary vector.

2. Submit arbitrary key vectors  $\vec{k}_1, \vec{k}_2, \dots, \vec{k}_n$ .
3. Choose  $\vec{s}$  as it would be computed by  $\mathcal{B}$  (i.e., the vector with the maximal number of non-zero entries that is still orthogonal to all  $\vec{k}_i$  orthogonal to  $\vec{t}$ ).
4. Choose plaintext  $m = m_{\text{success}}$ .
5. Submit challenge attribute vector  $(\vec{t}, \vec{s})$  and challenge plaintext  $(m, m)$  and receive  $x$ , which is  $t$  if  $b = 0$  or  $s$  if  $b = 1$ . Note that these submissions are admissible under the security definition of IPE because  $\vec{s}$  and  $\vec{t}$  are specifically constructed such that  $\vec{s} \cdot \vec{k}_i = \vec{t} \cdot \vec{k}_i$  for all  $\vec{k}_i$ , as is required when  $m_0 = m_1$ .
6. Compute  $\text{out}_{\mathcal{A}} \leftarrow \mathcal{A}(1^\lambda, \text{uk}_1, \text{uk}_2, \dots, \text{uk}_n, x, h(1^\lambda, \vec{t}))$ .
7. If  $\text{out}_{\mathcal{A}}$  is as  $\mathcal{A}(1^\lambda, \text{uk}_1, \text{uk}_2, \dots, \text{uk}_n, t, h(1^\lambda, \vec{t}))$ , output 0.
8. Otherwise, if the output  $\text{out}_{\mathcal{A}}$  is as  $\mathcal{A}(1^\lambda, \text{uk}_1, \text{uk}_2, \dots, \text{uk}_n, s, h(1^\lambda, \vec{t}))$ , output 1.

Clearly, if the adversary has non-negligible advantage in distinguishing the outputs of  $\mathcal{A}(1^\lambda, \text{uk}_1, \text{uk}_2, \dots, \text{uk}_n, t, h(1^\lambda, \vec{t}))$  (which is exactly the output of the adversary  $\mathcal{A}$ ) and  $\mathcal{A}(1^\lambda, \text{uk}_1, \text{uk}_2, \dots, \text{uk}_n, s, h(1^\lambda, \vec{t}))$  (which is exactly the output of the simulator  $\mathcal{B}$ ), then the adversary also wins the IPE security game with non-negligible advantage. But, for a secure IPE scheme no such adversary can exist. Thus no PPT algorithm exists that can distinguish the output of the simulator  $\mathcal{B}$  from the output of the  $\mathcal{A}$ .  $\square$

## 5.4 Choice of Parameters

Besides the choice of underlying IPE scheme, the IPE-based BBT scheme also allows the choice of parameters for the dimension of the vector space  $n$  and the number of nonzero components  $a$  in each user key. Choices of these parameters will affect the number users that the system can support as well as the available choices for tag probabilities.

The IPE construction uses the number of nonzero components in a tag vector to control the probability of a successful trial. Therefore, for a system of dimension  $n$  there are  $n$  discrete probability “tiers” where tags in the  $i$ th tier have  $i$  nonzero components. Given an IPE scheme of dimension  $n$ ,  $a$  nonzero components in each user key, and  $x$  nonzero components in a tag, the odds of a successful trial are:

$$\Pr[\text{success}] = \binom{n-x}{a} / \binom{n}{a}$$

Here, the numerator counts the number of ways to choose a user key that is orthogonal to the tag, and the denominator represents the total number of user keys possible.

This means that the probability tiers are not distributed uniformly. There are more tiers with lower probabilities of success than there are tiers with higher probabilities of success. For applications that require higher probabilities, we can simply invert the result of all trials to get a more favorable distribution. The remainder of this section follows this convention of inverting trial results. As a concrete example, figure 1 visualizes the case where  $n = 64$  components are used.

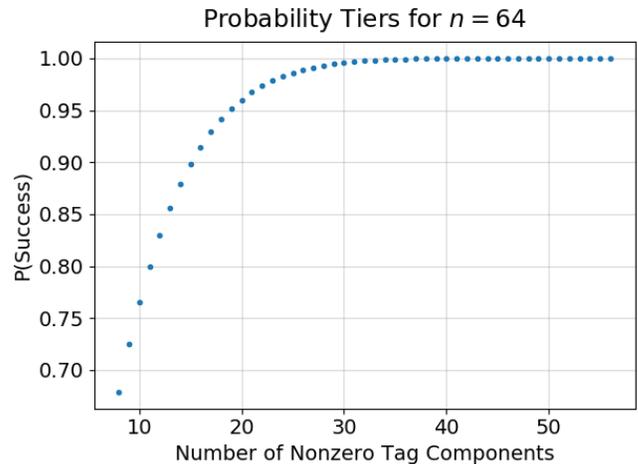

Figure 1: The distribution of probability tiers is biased toward the upper end of  $[0, 1]$  (using inverted trial results with  $n = 64, a = 8$ ).

Two user keys  $\text{uk}_1$  and  $\text{uk}_2$  are called functionally unique if there exists a tag  $t$  such that  $\text{Trial}(\text{uk}_1, t) \neq \text{Trial}(\text{uk}_2, t)$ . In other words, at least one of the associated key vectors has at least one non-zero component that is zero in the other vector, so that it is possible to construct a vector that is orthogonal to one but not the other. The number of functionally unique user keys depends on the number of components  $n$  and the choice of number of non-zero components in each user key  $a$  and is given simply as:

$$\binom{n}{a} = \frac{n!}{a!(n-a)!}$$

Table 5.4 compares the tag size in bits for IPE-BBT and the alternative scheme described in section 3. For the underlying IPE scheme, we used the state-of-the-art attribute-hiding IPE scheme due to Chen et al. [10] (our implementation using this scheme is discussed further in section 7). We assume a 1024-bit prime is used, for security equivalent to a symmetric key of 112 bits [16]. Chen’s IPE scheme requires  $4n + 4$  group elements for a ciphertext in an  $n$ -dimensional IPE scheme. We assume that group elements can be represented compactly by specifying only the  $x$  coordinate plus one bit indicating the  $y$  coordinate [25]. Thus the total size

Dimension	Users	IPE Size	ElGamal Size
9	9	5.1 KB	0.5 KB
10	45	5.6 KB	2.5 KB
11	165	6.2 KB	9.3 KB
12	495	6.7 KB	27.8 KB
16	12870	8.7 KB	723.9 KB
32	$1.1 \times 10^7$	16.9 KB	591.7 MB
64	$4.4 \times 10^9$	33.3 KB	249.0 GB

Table 1: Sizes of tags in a system supporting a given number of users in IPE-based BBT using Chen’s IPE scheme, compared with semantically secure cipher construction using ECC ElGamal variant.

of a tag using Chen’s IPE scheme is  $(1024 + 1)(4n + 4)$  for IPE dimension  $n$ .

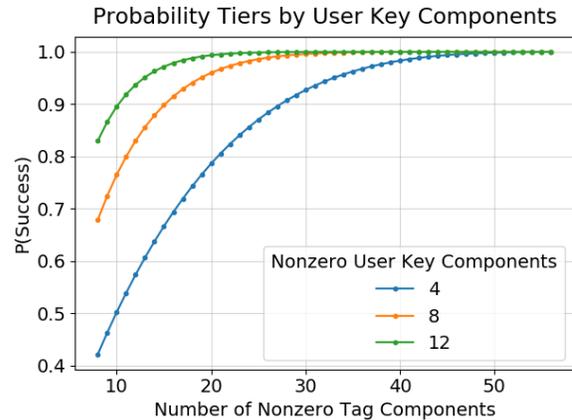

For comparison, we selected a public-key cryptosystem that represents minimal realistic storage requirements for a public key scheme at a comparable security level. We instantiated the semantically-secure encryption with an ECC variant of the ElGamal cryptosystem, which has been proven secure under elliptic curve discrete log assumptions [20]. This cryptosystem requires 2 group elements per ciphertext. We assume a 224-bit curve for a comparable level of security with the IPE scheme, again equivalent to a symmetric key strength of 112 [4]. This requires a total of 450 bits per ciphertext. The IPE scheme that supports 165 users (11 components with 8 non-zero user key components) uses less space than the corresponding public key scheme.

The number of possible tags is defined in the same way as it is for user keys. Two tags  $t_1$  and  $t_2$  are functionally unique if there exists a user key  $uk$  such that  $\text{Trial}(uk, t_1) \neq \text{Trial}(uk, t_2)$ . The number of functionally unique tags is different at each probability tier and depends on the total number of components in the vector space  $n$  and the number of nonzero components  $x$  used for that probability tier:

$$\binom{n}{x}$$

Therefore, it may be desirable to restrict the minimum and maximum probability tiers used so that the number of functionally unique tags at any probability tier does not fall below a chosen minimum. This means that the number of practically usable probability tiers may be less than  $n$ . For example, if one uses  $n = 64$  components then one may only use tags with at least 8 components and no more than 56, which ensures that the number of functionally unique tags in any probability tier is at least  $\binom{64}{8} \approx 2^{32}$ .

The number of nonzero components  $a$  in each user key also affects the range and number of probability tiers: lower values of  $a$  allow a wider range of probability tiers, but fewer functionally unique user keys. Individual applications will need to determine a suitable trade-off. Figure 5.4 visualizes

Nonzero Components	Users (to nearest power of 2)
4	$2^{19}$
8	$2^{32}$
12	$2^{41}$

Figure 2: Comparison of available probability tiers with IPE dimension  $n = 64$  with various values of  $a$  (nonzero user key components). Lower values of  $a$  give greater flexibility in probability choice but support fewer users.

the available probability tiers and number of user keys by the number of nonzero user key components.

## 6 Practical Security

In practice, the security of any BBT scheme will require that an adversary does not have access to too many keys. With enough keys, it is possible for an adversary to approximate the trial probability. As with any distributed system, the security of BBT in a system will break down if an adversary compromises enough nodes. In this section we first consider ways an adversary might attempt to compromise a system and then develop a model that quantifies the amount of information an attacker learns about trials based on the number of compromised nodes.

One of the most obvious way an adversary may attempt to compromise a system is a Sybil attack. In a Sybil attack, a single adversary creates multiple fake identities and appears to the network as many users instead of one [14]. Fortunately, there are wide range of known defenses against Sybil attacks for different domains. The authority can attempt to manually attempt to verify node identities before issuing user keys. In cases where this is impractical, automated defenses exist. Social network-based defenses such as SybilGuard [38], SybilLimit [37], and SybilInfer [13] are capable of detecting Sybil nodes using the social relationships between nodes in the network, under the assumption that attackers are unable to create many trust relationships with legitimate users. Behavior-based schemes seek to distinguish

between real and Sybil nodes via behaviors such as network activity and movement. For example, both work by Abbas et al. [1] and Jan et al. [17] utilize the heterogeneity of radio signals to detect Sybil attackers in MANETs and Wireless Sensor Networks respectively. Puzzle-based defenses such as SybilControl [22] utilize a proof of work based approach to mitigating Sybil attacks. Lastly, new approaches which leverage smart contracts, such as that proposed by Boehem et al. [7] put an economic price on Sybil identities.

Another simple attack is possible if a protocol misuses BBTs. For example, if a protocol requires multiple trials at the same probability protocol, then even a single user may be able to gain significant information about the probability of the associated tags. If a user observes several tags and knows (either from protocol specification or otherwise) that the tags all use the same probability parameter, then the user may use the differing results from the tags to approximate their shared probability.

In the event that an attacker does obtain multiple trial results, it is critical that we understand how much can be learned. The following subsections analyze the amount of knowledge that an attacker gains from multiple trial results, in both the ideal and the practical IPE schemes. Whether or not this amount of information leakage is considered acceptable is ultimately application-dependent.

### Attacks on the Ideal Scheme

In an ideal BBT construction, the adversary learns only the trial results corresponding to the keys that it holds. If the adversary with  $n$  keys has no auxiliary information about the underlying distribution of success probabilities, then its best estimate for the success probability of a tag is  $\frac{x}{n}$  where  $x$  is the number of observed successes. A confidence interval can also be computed to measure the uncertainty in this estimate. As an example, Figure 3 shows the upper and lower bounds of a 95% confidence interval on a tag with  $p = 0.5$  as the number of the adversary’s keys increases. The confidence interval is computed assuming that the adversary’s trial results approximate the true tag probability as closely as possible, which is the best possible case for an attacker. We use a normal approximation to compute the confidence interval. Figure 3 shows that the attacker’s knowledge increases with more trials. The attacker gains information rapidly at first, but trials beyond the first 10-15 bring diminishing returns. After 100 trials, the adversary is 95% confident that  $0.4 < p < 0.6$ .

However, if the adversary has a priori information on the underlying distribution of success probabilities, then the calculation is different. For example, if an adversary knows that all tags are drawn from discrete probability tiers (as in the case of the IPE-based scheme), then the adversary can use Bayesian inference to compute the likelihood that a tag comes from any tier given the a priori knowledge and the

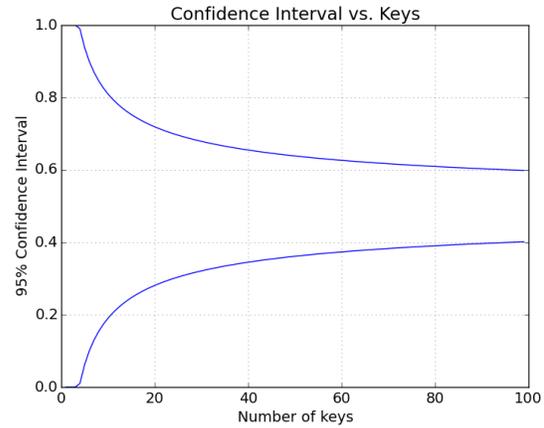

Figure 3: The upper and lower bounds of a 95% confidence interval for the probability of a tag with  $p = 0.5$ , as computed by an attacker whose trial results approximate a 50% success rate as closely as possible.

trial outcomes. Bayes’ theorem gives the likelihood that a tag is from tier  $T$  given trial results  $R$  as:

$$P(T|R) = \frac{P(T)P(R|T)}{P(R)} \quad (3)$$

where  $P(T)$  is the prior likelihood of a probability tier  $T$ ,  $P(R|T)$  can be modeled as a binomial distribution, and  $P(R)$  can be computed as  $\sum P(R|T_i)P(T_i)$  for each probability tier  $T_i$ . This represents, from the adversary’s point of view, the likelihood that a tag comes from a given probability tier given the observed trial results. This serves as an effective measure of what the adversary knows about the probability of a trial associated with the tag.

Figure 4 shows the expected view of an attacker in the ideal discrete case for two different tags in a simplified model that includes only 4 probability tiers. The tiers used are selected at roughly equal intervals from the tiers available in the IPE scheme with  $n = 64$ , and are listed in table 2. The attacker’s confidence in each probability tier was computed using the Bayesian model outlined above and taken as an average over all possible attacker trial results (weighted using the binomial distribution for the likelihood of each result). We assume that each probability tier is equally likely to an attacker as a prior likelihood. As the number of trial results available to the attacker increases, the confidence in the true probability tier increases while the confidence in other tiers decreases.

### Attacks on the IPE Scheme

We know that with ideal security, only the trial results are learned. In the IPE scheme, additional information is leaked (constrained by leakage function in the security proof). We

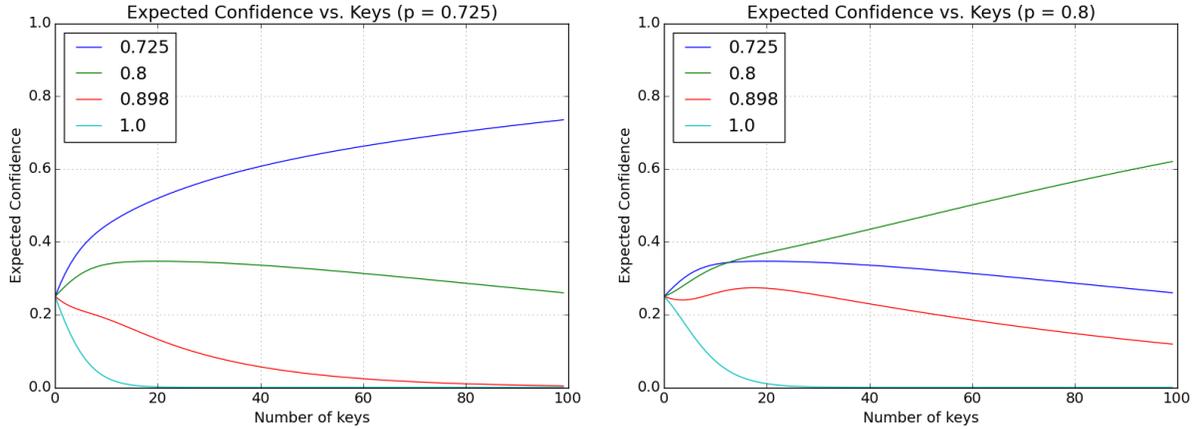

Figure 4: An attacker’s view of two tags in the ideal discrete case, using a simplified model with 4 probability tiers. Each graph shows the attacker’s expected confidence in each probability tier as a function of the number of trial results available to the attacker. The left graph shows the case where the true probability of the tag is  $p = 0.725$ , while the right graph shows a tag with  $p = 0.8$ .

Nonzero Components	$p$	Prior Likelihood
9	0.725	0.25
11	0.800	0.25
16	0.898	0.25
56	1.000	0.25

Table 2: Distribution of tags used in analysis.

wish to quantify how much an attacker can learn from the trial results, and how much more can be learned from the leaked information in the IPE scheme.

Essentially, the attacker can use information about the location of nonzero components in user keys to narrow down the set of possible tags. Knowing the components in each user key, together with their trial results for a tag, allows the attacker to quickly rule out any tag configurations that are inconsistent with the observed trial results.

The leakage function of the security proof takes this into account by allowing the public key of the underlying IPE scheme to leak. Since the public key is intentionally public in an IPE scheme, clearly this does not break the security guarantees of the underlying IPE; however, it does allow an adversary to potentially learn more about tags than the ideal case. Recall that the IPE public key allows one to encrypt a message under an arbitrary vector and obtain the ciphertext. In a BBT scheme, the IPE ciphertexts corresponds to BBT tags. Therefore, an adversary with the IPE public key can generate arbitrary tags, which allows the adversary to test user keys (but not tags) for the presence of any non-zero components. By repeated testing an adversary can determine exactly which components are zero and nonzero in each user key. In the rest of this analysis we assume the worst-case;

that is, that the adversary already has access to the upper bound of information allowed by our security proof.

If an adversary knows which components in each user key are nonzero, then it can narrow the set of possible tags to those that give the same trial results for the same keys. Now, the adversary can estimate  $P(R|T)$  as the proportion of possible tags from a tier that produce the same results when combined with same set of keys. For example, if trial result of testing a tag with one user key indicates that the two vectors are orthogonal, then any tags that share a nonzero component with the key are eliminated as possibilities. The attacker can count the number of consistent tags at each probability tier, and divide by the total number of possible tags in that tier to obtain a better estimate of  $P(R|T)$ . Again,  $P(R)$  can be computed as  $\sum P(R|T_i)P(T_i)$ . The adversary can then again compute the overall likelihood that a tag comes from a given probability tier using the Bayesian inference described by equation 3.

## Comparison

In order to determine the true impact of this attack, we compare the security of the IPE scheme to the ideal case by modelling two adversaries that each calculate the likelihood of tags differently. The component-aware adversary uses the full knowledge of the user keys components to compute the exact number of tags in each probability tier that could have produced the observed trial results, and then combines this with the prior likelihood of each probability tier to produce a confidence that a given tag comes from a given tier. Remember that no PPT adversary could hope to further distinguish between possible tags that would have produced the same trial results, since this directly contradicts the IPE security

definition.

On the other hand, the naive adversary uses only the number of success and number of failures to compute the likelihood of probability tiers. The likelihood of an observed result given a probability tier is modeled only as a binomial distribution. This is the best that an adversary could hope to do under the ideal security definition, where only trial results are revealed.

Figures 5 and 6 show a comparison of the two attacks in one case. For simulating the two attacks we chose parameters that provide a reasonable balance of performance, security, and number of users supported:  $n = 64$  as the dimension of the IPE scheme and  $a = 8$  for the number of nonzero components per user key. For simplicity, we limited tags to only a set of a few that provided roughly evenly-spaced probability tiers from about 0.72 to 1.0, in 0.10 intervals. Table 2 lists the exact tags used. For the prior distribution of tags, each probability tier was assumed to be equally likely.

For each attack, we sampled a given number of random keys, ran the attack with the keys on a randomly sampled tag at each probability tier, and then reported the resulting computed distribution of tag likelihood for each tag. We repeated this process many times to obtain an average over uniformly random sampled  $n$  keys and tags sampled randomly from our distribution of probability tiers. Shannon entropy, defined as  $-\sum p_i \log(p_i)$  can be used as a measure of the uncertainty over a distribution [33]. After each sampled attack, we computed the entropy of the computed probability tier distribution. We then computed the average expected entropy over the sampled sets of user keys and tags and graphed it as a function of number of user keys held by an attacker. Figure 5 shows that the difference in the attacker uncertainty is minimal between the ideal and IPE schemes. The expected entropy in a tag distribution from an attacker’s point of view diminishes with each additional key known, and it diminishes slightly faster for the IPE-based scheme than it does in an ideal scenario.

We also computed the expected Kullback-Leibler divergence between the component-aware model and the naive model, using the same tag distribution and random sampling method. The Kullback-Leibler divergence between two distributions  $P$  and  $Q$  is defined as  $-\sum p_i \log(\frac{p_i}{q_i})$ . This divergence measures the amount of information that an attacker gains about a tag probability by exploiting the information leakage in an IPE-based BBT scheme. Figure 6 shows that the additional information leaked to an attacker is minimal and quickly levels off around 0.02 bits.

## 7 Evaluation

We implemented IPE-based BBT using the adaptively attribute-hiding IPE scheme by Chen, Gong, and Wee, which is the current state of the art [10]. Chen et al. propose multiple variations with different performance characteris-

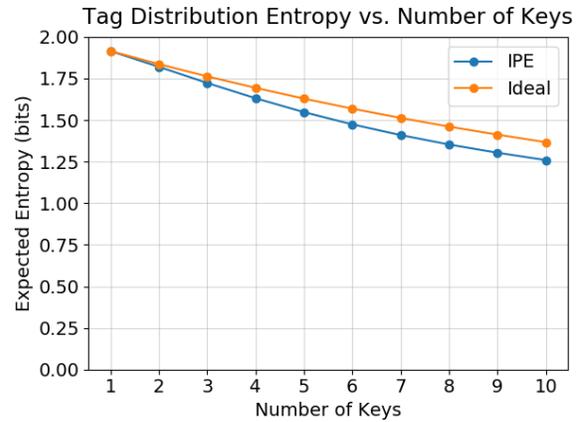

Figure 5: Expected entropy of computed tag likelihood as a function of attacker’s number of keys.

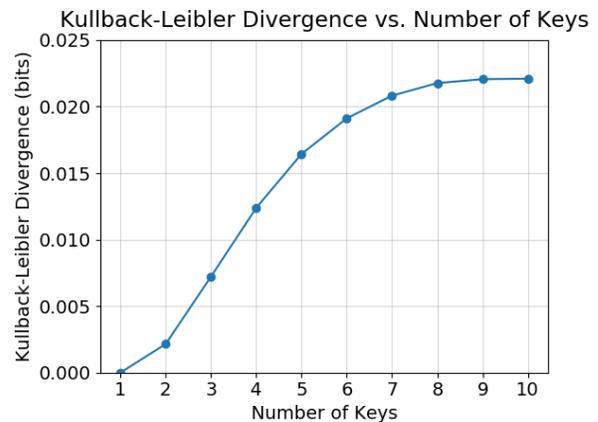

Figure 6: Expected Kullback-Leibler divergence between the component-aware model and the naive model as a function of attacker’s number of keys.

Object	Size (in elements)
Public key	$8n + 16$
User key	7
Tag	$4n + 4$

Table 3: Size of objects in IPE-BBT implemented with IPE scheme from Chen et al., in number of group elements.

tics using different standard assumptions. We implemented the variant described in Section 4.4 of their paper, which is proved secure under the external decisional linear assumption.

Under this scheme, tags and the public key both require space that is  $O(n)$  in the number of dimensions, or  $O(\log(l))$  in the number of functionally unique user keys. User keys have a constant space requirement of 7 group elements. Table 3 details the exact space requirements for each object.

Setup, trials, user key generation, and tag generation all run in  $O(n)$  time. For a typical number of dimensions, the trial run time is dominated by the pairing operations. Crucially, trials in this scheme require only 7 pairing operations, regardless of the number of dimensions.

We tested the speed of this implementation on a single core of an Intel Xeon E5-2680 v4 CPU clocked at 2.40GHz. For pairing operations, we used the Stanford Pairing-Based Cryptography (PBC) library [23, 24]. The curve used was of PBC’s “Type A,” which are curves of the form  $y^2 = x^3 + x$  over the field  $\mathbb{F}_q$ , where  $q$  is a prime such that  $q \equiv 3 \pmod{4}$ .  $q$  was chosen as a random 1024-bit prime, and the parameter  $r$  was chosen as a 224-bit number. Since the curve has embedding degree  $k = 2$ , these parameters are equivalent to the strength of an 112-bit symmetric key, according to the IEEE Standards for pairing-based cryptography [16].

Although the performance of all BBT steps must be reasonable, the Trial step is of the most concern. Trials are expected to be carried out by clients who may have limited resources, such as mobile devices. In contrast, Setup, TagGen, and KeyGen are all expected to be carried out by the single authority which would likely have access to significantly more resources.

Figure 7 shows the runtime of each BBT algorithm in our implementation using Chen, Gong, and Wee’s IPE scheme. As expected, each algorithm shows a clear linear trend as the dimension is increased. As previously mentioned, the performance of the trial algorithm is the most critical, since disconnected clients with limited computing resources will be running it. Our results show that the trial algorithm is quite practical with parameters that can support a large number of users. For example, with  $n = 64$  dimensions and  $a = 8$  nonzero components per user key, there are approximately  $2^{32}$  functionally unique user keys and a trial takes about 29 ms.

## 8 Applications

Any system that requires participants to take actions probabilistically can use BBTs to enhance privacy. Specifically, we envision several possible applications for BBTs in secure distributed systems. We provide two example scenarios that could benefit from deployment of blinded Bernoulli trials.

### Probabilistic Forwarding of Content in a Network

Some networks (especially peer-to-peer networks) employ random walks based on probabilistic forwarding of content for privacy reasons. For example, in the anonymous communication systems such as AP3 [26] and DiscountAN-ODR [36], when presented with a message, nodes randomly decide to either forward messages to another node in the mix or to send the message directly to its destination. The random process of forwarding obscures the origin of a message: when a node receives a message, it does not know if the message originated from the immediate preceding node or if it comes from 1, 2, or more hops away from that node. The use of the random coin rather than full circuit specification relieves the sending node from having to maintain state about the network topology outside of its immediate neighbors. The network uses a parameter  $p$  to specify the probability that nodes forward messages on to another node.

This approach introduces a trade-off between anonymity and network overhead: for lower values of  $p$ , messages take shorter paths (on average) through the network, but an observer can narrow down the set of likely originators to a smaller set based on the overlay distance to mix nodes and the distribution of random walk lengths. Higher values of  $p$  increase the number of possible nodes that might be the originator, but reduce network performance due to longer random walks. The authors of AP3 propose  $p$  between 0.5 and 0.9.

Using BBTs we can construct a network that allows for differential service, providing some users faster traffic, while still retaining the anonymity of longer paths. For example, consider a system with two classes of traffic. The Priority Class wants higher performance, and therefore shorter random walks, achievable with a low value of  $p$ . On the other hand, the Slow Class has no performance demands, so it can tolerate a higher value of  $p$ , increasing the size of its anonymity set. Without BBTs the traffic classes are trivial to distinguish, and as a result Priority traffic can be analyzed in a vacuum, leading to small anonymity sets. Marking a message’s  $p$  with a BBT means that the two classes can not be distinguished based on this value, and in turn the faster class can benefit from the adversary’s uncertainty about which peers should be included in the set of possible originators. This approach works especially well when the majority of the traffic falls into the Slow Class.

To evaluate the utility of BBT in this system, we simulated

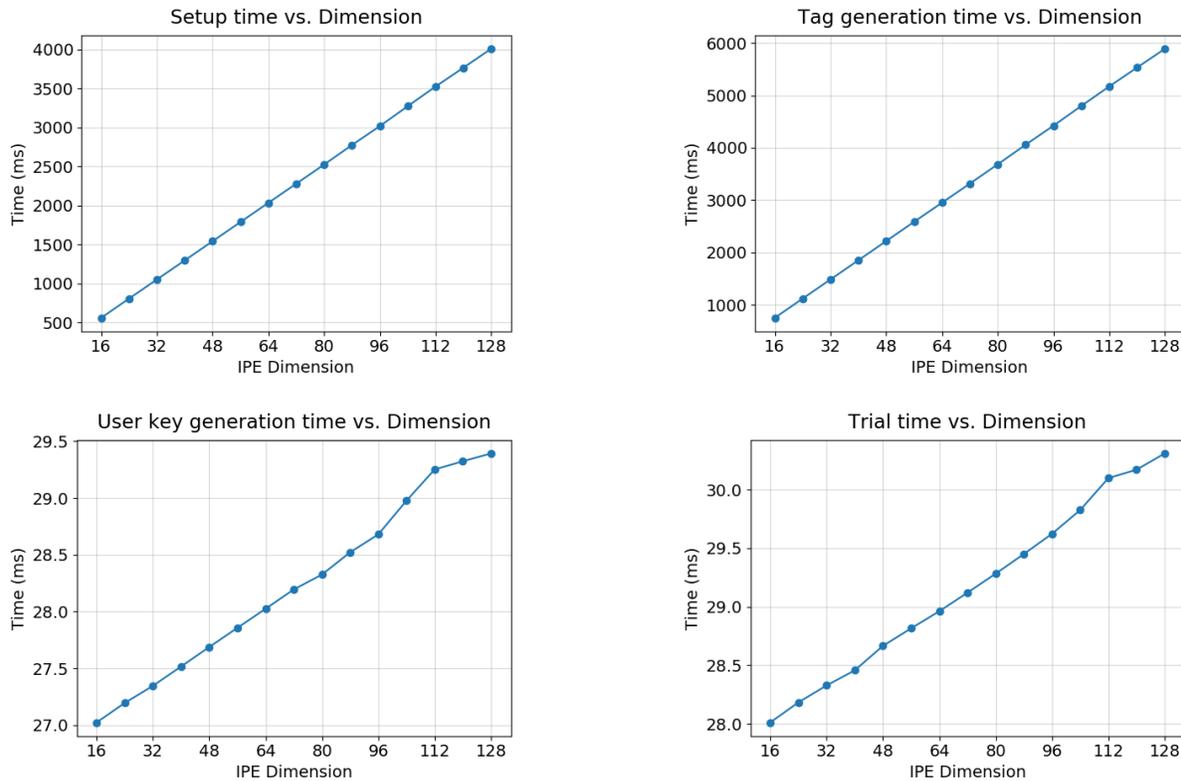

Figure 7: Runtimes for individual steps of IPE-based BBT implementation, by the dimension of the IPE.

a network that uses probabilistic forwarding with two traffic classes. Priority traffic uses  $p = 0.5$ , while Slow traffic in our test network uses  $p = 0.9$ . We simulated the operation of a network containing 1,000 nodes, with each node maintaining at least 4 connections to other nodes. The resulting graph had an average mixing time of slightly more than 7. In this network, Priority traffic represents 10% of total messages, and it is assumed that the adversary knows both the overall proportion of Priority traffic in the network and the full network topology. As expected, Figure 8 shows that Slow traffic takes drastically longer paths through the network, while Priority traffic reaches its destination much quicker. If an observer can distinguish Priority traffic, then this creates a privacy concern: because Priority traffic originates from nearby nodes with high probability, a node that receives it and recognizes it as Priority traffic has a high degree of confidence that the sender is in the small set of nodes that are nearby in the topology. However, if a BBT scheme is used to blind the priority class of traffic in the network, then Priority traffic can benefit from the reduced latency without resorting to unacceptably small anonymity sets. As Figure 9 illustrates, using BBT in the network increases the anonymity set sizes to levels that are near those of the Slow class. On average, anonymity sets for the merged class of traffic resulting from BBT blinding of priority is slightly lower than if only slow

traffic is considered. This is because the adversary knows the relative frequency of fast and slow traffic, and can adjust computation of likely nodes based on this information.

Beyond the example systems of AP3 and DiscountAN-ODR, many anonymous communication protocols feature a system parameter taking the form of a probability. Examples include Freenet [12], Crowds [35], and Imprecise Routing [11]. In each of these protocols, BBT can be used in a similar manner to adjust network behavior, allowing for different security properties while blending in with standard traffic.

### Intrusion Detection in Wireless Sensor Networks

Another application for BBTs is masking how many nodes are conducting a specific behavior. As an example, consider a wireless sensor networks comprised of a large number of low-cost embedded devices conducting measurements in an environment [32]. They rely on short-range wireless communication between low-power devices (often battery-powered), which makes power consumption a top concern. Because of the communication range constraints and large number of devices over a wide area, direct connectivity is limited; instead sensors distribute messages from device to device over multiple hops in the wireless network.

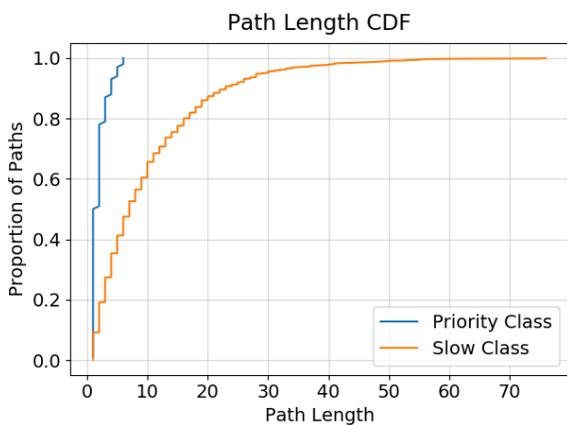

Figure 8: The distribution of path lengths for different traffic classes in the simulated network. Priority traffic takes significantly fewer hops to reach its destination, which translate to improved reliability and decreased latency.

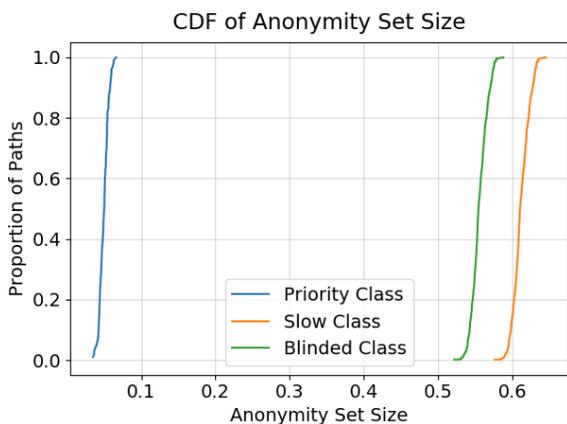

Figure 9: The distribution of anonymity set sizes for traffic classes. Without BBT, the anonymity set for nodes sending Priority traffic is less than 10% of the network. If the classes are indistinguishable, the anonymity set size is more than 50% of the network.

Sensor networks deployed in a hostile environment face the additional complication that certain compromised sensors may not be trustworthy. Adversaries may attempt to falsify sensor readings from compromised nodes. Recent work has examined methods for detecting compromised nodes in sensor networks [9, 34, 39]. In general, prior work has dealt with detecting falsified results by comparing them to a consensus of trustworthy results, under the assumption that an adversary is unable to compromise enough nodes to form a false consensus.

Of course, building a consensus requires a large number of measurements. Again, this leads to a trade-off between security and efficiency: employing many nodes in redundant measurements to build a consensus raises the bar for an attacker, but each sensor measurement uses energy (which is an extremely limited resource in wireless sensor networks). An obvious compromise would be to perform some fraction of measurements using only a small number of sensors, and sometimes use large-scale “audit” measurements to provide the necessary data for intrusion detection. If the metadata associated with a measurement reveals the number of nodes involved in the measurement, then this solution is vulnerable to an obvious attack: an adversary can simply refrain from lying during the audit measurements.

BBTs mitigate the aforementioned attack by limiting the adversary’s ability to distinguish typical measurements from audit measurements. The authority can control the scope of the measurement using the probability of a tag, and nodes can decide their involvement in the measurement with a trial. This prevents the attacker from selectively influencing measurements without detection. In addition, the authority can easily verify that nodes are not returning results for spurious measurements by duplicating the deterministic trial results and verifying that the node originating the measurement was in fact one of the nodes directed to take the measurement.

We evaluated the effect of applying this technique on a small network of sensor nodes. We modeled the network as 100 independent sensor nodes, each capable of a fixed finite number of measurements before it is considered expired. The adversary controls one node. We assume that the malicious node is detected if it lies on a measurement that is performed by at least half of the nodes. For normal measurements, the network uses a tag with  $p = 0.05$ . For audit measurements, the network sets  $p = 0.6$  (this ensures with high probability that at least half of the network does actually perform the measurement). We also assume that the authority verifies that each returned result is tied to an actual successful trial. This can be accomplished in general by requiring that nodes attach their user key to each result, encrypted so that only the authority can read it. Note that this is consistent with the threat model which already assumes that the authority has unlimited access to user keys.

By varying the “audit rate” (the fraction of measurements that are audit measurements), the authority can select an arbitrary

Audit Rate	Probability of Detection	Relative Lifetime
0.0	0.00	12.0
0.2	0.71	3.7
0.4	0.86	2.2
0.6	0.93	1.6
0.8	0.97	1.2
1.0	0.99	1.0

Table 4: The trade-off between sensor lifetime and detection probability. Here, the audit rate is the proportion of measurements that are audit measurements; the detection probability is the probability that a single lie is detected; and the relative lifetime is the lifetime of the entire network relative to the base case where all measurements are audit measurements. Allowing a small probability of an undetected attack can significantly increase the lifetime of the network.

bitrary trade-off between efficiency (conserving resources for more useful measurements) and security (performing redundant measurements to detect attacks). As the audit rate increases, so does the probability of detecting a malicious measurement; on the other hand, as the audit rate decreases, the lifetime of the network increases. Table 4 shows this trade-off. We sampled audit rates and computed both the resulting sensor lifetime and the probability that the adversary is detected each time it lies. The expected sensor lifetime is reported relative to the lifetime in the “safe” network (that is, one with an audit rate of 1). Even at a relatively low audit rate of 0.2, the probability of detection is high (71%) from the perspective of the sensor. This is because the number of sensors employed for normal measurements is much smaller than the number of sensors involved in an audit measurement. As a result, a given sensor is more likely to be selected via a large audit measurement than it is to be selected for a normal measurement.

Because the adversary cannot distinguish normal and audit measurements, it cannot selectively lie. This effectively limits the number of times an adversary can lie without detection (with overwhelming probability). Without using BBT, the adversary is only prevented from lying during audit measurements; otherwise, it can forge measurements without detection indefinitely. With BBT, if the adversary has a 50% chance of detection per measurement (for example) then it can expect to lie only about twice before detection, on average.

## Discussion

In practice, the bandwidth and computation overhead of a BBT scheme will determine its usefulness for any particular application. In the first application, we assume that the overhead of computing a trial is low relative to the work required for a message forward. This assumption is reason-

able, for example, in AP3, where a single forward requires a distributed hash table lookup and therefore multiple round-trip messages with peers. In this scenario the combined latency of one forward can be significantly slower than a trial in the IPE-based BBT construction.

For the sensor network application, the energy savings of skipping measurements will have to be weighed against the cost of performing the trials at each sensor. Depending on resource availability, different BBT constructions might be more appropriate. For example, if bandwidth is cheap but computational resources are constrained, then the IND-CPA construction presented 3 might actually be more suitable.

## 9 Conclusion

Although many distributed systems make use of probabilistic actions, systems so far either specify the probability as a fixed parameter or reveal the varying probabilities to each user. Blind Bernoulli trials are a privacy-enhancing measure that preserves the semantics of Bernoulli trials across a set of nodes, while hiding the exact parameters from individuals.

Fundamentally, Blind Bernoulli trials reveal the trial outcome without revealing the trial parameters. We create a definition that formalizes the idea that users should learn “no more” about the trial parameters than they would by receiving only the trial results corresponding to the keys held, and explore some possible solutions that meet our proposed definition.

Since BBTs are a special case of functional encryption (FE), they can easily be implemented with any FE primitive that allows arbitrary functions. However, since practical general functional encryption is not currently available, there is a need for a specific scheme that achieves the same results with a more efficient algorithm. Existing forms of functional encryption for specific classes of functions can be used to instantiate much more practical Blind Bernoulli trials, albeit with some security loss. Specifically, we can construct a near-ideal BBT scheme from inner product encryption by varying the number of nonzero components in tags to control the probability of their trials.

We prove the near-ideal security of the IPE-based scheme under our definition by showing a reduction to the security of the underlying IPE scheme. This definition takes into account the security loss and places an upper bound on exactly how much information is revealed to an adversary, even one who controls multiple keys. By simulating the attacker’s point of view on a large number of trials and keys, we can measure the average uncertainty towards the distribution of possible tags for an adversary with multiple keys: the expected entropy of a tag distribution decreases steadily with the number of trial results known. We compare the entropy loss in the ideal case to the IPE-based BBT scheme and show that the additional entropy loss in the IPE case is small.

Finally, we implement the IPE-based scheme in software and analyze its efficiency. We show that, in a system with realistic parameters, trials can be executed in a reasonable amount of time. Also, tags and keys in the IPE scheme are small (logarithmic in the number of users). Even with a relatively small number of users (on the order of 100), this is less storage than our simple semantically-secure cipher solution with linear keys.

We conclude that Blind Bernoulli trials can be efficiently implemented using IPE, and that they are an effective way obscure probability parameter metadata. This paper proposes two potential applications where this can prevent attacks that would otherwise exploit knowledge of the probability parameter. We hope that others in the security and distributed systems communities will explore additional uses for the primitive.

## Abstract

Advancements in deep learning enable cloud servers to provide inference-as-a-service for clients. In this scenario, clients send their raw data to the server to run the deep learning model and send back the results. One standing challenge in this setting is to ensure the privacy of the clients' sensitive data. Oblivious inference is the task of running the neural network on the client's input without disclosing the input or the result to the server. This paper introduces XONN (pronounced /zɒn/), a novel end-to-end framework based on Yao's Garbled Circuits (GC) protocol, that provides a paradigm shift in the conceptual and practical realization of oblivious inference. In XONN, the costly matrix-multiplication operations of the deep learning model are replaced with XNOR operations that are essentially free in GC. We further provide a novel algorithm that customizes the neural network such that the runtime of the GC protocol is minimized without sacrificing the inference accuracy.

We design a user-friendly high-level API for XONN, allowing expression of the deep learning model architecture in an unprecedented level of abstraction. We further provide a compiler to translate the model description from high-level Python (i.e., Keras) to that of XONN. Extensive proof-of-concept evaluation on various neural network architectures demonstrates that XONN outperforms prior art such as Gazelle (USENIX Security'18) by up to 7×, MiniONN (ACM CCS'17) by 93×, and SecureML (IEEE S&P'17) by 37×. State-of-the-art frameworks require one round of interaction between the client and the server for each layer of the neural network, whereas, XONN requires a *constant* round of interactions for *any* number of layers in the model. XONN is first to perform oblivious inference on Fitnet architectures with up to 21 layers, suggesting a new level of scalability compared with state-of-the-art. Moreover, we evaluate XONN on four datasets to perform privacy-preserving medical diagnosis. The datasets include breast cancer, diabetes, liver disease, and Malaria.

## 1 Introduction

The advent of big data and striking recent progress in artificial intelligence are fueling the impending industrial automation revolution. In particular, Deep Learning (DL)—a method based on learning Deep Neural Networks (DNNs)—is demonstrating a breakthrough in accuracy. DL models outperform human cognition in a number of critical tasks such as speech and visual recognition, natural language processing, and medical data analysis. Given DL's superior performance, several technology companies are now developing or already providing DL as a service. They train their DL models on a large amount of (often) proprietary data on their own servers; then, an inference API is provided to the users who can send their data to the server and receive the analysis results on their queries. The notable shortcoming of this remote inference service is that the inputs are revealed to the cloud server, breaching the privacy of sensitive user data.

Consider a DL model used in a medical task in which a health service provider withholds the prediction model. Patients submit their plaintext medical information to the server, which then uses the sensitive data to provide a medical diagnosis based on inference obtained from its proprietary model. A naive solution to ensure patient privacy is to allow the patients to receive the DL model and run it on their own trusted platform. However, this solution is not practical in real-world scenarios because: (i) The DL model is considered an essential component of the service provider's intellectual property (IP). Companies invest a significant amount of resources and funding to gather the massive datasets and train the DL models; hence, it is important to service providers not to reveal the DL model to ensure their profitability and competitive advantage. (ii) The DL model is known to reveal information about the underlying data used for training [1]. In the case of medical data, this reveals sensitive information about other patients, violating HIPAA and similar patient health privacy regulations.

*Oblivious inference* is the task of running the DL model on the client's input without disclosing the input or the re-

sult to the server itself. Several solutions for oblivious inference have been proposed that utilize one or more cryptographic tools such as Homomorphic Encryption (HE) [2, 3], Garbled Circuits (GC) [4], Goldreich-Micali-Wigderson (GMW) protocol [5], and Secret Sharing (SS). Each of these cryptographic tools offer their own characteristics and trade-offs. For example, one major drawback of HE is its *computational complexity*. HE has two main variants: Fully Homomorphic Encryption (FHE) [2] and Partially Homomorphic Encryption (PHE) [3, 6]. FHE allows computation on encrypted data but is computationally very expensive. PHE has less overhead but only supports a subset of functions or depth-bounded arithmetic circuits. The computational complexity drastically increases with the circuit’s depth. Moreover, non-linear functionalities such as the ReLU activation function in DL cannot be supported.

GC, on the other hand, can support an arbitrary functionality while requiring only a *constant* round of interactions regardless of the depth of the computation. However, it has a high communication cost and a significant overhead for multiplication. More precisely, performing multiplication in GC has quadratic computation and communication complexity with respect to the bit-length of the input operands. It is well-known that the complexity of the contemporary DL methodologies is dominated by matrix-vector multiplications. GMW needs less communication than GC but requires many rounds of *interactions* between the two parties.

A standalone SS-based scheme provides a computationally inexpensive multiplication yet requires three or more independent (non-colluding) computing servers, which is a strong assumption. Mixed-protocol solutions have been proposed with the aim of utilizing the best characteristics of each of these protocols [7, 8, 9, 10]. They require secure conversion of secrets from one protocol to another in the middle of execution. Nevertheless, it has been shown that the cost of secret conversion is paid off in these hybrid solutions. Roughly speaking, the number of interactions between server and client (i.e., round complexity) in existing hybrid solutions is *linear* with respect to the depth of the DL model. Since depth is a major contributor to the deep learning accuracy [11], scalability of the mixed-protocol solutions with respect to the number of layers remains an unsolved issue for more complex, many-layer networks.

This paper introduces XONN, a novel end-to-end framework which provides a paradigm shift in the conceptual and practical realization of privacy-preserving inference on deep neural networks. The existing work has largely focused on the development of customized security protocols while using conventional fixed-point deep learning algorithms. XONN, for the first time, suggests leveraging the concept of the Binary Neural Networks (BNNs) in conjunction with the GC protocol. In BNNs, the weights and activations are restricted to binary (i.e.,  $\pm 1$ ) values, substituting the costly multiplications with simple XNOR operations dur-

ing the inference phase. The XNOR operation is known to be *free* in the GC protocol [12]; therefore, performing oblivious inference on BNNs using GC results in the removal of costly multiplications. Using our approach, we show that oblivious inference on the standard DL benchmarks can be performed with minimal, if any, decrease in the prediction accuracy.

We emphasize that an effective solution for oblivious inference should take into account the deep learning algorithms and optimization methods that can tailor the DL model for the security protocol. Current DL models are designed to run on CPU/GPU platforms where many multiplications can be performed with high throughput, whereas, bit-level operations are very inefficient. In the GC protocol, however, bit-level operations are inexpensive, but multiplications are rather costly. As such, we propose to train deep neural networks that involve many bit-level operations but *no* multiplications in the inference phase; using the idea of learning binary networks, we achieve an average of  $21\times$  reduction in the number of gates for the GC protocol.

We perform extensive evaluations on different datasets. Compared to the Gazelle [10] (the prior best solution) and MiniONN [9] frameworks, we achieve  $7\times$  and  $93\times$  lower inference latency, respectively. XONN outperforms DeepSecure [13] (prior best GC-based framework) by  $60\times$  and CryptoNets [14], an HE-based framework, by  $1859\times$ . Moreover, our solution renders a *constant* round of interactions between the client and the server, which has a significant effect on the performance on oblivious inference in Internet settings. We highlight our contributions as follows:

- Introduction of XONN, the *first* framework for privacy preserving DNN inference with a *constant* round complexity that does not need expensive matrix multiplications. Our solution is the first that can be scalably adapted to ensure security against malicious adversaries.
- Proposing a novel conditional addition protocol based on Oblivious Transfer (OT) [15], which optimizes the costly computations for the network’s input layer. Our protocol is  $6\times$  faster than GC and can be of independent interest. We also devise a novel network trimming algorithm to remove neurons from DNNs that minimally contribute to the inference accuracy, further reducing the GC complexity.
- Designing a high-level API to readily automate fast adaptation of XONN, such that users only input a high-level description of the neural network. We further facilitate the usage of our framework by designing a compiler that translates the network description from Keras to XONN.
- Proof-of-concept implementation of XONN and evaluation on various standard deep learning benchmarks. To demonstrate the scalability of XONN, we perform oblivious inference on neural networks with as many as 21 layers for the first time in the oblivious inference literature.

## 2 Preliminaries

Throughout this paper, scalars are represented as lower-case letters ( $x \in \mathbb{R}$ ), vectors are represented as bold lower-case letters ( $\mathbf{x} \in \mathbb{R}^n$ ), matrices are denoted as capital letters ( $X \in \mathbb{R}^{m \times n}$ ), and tensors of more than 2 ways are shown using bold capital letters ( $\mathbf{X} \in \mathbb{R}^{m \times n \times k}$ ). Brackets denote element selection and the colon symbol stands for all elements — $W[i, :]$  represents all values in the  $i$ -th row of  $W$ .

### 2.1 Deep Neural Networks

The computational flow of a deep neural network is composed of multiple computational layers. The input to each layer is either a vector (i.e.,  $\mathbf{x} \in \mathbb{R}^n$ ) or a tensor (i.e.,  $\mathbf{X} \in \mathbb{R}^{m \times n \times k}$ ). The output of each layer serves as the input of the next layer. The input of the first layer is the raw data and the output of the last layer represents the network's prediction on the given data (i.e., inference result). In an image classification task, for instance, the raw image serves as the input to the first layer and the output of the last layer is a vector whose elements represent the probability that the image belongs to each category. Below we describe the functionality of neural network layers.

**Linear Layers:** Linear operations in neural networks are performed in Fully-Connected (FC) and Convolution (CONV) layers. The vector dot product (VDP) between two vectors  $\mathbf{x} \in \mathbb{R}^n$  and  $\mathbf{w} \in \mathbb{R}^n$  is defined as follows:

$$\text{VDP}(\mathbf{x}, \mathbf{w}) = \sum_{i=1}^n \mathbf{w}[i] \cdot \mathbf{x}[i]. \quad (1)$$

Both CONV and FC layers repeat VDP computation to generate outputs as we describe next. A fully connected layer takes a vector  $\mathbf{x} \in \mathbb{R}^n$  and generates the output  $\mathbf{y} \in \mathbb{R}^m$  using a linear transformation:

$$\mathbf{y} = W \cdot \mathbf{x} + \mathbf{b}, \quad (2)$$

where  $W \in \mathbb{R}^{m \times n}$  is the weight matrix and  $\mathbf{b} \in \mathbb{R}^m$  is a bias vector. More precisely, the  $i$ -th output element is computed as  $\mathbf{y}[i] = \text{VDP}(W[i, :], \mathbf{x}) + \mathbf{b}[i]$ .

A convolution layer is another form of linear transformation that operates on images. The input of a CONV layer is represented as multiple rectangular channels (2D images) of the same size:  $\mathbf{X} \in \mathbb{R}^{h1 \times h2 \times c}$ , where  $h1$  and  $h2$  are the dimensions of the image and  $c$  is the number of channels. The CONV layer maps the input image into an output image  $\mathbf{Y} \in \mathbb{R}^{h1' \times h2' \times f}$ . A CONV layer consists of a weight tensor  $\mathbf{W} \in \mathbb{R}^{k \times k \times c \times f}$  and a bias vector  $\mathbf{b} \in \mathbb{R}^f$ . The  $i$ -th output channel in a CONV layer is computed by sliding the kernel  $\mathbf{W}[:, :, :, i] \in \mathbb{R}^{k \times k \times c}$  over the input, computing the dot product between the kernel and the windowed input, and adding the bias term  $\mathbf{b}[i]$  to the result.

**Non-linear Activations:** The output of linear transformations (i.e., CONV and FC) is usually fed to an activation layer, which applies an element-wise non-linear transformation to the vector/tensor and generates an output with the

same dimensionality. In this paper, we particularly utilize the Binary Activation (BA) function for hidden layers. BA maps the input operand to its sign value (i.e., +1 or -1).

**Batch Normalization:** A batch normalization (BN) layer is typically applied to the output of linear layers to normalize the results. If a BN layer is applied to the output of a CONV layer, it multiplies all of the  $i$ -th channel's elements by a scalar  $\boldsymbol{\gamma}[i]$  and adds a bias term  $\boldsymbol{\beta}[i]$  to the resulting channel. If BN is applied to the output of an FC layer, it multiplies the  $i$ -th element of the vector by a scalar  $\boldsymbol{\gamma}[i]$  and adds a bias term  $\boldsymbol{\beta}[i]$  to the result.

**Pooling:** Pooling layers operate on image channels outputted by the CONV layers. A pooling layer slides a window on the image channels and aggregates the elements within the window into a single output element. Max-pooling and Average-pooling are two of the most common pooling operations in neural networks. Typically, pooling layers reduce the image size but do not affect the number of channels.

### 2.2 Secret Sharing

A secret can be securely shared among two or multiple parties using Secret Sharing (SS) schemes. An SS scheme guarantees that each share does not reveal any information about the secret. The secret can be reconstructed using all (or subset) of shares. In XONN, we use additive secret sharing in which a secret  $S$  is shared among two parties by sampling a random number  $\hat{S}_1 \in_R \mathbb{Z}_{2^b}$  (integers modulo  $2^b$ ) as the first share and creating the second share as  $\hat{S}_2 = S - \hat{S}_1 \text{ mod } 2^b$  where  $b$  is the number of bits to describe the secret. While none of the shares reveal any information about the secret  $S$ , they can be used to reconstruct the secret as  $S = \hat{S}_1 + \hat{S}_2 \text{ mod } 2^b$ . Suppose that two secrets  $S^{(1)}$  and  $S^{(2)}$  are shared among two parties where party-1 has  $\hat{S}_1^{(1)}$  and  $\hat{S}_1^{(2)}$  and party-2 has  $\hat{S}_2^{(1)}$  and  $\hat{S}_2^{(2)}$ . Party- $i$  can create a share of the sum of two secrets as  $\hat{S}_i^{(1)} + \hat{S}_i^{(2)} \text{ mod } 2^b$  without communicating to the other party. This can be generalized for arbitrary (more than two) number of secrets as well. We utilize additive secret sharing in our Oblivious Conditional Addition (OCA) protocol (Section 3.3).

### 2.3 Oblivious Transfer

One of the most crucial building blocks of secure computation protocols, e.g., GC, is the Oblivious Transfer (OT) protocol [15]. In OT, two parties are involved: a sender and a receiver. The sender holds  $n$  different messages  $m_j$ ,  $j = 1 \dots n$ , with a specific bit-length and the receiver holds an index ( $ind$ ) of a message that she wants to receive. At the end of the protocol, the receiver gets  $m_{ind}$  with no additional knowledge about the other messages and the sender learns nothing about the selection index. In GC, 1-out-of-2 OT is used where  $n = 2$  in which case the selection index is only one bit. The initial realizations of OT required costly public key

encryptions for each run of the protocol. However, the OT Extension [16, 17, 18] technique enables performing OT using more efficient symmetric-key encryption in conjunction with a *fixed* number of base OTs that need public-key encryption. OT is used both in the OCA protocol as well as the Garbled Circuits protocol which we discuss next.

## 2.4 Garbled Circuits

Yao’s Garbled Circuits [4], or GC in short, is one of the generic two-party secure computation protocols. In GC, the result of an arbitrary function  $f(\cdot)$  on inputs from two parties can be computed without revealing each party’s input to the other. Before executing the protocol, function  $f(\cdot)$  has to be described as a Boolean circuit with two-input gates.

GC has three main phases: garbling, transferring data, and evaluation. In the first phase, only one party, the Garbler, is involved. The Garbler starts by assigning two randomly generated  $l$ -bit binary strings to each wire in the circuit. These binary strings are called *labels* and they represent semantic values 0 and 1. Let us denote the label of wire  $w$  corresponding to the semantic value  $x$  as  $L_x^w$ . For each gate in the circuit, the Garbler creates a four-row garbled table as follows. Each label of the output wire is encrypted using the input labels according to the truth table of the gate. For example, consider an AND gate with input wires  $a$  and  $b$  and output wire  $c$ . The last row of the garbled table is the encryption of  $L_c^c$  using labels  $L_1^a$  and  $L_1^b$ .

Once the garbling process is finished, the Garbler sends all of the garbled tables to the Evaluator. Moreover, he sends the correct labels that correspond to input wires that represent his inputs to the circuit. For example, if wire  $w^*$  is the first input bit of the Garbler and his input is 0, he sends  $L_0^*$ . The Evaluator acquires the labels corresponding to her input through 1-out-of-2 OT where Garbler is the sender with two labels as his messages and the Evaluator’s selection bit is her input for that wire. Having all of the garbled tables and labels of input wires, the Evaluator can start decrypting the garbled tables one by one until reaching the final output bits. She then learns the plaintext result at the end of the GC protocol based on the output labels and their relationships to the semantic values that are received from the Garbler.

## 3 The XONN Framework

In this section, we explain how neural networks can be trained such that they incur a minimal cost during the oblivious inference. The most computationally intensive operation in a neural network is matrix multiplication. In GC, each multiplication has a *quadratic* computation and communication cost with respect to the input bit-length. This is the major source of inefficiency in prior work [13]. We overcome this limitation by changing the learning process such that the trained neural network’s weights become binary. As

a result, costly multiplication operations are replaced with XNOR gates which are essentially free in GC. We describe the training process in Section 3.1. In Section 3.2, we explain the operations and their corresponding Boolean circuit designs that enable a very fast oblivious inference. In Section 4, we elaborate on XONN implementation.

### 3.1 Customized Network Binarization

Numerical optimization algorithms minimize a specific cost function associated with neural networks. It is well-known that neural network training is a non-convex optimization, meaning that there exist many locally-optimum parameter configurations that result in similar inference accuracies. Among these parameter settings, there exist solutions where both neural network parameters and activation units are restricted to take binary values (i.e., either +1 or -1); these solutions are known as Binary Neural Networks (BNNs) [19].

One major shortcoming of BNNs is their (often) low inference accuracy. In the machine learning community, several methods have been proposed to modify BNN functionality for accuracy enhancement [20, 21, 22]. These methods are devised for *plaintext* execution of BNNs and are not efficient for oblivious inference with GC. We emphasize that, when modifying BNNs for accuracy enhancement, one should also take into account the implications in the corresponding GC circuit. With this in mind, we propose to modify the number of channels and neurons in CONV and FC layers, respectively. Increasing the number of channels/neurons leads to a higher accuracy but it also increases the complexity of the corresponding GC circuit. As a result, XONN provides a trade-off between the accuracy and the communication/runtime of the oblivious inference. This tradeoff enables cloud servers to customize the complexity of the GC protocol to optimally match the computation and communication requirements of the clients. To customize the BNN, XONN configures the per-layer number of neurons in two steps:

- **Linear Scaling:** Prior to training, we scale the number of channels/neurons in all BNN layers with the same factor ( $s$ ), e.g.,  $s = 2$ . Then, we train the scaled BNN architecture.
- **Network Trimming:** Once the (uniformly) scaled network is trained, a post-processing algorithm removes redundant channels/neurons from each hidden layer to reduce the GC cost while maintaining the inference accuracy.

Figure 1 illustrates the BNN customization method for an example baseline network with four hidden layers. Network trimming (pruning) consists of two steps, namely, Feature Ranking and Iterative Pruning which we describe next.

**Feature Ranking:** In order to perform network trimming, one needs to sort the channels/neurons of each layer based on their contribution to the inference accuracy. In conventional neural networks, simple ranking methods sort features based

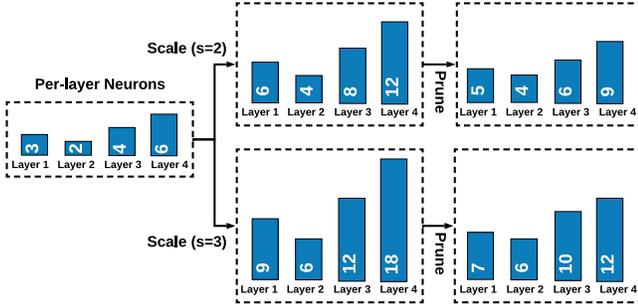

Figure 1: Illustration of BNN customization. The bars represent the number of neurons in each hidden layer.

on absolute value of the neurons/channels [23]. In BNNs, however, the weights/features are either  $+1$  or  $-1$  and the absolute value is not informative. To overcome this issue, we utilize first order Taylor approximation of neural networks and sort the features based on the magnitude of the gradient values [24]. Intuitively, the gradient with respect to a certain feature determines its importance; a high (absolute) gradient indicates that removing the neuron has a destructive effect on the inference accuracy. Inspired by this notion, we develop a feature ranking method described in Algorithm 1.

**Iterative Pruning:** We devise a step-by-step algorithm for model pruning which is summarized in Algorithm 2. At each step, the algorithm selects one of the BNN layers  $l^*$  and removes the first  $p^*$  features with the lowest importance (line 17). The selected layer  $l^*$  and the number of pruned neurons  $p^*$  maximize the following reward (line 15):

$$reward(l, p) = \frac{c_{curr} - c_{next}}{e^{a_{curr} - a_{next}}}, \quad (3)$$

where  $c_{curr}$  and  $c_{next}$  are the GC complexity of the BNN before and after pruning, whereas,  $a_{curr}$  and  $a_{next}$  denote the corresponding validation accuracies. The numerator of this reward encourages higher reduction in the GC cost while the denominator penalizes accuracy loss. Once the layer is pruned, the BNN is fine-tuned to recover the accuracy (line 18). The pruning process stops once the accuracy drops below a pre-defined threshold.

### 3.2 Oblivious Inference

BNNs are trained such that the weights and activations are binarized, i.e., they can only have two possible values:  $+1$  or  $-1$ . This property allows BNN layers to be rendered using a simplified arithmetic. In this section, we describe the functionality of different layer types in BNNs and their Boolean circuit translations. Below, we explain each layer type.

**Binary Linear Layer:** Most of the computational complexity of neural networks is due to the linear operations in CONV and FC layers. As we discuss in Section 2.1, linear operations are realized using vector dot product (VDP). In BNNs, VDP operations can be implemented using simplified circuits. We categorize the VDP operations of this work into

#### Algorithm 1 XONN Channel Sorting for CONV Layers

**Inputs:** Trained BNN with loss function  $\mathcal{L}$ , CONV layer  $l$  with output shape of  $h1 \times h2 \times f$ , subsampled validation data and labels  $\{(\mathbf{X}_1, z_1), \dots, (\mathbf{X}_k, z_k)\}$

**Output:** Indices of the sorted channels:  $\{i_0, \dots, i_f\}$

```

1:  $\mathbf{G} \leftarrow zeros(k \times h1 \times h2 \times f)$   $\triangleright$  define gradient tensor
2: for  $i = 1, \dots, k$  do
3:    $\mathcal{L} = \mathcal{L}(\mathbf{X}_i, z_i)$   $\triangleright$  evaluate loss function
4:    $\nabla_Y = \frac{\partial \mathcal{L}}{\partial Y^l}$   $\triangleright$  compute gradient w.r.t. layer output
5:    $\mathbf{G}[i, :, :, :] \leftarrow \nabla_Y$   $\triangleright$  store gradient
6: end for
7:  $\mathbf{G}_{abs} \leftarrow |\mathbf{G}|$   $\triangleright$  take elementwise absolute values
8:  $\mathbf{g}_s \leftarrow zeros(f)$   $\triangleright$  define sum of absolute values
9: for  $i = 1, \dots, f$  do
10:   $\mathbf{g}_s[i] \leftarrow sum(\mathbf{G}_{abs}[:, :, :, i])$ 
11: end for
12:  $\{i_0, \dots, i_f\} \leftarrow sort(\mathbf{g}_s)$ 
13: return  $\{i_0, \dots, i_f\}$ 

```

two classes: (i) Integer-VDP where only one of the vectors is binarized and the other has integer elements and (ii) Binary-VDP where both vectors have binary ( $\pm 1$ ) values.

**Integer-VDP:** For the first layer of the neural network, the server has no control over the input data which is not necessarily binarized. The server can only train binary weights and use them for oblivious inference. Consider an input vector  $\mathbf{x} \in \mathbb{R}^n$  with integer (possibly fixed-point) elements and a weight vector  $\mathbf{w} \in \{-1, 1\}^n$  with binary values. Since the elements of the binary vector can only take  $+1$  or  $-1$ , the Integer-VDP can be rendered using additions and subtractions. In particular, the binary weights can be used in a selection circuit that decides whether the pertinent integer input should be added to or subtracted from the VDP result.

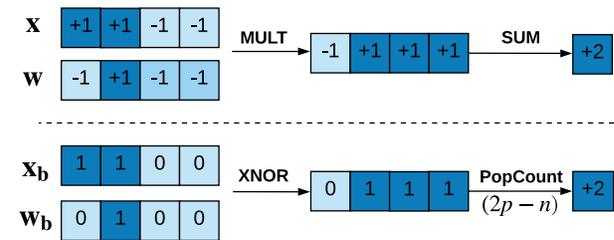

Figure 2: Equivalence of Binary-VDP and **XnorPopcount**.

**Binary-VDP:** Consider a dot product between two binary vectors  $\mathbf{x} \in \{-1, +1\}^n$  and  $\mathbf{w} \in \{-1, +1\}^n$ . If we encode each element with one bit (i.e.,  $-1 \rightarrow 0$  and  $+1 \rightarrow 1$ ), we obtain binary vectors  $\mathbf{x}_b \in \{0, 1\}^n$  and  $\mathbf{w}_b \in \{0, 1\}^n$ . It has been shown that the dot product of  $\mathbf{x}$  and  $\mathbf{w}$  can be efficiently computed using an *XnorPopcount* operation [19]. Figure 2 depicts the equivalence of VDP( $\mathbf{x}, \mathbf{w}$ ) and

**Algorithm 2** XONN Iterative BNN Pruning
 

---

**Inputs:** Trained BNN with  $n$  overall CONV and FC layers, minimum accuracy threshold  $\theta$ , number of pruning trials per layer  $t$ , subsampled validation data and labels  $data_V$ , training data and labels  $data_T$

**Output:** BNN with pruned layers

```

1:  $\mathbf{p} \leftarrow \text{zeros}(n-1)$ 
2:  $a_{curr} \leftarrow \text{Accuracy}(BNN, data_V | \mathbf{p})$ 
3:  $c_{curr} \leftarrow \text{Cost}(BNN | \mathbf{p})$ 
4: while  $a_{curr} > \theta$  do
5:   for  $l = 1, \dots, n-1$  do
6:      $inds \leftarrow \text{Rank}(BNN, l, data_V)$ 
7:      $f \leftarrow$  Number of neurons/channels
8:     for  $p = \mathbf{p}[l], \mathbf{p}[l] + \frac{f}{t}, \dots, f$  do
9:        $BNN_{next} \leftarrow \text{Prune}(BNN, l, p, inds)$ 
10:       $a_{next} \leftarrow \text{Accuracy}(BNN_{next}, data_V | \mathbf{p}[1], \dots, \mathbf{p}[l] = p, \dots, \mathbf{p}[n-1])$ 
11:       $c_{next} \leftarrow \text{Cost}(BNN_{next} | \mathbf{p}[1], \dots, \mathbf{p}[l] = p, \dots, \mathbf{p}[n-1])$ 
12:       $reward(l, p) = \frac{c_{curr} - c_{next}}{e^{(a_{curr} - a_{next})}}$ 
13:    end for
14:  end for
15:   $\{l^*, p^*\} \leftarrow \arg \max_{l, p} reward(l, p)$ 
16:   $\mathbf{p}[l^*] \leftarrow p^*$ 
17:   $BNN \leftarrow \text{Prune}(BNN, l^*, p^*, inds)$ 
18:   $BNN \leftarrow \text{Fine-tune}(BNN, data_T)$ 
19:   $a_{curr} \leftarrow \text{Accuracy}(BNN, data_V | \mathbf{p})$ 
20:   $c_{curr} \leftarrow \text{Cost}(BNN | \mathbf{p})$ 
21: end while
22: return  $BNN$ 
  
```

$XnorPopcount(\mathbf{x}_b, \mathbf{w}_b)$  for a VDP between 4-dimensional vectors. First, element-wise XNOR operations are performed between the two binary encodings. Next, the number of set bits  $p$  is counted, and the output is computed as  $2p - n$ .

**Binary Activation Function:** A Binary Activation (BA) function takes input  $x$  and maps it to  $y = \text{Sign}(x)$  where  $\text{Sign}(\cdot)$  outputs either  $+1$  or  $-1$  based on the sign of its input. This functionality can simply be implemented by extracting the most significant bit of  $x$ .

**Binary Batch Normalization:** in BNNs, it is often useful to normalize feature  $x$  using a Batch Normalization (BN) layer before applying the binary activation function. More specifically, a BN layer followed by a BA is equivalent to:

$$y = \text{Sign}(\gamma \cdot x + \beta) = \text{Sign}(x + \frac{\beta}{\gamma}),$$

since  $\gamma$  is a positive value. The combination of the two layers (BN+BA) is realized by a comparison between  $x$  and  $-\frac{\beta}{\gamma}$ .

**Binary Max-Pooling:** Assuming the inputs to the max-pooling layers are binarized, taking the maximum in a window is equivalent to performing logical OR over the binary encodings as depicted in Figure 3. Note that average-pooling layers are usually not used in BNNs since the average of multiple binary elements is no longer a binary value.

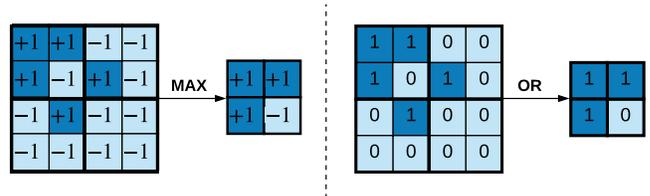

Figure 3: The equivalence between Max-Pooling and Boolean-OR operations in BNNs.

Figure 4 demonstrates the Boolean circuit for Binary-VDP followed by BN and BA. The number of non-XOR gates for binary-VDP is equal to the number of gates required to render the tree-adder structure in Figure 4. Similarly, Figure 5 shows the Integer-VDP counterpart. In the first level of the tree-adder of Integer-VDP (Figure 5), the binary weights determine whether the integer input should be added to or subtracted from the final result within the “Select” circuit. The next levels of the tree-adder compute the result of the integer-VDP using “Adder” blocks. The combination of BN and BA is implemented using a single *comparator*. Compared to Binary-VDP, Integer-VDP has a high garbling cost which is linear with respect to the number of bits. To mitigate this problem, we propose an alternative solution based on Oblivious Transfer (OT) in Section 3.3.

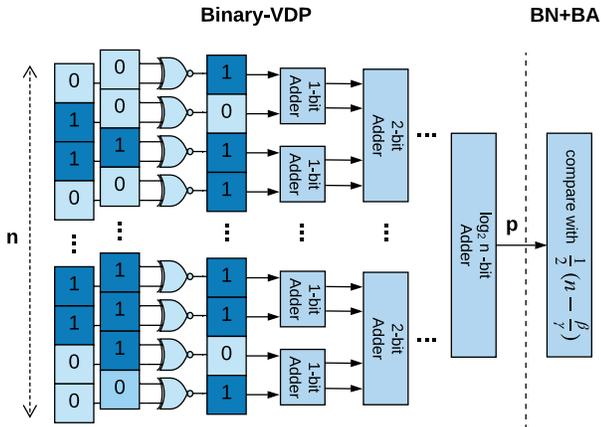

Figure 4: Circuit for binary-VDP followed by comparison for batch normalization (BN) and binary activation (BA).

### 3.3 Oblivious Conditional Addition Protocol

In XONN, all of the activation values as well as neural network weights are binary. However, the input to the neural network is provided by the user and is not necessarily binary. The first layer of a typical neural network comprises either an FC or a CONV layer, both of which are evaluated using oblivious Integer-VDP. On the one side, the user provides her input as non-binary (integer) values. On the other side, the network parameters are binary values representing  $-1$  and  $1$ . We now demonstrate how Integer-VDP can be described as an OT problem. Let us denote the user’s input as a vector  $\mathbf{v}_1$  of  $n$  ( $b$ -bit) integers. The server holds a vector of  $n$  binary values denoted by  $\mathbf{v}_2$ . The result of Integer-VDP is a number “ $y$ ” that can be described with

$$b' = \left\lceil \log_2(n \cdot (2^b - 1)) \right\rceil$$

bits. Figure 6 summarizes the steps in the OCA protocol. The first step is to *bit-extend*  $\mathbf{v}_1$  from  $b$ -bit to  $b'$ -bit. In other words, if  $\mathbf{v}_1$  is a vector of *signed* integer/fixed-point numbers, the most significant bit should be repeated ( $b' - b$ )-many times, otherwise, it has to be zero-padded for most significant bits. We denote the bit-extended vector by  $\mathbf{v}_1^*$ . The second step is to create the two’s complement vector of  $\mathbf{v}_1^*$ , called  $\overline{\mathbf{v}_1^*}$ . The client also creates a vector of  $n$  ( $b'$ -bit) randomly generated numbers, denoted as  $\mathbf{r}$ . She computes element-wise vector subtractions  $\mathbf{v}_1^* - \mathbf{r} \bmod 2^{b'}$  and  $\overline{\mathbf{v}_1^*} - \mathbf{r} \bmod 2^{b'}$ . These two vectors are  $n$ -many pair of messages that will be used as input to  $n$ -many 1-out-of-two OTs. More precisely,  $\overline{\mathbf{v}_1^*} - \mathbf{r} \bmod 2^{b'}$  is a list of first messages and  $\mathbf{v}_1^* - \mathbf{r} \bmod 2^{b'}$  is a list of second messages. The server’s list of selection bits is  $\mathbf{v}_2$ . After  $n$ -many OTs are finished, the server has a list of  $n$  transferred numbers called  $\mathbf{v}_t$  where

$$\mathbf{v}_t[i] = \begin{cases} \overline{\mathbf{v}_1^*}[i] - \mathbf{r}[i] \bmod 2^{b'} & \text{if } \mathbf{v}_2[i] = 0 \\ \mathbf{v}_1^*[i] - \mathbf{r}[i] \bmod 2^{b'} & \text{if } \mathbf{v}_2[i] = 1 \end{cases} \quad i = 1, \dots, n.$$

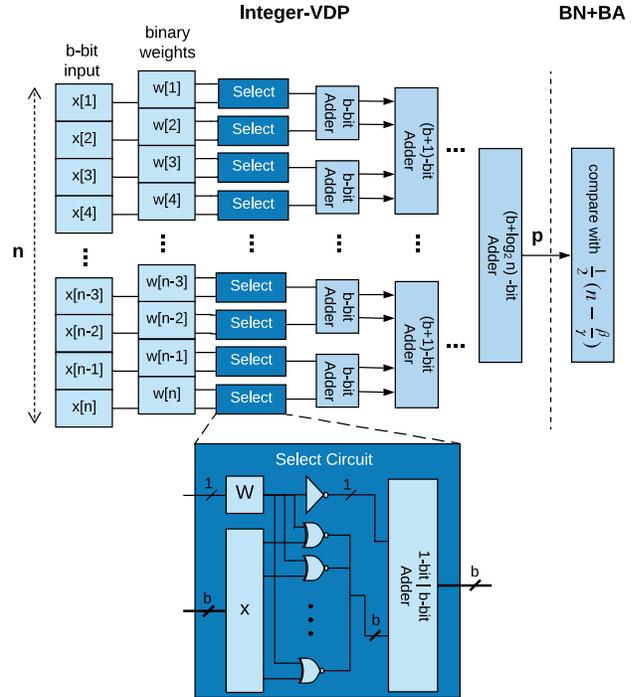

Figure 5: Circuit for Integer-VDP followed by comparison for batch normalization (BN) and binary activation (BA).

Finally, the client computes  $y_1 = \sum_{i=1}^n \mathbf{r}[i] \bmod 2^{b'}$  and the server computes  $y_2 = \sum_{i=1}^n \mathbf{v}_t[i] \bmod 2^{b'}$ . By OT’s definition, the receiver (server) gets only one of the two messages from the sender. That is, based on each selection bit (a binary weight), the receiver gets an additive share of either the sender’s number or its two’s complement. Upon adding all of the received numbers, the receiver computes an additive share of the Integer-VDP result. Now, even though the sender does not know which messages were selected by the receiver, she can add all of the randomly generated numbers  $\mathbf{r}[i]$ s which is equal to the other additive share of the Integer-VDP result. Since all numbers are described in the two’s complement format, subtractions are equivalent to the addition of the two’s complement values, which are created by the sender at the beginning of OCA. Moreover, it is possible that as we accumulate the values, the bit-length of the final Integer-VDP result grows accordingly. This is supported due to the bit-extension process at the beginning of the protocol. In other words, all additions are performed in a larger ring such that the result does not overflow.

Note that all numbers belong to the ring  $\mathbb{Z}_{2^{b'}}$  and by definition, a ring is closed under addition, therefore,  $y_1$  and  $y_2$  are true additive shares of  $y = y_1 + y_2 \bmod 2^{b'}$ . We described the OCA protocol for one Integer-VDP computation. As we outlined in Section 3.2, all linear operations in the first layer of the DL model (either FC or CONV) can be formulated as a series of Integer-VDPs.

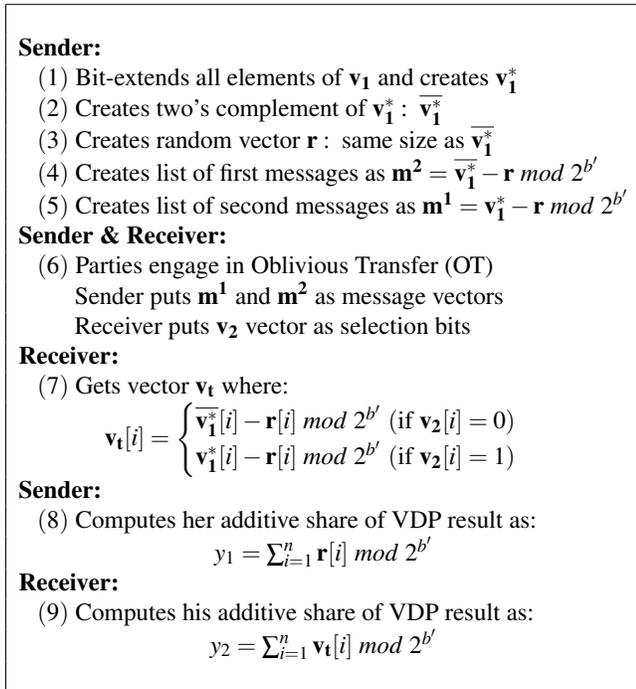

Figure 6: Oblivious Conditional Addition (OCA) protocol.

In traditional OT, public-key encryption is needed for each OT invocation which can be computationally expensive. Thanks to the Oblivious Transfer Extension technique [16, 17, 18], one can perform many OTs using symmetric-key encryption and only a fixed number of public-key operations.

**Required Modification to the Next Layer.** So far, we have shown how to perform Integer-VDP using OT. However, we need to add an “addition” layer to reconstruct the true value of  $y$  from its additive shares before further processing it. The overhead of this layer, as well as OT computations, are discussed next. Note that OCA is used only for the first layer and it does not change the overall constant round complexity of XONN since it is performed only once regardless of the number of layers in the DL model.

**Comparison to Integer-VDP in GC.** Table 1 shows the computation and communication costs for two approaches: (i) computing the first layer in GC and (ii) utilizing OCA. OCA removes the GC cost of the first layer in XONN. However, it adds the overhead of a set of OTs and the GC costs associated with the new ADD layer.

Table 1: Computation and communication cost of OCA.

Costs {Sender, Receiver}	GC	OCA	
		OT	ADD Layer
Comp. (AES ops)	$(n+1) \cdot b \cdot \{2, 4\}$	$n \cdot \{1, 2\}$	$b' \cdot \{2, 4\}$
Comm. (bit)	$(n+1) \cdot b \cdot 2 \cdot 128$	$n \cdot b$	$b' \cdot 2 \cdot 128$

### 3.4 Security of XONN

We consider the Honest-but-Curious (HbC) adversary model consistent with all of the state-of-the-art solutions for oblivious inference [7, 8, 9, 10, 13, 25]. In this model, neither of the involved parties is trusted but they are assumed to follow the protocol. Both server and client cannot infer any information about the other party’s input from the entire protocol transcript. XONN relies solely on the GC and OT protocols, both of which are proven to be secure in the HbC adversary model in [26] and [15], respectively. Utilizing binary neural networks does not affect GC and OT protocols in any way. More precisely, we have changed the function  $f(\cdot)$  that is evaluated in GC such that it is more efficient for the GC protocol: drastically reducing the number of AND gates and using XOR gates instead. Our novel Oblivious Conditional Addition (OCA) protocol (Section 3.3) is also based on the OT protocol. The sender creates a list of message pairs and puts them as input to the OT protocol. Each message is an additive share of the sender’s private data from which the secret data cannot be reconstructed. The receiver puts a list of selection bits as input to the OT. By OT’s definition, the receiver learns nothing about the unselected messages and the sender does not learn the selection bits.

During the past few years, several attacks have been proposed that extract some information about the DL model by querying the server many times [1, 27, 28]. It has been shown that some of these attacks can be effective in the black-box setting where the client only receives the prediction results and does not have access to the model. Therefore, considering the definition of an oblivious inference, these type of attacks are out of the scope of oblivious inference frameworks. However, in Appendix B, we show how these attacks can be thwarted by adding a simple layer at the end of the neural network which adds a negligible overhead.

**Security Against Malicious Adversaries.** The HbC adversary model is the standard security model in the literature. However, there are more powerful security models such as security against covert and malicious adversaries. In the malicious security model, the adversary (either the client or server) can deviate from the protocol at any time with the goal of learning more about the input from the other party. One of the main distinctions between XONN and the state-of-the-art solutions is that XONN can be automatically adapted to the malicious security using cut-and-choose techniques [29, 30, 31]. These methods take a GC protocol in HbC and readily extend it to the malicious security model. This modification increases the overhead but enables a higher security level. To the best of our knowledge, there is no practical solution to extend the customized mixed-protocol frameworks [7, 9, 10, 25] to the malicious security model. Our GC-based solution is more efficient compared to the mixed-protocol solutions and can be upgraded to the malicious security at the same time.

## 4 The XONN Implementation

In this section, we elaborate on the garbling/evaluation implementation of XONN. All of the optimizations and techniques proposed in this section do not change the security or correctness in anyway and only enable the framework’s scalability for large network architectures.

We design a new GC framework with the following design principles in mind: (i) *Efficiency*: XONN is designed to have a minimal data movement and low cache-miss rate. (ii) *Scalability*: oblivious inference inevitably requires significantly higher memory usage compared to plaintext evaluation of neural networks. High memory usage is one critical short-coming of state-of-the-art secure computation frameworks. As we show in our experimental results, XONN is designed to scale for very deep neural networks that have higher accuracy compared to networks considered in prior art. (iii) *Modularity*: our framework enables users to create Boolean description of different layers separately. This allows the hardware synthesis tool to generate more optimized circuits as we discuss in Section 4.1. (iv) *Ease-to-use*: XONN provides a very simple API that requires few lines of neural network description. Moreover, we have created a compiler that takes a Keras description and automatically creates the network description for XONN API.

XONN is written in C++ and supports all major GC optimizations proposed previously. Since the introduction of GC, many optimizations have been proposed to reduce the computation and communication complexity of this protocol. Bellare et al. [32] have provided a way to perform garbling using efficient fixed-key AES encryption. Our implementation benefits from this optimization by using Intel AES-NI instructions. Row-reduction technique [33] reduces the number of garbled tables from four to three. Half-Gates technique [34] further reduces the number of rows in the garbled tables from three to two. One of the most influential optimizations for the GC protocol is the *free-XOR* technique [12] which makes XOR, XNOR, and NOT almost free of cost. Our implementation for Oblivious Transfer (OT) is based on libOTe [35].

### 4.1 Modular Circuit Synthesis and Garbling

In XONN, each layer is described as multiple invocations of a *base* circuit. For instance, linear layers (CONV and FC) are described by a VDP circuit. MaxPool is described by an OR circuit where the number of inputs is the window size of the MaxPool layer. BA/BN layers are described using a comparison (CMP) circuit. The memory footprint is significantly reduced in this approach: we only create and store the base circuits. As a result, the connection between two invocations of two different base circuits is handled at the software level.

We create the Boolean circuits using TinyGarble [36] hardware synthesis approach. TinyGarble’s technology libraries are optimized for GC and produce circuits that have

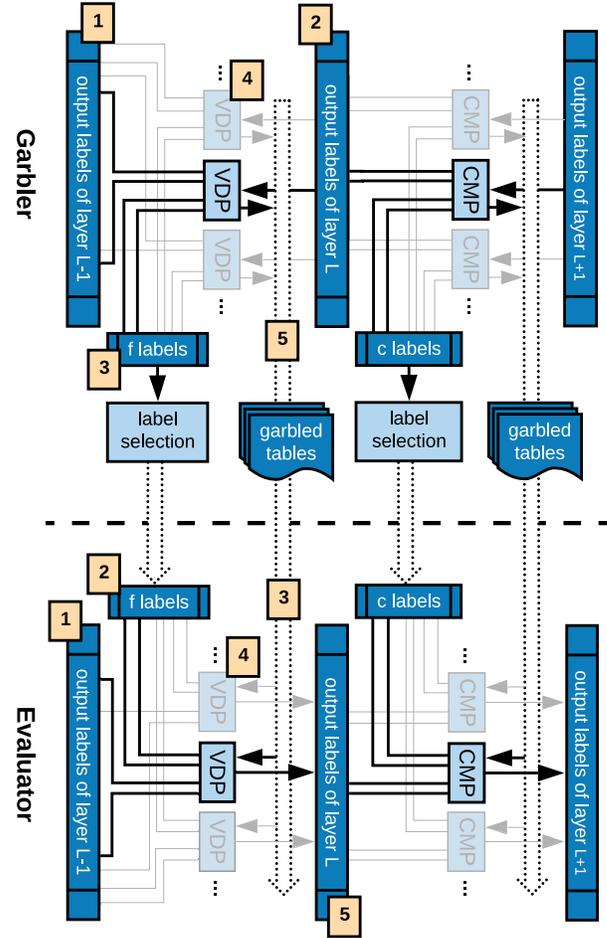

Figure 7: XONN modular and pipelined garbling engine.

low number of non-XOR gates. Note that the Boolean circuit description of the contemporary neural networks comprises between millions to billions of Boolean gates, whereas, synthesis tools cannot support circuits of this size. However, due to XONN modular design, one can synthesize each base circuit separately. Thus, the bottleneck transfers from the synthesis tool’s maximum number of gates to the system’s memory. As such, XONN effectively scales for any neural network complexity regardless of the limitations of the synthesis tool as long as enough memory (i.e., RAM) is available. Later in this section, we discuss how to increase the scalability by dynamically managing the allocated memory.

**Pipelined GC Engine.** In XONN, computation and communication are pipelined. For instance, consider a CONV layer followed by an activation layer. We garble/evaluate these layers by multiple invocations of the VDP and CMP circuits (one invocation per output neuron) as illustrated in Figure 7. Upon finishing the garbling process of layer  $L - 1$ , the Garbler starts garbling the  $L^{\text{th}}$  layer and creates the random labels for output wires of layer  $L$ . He also needs to create the random labels associated with his input (i.e., the weight

parameters) to layer  $L$ . Given a set of input and output labels, Garbler generates the garbled tables, and sends them to the Evaluator as soon as one is ready. He also sends one of the two input labels for his input bits. At the same time, the Evaluator has computed the output labels of the  $(L - 1)^{th}$  layer. She receives the garbled tables as well as the Garbler's selected input labels and decrypts the tables and stores the output labels of layer  $L$ .

**Dynamic Memory Management.** We design the framework such that the allocated memory for the labels is released as soon as it is no longer needed, reducing the memory usage significantly. For example, without our dynamic memory management, the Garbler had to allocate 10.41GB for the labels and garbled tables for the entire garbling of BC1 network (see Section 7 for network description). In contrast, in our framework, the size of memory allocation never exceeds 2GB and is less than 0.5GB for most of the layers.

## 4.2 Application Programming Interface (API)

XONN provides a simplified and easy-to-use API for oblivious inference. The framework accepts a high-level description of the network, parameters of each layer, and input structure. It automatically computes the number of invocations and the interconnection between all of the base circuits. Figure 8 shows the complete network description that a user needs to write for a sample network architecture (the BM3 architecture, see Section 7). All of the required circuits are automatically generated using TinyGarble [36] synthesis libraries. It is worth mentioning that for the task of oblivious inference, our API is much simpler compared to the recent *high-level* EzPC framework [25]. For example, the required lines of code to describe BM1, BM2, and BM3 network architectures (see Section 7) in EzPC are 78, 88, and 154, respectively. In contrast, they can be described with only 6, 6, and 10 lines of code in our framework.

<pre> 1 INPUT 28 1 8 2 CONV 5 16 1 0 OCA 3 ACT 4 MAXPOOL 2 5 CONV 5 16 1 0 6 ACT 7 MAXPOOL 2 8 FC 100 9 ACT 10 FC 10 </pre>	<pre> Description: INPUT #input_feature #channels #bit-length CONV #filter_size #filters #stride     #Pad #OCA (optional) MAXPOOL #window_size FC #output_neurons </pre>
---	--

Figure 8: Sample snippet code in XONN.

**Keras to XONN Translation.** To further facilitate the adaptation of XONN, a compiler is created to translate the description of the neural network in Keras [37] to the XONN format. The compiler creates the `.xonnn` file and puts the network parameters into the required format (HEX string) to be read by the framework during the execution of the GC protocol. All of the parameter adjustments are also automatically performed by the compiler.

## 5 Related Work

CryptoNets [14] is one of the early solutions that suggested the adaptation of Leveled Homomorphic Encryption (LHE) to perform oblivious inference. LHE is a variant of Partially HE that enables evaluation of depth-bounded arithmetic circuits. DeepSecure [13] is a privacy-preserving DL framework that relies on the GC protocol. CryptoDL [38] improves upon CryptoNets [14] and proposes more efficient approximation of the non-linear functions using low-degree polynomials. Their solution is based on LHE and uses mean-pooling in replacement of the max-pooling layer. Chou et al. propose to utilize the sparsity within the DL model to accelerate the inference [39].

SecureML [8] is a privacy-preserving machine learning framework based on homomorphic encryption, GC, and secret sharing. SecureML also uses customized activation functions and supports privacy-preserving training in addition to inference. Two non-colluding servers are used to train the DL model where each client XOR-shares her input and sends the shares to both servers. MiniONN [9] is a mixed-protocol framework for oblivious inference. The underlying cryptographic protocols are HE, GC, and secret sharing.

Chameleon [7] is a more recent mixed-protocol framework for machine learning, i.e., Support Vector Machines (SVMs) as well as DNNs. Authors propose to perform low-depth non-linear functions using the Goldreich-Micali-Wigderson (GMW) protocol [5], high-depth functions by the GC protocol, and linear operations using additive secret sharing. Moreover, they propose to use correlated randomness to more efficiently compute linear operations. EzPC [25] is a secure computation framework that enables users to write high-level programs and translates it to a protocol-based description of both Boolean and Arithmetic circuits. The back-end cryptographic engine is based on the ABY framework.

Shokri and Shmatikov [40] proposed a solution for privacy-preserving collaborative deep learning where the training data is distributed among many parties. Their approach, which is based on *differential privacy*, enables clients to train their local model on their own training data and update the central model's parameters held by a central server. However, it has been shown that a malicious client can learn significant information about the other client's private data [41]. Google [42] has recently introduced a new approach for securely aggregating the parameter updates from multiple users. However, none of these approaches [40, 42] study the oblivious inference problem. An overview of related frameworks is provided in [43, 44].

Frameworks such as ABY<sup>3</sup> [45] and SecureNN [46] have different computation models and they rely on three (or four) parties during the oblivious inference. In contrast, XONN does not require an additional server for the computation. In E2DM framework [47], the model owner can encrypt and outsource the model to an untrusted server to perform obliv-

ious inference. Concurrently and independently of ours, in TAPAS [48], Sanyal et al. study the binarization of neural networks in the context of oblivious inference. They report inference latency of 147 seconds on MNIST dataset with 98.6% prediction accuracy using custom CNN architecture. However, as we show in Section 7 (BM3 benchmark), XONN outperforms TAPAS by close to *three orders of magnitude*.

Gazelle [10] is the previously most efficient oblivious inference framework. It is a mixed-protocol approach based on additive HE and GC. In Gazelle, convolution operations are performed using the packing property of HE. In this approach, many numbers are packed inside a single ciphertext for faster convolutions. In Section 6, we briefly discuss one of the essential requirements that the Gazelle protocol has to satisfy in order to be secure, namely, *circuit privacy*.

**High-Level Comparison.** In contrast to prior work, we propose a DL-secure computation co-design approach. To the best of our knowledge, DeepSecure [13] is the only solution that preprocesses the data and network before the secure computation protocol. However, this preprocessing step is unrelated to the underlying cryptographic protocol and compacts the network and data. Moreover, in this mode, some information about the network parameters and structure of data is revealed. Compared to mixed-protocol solutions, not only XONN provides a more efficient solution but also maintains the *constant* round complexity regardless of the number of layers in the neural network model. It has been shown that round complexity is one of the important criteria in designing secure computation protocols [49] since the performance can significantly be reduced in Internet settings where the network latency is high. Another important advantage of our solution is the ability to upgrade to the security against malicious adversaries using cut-and-choose techniques [29, 30, 31]. As we show in Section 7, XONN outperforms all previous solutions in inference latency. Table 2 summarizes a high-level comparison between state-of-the-art oblivious inference frameworks.

Table 2: High-Level Comparison of oblivious inference frameworks. “C”onstant round complexity. “D”eep learning/secure computation co-design. “I”ndependence of secondary server. “U”pgradeable to malicious security using standard solutions. “S”upporting any non-linear layer.

## 6 Circuit Privacy

In Gazelle [10], for each linear layer, the protocol starts with a vector  $\mathbf{m}$  that is secret-shared between client  $\mathbf{m}_1$  and server  $\mathbf{m}_2$  ( $\mathbf{m} = \mathbf{m}_1 + \mathbf{m}_2$ ). The protocol outputs the secret shares of the vector  $\mathbf{m}' = A \cdot \mathbf{m}$  where  $A$  is a matrix known to the server but not to the client. The protocol has the following procedure: (i) Client generates a pair  $(pk, sk)$  of public and secret keys of an additive homomorphic encryption scheme HE. (ii) Client sends  $\text{HE.Enc}_{pk}(\mathbf{m}_1)$  to the server. Server adds its share ( $\mathbf{m}_2$ ) to the ciphertext and recovers encryption of  $\mathbf{m}$ :  $\text{HE.Enc}_{pk}(\mathbf{m})$ . (iii) Server homomorphically evaluates the multiplication with  $A$  and obtains the encryption of  $\mathbf{m}'$ . (iv) Server secret shares  $\mathbf{m}'$  by sampling a random vector  $\mathbf{r}$  and returns ciphertext  $\mathbf{c} = \text{HE.Enc}_{pk}(\mathbf{m}' - \mathbf{r})$  to the client. The client can decrypt  $\mathbf{c}$  using private key  $sk$  and obtain  $\mathbf{m}' - \mathbf{r}$ .

Gazelle uses the Brakerski-Fan-Vercauteren (BFV) scheme [50, 51]. However, the vanilla BFV scheme does not provide circuit privacy. At high-level, the circuit privacy requirement states that the ciphertext  $\mathbf{c}$  should not reveal any information about the private inputs to the client (i.e.,  $A$  and  $\mathbf{r}$ ) other than the underlying plaintext  $A \cdot \mathbf{m} - \mathbf{r}$ . Otherwise, some information is leaked. Gazelle proposes two methods to provide circuit privacy that are not incorporated in their implementation. Hence, we need to scale up their performance numbers for a fair comparison.

The first method is to let the client and server engage in a two-party secure decryption protocol, where the input of client is  $sk$  and input of server is  $\mathbf{c}$ . However, this method adds communication and needs extra rounds of interaction. A more widely used approach is *noise flooding*. Roughly speaking, the server adds a large noise term to  $\mathbf{c}$  before returning it to the client. The noise is big enough to drown any extra information contained in the ciphertext, and still small enough to so that it still decrypts to the same plaintext.

For the concrete instantiation of Gazelle, one needs to triple the size of ciphertext modulus  $q$  from 60 bits to 180 bits, and increase the ring dimension  $n$  from 2048 to 8192. The (amortized) complexity of homomorphic operations in the BFV scheme is approximately  $O(\log n \log q)$ , with the exception that some operations run in  $O(\log q)$  amortized time. Therefore, adding noise flooding would result in a *3-3.6 times slow down* for the HE component of Gazelle. To give some concrete examples, we consider two networks used for benchmarking in Gazelle: MNIST-D and CIFAR-10 networks. For the MNIST-D network, homomorphic encryption takes 55% and 22% in online and total time, respectively. For CIFAR-10, the corresponding figures are 35%, and 10%<sup>1</sup>. Therefore, we estimate that the total time for MNIST-D will grow from 0.81s to 1.16-1.27s (network BM3 in this paper). In the case of CIFAR-10 network, the total time will grow from 12.9s to 15.48-16.25s.

<sup>1</sup>these percentage numbers are obtained through private communication with the authors.

## 7 Experimental Results

We evaluate XONN on MNIST and CIFAR10 datasets, which are two popular classification benchmarks used in prior work. In addition, we provide four healthcare datasets to illustrate the applicability of XONN in real-world scenarios. For training XONN, we use Keras [37] with Tensorflow backend [52]. The source code of XONN is compiled with GCC 5.5.0 using O3 optimization. All Boolean circuits are synthesized using Synopsys Design Compiler 2015. Evaluations are performed on (Ubuntu 16.04 LTS) machines with Intel-Core i7-7700k and 32GB of RAM. The experimental setup is comparable (but has less computational power) compared to the prior art [10]. Consistent with prior frameworks, we evaluate the benchmarks in the LAN setting.

### 7.1 Evaluation on MNIST

There are mainly three network architectures that prior works have implemented for the MNIST dataset. We convert these reference networks into their binary counterparts and train them using the standard BNN training algorithm [19]. Table 3 summarizes the architectures for the MNIST dataset.

Table 3: Summary of the trained binary network architectures evaluated on the MNIST dataset. Detailed descriptions are available in Appendix A.2, Table 13.

Arch.	Previous Papers	Description
BM1	SecureML [8], MiniONN [9]	3 FC
BM2	CryptoNets [14], MiniONN [9], DeepSecure [13], Chameleon [7]	1 CONV, 2 FC
BM3	MiniONN [9], EzPC [25]	2 CONV, 2MP, 2FC

**Analysis of Network Scaling:** Recall that the classification accuracy of XONN is controlled by scaling the number of neurons in all layers (Section 3.1). Figure 9a depicts the inference accuracy with different scaling factors (more details in Table 11 in Appendix A.2). As we increase the scaling factor, the accuracy of the network increases. This accuracy improvement comes at the cost of a higher computational complexity of the (scaled) network. As a result, increasing the scaling factor leads to a higher runtime. Figure 9b depicts the runtime of different BNN architectures as a function of the scaling factor  $s$ . Note that the runtime grows (almost) quadratically with the scaling factor due to the quadratic increase in the number of *Popcount* operations in the neural network (see *BM3*). However, for the *BM1* and *BM2* networks, the overall runtime is dominated by the constant initialization cost of the OT protocol ( $\sim 70$  millisecond).

**GC Cost and the Effect of OCA:** The communication cost of GC is the key contributor to the overall runtime of XONN. Here, we analyze the effect of the scaling factor on the total message size. Figure 10 shows the communication cost of

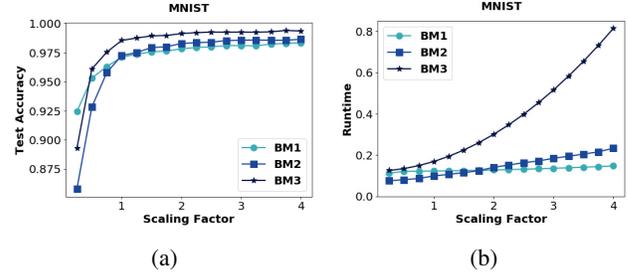

Figure 9: Effect of scaling factor on (a) accuracy and (b) inference runtime of MNIST networks. No pruning was applied in this evaluation.

GC for the *BM1* and *BM2* network architectures. As can be seen, the message size increases with the scaling factor. We also observe that the OCA protocol drastically reduces the message size. This is due to the fact that the first layer of *BM1* and *BM2* models account for a large portion of the overall computation; hence, improving the first layer with OCA has a drastic effect on the overall communication.

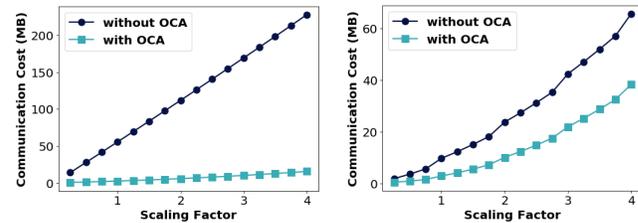

Figure 10: Effect of OCA on the communication of the *BM1* (left) and *BM2* (right) networks for different scaling factors. No pruning was applied in this evaluation.

**Comparison to Prior Art:** We emphasize that, unlike previous work, the accuracy of XONN can be customized by tuning the scaling factor ( $s$ ). Furthermore, our channel/neuron pruning step (Algorithm 2) can reduce the GC cost in a post-processing phase. To provide a fair comparison between XONN and prior art, we choose a proper scaling factor and trim the pertinent scaled BNN such that the corresponding BNN achieves the same accuracy as the previous work. Table 4 compares XONN with the previous work in terms of accuracy, latency, and communication cost (a.k.a., message size). The last column shows the scaling factor ( $s$ ) used to increase the width of the hidden layers of the BNN. Note that the scaled network is further trimmed using Algorithm 2.

In XONN, the runtime for oblivious transfer is at least  $\sim 0.07$  second for initiating the protocol and then it grows linearly with the size of the garbled tables; As a result, in very small architectures such as *BM1*, our solution is slightly slower than previous works since the constant runtime dominates the total runtime. However, for the *BM3* network which has higher complexity than *BM1* and *BM2*, XONN

achieves a more prominent advantage over prior art. In summary, our solution achieves up to  $7.7\times$  faster inference (average of  $3.4\times$ ) compared to Gazelle [10]. Compared to MiniONN [9], XONN has up to  $62\times$  lower latency (average of  $26\times$ ) Table 4. Compared to EzPC [25], our framework is  $34\times$  faster. XONN achieves  $37.5\times$ ,  $1859\times$ ,  $60.4\times$ , and  $14\times$  better latency compared to SecureML [8], CryptoNets [14], DeepSecure [13], and Chameleon [7], respectively.

Table 4: Comparison of XONN with the state-of-the-art for the MNIST network architectures.

Arch.	Framework	Runtime (s)	Comm. (MB)	Acc. (%)	s
BM1	SecureML	4.88	-	93.1	-
	MiniONN	1.04	15.8	97.6	-
	EzPC	0.7	76	97.6	-
	Gazelle	0.09	0.5	97.6	-
	XONN	0.13	4.29	97.6	1.75

	XONN	0.15	32.13	99.0	2.00

## 7.2 Evaluation on CIFAR-10

In Table 5, we summarize the network architectures that we use for the CIFAR-10 dataset. In this table, BC1 is the binarized version of the architecture proposed by MiniONN. To evaluate the scalability of our framework to larger networks, we also binarize the Fitnet [53] architectures, which are denoted as BC2-BC5. We also evaluate XONN on the popular VGG16 network architecture (BC6). Detailed architecture descriptions are available in Appendix A.2, Table 13.

Table 5: Summary of the trained binary network architectures evaluated on the CIFAR-10 dataset.

Arch.	Previous Papers	Description
BC1	MiniONN[9], Chameleon [7], EzPC [25], Gazelle [10]	7 CONV, 2 MP, 1 FC
BC2	Fitnet [53]	9 CONV, 3 MP, 1 FC
BC3	Fitnet [53]	9 CONV, 3 MP, 1 FC
BC4	Fitnet [53]	11 CONV, 3 MP, 1 FC
BC5	Fitnet [53]	17 CONV, 3 MP, 1 FC
BC6	VGG16 [54]	13 CONV, 5 MP, 3 FC

**Analysis of Network Scaling:** Similar to the analysis on the MNIST dataset, we show that the accuracy of our binary models for CIFAR-10 can be tuned based on the scaling factor that determines the number of neurons in each layer. Figure 11a depicts the accuracy of the BNNs with different scal-

ing factors. As can be seen, increasing the scaling factor enhances the classification accuracy of the BNN. The runtime also increases with the scaling factor as shown in Figure 11b (more details in Table 12, Appendix A.2).

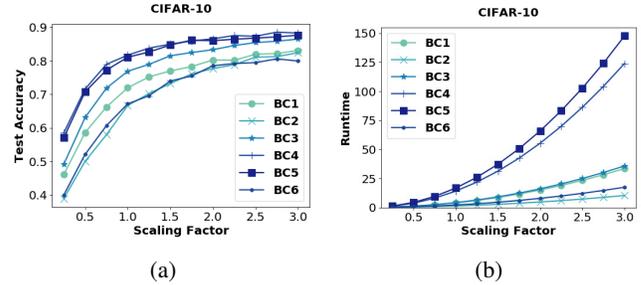

Figure 11: (a) Effect of scaling factor on accuracy for CIFAR-10 networks. (b) Effect of scaling factor on runtime. No pruning was applied in this evaluation.

**Comparison to Prior Art:** We scale the BC2 network with a factor of  $s = 3$ , then prune it using Algorithm 2. Details of pruning steps are available in Table 10 in Appendix A.1. The resulting network is compared against prior art in Table 6. As can be seen, our solution achieves  $2.7\times$ ,  $45.8\times$ ,  $9.1\times$ , and  $93.1\times$  lower latency compared to Gazelle, EzPC, Chameleon, and MiniONN, respectively.

Table 6: Comparison of XONN with prior art on CIFAR-10.

Framework	Runtime (s)	Comm. (MB)	Acc. (%)	s
MiniONN	544	9272	81.61	-
Chameleon	52.67	2650	81.61	-
EzPC	265.6	40683	81.61	-
Gazelle	15.48	1236	81.61	-
XONN	5.79	2599	81.85	3.00

## 7.3 Evaluation on Medical Datasets

One of the most important applications of oblivious inference is medical data analysis. Recent advances in deep learning greatly benefit many complex diagnosis tasks that require exhaustive manual inspection by human experts [55, 56, 57, 58]. To showcase the applicability of oblivious inference in real-world medical applications, we provide several benchmarks for publicly available healthcare datasets summarized in Table 7. We split the datasets into validation and training portions as indicated in the last two columns of Table 7. All datasets except Malaria Infection are normalized to have 0 mean and standard deviation of 1 per feature. The images of Malaria Infection dataset are resized to  $32 \times 32$  pictures. The normalized datasets are quantized up to 3 decimal digits. Detailed architectures are available in Appendix A.2, Table 13. We report the validation accuracy along with inference time and message size in Table 8.

Table 7: Summary of medical application benchmarks.

Task	Arch.	Description	# of Samples	
			Tr.	Val.
Breast Cancer [59]	BH1	3 FC	453	113
Diabetes [60]	BH2	3 FC	615	153
Liver Disease [61]	BH3	3 FC	467	116
Malaria Infection [62]	BH4	2 CONV, 2 MP, 2 FC	24804	2756

Table 8: Runtime, communication cost (Comm.), and accuracy (Acc.) for medical benchmarks.

Arch.	Runtime (ms)	Comm. (MB)	Acc. (%)
BH1	82	0.35	97.35
BH2	75	0.16	80.39
BH3	81	0.3	80.17
BH4	482	120.75	95.03

## 8 Conclusion

We introduce XONN, a novel framework to automatically train and use deep neural networks for the task of oblivious inference. XONN utilizes Yao’s Garbled Circuits (GC) protocol and relies on binarizing the DL models in order to translate costly matrix multiplications to XNOR operations that are free in the GC protocol. Compared to Gazelle [10], prior best solution, XONN achieves  $7\times$  lower latency. Moreover, in contrast to Gazelle that requires one round of interaction for each layer, our solution needs a constant round of interactions regardless of the number of layers. Maintaining constant round complexity is an important requirement in Internet settings as a typical network latency can significantly degrade the performance of oblivious inference. Moreover, since our solution relies on the GC protocol, it can provide much stronger security guarantees such as security against malicious adversaries using standard cut-and-choose protocols. XONN high-level API enables clients to utilize the framework with a minimal number of lines of code. To further facilitate the adaptation of our framework, we design a compiler to translate the neural network description in Keras format to that of XONN.

**Acknowledgements** We would like to thank the anonymous reviewers for their insightful comments.

## A Experimental Details

### A.1 Network Trimming Examples

Table 9 and 10 summarize the trimming steps for the MNIST and CIFAR-10 benchmarks, respectively.

Table 9: Trimming MNIST architectures.

Network	Property	Trimming Step				Change
		initial	step 1	step 2	step 3	
BM1 (s=1.75)	Acc. (%)	97.63	97.59	97.28	97.02	-0.61%
	Comm. (MB)	4.95	4.29	3.81	3.32	1.49× less
	Lat. (ms)	158	131	114	102	1.54× faster
BM2 (s=4)	Acc. (%)	98.64	98.44	98.37	98.13	-0.51%
	Comm. (MB)	38.28	28.63	24.33	15.76	2.42× less
	Lat. (ms)	158	144	134	104	1.51× faster
BM3 (s=2)	Acc. (%)	99.22	99.11	98.96	99.00	-0.22%
	Comm. (MB)	56.08	42.51	37.34	32.13	1.75× less
	Lat. (ms)	190	165	157	146	1.3× faster

Table 10: Trimming the BC2 network for CIFAR-10.

Property	Trimming Step				Change
	initial	step 1	step 2	step 3	
Acc. (%)	82.40	82.39	82.41	81.85	-0.55%
Com. (GB)	3.38	3.05	2.76	2.60	1.30× less
Lat. (s)	7.59	6.87	6.23	5.79	1.31× faster

### A.2 Accuracy, Runtime, and Communication

Runtime and communication reports are available in Table 11 and Table 12 for MNIST and CIFAR-10 benchmarks, respectively. The corresponding neural network architectures are provided in Table 13. Entries corresponding to a communication of more than 40GB are estimated using numerical runtime models.

Table 11: Accuracy (Acc.), communication (Comm.), and latency (Lat.) for MNIST dataset. Channel/neuron trimming is not applied.

Arch.	s	Acc. (%)	Comm. (MB)	Lat. (s)
BM1	1	97.10	2.57	0.12
	1.5	97.56	4.09	0.13
	2	97.82	5.87	0.13
	3	98.10	10.22	0.14
BM2	4	98.34	15.62	0.15
	1	97.25	2.90	0.10
	1.50	97.93	5.55	0.12
	2	98.28	10.09	0.14
BM3	3	98.56	21.90	0.18
	4	98.64	38.30	0.23
	1	98.54	17.59	0.17
	1.5	98.93	36.72	0.22
BM3	2	99.13	62.77	0.3
	3	99.26	135.88	0.52
	4	99.35	236.78	0.81

Table 12: Accuracy (Acc.), communication (Comm.), and latency (Lat.) for CIFAR-10 dataset. Channel/neuron trimming is not applied.

Arch.	s	Acc. (%)	Comm. (MB)	Lat. (s)
BC1	1	0.72	1.26	3.96
	1.5	0.77	2.82	8.59
	2	0.80	4.98	15.07
	3	0.83	11.15	33.49
BC2	1	0.67	0.39	1.37
	1.5	0.73	0.86	2.78
	2	0.78	1.53	4.75
	3	0.82	3.40	10.35
BC3	1	0.77	1.35	4.23
	1.5	0.81	3.00	9.17
	2	0.83	5.32	16.09
	3	0.86	11.89	35.77
BC4	1	0.82	4.66	14.12
	1.5	0.85	10.41	31.33
	2	0.87	18.45	55.38
	3	0.88	41.37	123.94
BC5	1	0.81	5.54	16.78
	1.5	0.85	12.40	37.29

	3	0.80	5.77	17.44

## B Attacks on Deep Neural Networks

In this section, we review three of the most important attacks against deep neural networks that are relevant to the context of oblivious inference [1, 27, 28]. In all three, a client-server model is considered where the client is the adversary and attempts to learn more about the model held by the server. The client sends many inputs and receives the inference results. He then analyzes the results to infer more information about either the network parameters or the training data that has been used in the training phase of the model. We briefly review each attack and illustrate a simple defense mechanism with negligible overhead based on the suggestions provided in these works.

**Model Inversion Attack [27].** In the black-box access model of this attack (which fits the computational model of this work), an adversarial client attempts to learn about a prototypical sample of one of the classes. The client iteratively creates an input that maximizes the confidence score corresponding to the target class. Regardless of the specific training process, the attacker can learn significant information by querying the model many times.

**Model Extraction Attack [1].** In this type of attack, an adversary's goal is to estimate the parameters of the machine learning model held by the server. For example, in a logistic regression model with  $n$  parameters, the model can be extracted by querying the server  $n$  times and upon receiving the confidence values, solving a system of  $n$  equations. Model extraction can diminish the pay-per-prediction business model of technology companies. Moreover, it can be used as a pre-step towards the model inversion attack.

**Membership Inference Attack [28].** The objective of this attack is to identify whether a given input has been used in the training phase of the model or not. This attack raises certain privacy concerns. The idea behind this attack is that the neural networks usually perform better on the data that they were trained on. Therefore, two inputs that belong to the same class, one used in the training phase and one not, will have noticeable differences in the confidence values. This behavior is called *overfitting*. The attack can be mitigated using regularization techniques that reduce the dependency of the DL model on a single training sample. However, overfitting is not the only contributor to this information leakage.

**Defense Mechanisms.** In the prior state-of-the-art oblivious inference solution [9], it has been suggested to limit the number of queries from a specific client to limit the information leakage. However, in practice, an attacker can impersonate himself as many different clients and circumvent this defense mechanism. Note that all three attacks rely on the fact that along with the inference result, the server provides the confidence vector that specifies how likely the client's input belongs to each class. Therefore, as suggested by prior work [1, 27, 28], it is recommended to augment a *filter* layer that (i) rounds the confidence scores or (ii) selects the index

of a class that has the highest confidence score.

1. *Rounding the confidence values:* Rounding the values simply means omitting one (or more) of the Least Significant Bit (LSB) of all of the numbers in the last layer. This operation is in fact *free* in GC since it means Garbler has to avoid providing the mapping for those LSBs.
2. *Reporting the class label:* This operation is equivalent to computing  $\text{argmax}$  on the last layer. For a vector of size  $c$  where each number is represented with  $b$  bits,  $\text{argmax}$  is translated to  $c \cdot (2b + 1)$  many non-XOR (AND) gates. For example, in a typical architecture for MNIST (e.g., BM3) or CIFAR-10 dataset (e.g., BC1), the overhead is 1.68E-2% and 1.36E-4%, respectively.

Note that the two aforementioned defense mechanisms can be augmented to any framework that supports non-linear functionalities [7, 9, 13]. However, we want to emphasize that compared to mixed-protocol solutions, this means that another round of communication is usually needed to support the filter layer. Whereas, in XONN the filter layer does not increase the number of rounds and has negligible overhead compared to the overall protocol.

# JEDI: Many-to-Many End-to-End Encryption and Key Delegation for IoT

Sam Kumar, Yuncong Hu, Michael P Andersen, Raluca Ada Popa, and David E. Culler  
*University of California, Berkeley*

## Abstract

As the Internet of Things (IoT) emerges over the next decade, developing secure communication for IoT devices is of paramount importance. Achieving end-to-end encryption for large-scale IoT systems, like smart buildings or smart cities, is challenging because multiple principals typically interact *indirectly* via intermediaries, meaning that the recipient of a message is not known in advance. This paper proposes JEDI (Joining Encryption and Delegation for IoT), a many-to-many end-to-end encryption protocol for IoT. JEDI encrypts and signs messages end-to-end, while conforming to the decoupled communication model typical of IoT systems. JEDI's keys support expiry and fine-grained access to data, common in IoT. Furthermore, JEDI allows principals to delegate their keys, restricted in expiry or scope, to other principals, thereby granting access to data and managing access control in a scalable, distributed way. Through careful protocol design and implementation, JEDI can run across the spectrum of IoT devices, including ultra low-power deeply embedded sensors severely constrained in CPU, memory, and energy consumption. We apply JEDI to an existing IoT messaging system and demonstrate that its overhead is modest.

## 1 Introduction

As the Internet of Things (IoT) has emerged over the past decade, smart devices have become increasingly common. This trend is only expected to continue, with tens of billions of new IoT devices deployed over the next few years [30]. The IoT vision requires these devices to communicate to discover and use the resources and data provided by one another. Yet, these devices collect privacy-sensitive information about users. A natural step to secure privacy-sensitive data is to use *end-to-end encryption* to protect it during transit.

Existing protocols for end-to-end encryption, such as SSL/TLS and TextSecure [44], focus on *one-to-one* communication between two principals: for example, Alice sends a message to Bob over an insecure channel. Such protocols, however, appear not to be a good fit for large-scale industrial IoT systems. Such IoT systems demand *many-to-many* communication among **decoupled** senders and receivers, and require **decentralized delegation of access** to enforce which devices can communicate with which others.

We investigate existing IoT systems, which currently do not encrypt data end-to-end, to understand the requirements on an end-to-end encryption protocol like JEDI. We use *smart cities* as an example application area, and data-collecting sensors in a large organization as a concrete use case. We identify three central requirements, which we treat in turn below:

Figure 1: IoT comprises a diverse set of devices, which span more than four orders of magnitude of computing power (estimated in Dhrystone MIPS).<sup>1</sup>

▷ **Decoupled senders and receivers.** IoT-scale systems could consist of thousands of principals, making it infeasible for consumers of data (e.g., applications) to maintain a separate session with each producer of data (e.g., sensors). Instead, senders are typically **decoupled** from receivers. Such decoupling is common in *publish-subscribe* systems for IoT, such as MQTT, AMQP, XMPP, and Solace [76]. In particular, many-to-many communication based on publish-subscribe is the *de-facto* standard in smart buildings, used in systems like BOSS [36], VOLTTRON [82], Brume [66] and bw2 [5], and adopted commercially in AllJoyn and IoTivity. Senders publish messages by addressing them to *resources* and sending them to a *router*. Recipients *subscribe* to a resource by asking the router to send them messages addressed to that resource.

Many systems for smart buildings/cities, like sMAP [35], SensorAct [7], bw2 [5], VOLTTRON [82], and BAS [56], organize resources as a **hierarchy**. A resource hierarchy matches the organization of IoT devices: for instance, smart cities contain buildings, which contain floors, which contain rooms, which contain sensors, which produce streams of readings. We represent each resource—a leaf in the hierarchy—as a Uniform Resource Indicator (**URI**), which is like a file path. For example, a sensor that measures temperature and humidity might send its readings to the two URIs `buildingA/floor2/roomLHall/sensor0/temp` and `buildingA/floor2/roomLHall/sensor0/hum`. A user can subscribe to a URI prefix, such as `buildingA/floor2/roomLHall/*`, which represents a subtree of the hierarchy. He would then receive all sensor readings in room “LHall.”

▷ **Decentralized delegation.** Access control in IoT needs to be fine-grained. For example, if Bob has an app that needs

<sup>1</sup>Image credits: <https://tweakers.net/pricewatch/1275475/asus-f5401a-dm1201t.html>, <https://www.lg.com/uk/mobile-phones/lg-H791>, <https://www.bestbuy.com/site/nest-learning-thermostat-3rd-generation-stainless-steel/4346501.p?skuId=4346501>, <https://www.macys.com/shop/product/fitbit-charge-2-heart-rate-fitness-wristband?ID=2999458>

access to temperature readings from a single sensor, that app should receive the decryption key for only that one URI, even if Bob has keys for the entire room. In an IoT-scale system, it is not scalable for a central authority to individually give fine-grained decryption keys to each person's devices. Moreover, as we discuss in §2, such an approach would pose increased security and privacy risks. Instead, Bob, who himself has access to readings for the entire room, should be able to delegate temperature-readings access to the app. Generally, a principal with access to a set of resources can give another principal access to a subset of those resources.

Vanadium [77] and bw2 [5] introduced *decentralized delegation* (SPKI/SDSI [31] and Macaroons [13]) in the smart buildings space. Since then, decentralized delegation has become the state-of-the-art for access control in smart buildings, especially those geared toward large-scale commercial buildings or organizations [42,52]. In these systems, a principal can access a resource if there exists a *chain* of delegations, from the owner of the resource to that principal, granting access. At each link in the chain, the extent of access may be qualified by *caveats*, which add restrictions to which resources can be accessed and when. While these systems provide delegation of permissions, they do not provide protocols for encrypting and decrypting messages end-to-end.

▷ **Resource constraints.** IoT devices vary greatly in their capabilities, as shown in Fig. 1. This includes devices constrained in CPU, memory, and energy, such as wearable devices and low-cost environmental sensors.

In smart buildings/cities, one application of interest is *indoor environmental sensing*. Sensors that measure temperature, humidity, or occupancy may be deployed in a building; such sensors are *battery-powered* and transmit readings using a *low-power* wireless network. To see ubiquitous deployment, they must cost only *tens of dollars* per unit and have *several years* of battery life. To achieve this price/power point, sensor platforms are heavily resource-constrained, with mere *kilo-bytes* of memory (farthest right in Fig. 1) [3,4,26,41,49,59,69]. The *power consumption* of encryption is a serious challenge, even more so than its latency on a slower CPU; the CPU and radio must be used sparingly to avoid consuming energy too quickly [55, 89]. For example, on the sensor platform used in our evaluation, an average CPU utilization of merely 5% would result in less than a year of battery life, *even if the power cost of using the transducers and network were zero*.

## 1.1 Overview of JEDI

This paper presents JEDI, a *many-to-many* end-to-end encryption protocol compatible with the above three requirements of IoT systems. JEDI encrypts messages end-to-end for confidentiality, signs them for integrity while preserving anonymity, and supports delegation with caveats, all while allowing senders and receivers to be decoupled via a resource hierarchy. JEDI differs from existing encryption protocols like SSL/TLS, requiring us to overcome a number of *challenges*:

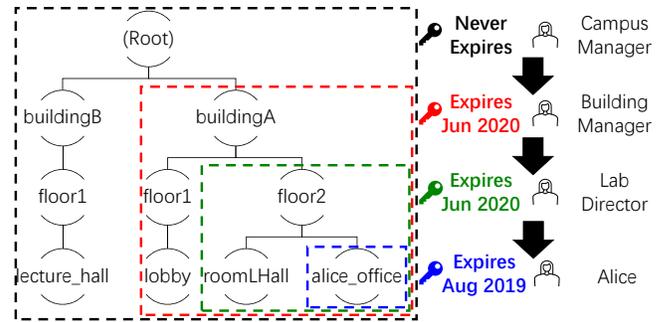

Figure 2: JEDI keys can be qualified and delegated, supporting decentralized, cryptographically-enforced access control via key delegation. Each person has a decryption key for the indicated resource subtree that is valid until the indicated expiry time. Black arrows denote delegation.

1. Formulating a new system model for end-to-end encryption to support **decoupled senders and receivers** and **decentralized delegation** typical of IoT systems (§ 1.1.1)
2. Realizing this expressive model while working within the **resource constraints** of IoT devices (§ 1.1.2)
3. Allowing receivers to verify the integrity of messages, while preserving the anonymity of senders (§ 1.1.3)
4. Extending JEDI's model to support revocation (§ 1.1.4)

Below, we explain how we address each of these challenges.

### 1.1.1 JEDI's System Model (§2)

Participants in JEDI are called *principals*. Any principal can create a **resource hierarchy** to represent some resources that it owns. Because that principal owns all of the resources in the hierarchy, it is called the *authority* of that hierarchy.

Due to the setting of **decoupled senders and receivers**, the sender can no longer encrypt messages with the receiver's public key, as in traditional end-to-end encryption. Instead, JEDI models principals as interacting with resources, rather than with other principals. Herein lies the key difference between JEDI's model and other end-to-end encryption protocols: the publisher of a message encrypts it according to the URI to which it is published, not the recipients subscribed to that URI. Only principals permitted to subscribe to a URI are given keys that can decrypt messages published to that URI.

IoT systems that support **decentralized delegation** (Vanadium, bw2), as well as related non-IoT authorization systems (e.g., SPKI/SDSI [31] and Macaroons [13]) provide principals with tokens (e.g., certificate chains) that they can present to prove they have access to a certain resource. Providing tokens, however, is not enough for end-to-end encryption; unlike these systems, JEDI allows *decryption keys* to be distributed via chains of delegations. Furthermore, the URI prefix and expiry time associated with each JEDI key can be restricted at each delegation. For example, as shown in Fig. 2, suppose Alice, who works in a research lab, needs access to sensor readings in her office. In the past, the campus facilities manager, who is the authority for the hierarchy, granted a key for `buildingA/*` to the building manager, who granted a key

for `buildingA/floor2/*` to the lab director. Now, Alice can obtain the key for `buildingA/floor2/alice_office/*` directly from her local authority (the lab director).

### 1.1.2 Encryption with URIs and Expiry (§3)

JEDI supports *decoupled* communication. The resource to which a message is published acts as a *rendezvous point* between the senders and receivers, used by the underlying system to route messages. Central to JEDI is the challenge of finding an analogous *cryptographic rendezvous point* that senders can use to encrypt messages without knowledge of receivers. A number of IoT systems [70, 74] use only simple cryptography like AES, SHA2, and ECDSA, but these primitives are not expressive enough to encode JEDI’s rendezvous point, which must support hierarchically-structured resources, non-interactive expiry, and decentralized delegation.

Existing systems [83–85] with similar expressivity to JEDI use Attribute-Based Encryption (ABE) [12, 48]. Unfortunately, ABE is not suitable for JEDI because it is too expensive, especially in the context of **resource constraints** of IoT devices. Some IoT systems rule it out due to its latency alone [74]. In the context of low-power devices, encryption with ABE would also consume too much power. JEDI circumvents the problem of using ABE or basic cryptography with two insights: (1) Even though ABE is too heavy for low-power devices, this does not mean that we must resort to only symmetric-key techniques. We show that certain IBE schemes [1] can be made practical for such devices. (2) **Time is another resource hierarchy**: a timestamp can be expressed as `year/month/day/hour`, and in this hierarchical representation, any time range can be represented efficiently as a logarithmic number of subtrees. With this insight, we can simultaneously support URIs and expiry via a nonstandard use of a certain type of IBE scheme: WKD-IBE [1]. Like ABE, WKD-IBE is based on bilinear groups (pairings), but it is an order-of-magnitude less expensive than ABE as used in JEDI. To make JEDI practical on low-power devices, we design it to invoke WKD-IBE *rarely*, while relying on AES most of the time, much like session keys. Thus, JEDI achieves expressivity commensurate to IoT systems that do not encrypt data—significantly more expressive than AES-only solutions—while allowing several years of battery life for low-power low-cost IoT devices.

### 1.1.3 Integrity and Anonymity (§4)

In addition to being encrypted, messages should be signed so that the recipient of a message can be sure it was not sent by an attacker. This can be achieved via a certificate chain, as in SPKI/SDSI or bw2. Certificates can be distributed in a decentralized manner, just like encryption keys in Fig. 2.

Certificate chains, however, are insufficient if anonymity is required. For example, consider an office space with an occupancy sensor in each office, each publishing to the same URI `buildingA/occupancy`. In aggregate, the occupancy sensors could be useful to inform, e.g., heating/cooling in the building, but individually, the readings for each room could be

considered privacy-sensitive. The occupancy sensors in different rooms could use different certificate chains, if they were authorized/installed by different people. This could be used to deanonymize occupancy readings. To address this challenge, we adapt the WKD-IBE scheme that we use for end-to-end encryption to achieve an *anonymous* signature scheme that can encode the URI and expiry and support decentralized delegation. Using this technique, anonymous signatures are practical even on low-power embedded IoT devices.

### 1.1.4 Revocation (§5)

As stated above, JEDI keys support expiry. Therefore, it is possible to achieve a lightweight revocation scheme by delegating each key with short expiry and periodically renewing it to extend the expiry. To revoke a key, one simply does not renew it. We expect this expiry-based revocation to be sufficient for most use cases, especially for low-power devices, which typically just “sense and send.”

Enforcing revocation cryptographically, without relying on expiration, is challenging. As we discuss in §5, any cryptographically-enforced scheme that provides immediate revocation (i.e., keys can be revoked without waiting for them to expire) is subject to the fundamental limitation that the sender of a message must know which recipients are revoked when it encrypts the message. JEDI provides a form of immediate revocation, subject to this constraint. We use techniques from tree-based broadcast encryption [37, 67] to encrypt in such a way that all decryption keys for that URI, *except for ones on a revocation list*, can be used to decrypt. Achieving this is nontrivial because we have to combine broadcast encryption with JEDI’s semantics of hierarchical resources, expiry, and delegation. First, we modify broadcast encryption to support delegation, in such a way that if a key is revoked, all delegations made with that key are also implicitly revoked. Then, we integrate broadcast revocation, in a *non-black-box* way, with JEDI’s encryption and delegation, as a third resource hierarchy alongside URIs and expiry.

## 1.2 Summary of Evaluation

For our evaluation, we use JEDI to encrypt messages transmitted over bw2 [5, 27], a deployed open-source messaging system for smart buildings, and demonstrate that JEDI’s overhead is small in the critical path. We also evaluate JEDI for a commercially available sensor platform called “Hamilton” [49], and show that a Hamilton-based sensor sending one sensor reading every 30 seconds would see several years of battery lifetime when sending sensor readings encrypted with JEDI. As Hamilton is among the least powerful platforms that will participate in IoT (farthest to the right in Fig. 1), this validates that JEDI is practical across the IoT spectrum.

## 2 JEDI’s Model and Threat Model

A principal can post a message to a resource in a hierarchy by encrypting it according to the resource’s URI, hierarchy’s public parameters, and current time, and passing it to the un-

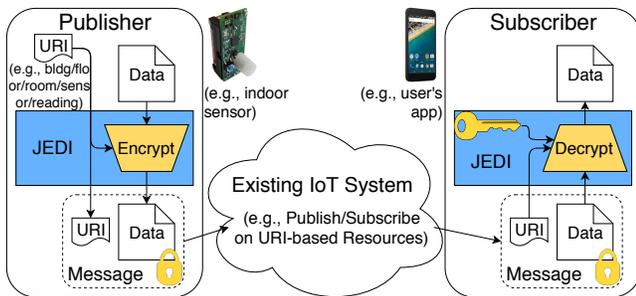

Figure 3: Applying JEDI to a smart buildings IoT system. Components introduced by JEDI are shaded. The subscriber’s key is obtained via JEDI’s decentralized delegation (Fig. 2).

derlying system that delivers it to the relevant subscribers. Given the secret key for a resource subtree and time range, a principal can generate a secret key for a subset of those resources and subrange of that time range, and give it to another principal, as in Fig. 2. The receiving principal can use the delegated key to decrypt messages that are posted to a resource in that subset at a time during that subrange.

*JEDI does not require the structure of the resource hierarchy to be fixed in advance.* In Fig. 2, the campus facilities manager, when granting access to `buildingA/*` to the building manager, need not be concerned with the structure of the subtree rooted at `buildingA`. This allows the building manager to organize `buildingA/*` independently.

## 2.1 Trust Assumptions

A principal is trusted for the resources it owns or was given access to (for the time ranges for which it was given access). In other words, an adversary who compromises a principal can read all resources that principal can read and forge new messages as if it were that principal. In particular, an adversary who compromises the authority for a resource hierarchy gains control over that resource hierarchy.

JEDI allows each principal to act as an authority for its own resource hierarchy in its own trust domain, without a single authority spanning all hierarchies. In particular, *principals* are not organized hierarchically; a principal may be delegated multiple keys, each belonging to a different resource hierarchy. In the example in Fig. 2, Alice might also receive JEDI keys from her landlord granting access to resources in her apartment building, in a separate hierarchy where her landlord is the authority. If Alice owns resources she would like to delegate to others, she can set up her own hierarchy to represent those resources. Existing IoT systems with decentralized delegation, like `bw2` and `Vanadium`, use a similar model.

## 2.2 Applying JEDI to an Existing System

As shown in Fig. 3, JEDI can be applied as a wrapper around existing many-to-many communication systems, including publish-subscribe systems, for smart cities. The transfer of messages from producers to consumers is handled by the existing system. A common design used by such systems is to have a central broker (or router) forward messages; how-

ever, an adversary who compromises the broker can read all messages. In this context, JEDI’s end-to-end encryption protects data from such an adversary. Publishers encrypt their messages with JEDI before passing them to the underlying communication system (without knowledge of who the subscribers are), and subscribers decrypt them with JEDI after receiving them from the underlying communication system (without knowledge of who the publishers are).

## 2.3 Comparison to a Naïve Key Server Model

To better understand the benefits of JEDI’s model, consider the natural strawman of a trusted key server. This key server generates a key for every URI and time. A publisher encrypts each message for that URI with the same key. A subscriber requests this key from the trusted key server, which must first check if the subscriber is authorized to receive it. The subscriber can decrypt messages for a URI using this key, and contact the key server for a new key when the key expires. JEDI’s model is better than this key server model as follows:

- *Improved security.* Unlike the trusted key server, which must always be online, the authority in JEDI can delegate qualified keys to some principals *and then go offline*, leaving these principals to qualify and delegate keys further. While the authority is offline, it is more difficult for an attacker to compromise it and easier for the authority to protect its secrets because it need only access them rarely. This reasoning is the basis of root Certificate Authorities (CAs), which access their master keys infrequently. In contrast, the trusted key server model requires a central trusted party (key server) to be online to grant/revoke access to any resource.
- *Improved privacy.* No single participant sees all delegations in JEDI. An adversary in JEDI who steals an authority’s secret key can decrypt all messages for that hierarchy, but still does not learn who has access to which resource, and cannot access separate hierarchies to which the first authority has no access. In contrast, an adversary who compromises the key server learns who has access to which resource and can decrypt messages for all hierarchies.
- *Improved scalability.* In the campus IoT example above, if a building admin receives access to all sensors and all their different readings for a building, the admin must obtain a potentially very large number of keys, instead of one key for the entire building. Moreover, the campus-wide key server needs to grant decryption keys to each application owned by each employee or student at the university. Finally, the campus-wide key server must understand which delegations are allowed at lower levels in the hierarchy, requiring the entire hierarchy to be centrally administered.

## 2.4 IoT Gateways

Low-power wireless embedded sensors, due to power constraints, often do not use network protocols like Wi-Fi, and instead use specialized low-power protocols such as Bluetooth or IEEE 802.15.4. It is common for these devices to rely on an *application-layer gateway* to send data to computers

outside of the low-power network [91]. This gateway could be in the form of a phone app (e.g., Fitbit), or in the form of a specialized border router [25, 92]. In some traditional setups, the gateway is responsible for performing encryption/authentication [70]. JEDI accepts that gateways may be necessary for Internet connectivity, but does not rely on them for security—JEDI’s cryptography is lightweight enough to run directly on the low-power sensor nodes. This approach prevents the gateway from becoming a single point of attack; an attacker who compromises the gateway cannot see or forge data for any device using that gateway.

## 2.5 Generalizability of JEDI’s Model

Since JEDI decouples senders from receivers, it has no requirements on what happens at any intermediaries (e.g., does not require messages to be forwarded from publishers to subscribers in any particular way). Thus, JEDI works even when messages are exchanged in a broadcast medium, e.g., multi-cast. This also means that JEDI is more broadly applicable to systems with hierarchically organized resources. For example, URIs could correspond to filepaths in a file system, or URLs in a RESTful web service.

## 2.6 Security Goals

JEDI’s goal is to ensure that principals can only read messages from or send messages to resources they have been granted access to receive from or send to. In the context of publish-subscribe, JEDI also hides the content of messages from an adversary who controls the router.

JEDI does not attempt to hide metadata relating to the actual transfer of messages (e.g., the URIs on which messages are published, which principals are publishing or subscribing to which resources, and timing). Hiding this metadata is a complementary task to achieving delegation and end-to-end encryption in JEDI, and techniques from the secure messaging literature [29, 32, 81] will likely be applicable.

## 3 End-to-End Encryption in JEDI

A central question answered in this section is: How should publishers encrypt messages before passing them to the underlying system for delivery (§3.4)? As explained in §1.1.2, although ABE, the obvious choice, is too heavy for low-power devices, we identify WKD-IBE, a more lightweight identity-based encryption scheme, as sufficient to achieve JEDI’s properties. The primary challenge is to encode a sufficiently expressive rendezvous point in the WKD-IBE ID (called a *pattern*) that publishers use to encrypt messages (§3.4).

### 3.1 Building Block: WKD-IBE

We first explain WKD-IBE [1], the encryption scheme that JEDI uses as a building block. Throughout this paper, we denote the security parameter as  $\kappa$ .

In WKD-IBE, messages are encrypted with *patterns*, and keys also correspond to patterns. A pattern is a list of values:  $P = (\mathbb{Z}_p^* \cup \{\perp\})^\ell$ . The notation  $P(i)$  denotes the  $i$ th compo-

nent of  $P$ , 1-indexed. A pattern  $P_1$  *matches* a pattern  $P_2$  if, for all  $i \in [1, \ell]$ , either  $P_1(i) = \perp$  or  $P_1(i) = P_2(i)$ . In other words, if  $P_1$  specifies a value for an index  $i$ ,  $P_2$  must match it at  $i$ . Note that the “matches” operation is not commutative; “ $P_1$  matches  $P_2$ ” does not imply “ $P_2$  matches  $P_1$ ”.

We refer to a component of a pattern containing an element of  $\mathbb{Z}_p^*$  as *fixed*, and to a component that contains  $\perp$  as *free*. To aid our presentation, we define the following sets:

**Definition 1.** For a pattern  $S$ , we define:

$$\text{fixed}(S) = \{(i, S(i)) \mid S(i) \neq \perp\}$$

$$\text{free}(S) = \{i \mid S(i) = \perp\}$$

A key for pattern  $P_1$  can decrypt a message encrypted with pattern  $P_2$  if  $P_1 = P_2$ . Furthermore, a key for pattern  $P_1$  can be used to derive a key for pattern  $P_2$ , as long as  $P_1$  matches  $P_2$ . In summary, the following is the syntax for WKD-IBE.

- **Setup**( $1^\kappa, 1^\ell$ )  $\rightarrow$  Params, MasterKey;
- **KeyDer**(Params, Key<sub>Pattern<sub>A</sub></sub>, Pattern<sub>B</sub>)  $\rightarrow$  Key<sub>Pattern<sub>B</sub></sub>, derives a key for Pattern<sub>B</sub>, where either Key<sub>Pattern<sub>A</sub></sub> is the MasterKey, or Pattern<sub>A</sub> matches Pattern<sub>B</sub>;
- **Encrypt**(Params, Pattern,  $m$ )  $\rightarrow$  Ciphertext<sub>Pattern,  $m$</sub> ;
- **Decrypt**(Key<sub>Pattern</sub>, Ciphertext<sub>Pattern,  $m$</sub> )  $\rightarrow m$ .

We use the WKD-IBE construction in §3.2 of [1], based on BBG HIBE [17]. Like the BBG construction, it has constant-size ciphertexts, but requires the maximum pattern length  $\ell$  to be known at Setup time. In this WKD-IBE construction, patterns containing  $\perp$  can only be used in **KeyDer**, not in **Encrypt**; we extend it to support encryption with patterns containing  $\perp$ . We include the WKD-IBE construction with our optimizations in the appendix of our extended paper [57].

### 3.2 Concurrent Hierarchies in JEDI

WKD-IBE was originally designed to allow delegation in a *single* hierarchy. For example, the original suggested use case of WKD-IBE was to generate secret keys for a user’s email addresses in all valid subdomains, such as `sysadmin@*.univ.edu` [1].

JEDI, however, uses WKD-IBE in a nonstandard way to simultaneously support *multiple* hierarchies, one for URIs and one for expiry (and later in §5, one for revocation), each in the vein of HIBE. We think of the  $\ell$  components of a WKD-IBE pattern as “slots” that are initially empty, and are progressively filled in with calls to **KeyDer**. To combine a hierarchy of maximum depth  $\ell_1$  (e.g., the URI hierarchy) and a hierarchy of maximum depth  $\ell_2$  (e.g., the expiry hierarchy), one can **Setup** WKD-IBE with the number of slots equal to  $\ell = \ell_1 + \ell_2$ . The first  $\ell_1$  slots are filled in left-to-right for the first hierarchy and the remaining  $\ell_2$  slots are filled in left-to-right for the second hierarchy (Fig. 4).

### 3.3 Overview of Encryption in JEDI

Each principal maintains a **key store** containing WKD-IBE decryption keys. To create a resource hierarchy, any principal

can call the WKD-IBE **Setup** function to create a resource hierarchy. It releases the *public parameters* and stores the *master secret key* in its key store, making it the authority of that hierarchy. To delegate access to a URI prefix for a time range, a principal (possibly the authority) searches its key store for a set of keys for a superset of those permissions. It then qualifies those keys using **KeyDer** to restrict them to the specific URI prefix and time range (§3.5), and sends the resulting keys to the recipient of the delegation.<sup>2</sup> The recipient accepts the delegation by adding the keys to its key store.

Before sending a message to a URI, a principal encrypts the message using WKD-IBE. The pattern used to encrypt it is derived from the URI and the current time (§3.4), which are included along with the ciphertext. When a principal receives a message, it searches its key store, using the URI and time included with the ciphertext, for a key to decrypt it.

In summary, JEDI provides the following API:

**Encrypt**(Message, URI, Time) → Ciphertext  
**Decrypt**(Ciphertext, URI, Time, KeyStore) → Message  
**Delegate**(KeyStore, URIPrefix, TimeRange) → KeySet  
**AcceptDelegation**(KeyStore, KeySet) → KeyStore'

Note that the WKD-IBE public parameters are an implicit argument to each of these functions. Finally, although the above API lists the arguments to **Delegate** as URIPrefix and TimeRange, JEDI actually supports succinct delegation over more complex sets of URIs and timestamps (see §3.7).

### 3.4 Expressing URI/Time as a Pattern

A message is encrypted using a pattern derived from (1) the URI to which the message is addressed, and (2) the current time. Let  $H : \{0, 1\}^* \rightarrow \mathbb{Z}_p^*$  be a collision-resistant hash function. Let  $\ell = \ell_1 + \ell_2$  be the pattern length in the hierarchy's WKD-IBE system. We use the first  $\ell_1$  slots to encode the URI, and the last  $\ell_2$  slots to encode the time.

Given a URI of length  $d$ , such as  $a/b/c$  ( $d = 3$  in this example), we split it up into individual components, and append a special terminator symbol  $\$$ : ("a", "b", "c",  $\$$ ). Using  $H$ , we map each component to  $\mathbb{Z}_p^*$ , and then put these values into the first  $d + 1$  slots. If  $S$  is our pattern, we would have  $S(1) = H("a")$ ,  $S(2) = H("b")$ ,  $S(3) = H("c")$ , and  $S(4) = H("\$")$  for this example. Now, we encode the time range into the remaining  $\ell_2$  slots. Any timestamp, with the granularity of an hour, can be represented hierarchically as (year, month, day, hour). We encode this into the pattern like the URI: we hash each component, and assign them to consecutive slots. The final  $\ell_2$  slots encode the time, so the depth of the time hierarchy is  $\ell_2$ . The terminator symbol  $\$$  is not needed to encode the time, because timestamps always have exactly  $\ell_2$  components. For example, suppose that a principal sends a message to  $a/b$  on June 8, 2017 at 6 AM. The

<sup>2</sup>JEDI does not govern *how* the key set is transferred to the recipient, as there are existing solutions for this. One can use an existing protocol for one-to-one communication (e.g., TLS) to securely transfer the key set. Or, one can encrypt the key set with the recipient's (normal, non-WKD-IBE) public key, and place it in a common storage area.

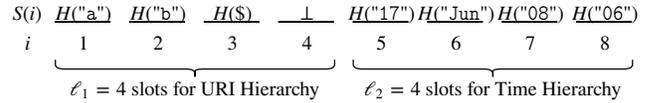

Figure 4: Pattern  $S$  used to encrypt message sent to  $a/b$  on June 08, 2017 at 6 AM. The figure uses 8 slots for space reasons; JEDI is meant to be used with more slots (e.g., 20).

message is encrypted with the pattern in Fig. 4.

### 3.5 Producing a Key Set for Delegation

Now, we explain how to produce a key set corresponding to a URI prefix and time range. To express a URI prefix as a pattern, we do the same thing as we did for URIs, without the terminator symbol  $\$$ . For example,  $a/b/*$  is encoded in a pattern  $S$  as  $S(1) = H("a")$ ,  $S(2) = H("b")$ , and all other slots free. Given the private key for  $S$ , one can use WKD-IBE's **KeyDer** to fill in slots  $3 \dots \ell_1$ . This allows one to generate the private key for  $a/b$ ,  $a/b/c$ , etc.—any URI for which  $a/b$  is a prefix. To grant access to only a specific resource (a full URI, not a prefix), the  $\$$  is included as before.

In encoding a time range into a pattern, single timestamps (e.g., granting access for an hour) are done as before. The hierarchical structure for time makes it possible to succinctly grant permission for an entire day, month, or year. For example, one may grant access for all of 2017 by filling in slot  $\ell_2$  with  $H("2017")$  and leaving the final  $\ell_2 - 1$  slots, which correspond to month, day, and year, free. Therefore, to grant permission over a time range, *the number of keys granted is logarithmic in the length of the time range*. For example, to delegate access to a URI from October 29, 2014 at 10 PM until December 2, 2014 at 1 AM, the following keys need to be generated: 2014/Oct/29/23, 2014/Oct/29/24, 2014/Oct/30/\*, 2014/Oct/31/\*, 2014/Nov/\*, 2014/Dec/01/\*, and 2014/Dec/02/01. The tree can be chosen differently to support longer time ranges (e.g., additional level representing decades), change the granularity of expiry (e.g., minutes instead of hours), trade off encryption time for key size (e.g., deeper/shallower tree), or use a more regular structure (e.g., binary encoding with logarithmic split). For example, our implementation uses a depth-6 tree (instead of depth-4), to be able to delegate time ranges with fewer keys.

In summary, to produce a key set for delegation, first determine which subtrees in the time hierarchy represent the time range. For each one, produce a separate pattern, and encode the time into the last  $\ell_2$  slots. Encode the URI prefix in the first  $\ell_1$  slots of each pattern. Finally, generate the keys corresponding to those patterns, using keys in the key store.

### 3.6 Optimizations for Low-Power Devices

On low-power embedded devices, performing a single WKD-IBE encryption consumes a significant amount of energy. Therefore, we design JEDI with optimizations to WKD-IBE.

### 3.6.1 Hybrid Encryption and Key Reuse

JEDI uses WKD-IBE in a hybrid encryption scheme. To encrypt a message  $m$  in JEDI, one samples a symmetric key  $k$ , and encrypts  $k$  with JEDI to produce ciphertext  $c_1$ . The pattern used for WKD-IBE encryption is chosen as in §3.4 to encode the *rendezvous point*. Then, one encrypts  $m$  using  $k$  to produce ciphertext  $c_2$ . The JEDI ciphertext is  $(c_1, c_2)$ .

For subsequent messages, one reuses  $k$  and  $c_1$ ; the new message is encrypted with  $k$  to produce a new  $c_2$ . One can keep reusing  $k$  and  $c_1$  until the WKD-IBE pattern for encryption changes, which happens at the end of each hour (or other interval used for expiry). At this time, JEDI performs *key rotation* by choosing a new  $k$ , encrypting it with WKD-IBE using the new pattern, and then proceeding as before. Therefore, *most messages only incur cheap symmetric-key encryption*.

This also reduces the load on subscribers. The JEDI ciphertexts sent by a publisher during a single hour will all share the same  $c_1$ . Therefore, the subscriber can decrypt  $c_1$  once for the first message to obtain  $k$ , and *cache* the mapping from  $c_1$  to  $k$  to avoid expensive WKD-IBE decryptions for future messages sent during that hour.

Thus, expensive WKD-IBE operations are only performed upon key rotation, which happens *rarely*—once an hour (or other granularity chosen for expiry) for each resource.

### 3.6.2 Precomputation with Adjustment

Even with hybrid encryption and key reuse to perform WKD-IBE encryption rarely, WKD-IBE contributes significantly to the overall power consumption on low-power devices. Therefore, this section explores how to perform individual WKD-IBE encryptions more efficiently.

Most of the work to encrypt under a pattern  $S$  is in computing the quantity  $Q_S = g_3 \cdot \prod_{(i,a_i) \in \text{fixed}(S)} h_i^{a_i}$ , where  $g_3$  and the  $h_i$  are part of the WKD-IBE public parameters. One may consider computing  $Q_S$  once, and then reusing its value when computing future encryptions under the same pattern  $S$ . Unfortunately, this alone does not improve efficiency because the pattern  $S$  used in one WKD-IBE encryption is different from the pattern  $T$  used for the next encryption.

JEDI, however, observes that  $S$  and  $T$  are similar; they match in the  $\ell_1$  slots corresponding to the URI, and the remaining  $\ell_2$  slots will correspond to adjacent leaves in the time tree. JEDI takes advantage of this by efficiently *adjusting* the precomputed value  $Q_S$  to compute  $Q_T$  as follows:

$$Q_T = Q_S \cdot \prod_{\substack{(i,b_i) \in \text{fixed}(T) \\ i \in \text{free}(S)}} h_i^{b_i} \cdot \prod_{\substack{(i,a_i) \in \text{fixed}(S) \\ i \in \text{free}(T)}} h_i^{-a_i} \cdot \prod_{\substack{(i,a_i) \in \text{fixed}(S) \\ (i,b_i) \in \text{fixed}(T) \\ a_i \neq b_i}} h_i^{b_i - a_i}$$

This requires one  $\mathbb{G}_1$  exponentiation per differing slot between  $S$  and  $T$  (i.e., the Hamming distance). Because  $S$  and  $T$  usually differ in only the final slot of the time hierarchy, this will usually require one  $\mathbb{G}_1$  exponentiation total, substantially faster than computing  $Q_T$  from scratch. Additional exponentiations are needed at the end of each day, month, and year, but they can be eliminated by maintaining additional

precomputed values corresponding to the start of the current day, current month, and current year.

The protocol remains secure because a ciphertext is distributed identically whether it was computed from a precomputed value  $Q_S$  or via regular encryption.

## 3.7 Extensions

Via simple extensions, JEDI can support (1) wildcards in the *middle* of a URI or time, and (2) forward secrecy. We describe these extensions in the appendix of our extended paper.

## 3.8 Security Guarantee

We formalize the security of JEDI’s encryption below.

**Theorem 1.** *Suppose JEDI is instantiated with a Selective-ID CPA-secure [1, 16], history-independent (defined in our extended paper [57]) WKD-IBE scheme. Then, no probabilistic polynomial-time adversary  $\mathcal{A}$  can win the following security game against a challenger  $\mathcal{C}$  with non-negligible advantage:*

**Initialization.**  $\mathcal{A}$  selects a (URI, time) pair to attack.

**Setup.**  $\mathcal{C}$  gives  $\mathcal{A}$  the public parameters of the JEDI instance.

**Phase 1.**  $\mathcal{A}$  can make three types of queries to  $\mathcal{C}$ :

1.  $\mathcal{A}$  asks  $\mathcal{C}$  to create a principal;  $\mathcal{C}$  returns a name in  $\{0, 1\}^*$ , which  $\mathcal{A}$  can use to refer to that principal in future queries. A special name exists for the authority.
2.  $\mathcal{A}$  asks  $\mathcal{C}$  for the key set of any principal;  $\mathcal{C}$  gives  $\mathcal{A}$  the keys that the principal has. At the time this query is made, the requested key may **not** contain a key whose URI and time are both prefixes of the challenge (URI, time) pair.
3.  $\mathcal{A}$  asks  $\mathcal{C}$  to make any principal delegate a key set of  $\mathcal{A}$ ’s choice to another principal (specified by names in  $\{0, 1\}^*$ ).

**Challenge.** When  $\mathcal{A}$  chooses to end Phase 1, it sends  $\mathcal{C}$  two messages,  $m_0$  and  $m_1$ , of the same length. Then  $\mathcal{C}$  chooses a random bit  $b \in \{0, 1\}$ , encrypts  $m_b$  under the challenge (URI, time) pair, and gives  $\mathcal{A}$  the ciphertext.

**Phase 2.**  $\mathcal{A}$  can make additional queries as in Phase 1.

**Guess.**  $\mathcal{A}$  outputs  $b' \in \{0, 1\}$ , and wins the game if  $b = b'$ . The advantage of an adversary  $\mathcal{A}$  is  $|\Pr[\mathcal{A} \text{ wins}] - \frac{1}{2}|$ .

We prove this theorem in our extended paper [57]. Although we only achieve selective security in the standard model (like much prior work [1, 17]), one can achieve adaptive security if the hash function  $H$  in §3.5 is modeled as a random oracle [1]. It is sufficient for JEDI to use a CPA-secure (rather than CCA-secure) encryption scheme because JEDI messages are signed, as detailed below in §4.

## 4 Integrity in JEDI

To prevent an attacker from flooding the system with messages, spoofing fake data, or actuating devices without permission, JEDI must ensure that a principal can only send a message on a URI if it has permission. For example, an application subscribed to `buildingA/floor2/roomLHall/sensor0/temp` should be able to verify that the readings it is receiving are produced by `sensor0`, not an attacker. In addition to subscribers, an intermediate party (e.g., the router in a

publish-subscribe system) may use this mechanism to filter out malicious traffic, without being trusted to read messages.

## 4.1 Starting Solution: Signature Chains

A standard solution in the existing literature, used by SPKI/SDSI [31], Vanadium [77], and bw2 [5], is to include a certificate chain with each message. Just as permission to subscribe to a resource is granted via a chain of delegations in §3, permission to publish to a resource is also granted via a chain of delegations. Whereas §3 includes WKD-IBE keys in each delegation, these integrity solutions delegate signed certificates. To send a message, a principal encrypts it (§3), signs the ciphertext, and includes a certificate chain that proves that the signing keypair is authorized for that URI and time.

## 4.2 Anonymous Signatures

The above solution reveals the sender’s identity (via its public key) and the particular chain of delegations that gives the sender access. For some applications this is acceptable, and its auditability may even be seen as a benefit. For other applications, the sender must be able to send a message anonymously. See §1.1.3 for an example. How can we reconcile *access control* (ensuring the sender has permission) and *anonymity* (hiding who the sender is)?

### 4.2.1 Starting Point: WKD-IBE Signatures

Our solution is to use a signature scheme based on WKD-IBE. Abdalla et al. [1] observe that WKD-IBE can be extended to a signature scheme in the same vein as has been done for IBE [18] and HIBE [46]. To sign a message  $m \in \mathbb{Z}_p^*$  with a key for pattern  $S$ , one uses **KeyDer** to fill in a slot with  $m$ , and presents the decryption key as a signature.

This is our starting point for designing anonymous signatures in JEDI. A message can be signed by first hashing it to  $\mathbb{Z}_p^*$  and signing the hash as above. Just as consumers receive decryption keys via a chain of delegations (§3), publishers of data receive these signing keys via chains of delegations.

### 4.2.2 Anonymous Signatures in JEDI

The construction in §4.2.1 has two shortcomings. First, signatures are *large*, linear in the number of fixed slots of the pattern. Second, it is unclear if they are truly *anonymous*.

**Signature size.** As explained in §3, we use a construction of WKD-IBE based on BBG HIBE [17]. BBG HIBE supports a property called *limited delegation* in which a secret key can be reduced in size, in exchange for limiting the depth in the hierarchy at which subkeys can be generated from it. We observe that the WKD-IBE construction also supports this feature. Because we need not support **KeyDer** for the decryption key acting as a signature, we use limited delegation to compress the signature to just two group elements.

**Anonymity.** The technique in §4.2.1 transforms an encryption scheme into a signature scheme, but the resulting signature scheme is not necessarily anonymous. For the particular construction of WKD-IBE that we use, however, we prove that the resulting signature scheme is indeed anonymous. Our

insight is that, for this construction of WKD-IBE, keys are *history-independent* in the following sense: **KeyDer**, for a fixed Params and Pattern<sub>B</sub>, returns a private key Key<sub>Pattern<sub>B</sub></sub> with the *exact same distribution* regardless of Key<sub>Pattern<sub>A</sub></sub> (see §3.1 for notation). Because signatures, as described in §4.2.1, are private keys generated with **KeyDer**, they are also history-independent; a signature for a pattern has the same distribution regardless of the key used to generate it. This is precisely the anonymity property we desire.

## 4.3 Optimizations for Low-Power Devices

As in §3.6.1, we must avoid computing a WKD-IBE signature for every message. A simple way to do this is to sample a digital signature keypair each hour, sign the verifying key with WKD-IBE at the beginning of the hour, and sign messages during the hour with the corresponding signing key.

Unfortunately, this may still be too expensive for low-power embedded devices because it requires a digital signature, which requires asymmetric-key cryptography, for *every* message. We can circumvent this by instead (1) choosing a *symmetric* key  $k$  every hour, (2) signing  $k$  at the start of each hour (using WKD-IBE for anonymity), and (3) using  $k$  in an *authenticated broadcast protocol* to authenticate messages sent during the hour. An authenticated broadcast protocol, like  $\mu$ TESLA [70], generates a MAC for each message using a key whose hash is the previous key; thus, the single signed key  $k$  allows the recipient to verify later messages, whose MACs are generated with hash preimages of  $k$ . In general, this design requires stricter time synchronization than the one based on digital signatures, as the key used to generate the MAC depends on the time at which it is sent. However, for the sense-and-send use case typical of smart buildings, sensors anyway publish messages on a fixed schedule (e.g., one sample every  $x$  seconds), allowing the key to depend only on the message index. Thus, timely message delivery is the only requirement. Our scheme differs from  $\mu$ TESLA because the first key (end of the hash chain) is signed using WKD-IBE.

Additionally, we use a technique similar to precomputation with adjustment (§3.6.2) for anonymous signatures. Conceptually, **KeyDer**, which is used to produce signatures, can be understood as a two-step procedure: (1) produce a key of the correct form and structure (called **NonDelegableKeyDer**), and (2) re-randomize the key so that it can be safely delegated (called **ResampleKey**). Re-randomization can be accelerated using the same precomputed value  $Q_S$  that JEDI uses for encryption (§3.6.2), which can be efficiently adjusted from one pattern to the next. The result of **NonDelegableKeyDer** can also be adjusted to obtain the corresponding result for a similar pattern more efficiently. We fully explain our adjustment technique for signatures in our extended paper [57].

Finally, WKD-IBE signatures as originally proposed (§4.2.1) are verified by encrypting a random message under the pattern corresponding to the signature, and then attempting to decrypt it using the key acting as a signature. We

provide a more efficient signature verification algorithm for this construction of WKD-IBE in our extended paper [57].

## 4.4 Security Guarantee

The integrity guarantees of the method in this section can be formalized using a game very similar to the one in Theorem 1, so we do not present it here for brevity. We do, however, formalize the anonymous aspect of WKD-IBE signatures:

**Theorem 2.** *For any well-formed keys  $k_1, k_2$  corresponding to the same (URI, time) pair in the same resource hierarchy, and any message  $m \in \mathbb{Z}_p^*$ , the distribution of signatures over  $m$  produced using  $k_1$  is information-theoretically indistinguishable from (i.e., equal to) the distribution of signatures over  $m$  produced using  $k_2$ .*

This implies that even a powerful adversary who observes the private keys held by all principals cannot distinguish signatures produced by different principals, for a fixed message and pattern. No computational assumptions are required. We prove Theorem 2 in the appendix of our extended paper [57].

## 5 Revocation in JEDI

This section explains how JEDI keys may be revoked.

### 5.1 Simple Solution: Revocation via Expiry

A simple solution for revocation is to rely on expiration. In this solution, all keys are time-limited, and delegations are periodically refreshed, according to a higher layer protocol, by granting a new key with a later expiry time. In this setup, the principal who granted a key can easily revoke it by not refreshing that delegation when the key expires. We expect this solution to be sufficient for many applications of JEDI.

### 5.2 Immediate Revocation

Some disadvantages of the solution in §5.1 are that (1) principals must periodically come online to refresh delegations, and (2) revocation only takes effect when the delegated key expires. We would like a solution without these disadvantages.

However, any revocation scheme that does not wait for keys to expire is subject to set of *inherent* limitations. The recipient of the revoked delegation still has the revoked decryption key, so it can still decrypt messages encrypted in the same way. This means that we must either (1) rely on intermediate parties to modify ciphertexts so that revoked keys cannot decrypt them, or (2) require senders to be aware of the revocation, and encrypt messages in a different way so that revoked keys cannot decrypt them. Neither solution is ideal: (1) makes assumptions about how messages are delivered, which we have avoided thus far (§2), and requires trust in an intermediary to modify ciphertexts, and (2) weakens the decoupling of senders and receivers (§1.1). We adopt the second compromise: while senders will not need to know who are the receivers, they will need to know who has been revoked.

### 5.3 Immediate Revocation in JEDI

We extend tree-based broadcast encryption [37, 67] to support decentralized delegation of decryption keys, and incorporate

it into JEDI. We use tree-based broadcast encryption because it only requires senders to know about *revoked* users when encrypting messages, as opposed to *all* users in the system (as is required by other broadcast encryption schemes).

#### 5.3.1 Tree-based Broadcast Encryption

Existing work [37, 67] proposes two methods of tree-based broadcast encryption: Complete Subtree (CS) and Subset Difference (SD). We focus on the CS method here.

The CS method is based on a binary tree (Fig. 5) where each node corresponds to a separate keypair. Each user corresponds to a leaf of the tree and has the secret keys for all nodes on the root-to-leaf path. To encrypt a message that is decryptable by a subset of users, one finds a collection of subtrees that include all leaves except those corresponding to revoked users and encrypts the message multiple times using the public keys corresponding to the root of each subtree. By associating each node with an ID and encrypting with IBE, one can avoid generating a separate keypair for each node.

#### 5.3.2 Modifying Broadcast Encryption for Delegation

Users in broadcast encryption do not map one-to-one to users in JEDI. To avoid confusion, we refer to “users” in broadcast encryption as “leaves” (abbreviated lf).

We modify the CS method to support delegation, as follows. Each key corresponds to a range of consecutive leaves. When a user qualifies a key to delegate to another principal, she produces a new key corresponding to a subrange of the leaves of the original key. When a key is revoked, publishers are informed of the range of leaves corresponding to the revoked key. Then, they encrypt new messages using the CS method, choosing subtrees that cover all leaves except those corresponding to revoked leaves. If a key is revoked, that key and all keys derived from it can no longer decrypt messages, which is a property that we want. Thus, if Alice has  $k$  leaves, she must store secret keys for  $O(k + \log n)$  nodes, where  $n$  is the total number of leaves (so the depth of the tree is  $\log n$ ).

In JEDI, we reduce this to  $O(\log n)$  secret keys by using HIBE. We give each node  $v_i$  an identifier  $\text{id}(v_i) \in \{0, 1\}^*$  that describes the path from the root of the tree to that node. In particular, if  $v_j$  is an ancestor of  $v_i$ , then  $\text{id}(v_j)$  is a prefix of  $\text{id}(v_i)$ . Note that if we use HIBE with these IDs directly, a user with the secret key for the root can generate keys for all nodes in the tree. To fix this, we use a property called *limited delegation*, introduced by prior work [17], to generate a HIBE key that is unqualifiable (i.e., cannot be extended). For example, if Alice has leaves lf<sub>3</sub> to lf<sub>4</sub> in Fig. 5, she stores an unqualifiable key for node  $v_1$  and a qualifiable key for node  $v_3$ . In general, each user must store  $O(\log k)$  qualifiable keys and  $O(\log n)$  unqualifiable keys, thus  $O(\log k + \log n)$  total.

#### 5.3.3 Using Delegable Broadcast Encryption in JEDI

Secret keys in our modified broadcast encryption scheme consist of HIBE keys, so incorporating it into JEDI is simple. As discussed in §3.2, JEDI uses WKD-IBE in a way that provides multiple concurrent hierarchies, each in the vein of

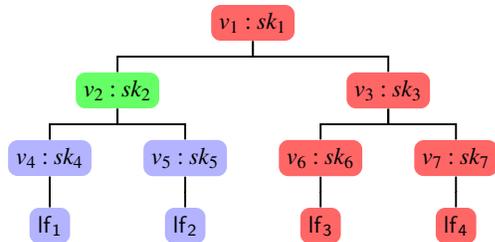

Figure 5: Key management of the CS method. Red nodes indicate nodes associated with revoked leaves. The green node is the root of the subtree covering unrevoked leaves.

HIBE. Therefore, we can instantiate a third hierarchy of depth  $\ell_3 = \log n$  and use it for revocation.

Let  $r$  be the number of revoked keys. The CS method has  $O(r \log \frac{n}{r})$ -size ciphertexts, so JEDI ciphertexts grow to this size when revocation is used. When encrypting a message, senders use the same encryption protocol from §3 for the first  $\ell_1 + \ell_2$  slots, and repeat the process, filling in the remaining  $\ell_3$  slots with the ID of each node used for broadcast encryption. The size of secret keys is  $O(\log k + \log n)$  after our modifications to the CS method, so JEDI keys grow by this factor, to a total of  $O((\log k + \log n) \cdot \log T)$  WKD-IBE keys, where  $T$  is the length of the time range for expiry.

The construction in this section works to revoke decryption keys, but cannot be used with anonymous signatures (§4.2). Extensions of tree-based broadcast encryption to signatures exist [60, 61], and we expect them to be useful to develop a construction for anonymous signatures.

How can JEDI inform publishers which leaves are revoked? One simple option is to have a global revocation list, which principals can append to. However, storing this information in a single list becomes a central point of attack, which we have avoided in our system thus far (§2). To avoid this, one can store the revocation list in a global-scale blockchain, such as Bitcoin or Ethereum, which would require an adversary to be exceptionally powerful to mount a successful attack. When revoking a set of leaves, a principal uses those keys to sign a predetermined object (as in §4.2), proving it owns an ancestor of that key in the hierarchy. To keep the revocation list private, one can use JEDI’s encryption to ensure that only principals with permission to publish to a particular resource can see which keys are revoked for that resource (since publishers too have signing keys, as described in §4).

## 5.4 Security Guarantee

The security guarantee for immediate revocation can be stated as a modification to the game in Theorem 1. In the Initialization Phase, when  $\mathcal{A}$  gives  $\mathcal{C}$  the challenge (URI, time),  $\mathcal{A}$  additionally submits a list of revoked leaves. Furthermore,  $\mathcal{A}$  may compromise principals in possession of private keys that can decrypt the challenge (URI, time) pair during Phases 1 and 2, as long as all leaves corresponding to those keys are in the revocation list submitted in the Initialization Phase. We provide a proof in the appendix of the extended paper [57].

## 5.5 Optimizing JEDI’s Immediate Revocation

A single JEDI ciphertext, with revocation enabled, consists of  $O(r \log \frac{n}{r})$  WKD-IBE ciphertexts. To compute them efficiently, we observe that there is a large overlap in the patterns used in individual WKD-IBE encryptions, allowing us to use the “precomputation with adjustment” strategy from §3.6.2.

Even with the above optimization, immediate revocation substantially increases the cost of JEDI’s cryptography. To reduce this cost, we make three observations. First, to extend JEDI’s hybrid encryption to work with revocation, it is sufficient to additionally rotate keys whenever the revocation list changes, in addition to the end of each hour (as in §3.6.1). This means that, in the common case where the revocation list does not change in between two messages, efficient symmetric-key encryption can be used. Second, the revocation list used to encrypt a message need only contain revoked leaves for the *particular URI* to which the message is sent. This not only makes the broadcast encryption more efficient (smaller  $r$ ), but also causes the effective revocation list for a stream of data to change even more rarely, allowing JEDI to benefit more from hybrid encryption. Third, we can do the same thing as above using the expiry time rather than the URI, allowing us to *cull* the revocation list by removing keys from it once they expire.

The efficiency of hybrid encryption depends on the revocation list changing *rarely*. We believe this is a reasonable assumption; most revocation will be handled by expiry, so immediate revocation is only needed if a principal must lose access *unexpectedly*. In the smart buildings use case (§1), for example, a key would need to be revoked if a principal unexpectedly transfers to another job.

The SD method for tree-based broadcast encryption can also be extended to support delegation and incorporated into JEDI (described in the appendix of our extended paper [57]). The SD method has smaller ciphertexts but larger keys.

## 6 Implementation

We implemented JEDI as a library in the Go programming language. We expect JEDI’s key delegation to be computed on relatively powerful devices, like laptops, smartphones, or Raspberry Pis; less powerful devices (e.g., right half of Fig. 1) will primarily send and receive messages, rather than generate keys for delegation. Therefore, our focus for low-power platforms was on the “sense-and-send” use case [26, 38, 41] typical of indoor environmental sensing, where a device periodically publishes sensor readings to a URI. Whereas our Go library provides higher-level abstractions, we expect low-power devices to use JEDI’s crypto library directly.

### 6.1 C/C++ Library for JEDI’s Cryptography

As part of JEDI, we implemented a cryptography library optimized in assembly for three different architectures typical of IoT platforms (Fig. 1). It implements WKD-IBE and JEDI’s optimizations and modifications (in §3.6, §4.3, and our full paper). The construction of WKD-IBE is based on a bilinear

group in which the Bilinear Diffie-Hellman Exponent assumption holds. We use the recent BLS12-381 elliptic curve [24].

State-of-the-art cryptography libraries implement BLS12-381, but none of them, to our knowledge, optimize for microarchitectures typical of low-power embedded platforms. To improve energy consumption, we implemented BLS12-381 in C/C++, profiled our implementation, and re-wrote performance-critical routines in assembly. We focus on ARM Cortex-M, an IoT-focused family of 32-bit microprocessors typical of contemporary low-power embedded sensor platforms [28, 49, 53]. Cortex-M processors have been used in billions of devices, including commercial IoT offerings such as Fitbit and Nest Protect. Our assembly targets Cortex-M0+, which is among the least powerful of processors in the Cortex-M series, and of those used in IoT devices (farthest to the right in Fig. 1). By demonstrating the practicality of JEDI on Cortex-M0+, we establish that JEDI is viable across the spectrum of IoT devices (Fig. 1).

The main challenge in targeting Cortex-M0+ is that the 32-bit multiply instruction provides only the lower 32 bits of the product. Even on more powerful microarchitectures without this limitation (e.g., Intel Core i7), most CPU time ( $\geq 80\%$ ) is spent on multiply-intensive operations (e.g., BigInt multiplication and Montgomery reduction), so the lack of such an instruction was a performance bottleneck. As a workaround, our assembly code emulates multiply-accumulate with carry in 23 instructions. Cortex-M3 and Cortex-M4, which are more commonly used than Cortex-M0+, have instructions for 32-bit multiply-accumulate which produce the entire 64-bit result; we expect JEDI to be more efficient on those processors.

We also wrote assembly to optimize BLS12-381 for x86-64 and ARM64, representative of server/laptop and smartphone/Raspberry Pi, respectively (first two tiers in Fig. 1). Thus, our Go library, which runs on these non-low-power platforms, also benefits from low-level assembly optimizations.

## 6.2 Application of JEDI to bw2

We used our JEDI library to implement end-to-end encryption in bw2, a syndication and authorization system for IoT. bw2’s syndication model is based on publish-subscribe, explained in §1. Here we discuss bw2’s authorization model. Access to resources is granted via certificate chains from the authority of a resource hierarchy to a principal. Individual certificates are called Declarations of Trust (DOTs). bw2 maintains a publicly accessible registry of DOTs, implemented using blockchain smart contracts, so that principals can find the DOTs they need to form DOT chains. A *trusted* router enforces permissions granted by DOTs. Principals must present DOT chains when publishing/subscribing to resources, and the router verifies them. Note that a compromised router can read messages.

We use JEDI to enforce bw2’s authorization semantics with end-to-end encryption. DOTs granting permission to subscribe now contain WKD-IBE keys to decrypt messages. By default, DOTs granting permission to publish to a URI

Table 1: Latency of JEDI’s implementation of BLS12-381

Operation	Laptop	Rasp. Pi	Sensor
$\mathbb{G}_1$ Mul. (Chosen Scalar)	109 $\mu$ s	1.33 ms	509 ms
$\mathbb{G}_2$ Mul. (Chosen Scalar)	343 $\mu$ s	3.86 ms	1.44 s
$\mathbb{G}_T$ Mul. (Rand. Scalar)	504 $\mu$ s	5.47 ms	1.90 s
$\mathbb{G}_T$ Mul. (Chosen Scalar)	507 $\mu$ s	5.48 ms	2.81 s
Pairing	1.29 ms	14.0 ms	3.83 s

remain unchanged, and are used as in §4.1. WKD-IBE keys may also be included in DOTs granting publish permission, for anonymous signatures (§4.2). Using our library for JEDI, we implemented a wrapper around the bw2 client library. It transparently encrypts and decrypts messages using WKD-IBE, and includes WKD-IBE parameters and keys in DOTs and principals, as needed for JEDI. bw2 signs each message with a digital signature (first alternative in §4.3).

The bw2-specific wrapper is less than 900 lines of Go code. Our implementation required no changes to bw2’s client library, router, blockchain, or core—it is a separate module. Importantly, it provides the same API as the standard bw2 client library. Thus, it can be used as a drop-in replacement for the standard bw2 client library, to easily add end-to-end encryption to existing bw2 applications with minimal changes.

## 7 Evaluation

We evaluate JEDI via microbenchmarks, determine its power consumption on a low-power sensor, measure the overhead of applying it to bw2, and compare it to other systems.

### 7.1 Microbenchmarks

Benchmarks labeled “Laptop” were produced on a Lenovo T470p laptop with an Intel Core i7-7820HQ CPU @ 2.90 GHz. Benchmarks labeled “Raspberry Pi” were produced on a Raspberry Pi 3 Model B+ with an ARM Cortex-A53 @ 1.4 GHz. Benchmarks labeled “Sensor” were produced on a commercially available ultra low-power environmental sensor platform called “Hamilton” with an ARM Cortex-M0+ @ 48 MHz. We describe Hamilton in more detail in §7.3.

#### 7.1.1 Performance of BLS12-381 in JEDI

Table 1 compares the performance of JEDI’s BLS12-381 implementation on the three platforms, with our assembly optimizations. As expected from Fig. 1, the Raspberry Pi performance is an order of magnitude slower than Laptop performance, and performance on the Hamilton sensor is an additional two-to-three orders of magnitude slower.

#### 7.1.2 Performance of WKD-IBE in JEDI

Fig. 6 depicts the performance of JEDI’s cryptography primitives. Fig. 6 does not include the sensor platform; §7.3 thoroughly treats performance of JEDI on low-power sensors.

In Figure 6a, we used a pattern of length 20 for all operations, which would correspond to, e.g., a URI of length 14 and an Expiry hierarchy of depth 6. To measure decryption and signing time, we measure the time to decrypt the ciphertext or sign the message, plus the time to generate a decryption key for that pattern or ID. For example, if one receives a message

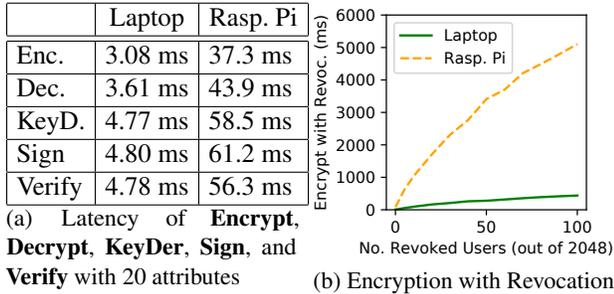

Figure 6: Performance of JEDI’s cryptography

on  $a/b/c/d/e/f$ , but has the key for  $a/*$ , he must generate the key for  $a/b/c/d/e/f$  to decrypt it.

Figure 6a demonstrates that the JEDI encrypts and signs messages and generates qualified keys for delegation at practical speeds. On a laptop, all WKD-IBE operations take less than 10 ms with up to 20 attributes. On a Raspberry Pi, they are 10x slower (as expected), but still run at interactive speeds.

### 7.1.3 Performance of Immediate Revocation in JEDI

Figure 6b shows the cost of JEDI’s immediate revocation protocol (§5). A private key containing  $k$  leaves consists of  $O(\log k + \log n)$  WKD-IBE secret keys where  $n$  is the total number of leaves. Therefore, the performance of immediate revocation depends primarily on the number of leaves.

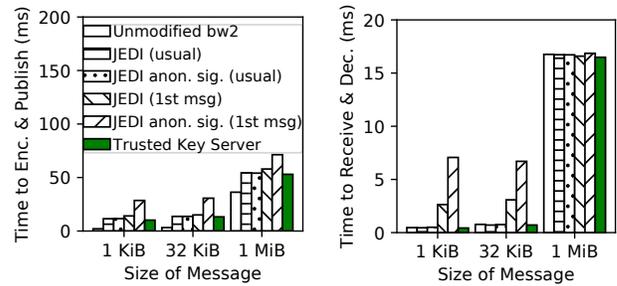

To encrypt a message, one WKD-IBE encryption is performed for each subtree needed to cover all unrevoked leaves. In general, encryption is  $O(r \log \frac{n}{r})$ , where  $r$  is the number of revoked leaves. Each key contains a set of *consecutive* leaves, so encryption is also  $O(R \log \frac{n}{R})$ , where  $R$  is the number of revoked JEDI keys. Decryption time remains almost the same, since only one WKD-IBE decryption is needed.

To benchmark revocation, we use a complete binary tree of depth 16 ( $n = 65536$ ). The time to generate a new key for delegation is essentially independent of the number of leaves conveyed in that key, because  $\log k \ll \log n$ . We empirically confirmed this; the time to generate a key for delegation was constant at 2.4 ms on a laptop and 31 ms on a Raspberry Pi as the number of leaves in the key was varied from 5 to 1,000.

To benchmark encryption with revocation, we assume that there exist 2,048 users in the system each with 32 leaves. We measure encryption time with a pattern with 20 fixed slots (for URI and time) as we vary the number of revoked users. Figure 6b shows that encryption becomes expensive when the revocation list is large (500 milliseconds on laptop and  $\approx 5$  seconds on Raspberry Pi). However, such an encryption only needs to be performed by a publisher when the URI, time, or revocation list changes; subsequent messages can reuse the underlying symmetric key (§5.5). Furthermore, the revocation list includes only revoked keys that match the (URI, time) pair being used, so it is not expected to grow very large.

## 7.2 Performance of JEDI in bw2

In bw2, the two critical-path operations are publishing a message to a URI, and receiving a message as part of a subscrip-

(a) Encrypt/publish message (b) Receive/decrypt message

Figure 7: Critical-path operations in bw2, with/without JEDI

tion. We measure the overhead of JEDI for these operations because they are core to bw2’s functionality and would be used by any messaging application built on bw2. Our methodology is to perform each operation repeatedly in a loop, to measure the sustained performance (operations/second), and report the average time per operation (inverse). To minimize the effect of the network, the router was on the same link as the client, and the link capacity was 1 Gbit/s. In our experiments, we used a URI of length 6 and an Expiry tree of depth 6. We also include measurements from a strawman system with pre-shared AES keys—this represents the critical-path overhead of an approach based on the Trusted Key Server discussed in §2. Our results are in Fig. 7.

We implement the optimizations in §3.6.1, so only symmetric key encryption/decryption must be performed in the common case (labeled “usual” in the diagram). However, the symmetric keys will *not* be cached for the first message sent every hour, when the WKD-IBE pattern changes. A WKD-IBE operation must be performed in this case (labeled “1st message” in the diagram). For large messages, the cost of symmetric key encryption dominates. JEDI has a particularly small overhead for 1 MiB messages in Fig. 7b, perhaps because 1 MiB messages take several milliseconds to transmit over the network, allowing the client to decrypt a message while the router is sending the next message.

We also consider creating DOTs and initiating subscriptions, which are not in the critical path of bw2. These results are in Fig. 8 (note the log scale in Fig. 8a). Creating DOTs is slower with JEDI, because WKD-IBE keys are generated and included in the DOT. Initiating a subscription in bw2 requires forming a DOT chain; in JEDI, one must also derive a private key from the DOT chain. Fig. 8a shows the time to form a short one-hop DOT chain, and in the case of JEDI, includes the time to derive the private key. For JEDI’s encryption (§3), these additional costs are incurred only by DOTs that grant permission to subscribe. With anonymous signatures, DOTs granting permission to publish incur this overhead as well, as WKD-IBE keys must be included. Fig. 8b puts this in context by measuring the end-to-end latency from initiating a subscription to receiving the first message (measured using bw2’s “query” functionality).

For a DOT to be usable, it must be inserted into bw2’s

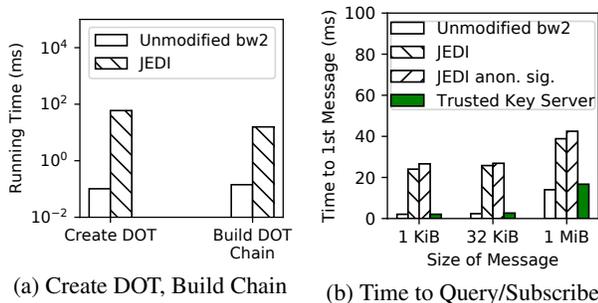

Figure 8: Occasional bw2 operations, with and without JEDI

registry. This requires a blockchain transaction (not included in Fig. 8). An important consideration in this regard is *size*. In the unmodified bw2 system, a DOT that grants permission on *a/b/c/d/e/f* is 198 bytes. With JEDI, each DOT also contains multiple WKD-IBE keys, according to the time range. In the “worst case,” where the start time of a DOT is Jan 01 at 01:00, and the end time is Dec 31 at 22:59, a total of 45 keys are needed. Each key is approximately 1 KiB, so the size of this DOT is approximately 45 KiB.

Because bw2’s registry of DOTs is implemented using blockchain smart contracts, the bandwidth for inserting DOTs is limited. Using JEDI would increase the size of DOTs as above, resulting in an approximately 100-400x decrease in aggregate bandwidth for creating DOTs. However, this can be mitigated by changing bw2 to not store DOTs directly in the blockchain. DOTs can be stored in untrusted storage, with only their hashes stored in the blockchain-based registry. Such a solution could be based on Swarm [79] or Filecoin [43].

### 7.3 Feasibility on Ultra Low-Power Devices

We use a commercially available sensor platform called “Hamilton” [4, 49] built around the Atmel SAMR21 system-on-chip (SoC). The SAMR21 costs approximately \$2.25 per unit [40] and integrates a low-power microcontroller and radio. The sensor platform we used in this study costs \$18 to manufacture [55]. For battery lifetime calculations, we assume that the platform is powered using a CR123A Lithium battery that provides 1400 mAh at 3.0 V (252 J of energy). Such a battery costs \$1. The SAMR21 is heavily constrained: it has only a 48 MHz CPU frequency based on the ARM Cortex-M0+ microarchitecture, and a total of only 32 KiB of data memory (RAM). Our goal is to validate that JEDI is practical for an ultra low-power sensor platform like Hamilton, in the context of a “sense-and-send” application in a smart building. Since most of the platform’s cost (\$18) comes from the on-board transducers and assembly, rather than the SAMR21 SoC, *using an even more resource-constrained SoC would not significantly decrease the platform’s cost*. An analogous argument applies to energy consumption, as the transducers account for more than half of Hamilton’s idle current [55].

Hamilton/SAMR21 is on the lower end of platforms typically used for sense-and-send applications in buildings. Some older studies [41, 59] use even more constrained hardware like

Table 2: CPU and power costs on the Hamilton platform

Operation	Time	Average Current
Sleep (Idle)	N/A	0.0063 mA
WKD-IBE Encrypt	6.50 s	10.2 mA
WKD-IBE Encrypt and Sign	9.89 s	10.2 mA

Table 3: Average current and expected battery life (for 1400 mAh battery) for sense-and-send, with varying sample interval

	AES Only	JEDI (enc)	JEDI (enc & sign)
10 s	32 $\mu$ A / 5.1 y	50 $\mu$ A / 3.2 y	60 $\mu$ A / 2.6 y
20 s	20 $\mu$ A / 8.1 y	38 $\mu$ A / 4.2 y	48 $\mu$ A / 3.3 y
30 s	15 $\mu$ A / 10 y	34 $\mu$ A / 4.7 y	44 $\mu$ A / 3.6 y

the TelosB; this is because those studies were constrained by hardware available at the time. Modern 32-bit SoCs, like the SAMR21, offer substantially better performance at a similar price/power point to those older platforms [55].

#### 7.3.1 CPU Usage

Table 2 shows the time for encryption and anonymous signing in JEDI on Hamilton. The results use the optimizations discussed in §3.6 and §4.3, and include the time to “adjust” precomputed state. They indicate that symmetric keys can be encrypted and anonymously signed in less than 10 seconds. This is feasible given that encryption and anonymous signing occur rarely, once an hour, and need not be produced at interactive speeds in the normal “sense-and-send” use case.

#### 7.3.2 Power Consumption

To calculate the impact on battery lifetime, we consider a “sense-and-send” application, in which the Hamilton device obtains readings from its sensors at regular intervals, and immediately sends the readings encrypted over the wireless network. We measured the average current consumed for varying sample intervals, when each message is encrypted with AES-CCM, without using JEDI (“AES Only” in Table 3). We estimate JEDI’s average current based on the current, duration, and frequency (once per hour, for these estimates) of JEDI operations, and add it to the average current of the “AES Only” setup. Our estimates assume that the  $\mu$ TESLA-based technique in §4.3 is used to avoid attaching a digital signature to each message. We divide the battery’s energy capacity by the result to compute lifetime. As shown in Table 3, JEDI decreases battery life by about 40-60%. Battery life is several years even with JEDI, acceptable for IoT sensor platforms.

JEDI’s overhead depends primarily on the granularity of expiry times (one hour, for these estimates), *not* the sample interval. To improve power consumption, one could use a time tree with larger leaves, allowing principals to perform WKD-IBE encryptions and anonymous signatures less often. This would, of course, make expiry times coarser.

#### 7.3.3 Memory Budget

Performing WKD-IBE operations requires only 6.5 KiB of data memory, which fits comfortably within the 32 KiB of data memory (RAM) available on the SAMR21. The code space required for our implementation of WKD-IBE and BLS12-

381 is about 74 KiB, which fits comfortably in the 256 KiB of code memory (ROM) provided by the SAMR21.

A related question is whether storing a hash chain in memory (as required for authenticated broadcast, §4.3) is practical. If we use a granularity of 1 minute for authenticated broadcast, the length of the hash chain is 60. At the start of an hour, one computes the entire chain, storing 10 hashes equally spaced along the chain, each separated by 5 hashes. As one progresses along the hash chain, one re-computes each set of 5 hashes one additional time. This requires storage for only 15 hashes (< 4 KiB memory) and computation of only 105 hashes *per hour*, which is practical. One could possibly optimize performance further using *hierarchical hash chains* [50].

#### 7.3.4 Impact of JEDI's Optimizations

JEDI's cryptographic optimizations (§3.6.2, §4.2.2, §4.3), which use WKD-IBE in a non-black-box manner, provide a 2-3x performance improvement. Our assembly optimizations (§6) provide an additional 4-5x improvement. Without both of these techniques, JEDI would not be practical on low-power sensors. Hybrid encryption and key reuse (§3.6.1), which let JEDI use WKD-IBE *rarely*, are also crucial.

### 7.4 Comparison to Other Systems

Table 4 compares JEDI to other systems and cryptographic approaches, particularly those geared toward IoT, in regard to security, expressivity and performance. We treat these existing systems as they would be used in a messaging system for smart buildings (§1). Table 4 contains quantitative comparisons to the cryptography used by these systems; for those schemes based on bilinear groups, we re-implemented them using our JEDI crypto library (§6.1) for a fair comparison.

**Security.** The owner of a resource is considered *trusted* for that resource, in the sense that an adversary who compromises a principal can read all of that principal's resources. In Table 4, we focus on whether a single component is trusted for *all* resources in the system. Note that, although Trusted Key Server (§2) and PICADOR [23] encrypt data in flight, granting or revoking access to a principal requires participation of an *online trusted party* to generate new keys.

**Expressivity.** PRE-based approaches, which associate public keys with users and support delegation via proxy re-encryption, are fundamentally coarse-grained—a re-encryption key allows *all* of a user's data to be re-encrypted. PICADOR [23] allows more fine-grained semantics, but does not enforce them cryptographically. ABE-based approaches typically do not support delegation beyond a single hop, whereas JEDI achieves multi-hop delegation. In ABE-based schemes, however, attributes/policies attached to keys can describe more complex sets of resources than JEDI. That said, a hierarchical resource representation is sufficient for JEDI's intended use case, namely smart cities; existing syndication systems for smart cities, which do not encrypt data and are unconstrained by the expressiveness of crypto schemes, choose a hierarchical rather than attribute-based representation (§1).

**Performance.** The Trusted Key Server (§2) is the most naïve approach, requiring an online trusted party to enforce all policy. Even so, JEDI's performance in the common case is the same as the Trusted Key Server (Fig. 7), because of JEDI's hybrid encryption—JEDI invokes WKD-IBE *rarely*. Even when JEDI invokes WKD-IBE, its performance is not significantly worse than PRE-based approaches. An alternative design for JEDI uses the GPSW KP-ABE construction instead of WKD-IBE, but it is significantly more expensive. Based Table 3, the power cost of a WKD-IBE operation *even when only invoked once per hour* contributes significantly to the overall energy consumption on the low-power IoT device; using KP-ABE instead of WKD-IBE would increase this power consumption by an order of magnitude, reducing battery life significantly.

**In summary**, existing systems fall into one of three categories. (1) The Trusted Key Server allows access to resources to be managed by arbitrary policies, but relies on a *central trusted party* who must be online whenever a user is granted access or is revoked. (2) PRE-based approaches, which permit sharing via re-encryption, cannot cryptographically enforce fine-grained policies or support multi-hop delegation. (3) ABE-based approaches, if carefully designed, *can* achieve the same expressivity as JEDI, but are substantially less performant and are not suitable for low-power embedded devices.

## 8 Related Work

We organize related work into the following categories.

**Traditional Public-Key Encryption.** SiRiUS [47] and Plutus [54] are encrypted filesystems based on traditional public-key cryptography, but they do not support delegable and qualifiable keys like JEDI. Akl et al. [2] and further work [33, 34] propose using key assignment schemes for access control in a hierarchy. A line of work [8, 9, 51, 80] builds on this idea to support both hierarchical structure and temporal access. Key assignment approaches, however, require the full hierarchy to be known at setup time, which is not flexible in the IoT setting. JEDI does not require this, allowing different subtrees of the hierarchy to be managed separately (§1.1, "Delegation").

**Identity-Based Encryption.** Tariq et al. [78] use Identity-Based Encryption (IBE) [18] to achieve end-to-end encryption in publish-subscribe systems, without the router's participation in the protocol. However, their approach does not support hierarchical resources. Further, encryption and private keys are on a credential-basis, so each message is encrypted multiple times according to the credentials of the recipients.

Wu et al. [87] use a prefix encryption scheme based on IBE for mutual authentication in IoT. Their prefix encryption scheme is different from JEDI, in that users with keys for identity  $a/b/c$  can decrypt messages encrypted with prefix identity  $a$ ,  $a/b$  and  $a/b/c$ , but not identities like  $a/b/c/d$ .

**Hierarchical Identity-Based Encryption.** Since the original proposal of Hierarchical Identity-Based Encryption (HIBE) [46], there have been multiple HIBE constructions [16, 17, 45, 46] and variants of HIBE [1, 88]. Although

Table 4: Comparison of JEDI with other crypto-based IoT/cloud systems

Crypto Scheme / System	Avoids Central Trust?	Expressivity	Performance
Trusted Key Server (§2)	- No	+ Supports arbitrary policies (beyond hierarchies) - No delegation	+ $\approx 10 \mu\text{s}$ to encrypt 1 KiB message (same as JEDI in common case, faster for first message after key rotation) - Trusted party generates one key <i>per resource</i>
PRE (Lattice-Based), as used in PICADOR [23]	- No	+ Supports arbitrary policies (beyond hierarchies) - No delegation	+ $\approx 5 \text{ ms}$ encrypt, $\approx 3 \text{ ms}$ decrypt (similar to JEDI: 3-4 ms) - Trusted party must generate one key per sender-receiver pair
PRE (Pairing-Based), as used in Pilatus [75]	+ Yes	- Delegation is single-hop - Delegation is coarse (all-or-nothing) + Can compute aggregates on encrypted data	+ 0.6 ms encrypt, 1.3 ms re-encrypt, 0.5 ms decrypt (faster than JEDI: 3-4 ms) + Practical on constrained IoT device with crypto accelerator
CP-ABE [12]	+ Yes	+ Good fit for RBAC policies - Cannot support JEDI’s hierarchy abstraction with delegation	+ Only symmetric crypto in common case - 14 ms encrypt for first time after key rotation (4-5x slower than JEDI: 3 ms)
KP-ABE, as used in Sieve [83]	+ Yes	+ Succinct delegation based on attributes - Delegation is single-hop	+ Only symmetric crypto in common case - 25 ms encrypt for first time after key rotation (8-9x slower than JEDI: 3 ms)
Delegable Large Univ. KP-ABE [48] (used in Alternative JEDI Design)	+ Yes	+ Generalizes beyond hierarchies and supports multi-hop delegation (subsumes JEDI)	+ Only symmetric crypto in common case - 60 ms encrypt for first time after key rotation (20x slower than JEDI: 3 ms) - Impractical for low-power sense-and-send
<b>This paper:</b> WKD-IBE [1] with Optimizations, as used in JEDI	+ Yes	+ Delegation is multi-hop + Succinct delegation of <i>subtrees</i> of resources (or more complex sets, §3.7) + Non-interactive expiry	+ After key rotation (e.g., once per hour), 3 ms encrypt, 4 ms decrypt (Fig. 6a) + Only symmetric crypto in common case + Practical for ultra low-power “sense-and-send” <i>without crypto accelerator</i>

seemingly a good match for resource hierarchies, HIBE cannot be used as a black box to efficiently instantiate JEDI. We considered alternative designs of JEDI based on existing variants of HIBE, but as we elaborate in the appendix of our extended paper [57], each resulting design is either less expressive or significantly more expensive than JEDI.

**Attribute-Based Encryption.** A line of work [83, 90] uses Attribute-Based Encryption (ABE) [12, 48] to delegate permission. Our work additionally supports hierarchically-organized resources and decentralized delegation of keys, which [90] and [83] do not address. As discussed in §7.4, WKD-IBE is substantially more efficient than KP-ABE and provides enough functionality for JEDI.

Other approaches prefer Ciphertext-Policy ABE (CP-ABE) [12]. Existing work [84, 85] combines HIBE with CP-ABE to produce Hierarchical ABE (HABE), a solution for sharing data on untrusted cloud servers. The “hierarchical” nature of HABE, however, corresponds to the hierarchical organization of domain managers in an enterprise, not a hierarchical organization of *resources* as in our work.

**Proxy Re-Encryption.** NuCypher KMS [39] allows a user to store data in the cloud encrypted under her public key,

and share it with another user using Proxy Re-Encryption (PRE) [14]. While NuCypher assumes limited collusion among cloud servers and recipients (e.g.,  $m$  of  $n$  secret sharing) to achieve properties such as expiry, JEDI enforces expiry via cryptography, and therefore remains secure against *any* amount of collusion. Furthermore, NuCypher’s solution for resource hierarchies requires a keypair for each node in the hierarchy, meaning that the creation of resources is centralized. Finally, keys in NuCypher are not qualifiable.

PICADOR [23], a publish-subscribe system with end-to-end encryption, uses a lattice-based PRE scheme. However, PICADOR requires a central Policy Authority to specify access control, by creating a re-encryption key for every permitted pair of publisher and subscriber. In contrast, JEDI’s access control is decentralized.

**Revocation Schemes.** Broadcast encryption (BE) [19–22, 37, 58, 67] is a mechanism to achieve revocation, by encrypting messages such that they are only decryptable by a specific set of users. However, these existing schemes do not support key qualification and delegation, and therefore, cannot be used in JEDI directly. Another line of work builds revocation directly into the underlying cryptography primitive, achieving

Revocable IBE [15, 62, 72, 86], Revocable HIBE [63, 71, 73] and Revocable KP-ABE [10]. These papers use a notion of revocation in which URIs are revoked. In contrast, JEDI supports revocation at the level of keys. If multiple principals have access to a URI, and one of their keys is revoked, then the other principal can still use its key to access the resource. Some systems [11, 39] rely on the participation of servers or routers to achieve revocation.

**Secure Reliable Multicast Protocol.** Secure Reliable Multicast [64, 65] also uses a many-to-many communication model, and ensures correct data transfer in the presence of malicious routers. JEDI, as a protocol to *encrypt* messages, is complementary to those systems.

**Authorization Services.** JEDI is complementary to authorization services for IoT, such as bw2 [5], Vanadium [77], WAVE [6], and AoT [68], which focus on expressing authorization policies and enabling principals to prove they are authorized, rather than on encrypting data. Droplet [74] provides encryption for IoT, but does not support delegation beyond one hop and does not provide hierarchical resources.

An authorization service that provides secure in-band permission exchange, like WAVE [6], can be used for key distribution in JEDI. JEDI can craft keys with various permissions, while WAVE can distribute them without a centralized party by including them in its attestations.

## 9 Conclusion

In this paper, we presented JEDI, a protocol for end-to-end encryption for IoT. JEDI provides *many-to-many* encrypted communication on complex resource hierarchies, supports decentralized key delegation, and decouples senders from receivers. It provides expiry for access to resources, reconciles anonymity and authorization via anonymous signatures, and allows revocation via tree-based broadcast encryption. Its encryption and integrity solutions are capable of running on embedded devices with strict energy and resource constraints, making it suitable for the Internet of Things.

### Availability

The JEDI cryptography library is available at <https://github.com/ucbrise/jedi-pairing> and our implementation of the JEDI protocol for bw2 is available at <https://github.com/ucbrise/jedi-protocol>.

### Acknowledgments

We thank our anonymous reviewers and our shepherd William Enck for their invaluable feedback. We would also like to thank students from the RISE Security Group and BETS Research Group for giving us feedback on early drafts of this paper. This research was supported by Intel/NSF CPS-Security #1505773 and #20153754, DoE #DE-EE000768, California Energy Commission #EPC-15-057, NSF CISE Expeditions #CCF-1730628, NSF GRFP #DGE-1752814, and gifts from the Sloan Foundation, Hellman Fellows Fund, Alibaba, Amazon, Ant Financial, Arm, Capital One, Ericsson, Facebook,

## Abstract

Much attention has been paid to passwords chosen by English speaking users, yet only a few studies have examined how *non-English* speaking users select passwords. In this paper, we perform *an extensive, empirical analysis* of 73.1 million real-world Chinese web passwords in comparison with 33.2 million English counterparts. We highlight a number of interesting structural and semantic characteristics in Chinese passwords. We further evaluate the security of these passwords by employing two state-of-the-art cracking techniques. In particular, our cracking results reveal the *bifacial-security* nature of Chinese passwords. They are weaker against online guessing attacks (i.e., when the allowed guess number is small,  $1\sim 10^4$ ) than English passwords. But out of the remaining Chinese passwords, they are stronger against offline guessing attacks (i.e., when the guess number is large,  $>10^5$ ) than their English counterparts. This reconciles two conflicting claims about the strength of Chinese passwords made by Bonneau (IEEE S&P'12) and Li et al. (Usenix Security'14 and IEEE TIFS'16). At  $10^7$  guesses, the success rate of our improved PCFG-based attack against the Chinese datasets is 33.2%~49.8%, indicating that our attack can crack 92% to 188% *more* passwords than the state of the art. We also discuss the implications of our findings for password policies, strength meters and cracking.

## 1 Introduction

Textual passwords are the dominant form of access control in almost every web service today. Although their security pitfalls were revealed as early as four decades ago [39] and various alternative authentication methods (e.g., graphical passwords and multi-factor authentication) have been proposed since then, passwords are still widely used. For one reason, passwords offer many advantages, such as low deployment cost, easy recovery, and remarkable simplicity, which cannot always be of-

fered by other authentication methods [6]. For another reason, there is a lack of effective tools to quantify the less obvious costs of replacing passwords [8] because the marginal gains are often insufficient to make up for the significant transition costs. Furthermore, users also favor passwords. A recent survey on 1,119 US users [49] showed that 58% of the participants prefer passwords as their online login credentials, while only 16% prefer biometrics, and 10% prefer other ways. Thus, passwords are likely to persist in the foreseeable future.

Despite its ubiquity, password authentication is confronted with a challenge [62]: truly random passwords are difficult for users to memorize, while easy-to-remember passwords tend to be highly predictable. To eliminate this notorious “security-usability” dilemma, researchers have put a lot of effort [12, 17, 36, 46, 47] into the following two types of studies.

*Type-1* research aims at evaluating the strength of a password dataset (distribution) by measuring its statistical properties (e.g., Shannon entropy [10],  $\alpha$ -guesswork [7],  $\lambda$ -success-rate [53]) or by gauging its “guessability” [24, 59]. Guessability characterizes the fraction of passwords that, at a given number of guesses, can be cracked by cracking algorithms such as Markov-Chains [36] and probabilistic context-free grammars (PCFG) [58]. As with most of these previous studies, we mainly consider *trawling guessing* [55], while other attacking vectors (e.g., phishing, shoulder-surfing and targeted guessing [56]) are outside of our focus. Hereafter, whenever the term “guessing” is used, it means trawling guessing.

*Type-2* research attempts to reduce the use of weak passwords. Two approaches have been mainly utilized: proactive password checking [25, 32] and password strength meter [13, 59]. The former checks the user-selected passwords and only accepts those that comply with the system policy (e.g., at least 8 characters long). The latter is typically a visual feedback of password strength, often presented as a colored bar to help users create stronger passwords [17]. Most of today’s leading

sites employ a combination of these two approaches to prevent users from choosing weak passwords. In this work, though we mainly focus on type-1 research, our findings are also helpful for type-2 research.

Existing work (e.g., [14, 17, 27, 37, 42]) mainly focuses on passwords chosen by English speaking users. Relatively little attention has been paid to the characteristics and strength of passwords chosen by those who speak other native languages. For instance, “woaini1314” is currently deemed “Strong” by password strength meters (PSMs) of many leading services like AOL, Google, IEEE, and Sina weibo. However, this password is highly popular and prone to guessing [56]: “woaini” is a Chinese Pinyin phrase that means “I love you”, and “1314” has a similar pronunciation of “for ever” in Chinese. Failing to catch this would overlook the weaknesses of Chinese passwords, thus posing high risks to the corresponding web accounts.

## 1.1 Motivations

There have been 802 million Chinese netizens by June, 2018 [1], which account for over 20% (and also the largest fraction) of the world’s Internet population. However, to the best of our knowledge, there has been no satisfactory answer to the key questions: (1) *Are there structural or semantic characteristics that differentiate Chinese passwords from English ones?* (2) *How will Chinese passwords perform against the foremost attacks?* (3) *Are they weaker or stronger than English ones?* It is imperative to address these questions to provide both security engineers and Chinese users with necessary security guidance. For instance, if the answer to the first question is affirmative, then it indicates that *the password policies (e.g., length-8<sup>+</sup> [25] and 2Class12 [44]) and strength meters (e.g., RNN-PSM [38] and Zxcvbn [59]) originally designed for English speaking users cannot be readily applied to Chinese speaking users.*

A few password studies (e.g., [30, 36, 52, 53, 56]) have employed some Chinese datasets, yet they mainly deal with the effectiveness of various probabilistic cracking models. Relatively little attention has been given to the above three questions. As far as we know, Li et al.’s work [26, 34] may be the closest to this paper, but our work differs from it in several aspects. First, we explore a number of fundamental characteristics not covered in [26, 34], such as the extent of language dependence, length distribution, frequency distribution and various semantics. Second, our improved PCFG-based algorithm can achieve success rates from 29.41% to 39.47% at just 10<sup>7</sup> guesses, while the best success rate of their improved PCFG-based algorithm is only 17.3% at 10<sup>10</sup> guesses (i.e., significantly underestimate attackers). Third, based on more comprehensive experiments, we outline the need for pairing passwords in terms of site

service type when comparing password strength, which is overlooked by Li et al.’s [26, 34] and Bonneau’s [7] work. Fourth, as shown in Sec. 3.2, two of Li et al.’s five Chinese datasets are improperly pre-processed when they perform data cleaning,<sup>1</sup> which impairs their results.

## 1.2 Contributions

We perform a large-scale empirical analysis by leveraging 73.1 million passwords from six popular Chinese sites and 33.2 million passwords from three English sites. Particularly, we seek for fundamental properties of user-generated passwords and systematically measure their structural patterns, semantic characteristics and strength. In summary, we make the following key contributions:

- **An empirical analysis.** By leveraging 73.1 million real-life Chinese passwords, *for the first time*, we: (1) provide a *quantitative* measurement of to what extent user passwords are influenced by their native language; (2) *systematically* explore the common semantics (e.g., date, name, place and phone #) in passwords; and (3) show that passwords of these two distinct user groups follow quite similar Zipf frequency distributions, despite being created under diversified password policies.
- **A reversal principle.** We employ two state-of-the-art password-cracking algorithms (i.e., PCFG-based and Markov-based [36]) to measure the strength of Chinese web passwords. We also improve the PCFG-based algorithm to more accurately capture passwords that are of a monotonically long structure (e.g., “1qa2ws3ed”). At 10<sup>7</sup> guesses, our algorithm can crack 92% to 188% more passwords than the best results in [34]. Particularly, we reveal a “reversal principle”, i.e. the *bifacial-security* nature of Chinese passwords: when the guess number allowed is small, they are much weaker than their English counterparts, yet this relationship is reversed when the guess number is large, thereby reconciling the contradictory claims made in [7, 34].
- **Some insights.** We highlight some insights for password policies, strength meters and cracking. We provide a large-scale empirical evidence that supports the hypothesis raised in the HCI community [17, 46]: users self-reported to rationally choose stronger passwords for accounts associated with a higher value, and knowingly select weaker passwords for a lower-value service even if the latter imposes a stricter policy. Our methodological approaches would also be useful for analyzing passwords of other non-English speaking users.

<sup>1</sup> We reported this issue to the authors of [26, 34], they have acknowledged it. As their journal paper [26] is technically a verbatim of their conference version [34], we mainly use [34] for discussion.

## 2 Related work

In this section, we briefly review prior research on password characteristics and security.

### 2.1 Password characteristics

**Basic statistics.** In 1979, Morris and Thompson [39] analyzed a corpus of 3,000 passwords. They reported that 71% of the passwords are no more than 6 characters long and 14% of the passwords are non-alphanumeric characters. In 1990, Klein [32] collected 13,797 computer accounts from his friends and acquaintances around US and UK. They observed that users tend to choose passwords that can be easily derived from dictionary words: a dictionary of 62,727 words is able to crack 24% of the collected accounts and 52% of the cracked passwords are shorter than 6 characters long. In 2004, Yan et al. [62] found that passwords are likely to be dictionary words since users have difficulty in memorizing random strings. On average, the password length in their user study (288 participants) is 7~8.

In 2012, Bonneau [7] conducted a systematic analysis of 70 million Yahoo private passwords. This work examined dozens of subpopulations based on demographic factors (e.g., age, gender, and language) and site usage characteristics (e.g., email and retail). They found that even seemingly distant language communities choose the same weak passwords. This research was recently reproduced in [3] by using differential privacy techniques. Particularly, Chinese passwords are found among the most difficult ones to crack [7]. In 2014, however, Li et al. [34] argued that Bonneau's dataset is not representative of general Chinese users, because Yahoo users are familiar with English. Accordingly, Li et al. leveraged a corpus of five datasets from Chinese sites and observed that Chinese users like to use digits when creating passwords, as compared to English speaking users who like to use letters to create passwords. However, as an elementary defect, two of their Chinese datasets have not been cleaned properly (see Section 3.2), which might lead to inaccurate measures and biased comparisons. More importantly, several critical password properties (such as length distributions, frequency distributions and semantics) remain to be explored.

In 2014, Ma et al. [36] investigated password characteristics about the length and the structure of six datasets, three of which are from Chinese websites. Nonetheless, this work mainly focuses on the effectiveness of probabilistic password cracking models and pays little attention to the deeper semantics (e.g., no information is provided about the role of Pinyins, names or dates). In 2017, Pearman et al. [42] reported on an in situ examination of 4057 passwords from 154 English-speaking users over an average of 147 days. They found that the average

password is composed of 2.77 character classes and is of length 9.92 characters, including 5.91 lowercase letters, 2.70 digits, 0.84 uppercase letters, and 0.46 symbols.

**Semantic patterns.** In 1989, Riddle et al. [43] found that birth dates, personal names, nicknames and celebrity names are popular in user-generated passwords. In 2004, Brown et al. [9] confirmed this by conducting a thorough survey that involved 218 participants and 1,783 passwords. They reported that the most frequent entity in passwords is the self (67%), followed by relatives (7%), lovers and friends; Also, names (32%) were found to be the most common information used, followed by dates (7%). Veras et al. [51] examined the 32M RockYou dataset by employing visualization techniques and observed that 15% of passwords contain sequences of 5~8 consecutive digits, 38% of which could be further classified as dates. They also found that repeated days/months and holidays are popular, and when non-digits are paired with dates, they are most commonly single-characters or names of months.

In 2014, Li et al. [34] showed that Chinese users tend to insert Pinyins and dates into their passwords. However, many other important semantic patterns (e.g., Pinyin name and mobile number) are left unexplored. In addition, we improve upon the processes of data cleaning (see Sec. 3.2) and tuning of cracking algorithms (see Sec. 4.1) to advance beyond Li et al.'s measurement of the strength of Chinese passwords. In 2015, Ji et al. [30] noted that user-IDs and emails have a great impact on password security. For instance, 53% of Dodonew passwords can be guessed by using user-IDs within an average of 706 guesses. This motivates us to investigate to what extent the Pinyin names and Chinese-style dates impact the security of Chinese passwords. In 2018, AISabah et al. [2] studied 79,760 passwords leaked from the Qatar National Bank, customers of which are mainly Middle Easterners. They observed that over 30% of passwords contain names, over 5% use a 2-digit birth year, and 4% include their own phone number in whole as part of their password.

### 2.2 Password security

A crucial password research subject is password strength. Instead of using brute-force attacks, earlier works (e.g., [32, 43]) use a combination of ad hoc dictionaries and mangling rules, in order to model the common password generation practice and see whether user passwords can be successfully rebuilt in a period of time. This technique has given rise to automated tools like John the Ripper (JTR), hashcat and L0phtCrack.

Borrowing the idea of Shannon entropy, the NIST-800-63-2 guide [10] attempts to use the concept of *password entropy* for estimating the strength of password creation policy underlying a password system. Password

entropy is calculated mainly according to the length of passwords and augmented with a bonus for special checks. Florencio and Herley [19], and Egelman et al. [17] improved this approach by adding the size of the alphabet into the calculation and called the resulting value  $\log_2((\text{alpha.size})^{\text{pass.len}})$  the bit length of a password.

However, previous ad hoc metrics (e.g., password entropy and bit length) have recently been shown far from accurate by Weir et al. [57]. They suggested that the approach based on simulating password cracking sessions is more promising. They also developed a novel method that first automatically derives word-mangling rules from password datasets by using PCFG, and then instantiates the derived grammars by using string segments from external input dictionaries to generate guesses in decreasing probability order [58]. This PCFG-based cracking approach is able to crack 28% to 129% more passwords than JTR when allowed the same guess number. It is considered as a leading password cracking technique and used in a number of recent works [36, 56].

Differing from the PCFG-based approach, Narayanan and Shmatikov [40] introduced the Markov-Chain theory for assigning probabilities to letter segments, which substantially reduces the password search space. This approach was tested in an experiment against 142 real user passwords and could break 68% of them. In 2014, by utilizing various normalization and smoothing techniques from the natural language processing domain, Ma et al. [36] systematically evaluated the Markov-based model. They found it performs significantly better than the PCFG-based model at large guesses (e.g.,  $2^{30}$ ) in some cases when parameterized appropriately. In this work, we perform extensive experiments by using both models to evaluate the strength of Chinese passwords.

When these password models are coupled with tools (e.g., AUTOFORGE [63]) that can automatically forge valid online login requests from the client side, server-side mechanisms like rate-limiting (see Sec. 5.2.2 of [25]) and password leakage detection [31] become necessary. However, in reality, few sites have implemented proper countermeasures to thwart online guessing. Among the 182 sites in the Alexa Top 500 sites in the US that Lu et al. [35] were able to examine, 131 sites (72%) allow frequent unsuccessful login attempts, and another 28 sites (15%) can be easily locked out, leading to denial of service attacks. This further suggests the necessity of our work—understanding the strength of Chinese passwords against online guessing.

### 3 Characteristics of Chinese passwords

We now investigate Chinese password characteristics, most of which are underexplored. In addition, we discuss weaknesses in previous major studies [26, 34].

### 3.1 Dataset and ethics consideration

Our empirical analysis employs six password datasets from Chinese websites and three password datasets from English websites. In total, these nine datasets consist of 106.3 million real-life passwords. As summarized in Table 1, these nine datasets are different in terms of service, language, culture, and size. The role of each dataset will be specified in Sec. 4 when performing strength comparison. They were hacked and made public on the Internet between 2009 and 2012, and may be a bit old. However, they can represent current passwords due to two reasons. First, Bonneau has shown that “passwords have changed only marginally since then (1990)” [7]. Second, the password ecosystem evolves very slowly. A number of recent researches (see [21, 24, 55]) reveal that password guidance and practices implemented on leading sites have seldom changed over time.

We realize that though publicly available and widely used in the literature [36, 52, 56], these datasets are private data. Thus, we only report the aggregated statistical information, and treat each individual account as confidential so that using it in our research will not increase risk to the corresponding victim, i.e., no personally identifiable information can be learned. Furthermore, these datasets may be exploited by attackers as cracking dictionaries, while our use is both beneficial for the academic community to understand password choices of Chinese netizens and for security administrators to secure user accounts. As our datasets are all publicly available, the results in this work are reproducible.

### 3.2 Data cleaning

We note that some original datasets (e.g., Rockyou and Tianya) include *un-necessary* headers, descriptions, footnotes, password strings with  $\text{len} > 100$ , etc. Thus, before any exploration, we first launch data cleaning. We remove email addresses and user names from the original data. As with [36], we also remove strings that include symbols beyond the 95 printable ASCII characters. We further remove strings with  $\text{len} > 30$ , because after manually scrutinizing the original datasets, we find that these long strings do *not* seem to be generated by users, but more likely by password managers or simply junk information. Moreover, such unusually long passwords are often beyond the scope of attackers who care about cracking efficiency [4]. In all, the fraction of excluded passwords is *negligible* (see the last column but two in Table 1), yet this cleaning step unifies the input of cracking algorithms and simplifies the later data processing.

We find that either Tianya or 7k7k has been contaminated: there is a *non-negligible* overlap between the Tianya dataset and 7k7k dataset (i.e., 40.85% of 7k7k and 24.62% of Tianya). More specifically, we were first puzzled by the fact that the password “111222tianya”

Table 1: Data cleaning of the password datasets leaked from nine web services (“PWs” stands for passwords).

Dataset	Web service	Language	Leaked Time	Original PWs	Miscellany	Length>30	Removed %	After cleaning	Unique PWs
Tianya	Social forum	Chinese	Dec. 2011	31,761,424	860,178	5	2.71%	30,901,241	12,898,437
7k7k	Gaming	Chinese	Dec. 2011	19,138,452	13,705,087	10,078	71.66%*	5,423,287	2,865,573
Dodonew	E-commerce&Gaming	Chinese	Dec. 2011	16,283,140	10,774	13,475	0.15%	16,258,891	10,135,260
178	Gaming	Chinese	Dec. 2011	9,072,966	0	1	0.00%	9,072,965	3,462,283
CSDN	Programmer forum	Chinese	Dec. 2011	6,428,632	355	0	0.01%	6,428,277	4,037,605
Duowan	Gaming	Chinese	Dec. 2011	5,024,764	42,024	10	0.83%	4,982,730	3,119,060
Rockyou	Social forum	English	Dec. 2009	32,603,387	18,377	3140	0.07%	32,581,870	14,326,970
Yahoo	Portal(e.g., E-commerce)	English	July 2012	453,491	10,657	0	2.35%	442,834	342,510
Phpbbs	Programmer forum	English	Jan. 2009	255,421	45	3	0.02%	255,373	184,341

\*We remove 13M duplicate accounts from 7k7k, because we identify that they are copied from Tianya as we will detail in Section 3.2.

was originally in the top-10 most popular list of both datasets. We manually scrutinize the original datasets (before removing the email addresses and user names) and are surprised to find that there are around 3.91 million (actually 3.91\*2 million due to a split representation of 7k7k accounts, as we will discuss later) joint accounts in both datasets. In Appendix A, we provide strong evidence that someone has copied these joint accounts from Tianya to 7k7k, but *not* from 7k7k to Tianya as concluded in previous major studies [26, 34].

### 3.3 Password characteristics

**Language dependence.** There is a folklore that user-generated passwords are greatly influenced by their native languages, yet so far no large-scale quantitative measurement has ever been given. To fill this gap, we first illustrate the character distributions of the nine datasets, and then measure the closeness of passwords with their native languages in terms of inversion number of the character distributions (in descending order).

As expected, passwords from different language groups have significantly varied letter distributions (see Fig. 1). What’s unexpected is that, even though generated and used in vastly diversified web services, passwords from the same language group have quite similar letter distributions. This suggests that, when given a password dataset, one can largely determine what the native language of its users is by investigating its letter distribution. Arranged in descending order, the letter distribution of all Chinese passwords is `aineo hglwyszxqcdjmbtfrkpv`, while this distribution for all English passwords is `aeionrlstmcdyhubkpgjvfw zxq`. While some letters (e.g., ‘a’, ‘e’ and ‘i’) occur frequently in both groups, some letters (e.g., ‘q’ and ‘r’) only occur frequently in one group. Such information can be exploited by attackers to reduce the search space and optimize their cracking strategies. Note that, here all the percentages are handled case-insensitively.

While users’ passwords are greatly affected by their native languages, the letter frequency of general language may be somewhat different from the letter frequency of passwords. *To what extent do they differ?* According to Huang et al.’s work [28], the letter

distribution of Chinese language (i.e., written Chinese texts like literary work, newspapers and academic papers), when converted into Chinese Pinyin, is `inauhegoyszdxmwxqbcrlpfrkv`. This shows that some letters (e.g., ‘l’ and ‘w’), which are popular in Chinese passwords, appear much less frequently in written Chinese texts. A plausible reason may be that ‘l’ and ‘w’ is the first letter of the family names `li` and `wang` (which are the top-2 family names in China), respectively, while Chinese users, as we will show, love to use names to create their passwords.

A similar observation holds for passwords of English speaking users. The letter distribution of English language (i.e., `etaoinshrdlcumwfgypbvkjxqz`) is from [www.cryptograms.org/letter-frequencies.php](http://www.cryptograms.org/letter-frequencies.php). For example, ‘t’ is common in English texts, but not so common in English passwords. A plausible reason may be that ‘t’ is used in popular words like `the`, `it`, `this`, `that`, `at`, `to`, while such words are rare in passwords.

To further explore the closeness of passwords with their native languages and with the passwords from other datasets, we measure the inversion number of the letter distribution sequences (in descending order) between two password datasets (as well as languages). The results are summarized in Table 2. “Pinyin\_fullname” is a dictionary consisting of 2,426,841 unique Chinese full names (e.g., `wangLei` and `zhangwei`), “Pinyin\_word” is a dictionary consisting of 127,878 unique Chinese words (e.g., `chang` and `cheng`), and these two dictionaries are detailed in Appendix B. Note that the inversion number of sequence *A* to sequence *B* is equal to that of *B* to *A*. For instance, the inversion number of `inauh` to `aniuh` is 3, which is equal to that of `aniuh` to `inauh`.

As shown in Table 2, the inversion number of letter distributions between passwords from the same language group is generally much smaller than that of passwords from different language groups. This value is also distinctly smaller than that of the letter distributions between passwords and their native language (see the bold values in Table 2). The latter is less expected. All this indicates that passwords from different languages are intrinsically different from each other in letter distributions, and that passwords are close to their native language yet the distinction is still significant (measurable).

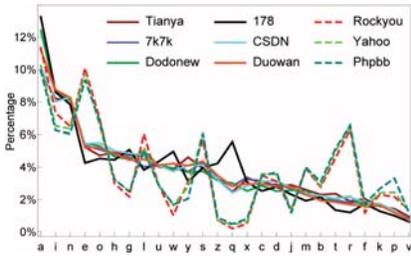

Figure 1: Letter distributions of passwords.

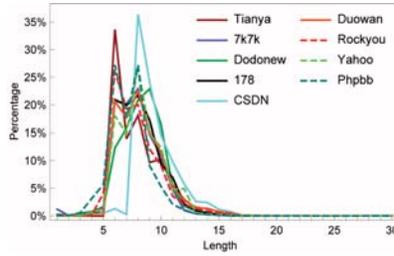

Figure 2: Length distributions of passwords.

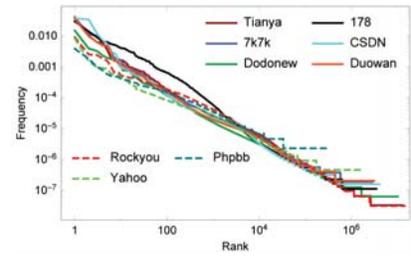

Figure 3: Freq. distributions of passwords.

Table 2: Inversion number of the letter distributions (in descending order) between two datasets.

	Tianya	7k7k	178	CSDN	Dodonew	Duowan	All Chinese PWs	Chinese language	Pinyin fullname	Pinyin word	Rockyou	Yahoo	Phpb	All English PWs	English language

Note that, among all Chinese datasets, Duowan has the least inversion number (i.e., 9 in dark gray) with the dataset “All.Chinese.PWs”. This indicates that *Duowan passwords are likely to best represent general Chinese web passwords, and thus Duowan will be selected as the training set for attacking other Chinese datasets (see Sec 5)*. For a similar reason, Rockyou will be selected as the training set when attacking English passwords.

**Length distribution.** Fig. 2 depicts the length distributions of passwords. Irrespective of the web service, language and culture differences, the most common password lengths of every dataset are between 6 and 10, among which length-6 and 8 take the lead. Merely passwords with lengths of 6 to 10 can account for more than 75% of every entire dataset, and this value will rise to 90% if we consider passwords with lengths of 5 to 12. Very few users prefer passwords longer than 15 characters. Notably, people seem to prefer even lengths over odd ones. Another interesting observation is that, CSDN exhibits only one peak in its length distribution curve and has many fewer passwords (i.e., only 2.16%) with length < 8. This might be due to the password policy that requires the length to be no shorter than 8 on this site.

**Frequency distribution.** Fig. 3 portrays the frequency vs. the rank of passwords from different datasets in a log-log scale. We first sort each dataset according to the password frequency in descending order. Then, each individual password will be associated with a frequency  $f_r$ , and its rank in the frequency table is denoted by  $r$ . Interestingly, the curve for each dataset closely ap-

proximates a straight line, and this trend will be more pronounced if we take all the nine curves as a whole. This well accords with the Zipf’s law [53]:  $f_r$  and  $r$  follow a relationship of the type  $f_r = C \cdot r^{-s} - C \cdot (r - 1)^s \approx C \cdot s \cdot r^{s-1}$ , where  $C \in [0.01, 0.06]$  and  $s \in [0.15, 0.40]$  are constants. Particularly,  $1 - s$  is the absolute value of the Zipf linear regression line’s slope. The Zipf theory indicates that *the popularity of passwords decreases polynomially with the increase of their rank*. This further implies that a few passwords are overly popular (explaining why online guessing [56] can be effective, even if security mechanisms like rate-limiting and suspicious login detection [16] are implemented at the server), while the least frequent passwords are very sparsely scattered in the password space (explaining why offline guessing attackers need to consider cost-effectiveness [4] and weigh when to stop).

**Top popular passwords.** Table 3 shows the top-10 most frequent passwords from different services. The most frequent password among all datasets is “123456”, with CSDN being the only exception due to its password policy that requires passwords to be of length  $8^+$  (see Fig. 2). “111111” follows on the heel. Other popular Chinese passwords include “123123”, “123321” and “123456789”, all composed of digits and in simple patterns such as repetition and palindrome. Love also shows its magic power: “5201314”, which has a similar pronunciation of “I love you forever and ever” in Chinese,<sup>2</sup> appears in the top-10 lists of four Chinese

<sup>2</sup><https://ninchinese.com/blog/2016/05/20/520-chinese-love-word-number/>

datasets. In contrast, popular ones in English datasets tend to be meaningful letter strings (e.g., “sunshine” and “letmein”). The eternal theme of love—frankly, “iloveyou” or perhaps euphemistically, “princess”—also show up in top-10 lists of English datasets. Our results confirm the folklore [50] that “back at the dawn of the Web, the most popular password was 12345. Today, it is one digit longer but hardly safer: 123456.”

It is interesting to see that only the top-10 most popular ones account for as high as 6.78%~10.44% of each entire dataset, with Dodonew being the only exception. However, this figure for Dodonew even achieves 3.24%, while the English datasets are all below 2.80%. This indicates that top-popular Chinese passwords are more concentrated than their English counterparts, which is likely to make Chinese passwords more vulnerable to online guessing. This will be confirmed in Sec. 4.1.

**Top popular structures.** We have seen that digits are popular in top-10 passwords of Chinese datasets. Are they also popular in the whole datasets? We investigate the frequencies of password patterns that involve *digits*, and show the results of the top 3 most frequent ones in the left hand of Table 4. The first column of the table denotes the pattern of a password as in [58] (i.e., L denotes a lower-case sequence, D for digit sequence, U for upper-case sequence, S for symbol sequence, and the structure pattern of the password “Wanglei123” is ULD). Over 50% of the average Chinese web passwords are only composed of digits, while this value for English datasets is only 11.30%. In contrast to first D then DL, English speaking users prefer the patterns L and LD.

It is somewhat surprising to see that the sum of merely the top-3 digit-based patterns (i.e., D, LD, and DL)

accounts for an average of 81.90% for Chinese dataset. In contrast, English speaking users favor letter-related patterns, and on average, their top-3 structures (i.e., L, LD and D) also account for slightly over 80%. This indicates that, unlike English speaking users, Chinese speaking users are inclined to employ digits to build their passwords — digits in Chinese passwords serve the role of letters that play in English passwords, while letters in Chinese passwords mainly come from Pinyin words/ names. This is probably due to that most Chinese users are unfamiliar with English language (and Roman letters on the keyboard). If this is the case, is there any meaningful information in these digit sequences?

**Semantics in passwords.** As there is little existing work, to gain an insight into the underlying semantic patterns, we have to construct semantic dictionaries from scratch by ourselves. Finally, we construct 22 dictionaries of different semantic categories (see the first column in Table 5). The detailed information about how we construct them is referred to Appendix B. To eliminate ambiguities, we use the “left-most longest match” when matching a password with each item in our dictionaries. Table 5 shows the prevalence of various semantic patterns in passwords. Lots of English speaking users tend to use raw English words as their password building blocks: 25.88% insert a 5<sup>+</sup>-letter word into their passwords. Passwords with a 5<sup>+</sup>-letter word account for over a third of the total passwords with a 5<sup>+</sup>-letter substring. In comparison, fewer Chinese users (2.41%) choose English words to build passwords, yet they prefer Pinyin names (11.50%), especially *full names*.

Particularly, of all the Chinese passwords (22.42%) that include a 5<sup>+</sup>-letter substring, more than half

Table 5: Popularity of 22 kinds of semantics in passwords (by matching our 22 semantic dictionaries).\*

\*Each percentage (%) is counted by the rule of “left-most longest” match and taken by dividing the corresponding password dataset size.

(11.24%) include a 5<sup>+</sup>-letter Pinyin full name. There is also 4.10% of English passwords that contain a 5<sup>+</sup>-letter full Pinyin name. A reasonable explanation is that many Chinese users have created accounts in these English sites. For instance, the popular Chinese Pinyin name “zhangwei” appears in both Rockyou and Yahoo. We also note that English names are also widely used in English passwords, yet full names are less popular than last names and first names.

Equally interestingly, we find that, on average, 16.99% of Chinese users insert a six-digit date into their passwords. Further considering that users love to include self information into passwords [9, 56], such dates are likely to be users’ *birthdays*. Besides, about 30.89% of Chinese speaking users use a 4<sup>+</sup>-digit date to create passwords, which is 3.59 times higher than that of English speaking users (i.e. 8.61%). Also, there are 13.49% of Chinese users inserting a four-digit year into their passwords, which is 3.55 times higher than that of English speaking users (3.80%, which is comparable to the results in [14]). We note that there might be some overestimates, for there is no way to definitely tell apart whether some digit sequences are dates or not, e.g., 010101 and 520520. These two sequences may be dates, yet they are also likely to be of other semantic meanings (e.g., 520520 sounds like “I love you I love you”). As discussed later, we have devised reasonable ways to address this issue. In all, dates play a vital role in passwords of Chinese users.

We mainly pay attention to length-4, 6 and 8 digits in passwords, because: 1) Length-4 and 6 are the most widely used lengths of PINs in the West and Asia; and 2) 6&8 are the two most frequent password lengths (see Fig. 2). It is interesting to see that 2.91% of Chinese users are likely to use their 11-digit mobile numbers as passwords, making up 39.59% of all passwords with an 11<sup>+</sup>-digit

substring. On average, 12.39% of Chinese passwords are longer than 11. Thus, if an attacker can determine (e.g., by shoulder-surfing) that the victim uses a long password, she is likely to succeed with a high chance of 23.48%(=  $\frac{2.91\%}{12.39\%}$ ) by just trying the victim’s 11-digit mobile number. *This reveals a practical attacking strategy against long Chinese passwords.*

Note that there are some unavoidable ambiguities when determining whether a text/digit sequence belongs to a specific dictionary, and an improper resolution of these ambiguities would lead to an overestimation or underestimation. Here we take “YYMMDD” for illustration. For example, both 111111 and 520521 fall into “YYMMDD” and are highly popular. However, it is more likely that users choose them simply because they are easily memorable repetition numbers or meaningful strings, and counting them as dates would lead to an *overestimation*. Yet they can really be dates (e.g., 111111 stands for “Nov. 11th, 2011” and 520131 for “Jan 31th, 1952”) and completely excluding them from “YYMMDD” would lead to *underestimation* of dates.

Thus, we assume that user birthdays are randomly distributed and assign the expectation of the frequency of dates (denoted by  $E$ ), instead of zero, to the frequency of these abnormal dates. We manually identify 17 abnormal dates in the dictionary “YYMMDD”, each of which originally has a frequency  $> 10E$  and appears in every top-1000 list of the six Chinese datasets. In this way, the ambiguities can be largely resolved. We similarly tackle 16 abnormal items in “MMDD”. The detailed info about these abnormal dates can be found in Appendix B. As for the other 19 dictionaries in Table 5, few abnormal items can be identified, and they are processed as usual.

**Summary.** We have measured nine password datasets in terms of letter distribution, length distribution, frequency

distribution and semantic patterns. To our knowledge, most of these fundamental characteristics have at most been mentioned/ exemplified in the literature (see [26, 30, 34, 36, 53]) but never *systematically* examined. We have identified a number of *similarities* (e.g., frequency distribution and the theme of love) and *differences* (e.g., letter distribution, structural patterns, and semantic patterns) between passwords of these two user groups.

## 4 Strength of Chinese web passwords

Now we employ two state-of-the-art password attacking algorithms (i.e., PCFG-based [58] and Markov-based [36]) to evaluate the strength of Chinese web passwords. We further investigate whether the characteristics identified in Sec. 3.3 (e.g., dates and Pinyin names) can be practically exploited to facilitate password guessing.

**Necessity of pairing passwords by service type.** There are a number of confounding factors that impact password security, among which language, service type, and password policy are the three most important ones [29, 53, 56]. As shown in [36, 53], except for CSDN that imposes a length  $8^+$  policy, all our datasets (Table 1) reflect no explicit policy requirements. It has recently been revealed that users often rationally choose robust passwords for accounts perceived to be important [46], while knowingly choose weak passwords for unimportant accounts [17]. Since accounts of the same service would generally have the same level of value for users, we divide datasets into three pairs according to their types of services (i.e., Tianya vs. Rockyou, Dodonew vs. Yahoo, and CSDN vs. Phpbb) for fairer strength comparison, as opposed to existing works [7, 26, 34] that do not take into account the site service type. We emphasize that it is less reasonable if one compares Dodonew passwords (from an e-commerce site) with Phpbb passwords (from a low-value programmer forum): Even if Dodonew passwords are stronger than Phpbb passwords, one can not conclude that Chinese passwords are more secure than English ones, because there is a potential that Dodonew passwords will be weaker than Yahoo e-commerce passwords.

### 4.1 PCFG-based attacks

The PCFG-based model [58] is one of the state-of-the-art cracking models. Firstly, it divides all the passwords in a training set into segments of similar character sequences and obtains the corresponding base structures and their associated probabilities of occurrence. For example, “wanglei@123” is divided into the L segment “wanglei”, S segment “@” and D segment “123”, resulting in a base structure  $L_7S_1D_3$ . The probability of  $L_7S_1D_3$  is  $\frac{\# \text{of } L_7S_1D_3}{\# \text{of base structures}}$ . Such information is used to generate the probabilistic context-free grammar.

Then, one can derive password guesses in decreasing order of probability. The probability of each guess is the product of the probabilities of the productions used in its derivation. For instance, the probability of “liwei@123” is computed as  $P(\text{“liwei@123”}) = P(L_5S_1D_3) \cdot P(L_5 \rightarrow \text{liwei}) \cdot P(S_1 \rightarrow @) \cdot P(D_3 \rightarrow 123)$ . In Weir et al.’s original proposal [58], the probabilities for D and S segments are learned from the training set by counting, yet L segments are handled either by learning from the training set or by using an external input dictionary. Ma et al. [36] revealed that PCFG-based attacks with L segments directly learned from the training set generally perform better than using an external input dictionary. Thus, we prefer to instantiate the PCFG L segments of password guesses by directly learning from the training set.

We divide the nine datasets into two groups by language. For the Chinese group of test sets, we randomly select 1M passwords from the Duowan dataset as the training set (denoted by “Duowan\_1M”). The reason is that: Duowan has the least inversion number with the dataset “All Chinese PWs” (see Sec. 3.3) and is likely to best represent general Chinese web passwords. Similarly, for the English test sets, we select 1M passwords from Rockyou as the training set. Since we have only used part of Duowan and Rockyou, their remaining passwords and the other 7 datasets are used as the test sets. The attacking results on the Chinese group and English group are depicted in Fig. 4(a) and Fig. 4(b), respectively.

**Bifacial-security.** When the guess number (i.e., search space size) allowed is below 3,000, Chinese passwords are generally much *weaker* than English passwords from the same service (i.e., Tianya vs. Rockyou, Dodonew vs. Yahoo, and CSDN vs. Phpbb). For example, at 100 guesses, the success rate against Tianya, Dodonew and CSDN is 10.2%, 4.3% and 9.7%, respectively, while their English counterparts are 4.6%, 1.9% and 3.7%, respectively. However, when the search space size is above 10,000, Chinese web passwords are generally much *stronger* than their English counterparts. For example, at 10 million guesses, the success rate against Tianya, Dodonew and CSDN is 37.5%, 28.8% and 29.9%, respectively, while their English counterparts are 49.7%, 39.0% and 41.4%, respectively. The strength gap will be even wider when the guess number further increases. This reveals a reversal principle, i.e., the bifacial-security nature of Chinese passwords: they are more vulnerable to online guessing attacks (i.e., when the guess number allowed is small) than English passwords; But out of the remaining Chinese passwords, they are more secure against offline guessing. This reconciles two drastically conflicting claims (see Sec. 1.1) made about the strength of Chinese passwords. This bifacial-security is highly due to the bifacial-density nature of digit-based passwords: *Top* digit-based passwords are

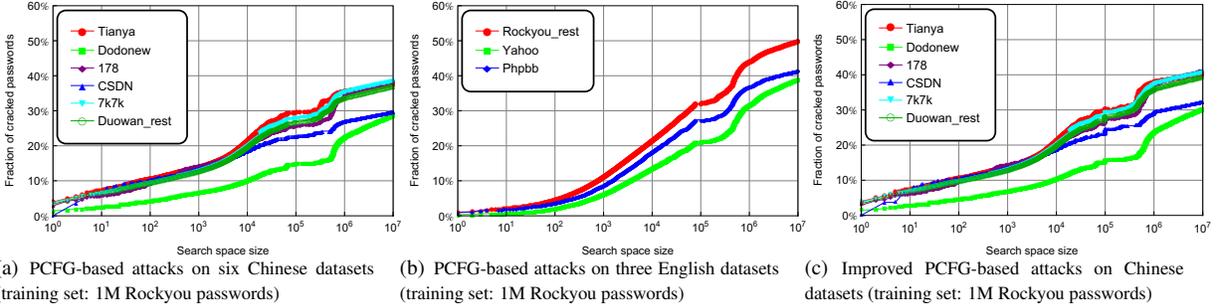

Figure 4: General and our improved PCFG attacks on different groups of datasets. Our algorithm gains tangible advantages.

more converging (see Table 3), while digits *in general* are more random (and diverging) than letters.

**A weakness in PCFG.** We observe that, the original PCFG algorithm [36, 58] inherently gives extremely low probabilities to password guesses (e.g., “1q2w3e4r” and “1a2b3c4d”) that are of a monotonically long base structure (e.g.,  $D_1L_1D_1L_1D_1L_1D_1L_1$ , or  $(D_1L_1)_4$  for short). For example,  $P(\text{“1q2w3e4r”}) = P((D_1L_1)_4) \cdot P(D_1 \rightarrow 1) \cdot P(L_1 \rightarrow q) \cdot P(D_1 \rightarrow 2) \cdot P(L_1 \rightarrow w) \cdot P(D_1 \rightarrow 3) \cdot P(L_1 \rightarrow e) \cdot P(D_1 \rightarrow 4) \cdot P(L_1 \rightarrow r)$  can hardly be larger than  $10^{-9}$ , for it is a multiplication of *nine* probabilities. Thus, some guesses (e.g., “1q2w3e4r” and “a12b34c56”) will never appear in the top- $10^7$  guess list generated by the original PCFG algorithm, even if they are popular (e.g., “1q2w3e4r” appears in the top-200 list of every dataset). The essential reason is that the PCFG algorithm simply assumes that each segment in a structure is independent. Yet, in many situations this is *not* true. For instance, the four  $D_1$  segments and  $L_1$  segments in the structure  $(D_1L_1)_4$  of password “1q2w3e4r” are evidently interrelated with each other (i.e.,  $D_4$ : 1234 and  $L_4$ : qw3e).

**Our solution.** To address this problem, we specially tackle a few password structures that are long but simple alternations of short segments by treating them as short structures. For instance,  $(D_1L_1)_4$  is converted to  $D_4L_4$ , and  $(D_1L_2)_3$  to  $D_3L_6$ . In this way, the probability of “1q2w3e4r” now is computed as  $P(\text{“1q2w3e4r”}) = P((D_1L_1)_4) \cdot P((D_1L_1)_4 \rightarrow D_4L_4) \cdot P(D_4 \rightarrow 1234) \cdot P(L_4 \rightarrow qw3e)$ . *Our approach is language-agnostic and constitutes a general amendment to the state-of-the-art PCFG-based algorithm in [36].*

To further exploit the characteristics of Chinese passwords, we insert the “Pinyin\_name\_any” dictionary and the six-digit date dictionary (see Sec. 3.3) into the original PCFG L-segment and D-segment dictionaries, respectively. Details about this insertion process and our improved algorithm for password-guess generation are shown in Algorithm 1. The resulting changes to the original PCFG grammars are given in Table 6.

Fig. 4(c) illustrates that, when the guess number allowed is small (e.g.,  $10^3$ ), our improved attack exhibits little improvement; As the guess number grows, the

### Algorithm 1: Our improved PCFG-based attack

**Input:** A training set  $S$ ; A name list  $nameList$ ; A date list  $dateList$ ; A parameter  $k$  indicating the desired size of the PW guess list that will be generated (e.g.,  $k = 10^7$ )

**Output:** A PW guess list  $L$  with the top- $k$  items

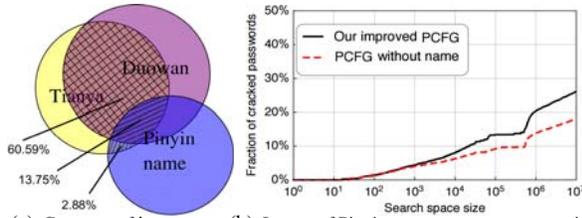

- 1 **Training (lastly tackle monotonically long PWs):**
- 2   **for**  $password \in S$  **do**
- 3     **for**  $segment \in splitToSegments(password)$  **do**
- 4        $segmentSet.insert(segment)$
- 5        $baseStructure \leftarrow getBaseStructure(password)$
- 6       **if**  $monotonicallyLong(baseStructure)$  **then**
- 7          $transformStructureSet.insert(baseStructure)$
- 8          $baseStructure \leftarrow convertToShort(baseStructure)$
- 9          $baseStructureSet.insert(baseStructure)$
- 10         $trainingSet.insert(password)$
- 11 **Append name and date lists to the learned segment list:**
- 12   **for**  $name \in nameList$  **do**
- 13      $correctedCount = totalOverlapNameInSegmentSet * nameList.getCount(name) / totalOverlapNameInNameList$
- 14     **if**  $name \notin segmentSet$  **and**  $correctedCount \geq 1$  **then**
- 15        $segmentSet.insert(name, correctedCount)$
- 16   **for**  $date \in dateList$  **do**
- 17     **if**  $date \notin segmentSet$  **then**
- 18        $segmentSet.insert(date)$
- 19 **Produce  $k$  guesses: As with [36] and the details are omitted.**

Table 6: Changes caused to the original PCFG grammars

Training set	Base structures	L segments	D segments	S segments
Duowan_1M	8905+0	155693+24416	465157+20341	865+0
Duowan_All	20961+0	559017+98654	1824404+9744	2417+0

improvement increases. For example, at  $10^5$  guesses, there is 0.09%~0.85% improvement in success rate; at  $10^6$  guesses, this figure is 1.32~4.32%; at  $10^7$  guesses, this figure reaches 1.70%~4.29%. This indicates that the vulnerable behaviors of using monotonically long passwords, Pinyin names and birthdays help an attacker reduce her search space, and this issue is more serious when large guesses are allowed.

**Comparison.** Li et al. [34] reported that using 2M Dodonew passwords as the training set and at  $10^{10}$  guesses, their best success rates ( $= \frac{\# \text{ of successfully cracked PWs}}{\text{the size of test set}}$ ) is about 17.30%. However, against the same Chinese test sets, our improved attack can achieve much higher success rates (29.41%~39.47%) at only  $10^7$  guesses.

(a) Coverage of L-segments (b) Impact of Pinyin-name-segments on security  
 Figure 5: Coverage and security impacts of Pinyin-name-segments in the test set Tianya with L-segments involved (Duowan is the training set, Pinyin\_name is an extra input dictionary in our improved PCFG attack).

This means that we can crack 70% to 128% more passwords than Li et al.’s best record. Our attacks are better because: 1) Our training-set (i.e., Duowan) is more effective than [34], for we find Duowan represents Chinese password distributions better (see Table 2) than Dodonew as used in [34]; 2) We optimize PCFG not only through adding semantic dictionaries as [34] but also through transforming monotonically long base structures.

**The role of Names.** In our improved PCFG-based attacks, external name segments are added into the PCFG L-segment dictionary during training, and we get glad-some increases in success rates (see Fig. 4(c)). However, such improvements are still not so prominent as compared to the prevalence of names in Chinese passwords. *To explicate this paradox, we scrutinize the internal process of PCFG-based guess generation and manage to identify its crux.* Here we take the improved PCFG attack against Tianya (trained on Duowan) as an example. During training, we have added 98K name segments (see Table 6) into the L-segment dictionary.

Fig. 5(a) demonstrates that these 98K name segments *only* cover 2.88% of the total L segments of the test set Tianya. However, the original L segments trained from Duowan can cover 13.75% of the name segments and 60.59% of the non-name L segments in Tianya. This suggests that Duowan can *well* cover the name segments in the test set Tianya, and thus the addition of some extra names would have limited impacts. This observation also holds for the other eight test sets. The detailed results are summarized in Table 7, where “Duowan1M” is Duowan\_1M for short and “PY\_name” is Pinyin\_name for short. The fraction of L-segments in the test set  $y$  that can be covered by the set  $x$  is denoted by  $\text{CoL}(x)$ .

Table 7 shows that no matter  $x=\text{Duowan}_1\text{M}$  or Duowan: 1)  $\text{CoL}(x)$  is at least 11.12 times ( $= 65.64\%/5.90\%$ ) larger than  $\text{CoL}(\text{Pinyin\_name})-\text{CoL}(x)$ ; 2)  $\text{CoL}(\text{Pinyin\_name})\cap\text{CoL}(x)$  is at least 1.92 times ( $=11.35\%/5.90\%$ ) larger than  $\text{CoL}(\text{Pinyin\_name})-\text{CoL}(x)$ . This suggests that adding extra names into the PCFG L-segments when training is of limited yields. Note that, this does *not* contradict our observation that Pinyin names are prevalent in Chinese web passwords and pose

Table 8: Five Markov-based attacking scenarios

Attacking scenario	Smoothing	Normalization	Markov order
#1	Laplace	End-symbol	3/4/5
#2	Laplace	Distribution	3/4/5
#3	Good-Turing	End-symbol	3/4/5
#4	Good-Turing	Distribution	3/4/5
#5	Backoff	End-symbol	Backoff

a serious vulnerability. Actually, this *does* suggest that when the training set is selected properly, the name segments in passwords can be well guessed. Still, when there is no proper training set available, our improved attack would demonstrate its advantages (see Fig. 5(b)). Though our improved PCFG algorithm might not be optimal, its cracking results represent a new benchmark that any future algorithm should aim to decisively clear.

**Limitations.** We mainly investigate the impacts of names on password cracking, and similar observations and implications are likely to hold for dates (but with no confirmation). We leave it as future work. In addition, as our focus is the overall security of Chinese passwords (and its comparison with English counterparts), we only show the overall effectiveness of our improved PCFG attack. It is also interesting to see to what extent the improved PCFG structure and the usage of Duowan would respectively have impacts on the cracking effectiveness, but it is independent of the presented work.

## 4.2 Markov-based attacks

To show the robustness of our findings about password security, we further conduct Markov-based attacks.

### 4.2.1 Markov-based experimental setups

To make our experiments as reproducible as possible, we now detail the setups. As recommended in [36], we consider two smoothing techniques (i.e., Laplace Smoothing and Good-Turing Smoothing) to deal with the data sparsity problem and two normalization techniques (i.e., distribution-based and end-symbol-based) to deal with the unbalanced length distribution problem of passwords. This brings four attacking scenarios in Table 8. In each scenario we consider three types of Markov order (i.e., order-5, 4 and 3) to investigate which order performs best. It is reported that another scenario (i.e., backoff with end-symbol normalization) performs “slightly better” than the above 4 scenarios, yet it is “approximately 11 times slower, both for guess generation and for probability estimation” [36]. We also investigate this scenario and observe similar results. Thus, attackers, who particularly care about the cost-effectiveness [4], are highly unlikely to exploit this scenario.

Particularly, there is a challenge to be addressed when implementing the Good-Turing (GT) smoothing technique. To our knowledge, we for the first time explicate how to combine GT and simple GT in Markov-based

Table 7: Coverage of letter (CoL) segments in corresponding test sets (“PY” stands for Pinyin).

Test set	CoL (PY_name)	CoL (Duowan1M)	CoL(PY_name)∩ CoL(Duowan1M)	CoL(PY_name)− CoL(Duowan1M)	CoL(Duowan1M) − CoL(PY_name)	CoL (Duowan)	CoL(PY_name) ∩ CoL(Duowan)	CoL(PY_name) − CoL(Duowan)	CoL(Duowan) − CoL(PY_name)
Tianya	16.63%	67.53%	11.82%	<b>4.81%</b>	55.71%	74.34%	13.75%	<b>2.88%</b>	60.59%
7k7k	16.70%	71.60%	12.35%	<b>4.35%</b>	59.25%	79.84%	14.49%	<b>2.20%</b>	65.35%
Dodonew	15.76%	75.79%	11.79%	<b>3.97%</b>	63.99%	81.19%	13.47%	<b>2.29%</b>	67.72%
178	20.30%	79.15%	15.42%	<b>4.88%</b>	63.73%	83.98%	17.49%	<b>2.81%</b>	66.49%
CSDN	17.26%	65.64%	11.35%	<b>5.90%</b>	54.28%	72.70%	13.43%	<b>3.83%</b>	59.27%
Duowan	18.06%	80.05%	14.38%	<b>3.68%</b>	65.67%	100.00%	18.06%	<b>0.00%</b>	81.94%
Duowan_rest	18.07%	75.03%	13.46%	<b>4.61%</b>	61.57%	100.00%	18.07%	<b>0.00%</b>	81.93%

attacks (see details in Appendix C). As with PCFG-based attacks, in our implementation we use a max-heap to store the interim results to maintain efficiency. To produce  $k=10^7$  guesses, we employ the strategy of first setting a lower bound (i.e.,  $10^{-10}$ ) for the probability of guesses generated, then sorting all the guesses, and finally selecting the top  $k$  ones. In this way, we can reduce the time overheads by 170% at the cost of about 110% increase in storage overheads, as compared to the strategy of producing exactly  $k$  guesses. In Laplace Smoothing, it is required to add  $\delta$  to the count of each substring and we set  $\delta=0.01$  as suggested in [36].

#### 4.2.2 Markov-based experimental results

The experiment results for these five scenarios are quite similar. Here we mainly show the cracking results of Scenario #1 in Fig. 6, while the experiment results for Scenarios #2~#5 are omitted due to space constraints.

We can see that, for both Chinese and English test sets: (1) At large guesses (i.e.,  $>2*10^6$ ), order-4 markov-chain evidently performs better than the other two orders, while at small guesses (i.e.,  $<10^6$ ) the larger the order, the better the performance will be; (2) There is little difference in performance between Laplace and GT Smoothing at small guesses, while the advantage of Laplace Smoothing gets greater as the guess number increases; (3) End-symbol normalization always performs better than the distribution-based approach, while at small guesses its advantages will be more obvious. Such observations have not been reported in previous major studies [15, 36]. This suggests that: 1) At large guesses, the attacks with order-4, Laplace Smoothing and end-symbol normalization (see Figs. 6(b) and 6(e)) perform best; and 2) At small guesses, the attacks preferring order-5, Laplace Smoothing and end-symbol normalization (see Figs. 6(a) and 6(d)) perform best.

Results show that *the bifacial-security nature found in our PCFG attacks (see Sec. 5.1) also applies in all the Markov attacks*. For example, in order-4 markov-chain-based experiments (see Fig.6(b) and Fig.6(e)), we can see that, when the guess number is below about 7000, Chinese web passwords are generally much *weaker* than their English counterparts. For example, at 1000 guesses, the success rate against Tianya, Dodonew and CSDN is 11.8%, 6.3% and 11.6%, respectively, while their English counterparts (i.e., Rockyou, Yahoo and Phpbb) is merely 8.1%, 4.3% and 7.1%, respectively. However,

Table 9: Bifacial-security nature of Chinese passwords.<sup>†</sup>

Algorithm*	Attacking scenario	Online guessing			Offline guessing				
		Test set	10 <sup>1</sup>	10 <sup>2</sup>	10 <sup>3</sup>	10 <sup>4</sup>	10 <sup>5</sup>	10 <sup>6</sup>	10 <sup>7</sup>

	Rockyou_rest		0.020	0.044	0.110	<b>0.214</b>	<b>0.320</b>	<b>0.438</b>	<b>0.497</b>
	CSDN		<b>0.070</b>	<b>0.105</b>	<b>0.136</b>	0.189	0.229	0.272	0.300
	Phpbb		0.021	0.038	0.087	<b>0.183</b>	<b>0.274</b>	<b>0.369</b>	<b>0.415</b>
Markov	Dodonew		<b>0.024</b>	<b>0.040</b>	<b>0.060</b>	0.085	0.145	0.212	0.305
	Yahoo		0.007	0.016	0.043	<b>0.097</b>	<b>0.165</b>	<b>0.261</b>	<b>0.361</b>
	Tianya		<b>0.062</b>	<b>0.087</b>	<b>0.118</b>	0.154	0.269	0.386	0.516
	Rockyou_rest		0.018	0.035	0.081	<b>0.159</b>	<b>0.259</b>	<b>0.392</b>	<b>0.503</b>
	CSDN		<b>0.037</b>	<b>0.098</b>	<b>0.116</b>	0.144	0.211	0.260	0.316
	Phpbb		0.019	0.034	0.071	<b>0.146</b>	<b>0.230</b>	<b>0.333</b>	<b>0.436</b>

<sup>†</sup>A value in bold green (e.g., the leftmost 0.027) means that: it is a success-rate under a given guess number (resp. 10<sup>1</sup>) against a Chinese dataset (resp. Dodonew) and is *greater* than that of its English counterpart (resp. Yahoo). A value in bold blue is on the contrary: it is a guessing success-rate against a English dataset and *greater* than that of its Chinese counterpart.

\*For both PCFG- and Markov-based attacks, the training set is Duowan\_1M for each Chinese test set and Rockyou\_1M for English test sets. Here the Markov setups are from Scenario#1 in Table 8. Other Markov scenarios show the same trends.

when the guess number allowed is over 10<sup>4</sup>, Chinese web passwords are generally *stronger* than their English counterparts. For example, at 10<sup>6</sup> guesses, the success rate against Tianya, Dodonew and CSDN is 38.2%, 20.4% and 25.4%, respectively, while their English counterparts is 38.6%, 24.8% and 32.3%, respectively.

As summarized in Table 9, for both PCFG and Markov attacks, the cracking success-rates against Chinese passwords are *always higher* than those of English passwords when the guess number is below 10<sup>4</sup>, while this trend is reversed when the guess number is above 10<sup>4</sup>. Here we mainly use order-4 Markov attacks (see Figs. 6(b) and 6(e)) as an example, and the other Markov setup scenarios all show the same trends.

**Summary.** Both PCFG- and Markov-based cracking results reveal the bifacial-security nature of Chinese passwords: They are more prone to online guessing as compared to English passwords; But out of the remaining Chinese passwords, they are more secure against offline guessing. This reconciles the conflicting claims made in [7, 26, 34]. Alarming high cracking rates (40%~50%) highlight the urgency of developing defense-in-depth countermeasures (e.g., cracking-resistant honeywords [31] and password-hardening services [33]) to alleviate the situation. We provide a large-scale empirical evidence for the hypothesis raised by the HCI community [17, 46]: users rationally choose stronger passwords for accounts with higher value.

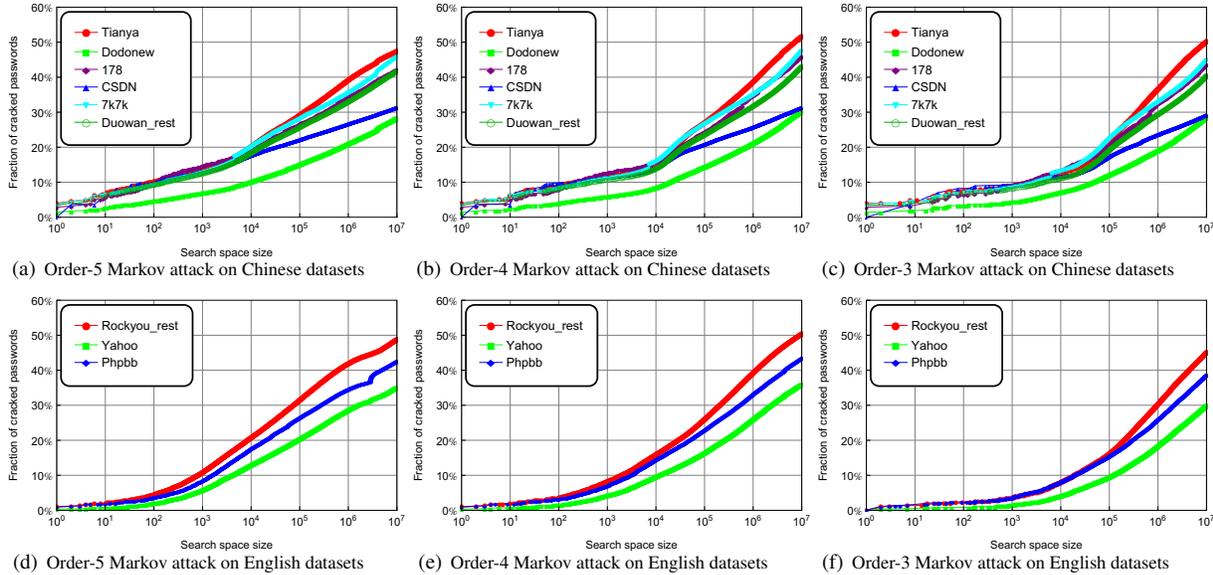

Figure 6: Markov-chain-based attacks on different groups of datasets (scenario #1: *Laplace Smoothing* and *End-Symbol Normalization*). Attacks (a)~(c) use 1 million Duowan passwords as the training set, while attacks (d)~(f) use 1 million Rockyou passwords as the training set. The reversal principle also holds. The other four scenarios #2~#5 show similar cracking results.

## 5 Some implications

We now elaborate on lessons learned and key takeaways.

### 5.1 For password creation policies

Interestingly, 2.18% of the passwords in CSDN are of length  $len \leq 7$ , 97.82% are of length 8-20, no password is of length  $len \geq 21$ . This means that short passwords (i.e.,  $len \leq 7$ ) in the other eight sites are 14~25 times higher than CSDN. This also suggests that CSDN has changed its password policy at least once before the data breach (i.e., Dec. 2011), but whether the strict policy (i.e.,  $8 \leq len \leq 20$ ) is enforced before or later than the weaker policy (i.e., no length requirement) is unknown.<sup>3</sup> Still, what’s certain is that most CSDN passwords are generated under the strict policy  $8 \leq len \leq 20$ . In contrast, no apparent policy can be inferred from the Dodonew data, i.e., neither minimum length (see Fig. 2) nor charset requirement (see Table 3 and Table 2 of [53]).<sup>4</sup> However, Figs. 4 and 6 indicate that, given any guess number below  $10^7$ , passwords from CSDN are significantly weaker than passwords from Dodonew. A plausible reason is that Dodonew provides e-commerce services and users perceive it as more important. As a result, users “rationally” [17, 46] choose more complex passwords for it. As for CSDN, since it is only a technology forum, users knowingly choose weaker passwords for it.

<sup>3</sup>We note that CSDN enforced the policy  $6 \leq len \leq 20$  (and no charset requirement) at Jan. 2015 [55], and currently it requires passwords to be  $11 \leq len \leq 20$  and consist at least a letter and a digit.

<sup>4</sup>This situation even held at Aug. 2017 (and April 2019): the length-7 letter string “dodonew” is allowed as the default password, see <https://www.5636.com/netbar/money/15886.html>.

In 2012, Bonneau [7] cast doubt on the hypothesis that users rationally select more secure passwords to protect their more important accounts. In 2013, Egelman et al. [17] initiated a field study involving 51 students and confirmed this hypothesis. In 2018, Stobert and Biddle [46] surveyed three groups of English speaking users (i.e., 27 non-experts, 15 experts and 345 MTurk participants), and their results also corroborated this hypothesis. Fortunately, our work provides a large-scale empirical evidence (i.e., on the basis of 6.43M CSDN passwords and 16.26M Dodonew passwords) that confirms this hypothesis.

We also note that though the overall security of Dodonew passwords is higher than that of passwords from the five other Chinese sites, many seemingly complex yet popular passwords (e.g., 5201314, 321654a and love4ever) dwelling in Dodonew also appear in other less sensitive sites. This can be understood: 1) “Users never see other users’ passwords” [47] (and are unaware of how similar their passwords are with other users, and thus they may inadvertently choose popular passwords; 2) Users tend to reuse the same password across multiple sites [27, 42, 56]. What’s more, users generally “show a lack of situation awareness” [46] and fail to recognize different categories of accounts [41], and most of them reuse (84% [27]) or simply modify a password from an important site for a non-important site.

Further considering the great password burden already placed on users [8] and the “bounded rationality” [27] and “finite-effort” [20] of users, we outline the need for

HCI research to explore nudges that appropriately frame the importance of accounts and study their impacts on password creation. When designing password creation policies, instead of merely insisting on stringent rules, administrators can employ such nudges to help users gain *more accurate perceptions of the importance* of the accounts to be protected and improve their *ability to recognize different categories* of accounts. Both would help enhance user internal impetus and facilitate users to responsibly allocate passwords (i.e., selecting one candidate from their limited pool of passwords memorized [41, 46]).

In addition, the finding of “bifacial-security nature” suggests that Chinese passwords are more vulnerable to online guessing attacks. This is because top popular Chinese passwords are more concentrated (see Table 3). Thus, a special blacklist that includes a moderate number of most common Chinese passwords (e.g., 10K~20K as suggested in [61]) would be very helpful for Chinese sites to resist against online guessing. Such a blacklist can be learned from various leaked Chinese datasets (see a concrete list at <http://t.cn/RG88tvF> as built according to [56]). Any password falling into this list would be deemed weak. However, it is well known that if some popular passwords (e.g., `woaini1314`) are banned, new popular ones (e.g., `w0aini1314`) will arise. These new popular passwords may be out of static blacklists and subtle to detect. Hence, password creation policies alone (e.g., length and blacklist rules [25, 55]) are inadequate for preventing such weak passwords. An in-depth defense approach is needed: whenever possible, in addition to password creation policies, password strength meters (e.g., `fuzzyPSM` [54] and `Zxcvbn` [59]) can be further employed by security-critical services to detect and prevent weak passwords.

## 5.2 For password strength meters

Leading password strength meters (PSMs) employ the guess number needed for a password-cracking algorithm (e.g. PCFG) to break that password as an indicator of password strength [24]. In Sec. 1, we have exemplified that the PSMs of four popular services are highly inconsistent in assessing the security of (weak) Chinese passwords. Failing to provide accurate/coherent feedback on user password choices would have negative effects such as user confusion, frustration and distrust [48, 60]. Thus, Carnavalet and Mannan [12] suggested that PSMs “can simplify challenges by limiting their primary goal only to detect *weak* passwords, instead of trying to distinguish a good, very good, or great password.”

It follows that an essential step of a PSM would be to identify the characteristics of weak passwords. From our findings in Section 3.3 and Section 4.1, it is evident that for passwords of Chinese users, the incorporation of long Pinyin words or full/family names is an important

evidence/weight for a “weak” decision. Other signs of weak Chinese passwords are the incorporation of birth-dates and simple patterns like repetition, palindrome and keyboard. As a caveat, even if signs of weak passwords are found, one cannot simply deem such passwords as weak and reject them as is done in many high-profile sites (e.g., Microsoft Azure [18]) and by the “substring blacklist” approach recommended in [44]. Instead, such undesirable/insecure signs should be weighted (see some promising attempts in [54, 59]).

The superiority of our improved PCFG-based attacks over Li et al.’s [34] (see Sec. 4.1) is partly attributed to the proper selection of Duowan (instead of Dodonew as in [34]) as the training set. This indicates that, for a PSM to be accurate, its training set should be representative of the password base of the target site. The distance of letter distributions (see Table 2) would be an effective metric. In addition, the universal “bifacial-security nature” revealed in Sec. 4 implies that, the language factor is more impactful than service type. We also find that CSDN passwords are weaker than Dodonew passwords (see Figs. 4 and 6), but CSDN imposes a stricter policy than Dodonew, and this suggests that the service-type factor might be more impactful than password policy.

Thus, when measuring the letter distributions is infeasible, these con-founding factors underlying a password distribution can be considered for training-set selection: 1) In the order of language, service, and password policy; and 2) The closer the training set to the target password, the better. This suggests that there is no single training set that can fit all PSMs. Thus, PSMs that are originally designed for English speaking users and also do *not* employ a training set (e.g., NIST entropy [10], RNN-PSM [38] and `Zxcvbn` [59]) cannot be readily applied to Chinese users. This also explains why such PSMs are generally less accurate than those using a training set (e.g., `fuzzyPSM` [54]) as observed in [24].

## 5.3 For password cracking

Password cracking algorithms are not only necessary tools for security administrators to measure password strength, but also they can be used to facilitate information forensics (e.g., for law enforcement agencies to recover encrypted data of criminal suspects). Three main lessons for password cracking can be learned from our above results. Firstly, our findings in Sec. 3.3 show that Chinese passwords have a vastly different letter distribution, structure and semantic patterns as compared to English passwords, and thus when targeting a Chinese password, it is crucial for cracking algorithms to be trained on datasets from Chinese sites. Such sites should also have the same password creation policy and the same (or a similar) service type as the target site.

Secondly, for PCFG-based attacks, when the training set is sufficiently large (e.g., over 1M as ours), besides the D and S-segments, it is better to also directly learn the L-segments of guesses from the training set. This can be well established by the fact that, given the same guess numbers and against the same test sets, our PCFG-based attacks can obtain much higher success rates (see Sec. 4.1) than those of the PCFG-based attacks in [34,58] where external dictionaries are used to instantiate the L-segments. This practice has been recommended by Ma et al. [36], but they did not specify when to apply it. Further, one may include some external semantic dictionaries to instantiate the L and D-segments as we do.

Thirdly, as compared to Markov-based attacks, PCFG-based ones are simpler to implement (31% less computation and 70% less memory cost), and they perform equally well, or even better, when the guess number is small (e.g.  $10^3$ , see Figs. 4 and 6). For large guess numbers, order-4 Markov attacks are the best choices. As far as we know, these observations have not been elucidated in previous major studies [15,36]. Note that, we have only shown the Markov-based cracking results when the guess number is below  $10^7$ . There is potential that order-3 Markov-based attacks will outperform order-4 and 5 ones at larger guess numbers (e.g.,  $10^{14}$ ).

## 6 Conclusion

In this paper, we performed a large-scale empirical analysis of 73.1 million real-world Chinese web passwords. In our empirical analysis, we systematically explored several fundamental password properties (e.g., the distance between passwords and languages, and various semantic patterns) and uncovered the bifacial-security nature of Chinese passwords: They are more prone to online guessing than English passwords; But out of the remaining Chinese passwords, they are stronger against offline guessing. This reconciles two conflicting claims in [7,26,34]. We hope this work will help both security administrators and individual Chinese users to more informedly secure their password accounts.

## Acknowledgment

The authors are grateful to Mary Ellen Zurko for shepherding our paper. We thank Haibo Cheng, Qianchen Gu, and anonymous referees for invaluable help and comments. Ping Wang is the corresponding author. This research was supported by the National Natural Science Foundation of China under Grants No. 61802006 and No. 61572379, and by the National Key Research and Development Plan under Grant No.2017YFB1200700.

## APPENDIX

### A Justification for our cleaning approach

**Contaminated datasets.** Interestingly, we observe that there is a non-negligible overlap between the Tianya dataset and 7k7k dataset. We were first puzzled by the fact that the password “111222tianya” was originally in the top-10 most popular list of both datasets. We manually scrutinized the original datasets (i.e., before removing the email addresses and user names) and are

surprised to find that there are around 3.91 million (actually  $3.91 \times 2$  million due to a split representation of 7k7k accounts, as we will discuss later) joint accounts in both datasets. We posit that someone probably has copied these joint accounts from one dataset to the other.

**Our cleaning approach.** Now, a natural question arises: *From which dataset have these joint accounts been copied?* We conclude that these joint accounts were copied from Tianya to 7k7k, *mainly for two reasons*. Firstly, it is unreasonable for 0.34% users in 7k7k to insert the string “tianya” into their 7k7k passwords, while users from tianya.cn naturally include the site name “tianya” into their passwords for convenience. The following second reason is quite subtle yet convincing. In the original Tianya dataset, the joint accounts are of the form {user name, email address, password}, while in the original 7k7k dataset such joint accounts are divided into two parts: {user name, password} and {email address, password}. The password “111222tianya” occurs 64822 times in 7k7k and 48871 times in Tianya, and one gets that  $64822/2 < 48871$ . Thus, it is more plausible for users to copy *some* (i.e.,  $64822/2$  of a total of 48871) accounts using “111222tianya” as the password from Tianya to 7k7k, rather than to first copy all the accounts (i.e.,  $64822/2$ ) using “111222tianya” as the password from 7k7k to Tianya and then reproduces  $16460 (= 48871 - 64822/2)$  such accounts.

After removing 7.82 million joint accounts from 7k7k, we found that all of the passwords in the remaining 7k7k dataset occur even times (e.g., 2, 4 and 6). This is expected, for we observe that in 7k7k half of the accounts are of the form {user name, password}, while the rest are of the form {email address, password}. It is likely that both forms are directly derived from the form {user name, email address, password}. For instance, both {wanglei, wanglei123} and {wanglei@gmail.com, wanglei123} are actually derived from the single account {wanglei, wanglei@gmail.com, wanglei123}. Consequently, we further divide 7k7k into two equal parts and discard one part. The detailed information on data cleaning is summarized in Table 1.

**Previous studies.** In 2014, Li et al. [34] has also exploited the datasets Tianya and 7k7k. However, contrary to us, they think that the 3.91M joint accounts are copied from 7k7k to Tianya. Their main reason is that, when dividing these two datasets into the reused passwords group (i.e., the joint accounts) and the not-reused passwords group, they find that “the proportions of various compositions are similar between the reused passwords and the 7k7k’s not-reused passwords, but different from Tianya’s not-reused passwords”. However, they did not explain what the “various compositions” are. Their explanation also does not answer the critical question: why are there so many 7k7k users using “111222tianya”

as their passwords? We posit they had removed  $3.91 \times 2$  million joint accounts from 7k7k but the not 3.91 million ones from Tianya. In addition, they did not observe the extremely *abnormal* fact that all the passwords in 7k7k occur even times. Such contaminated data would lead to inaccurate results. For example, Li et al. [34] reported that there are 32.41% of passwords in 7k7k containing dates in “YYMMDD”, yet the actual value is 6 times lower: 5.42%.

We have reported this issue to the authors of [34], they responded to us and acknowledged this flaw in their journal version [26]. Unfortunately, Han et al. [26] do not clean the datasets in the journal version in the manner that we outlined.

## B Detailed information about our 22 semantic dictionaries

In order to make our work as reproducible as possible and to facilitate the community, we now detail how to construct our 22 semantic-based dictionaries. All dictionaries are built with natural lengths. The  $\text{length} \geq 5$  requirement in the upper-part of Table 5 is set *conservatively* for ensuring accuracy only when we perform matching. Actually, we also performed measurements for  $\text{length} \geq 3$  and  $\text{length} \geq 4$ , and got higher figures (percentages) but less accuracy. Thus, we omit them.

The first dictionary “English\_word\_lower” is from <http://www.mieliestronk.com/wordlist.html> and it contains about 58,000 popular lower-case English words. “English\_lastname” is a dictionary consisting of 18,839 last names with over 0.001% frequency in the US population during the 1990 census, according to the US Census Bureau [11]. “English\_firstname” contains 5,494 most common first names (including 1,219 male and 4,275 female names) in US [11]. The dictionary “English\_fullname” is a cartesian product of “English\_firstname” and “English\_lastname”, consisting of 1.04 million most common English full names.

To get a Chinese full name dictionary, we employ the 20 million hotel reservations dataset [23] leaked in Dec. 2013. The Chinese family name dictionary includes 504 family names which are officially recognized in China. Since the first names of Chinese users are widely distributed and can be almost any combinations of Chinese words, we do not consider them in this work. As the names are originally in Chinese, we transfer them into Pinyin without tones by using a Python procedure from <https://pypinyin.readthedocs.org/en/latest/> and remove the duplicates. We call these two dictionaries “Pinyin\_fullname” and “Pinyin\_familyname”, respectively.

“Pinyin\_word\_lower” is a Chinese word dictionary known as “SogouLabDic.dic”, and “Pinyin\_place” is a Chinese place dictionary. Both of them are from [45]

and also originally in Chinese. We translate them into Pinyin in the same way as we tackle the name dictionaries. “Mobile\_number” consists of all potential Chinese mobile numbers, which are 11-digit strings with the first seven digits conforming to pre-defined values and the last four digits being random. Since it is almost impossible to build such a dictionary on ourselves, we instead write a Python script and automatically test each 11-digit string against the mobile-number search engine <https://shouji.supfree.net/>.

As for the birthday dictionaries, we use date patterns to match digit strings that might be birthdays. For example, “YYYYMMDD” stands for a birthday pattern that the first four digits indicate years (from 1900 to 2014), the middle two represent months (from 01 to 12) and the last two denote dates (from 01 to 31). Similarly, we build the date dictionaries “YYYY”, “MMDD” and “YYMMDD”. Note that, “PW with a  $l^+$ -letter substring” means a subset of the corresponding dataset and consists of all passwords that include a letter substring *no shorter than  $l$* , and similarly for “PW with a  $l^+$ -digit substring”.

Though we use the “left-most longest” rule to minimize ambiguities when matching, there are some unavoidable ambiguities when determining whether a text/digit sequence belongs to a semantic dictionary. An improper resolution would lead to an overestimation or underestimation. For instance, 111111 falls into “YYMMDD” and is highly popular, yet it is more likely that users choose it simply because it is easily memorable repetition numbers. To tackle this issue, we manually identify 17 abnormal dates in “YYMMDD”, each of which originally has a frequency  $> 10E$  and appears in every top-1000 list of the six Chinese datasets: 111111, 520131, 111222, 121212, 520520, 110110, 231231, 101010, 110119, 321123, 010203, 110120, 010101, 520530, 000111, 000123, 080808. Similarly, we identify 16 abnormal items in “MMDD”: 1111, 1122, 1231, 1212, 1112, 1222, 1010, 0101, 1223, 1123, 0123, 1020, 1230, 0102, 0520, 1110. Few abnormal items can be identified in the other 19 dictionaries (Table 5), and they are processed as usual.

## C A subtlety about Good-Turing smoothing in Markov-based cracking

In 2014, Ma et al. [36] introduced the Good-Turing (GT) smoothing into password cracking, yet little attention has been paid to the unsoundness of GT for popular password segments. We illustrate the following subtlety.

We denote  $f$  to be the frequency of an event and  $N_f$  to be the frequency of frequency  $f$ . According to the basic GT smoothing formula, the probability of a string “ $c_1c_2 \cdots c_l$ ” in a Markov model of order  $n$  is denoted by

$$P(“c_1 \cdots c_{l-1}c_l”) = \prod_{i=1}^l P(“c_i|c_{i-n}c_{i-(n-1)} \cdots c_{i-1}”), \quad (1)$$

where the individual probabilities in the product are computed empirically by using the training sets. More specifically, each empirical probability is given by

$$P(“c_i|c_{i-n} \cdots c_{i-1}”) = \frac{S(\text{count}(c_{i-n} \cdots c_{i-1}c_i))}{\sum_{c \in \Sigma} S(\text{count}(c_{i-n} \cdots c_{i-1}c))}, \quad (2)$$

where the alphabet  $\Sigma$  includes 95 printable ASCII characters on the keyboard (plus one special end-symbol  $c_E$  denoting the end of a password), and  $S(\cdot)$  is defined as:

$$S(f) = (f+1) \frac{N_{f+1}}{N_f}. \quad (3)$$

This kind of smoothing works well when  $f$  is small, but it fails for passwords with a high frequency because the estimates for  $S(f)$  are not smooth. For instance, 12345 is the most common 5-character string in Rockyou and occurs  $f = 490,044$  times. Since there is no 5-character string that occurs 490,045 times,  $N_{490045}$  will be zero, implying the basic GT estimator will set  $P(“12345”) = 0$ . A similar problem regarding the smoothing of password frequencies is identified in [5].

There have been various improvements suggested in linguistics to tackle this problem, among which is the “simple Good-Turing smoothing” [22]. This improvement (denoted by SGT) is famous for its simplicity and accuracy. SGT takes two steps of smoothing. Firstly, SGT performs a smoothing operation for  $N_f$ :

$$SN(f) = \begin{cases} N(1) & \text{if } f = 1 \\ \frac{2N(f)}{f^+ - f^-} & \text{if } 1 < f < \max(f) \\ \frac{2N(f)}{f - f^-} & \text{if } f = \max(f) \end{cases} \quad (4)$$

where  $f^+$  and  $f^-$  stand for the next-largest and next-smallest values of  $f$  for which  $N_f > 0$ . Then, SGT performs a linear regression for all values  $SN_f$  and obtains a Zipf distribution:  $Z(f) = C \cdot (f)^s$ , where  $C$  and  $s$  are constants resulting from regression. Finally, SGT conducts a second smoothing by replacing the raw count  $N_f$  from Eq.3 with  $Z(f)$ :

$$S(f) = \begin{cases} (f+1) \frac{N_{f+1}}{N_f} & \text{if } 0 \leq f < f_0 \\ (f+1) \frac{Z(f+1)}{Z(f)} & \text{if } f_0 \leq f \end{cases} \quad (5)$$

where  $t(f) = |(f+1) \cdot \frac{N_{f+1}}{N_f} - (f+1) \cdot \frac{Z(f+1)}{Z(f)}|$  and  $f_0 = \min \left\{ f \in \mathbb{Z} \mid N_f > 0, t(f) > 1.65 \sqrt{(f+1)^2 \frac{N_{f+1}}{N_f^2} \left(1 + \frac{N_{f+1}}{N_f}\right)} \right\}$ .

To the best of our knowledge, we for the first time well explicate how to combine the two smoothing techniques (i.e., GT and SGT) in Markov-based password cracking.

# Protecting accounts from credential stuffing with password breach alerting

## Abstract

Protecting accounts from credential stuffing attacks remains burdensome due to an asymmetry of knowledge: attackers have wide-scale access to billions of stolen usernames and passwords, while users and identity providers remain in the dark as to which accounts require remediation. In this paper, we propose a privacy-preserving protocol whereby a client can query a centralized breach repository to determine whether a specific username and password combination is publicly exposed, but without revealing the information queried. Here, a client can be an end user, a password manager, or an identity provider. To demonstrate the feasibility of our protocol, we implement a cloud service that mediates access to over 4 billion credentials found in breaches and a Chrome extension serving as an initial client. Based on anonymous telemetry from nearly 670,000 users and 21 million logins, we find that 1.5% of logins on the web involve breached credentials. By alerting users to this breach status, 26% of our warnings result in users migrating to a new password, at least as strong as the original. Our study illustrates how secure, democratized access to password breach alerting can help mitigate one dimension of account hijacking.

## 1 Introduction

The wide-spread availability of usernames and passwords exposed by data breaches has trivialized criminal access to billions of accounts. In the last two years alone, breach compilations like Antipublic (450 million credentials), Exploit.in (600 million credentials), and Collection 1-5 (2.2 billion credentials) have steadily grown as their creators aggregated material shared on underground forums [21, 25]. Despite the public nature of this data, it remains no less potent. Previous studies have shown that 6.9% of breached credentials remain valid due to reuse, even multiple years after their initial exposure [51]. Absent defense in depth techniques that expand authentication to include a user’s location and device details [12, 17], hijackers need only conduct a credential

stuffing attack—attempting to log in with every breached credential—to isolate vulnerable accounts.

While users (or identity providers) can mitigate this hijacking risk by resetting an account’s password, in practice, discovering which accounts require attention remains a critical barrier. This has given rise to breach alerting services like HaveIBeenPwned and PasswordPing that actively source breached credentials to notify affected users [26, 43]. At present, these services make a variety of tradeoffs spanning user privacy, accuracy, and the risks involved with sharing ostensibly private account details through unauthenticated public channels. One consequence of these tradeoffs is that users may receive inaccurate remediation advice due to false positives. For example, both Firefox and LastPass check the breach status of usernames to encourage password resetting [13, 42], but they lack context for whether the user’s password was actually exposed for a specific site or whether it was previously reset. Equally problematic, other schemes implicitly trust breach alerting services to properly handle plaintext usernames and passwords provided as part of a lookup. This makes breach alerting services a liability in the event they become compromised (or turn out to be adversarial).

In this paper, we present the design, implementation, and deployment of a new privacy-preserving protocol that allows a client to learn whether their username and password appears in a breach without revealing the information queried. Our protocol offers two main advantages compared to existing schemes. First, our design takes into account the threat of both an adversarial client (e.g., an attacker attempting to steal usernames and passwords from our service) and an adversarial server (e.g., an attacker harvesting usernames and passwords sent to the service). We address these risks using a combination of computationally expensive hashing, k-anonymity, and private set intersection. Second, these privacy requirements allow us to check a client’s exact username and password against a database of breached credentials (versus only usernames, or only passwords currently), thus reducing false positives that lead to warning fatigue.

To demonstrate the feasibility of our protocol, we publicly

released a Chrome extension that warns users when they log in to a website using one of over 4 billion breached usernames and passwords. While in theory any identity provider or password manager can integrate with our protocol, we opted for in-browser alerting first as it scales to the long tail of domains. Nearly 670,000 users from around the world installed our extension over a period of February 5–March 4, 2019. During this measurement window, we detected that 1.5% of over 21 million logins were vulnerable due to relying on a breached credential—or one warning for every two users. By alerting users to this breach status, 26% of our warnings resulted in users migrating to a new password. Of these new passwords, 94% were at least as strong as the original.

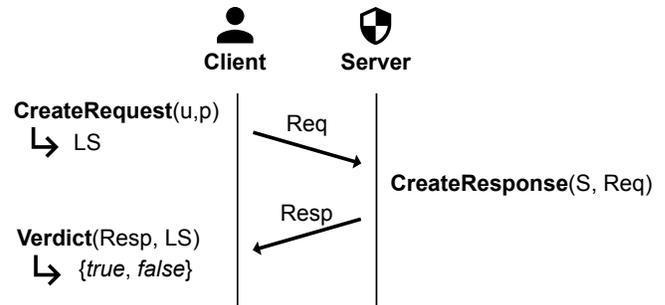

Anonymous telemetry reported by our extension reveals that users reused breached credentials on over 746,000 distinct domains. The risk of hijacking was highest for video streaming and adult sites, where 3.6–6.3% of logins relied on breached credentials. Conversely, users appeared to internalize password security advice (or were forced to do so via password composition policies) specifically for financial and government sites, where only 0.2–0.3% of logins involved breached credentials. Despite variations across industries, our analysis reveals that the threat of credential stuffing extends well into the long tail of the Internet. Absent new forms of authentication, we believe that it is critical to democratize access to breach alerting so that both users and identity providers can proactively resecure their accounts.

In summary, we frame our key contributions as follows:

- We develop and publicly release a new protocol for detecting whether a username and password pair appears in a data breach without revealing the information queried. Our protocol improves on the privacy of existing schemes while also reducing the risk of false positives.
- We outline the technical challenges of deploying this scheme in practice, including the computational overhead, latency, and cost required to mediate access to over 4 billion breached usernames and passwords.
- Based on a real-world deployment, we find that 1.5% of logins across the web involve breached credentials. We caution this is a lower bound as logins are not unique. Roughly one in two of our 670,000 users received a warning.
- Users responded to 26% of our warnings by resetting their password; 94% of new passwords were as strong or stronger than the original passwords.

## 2 Background and requirements

To start, we establish the design principles and threat model that underpin our breach alerting protocol. We compare these

**Figure 1:** Abstract protocol for a breach alerting service. At a high level, a client generates a request based on some computation over a username and password. The server then returns a response that allows the client to arrive at a verdict for whether their credential is in a breach.

requirements against existing solutions from HaveIBeenPwned and PasswordPing—as well as related cryptographic protocols like private information retrieval and oblivious transfer—to highlight the tradeoffs that all of these approaches make in terms of privacy, overhead, accuracy, and trust.

### 2.1 Abstract protocol

We provide an abstract protocol for our breach alerting service in Figure 1. We reuse these function names and terminology throughout our work. Here, a client with access to a username and password tuple  $(u, p)$  executes some computation via  $\text{CreateRequest}(u, p)$  that produces a local state  $LS$  and request  $Req$  that it sends to the breach alerting service. This service stores and regularly updates a database of unsafe credentials  $S = \{(u_1, p_1), \dots, (u_n, p_n)\}$ . Upon receiving a request, the server accesses its credential store  $S$ , runs  $\text{CreateResponse}(S, Req)$ , and sends the resulting response  $Resp$  to the client. Finally, the client arrives at a verdict whether the credential queried was exposed through a breach by calculating  $\text{Verdict}(Resp, LS)$ . Because new breaches emerge over time, a client should regularly repeat this process as prior verdicts may no longer be valid.

### 2.2 Design principles

**Democratized access:** At present, identity providers individually collect breached password data to reset their affected user accounts [4, 58]. This fails to scale to all identity providers, resulting in patchy protection across services and incidents. Any breach alerting service should be accessible to all end users and identity providers, and as such, not require trust between the parties involved. This means we cannot rely on authenticated accounts as a form of rate limiting. We define trust more formally in our threat model in Section 2.3.

**Actionable, not informational:** Any breach alerting service should provide users with accurate and actionable security ad-

vice such as re-securing an account via a password reset. An alert that warns a client about the mere presence of exposed data such as a client’s email address, phone number, or physical address lacks a straightforward recovery step and is thus out of scope for our design. Similarly, an alert merely warning a client that password material was exposed (rather than the specific password involved) may lead to false positives.

**Breached, not weak:** Alerting should only trigger when all the information necessary to access an account (e.g., a username and password) is exposed. While cracking dictionaries (often composed from breached passwords) may include a client’s weak, guessable password, any subsequent attack potentially requires multiple guesses and thus represents a smaller threat than full credential exposure. We assume that most online services employ sufficient throttling to make such bruteforcing impractical. Conversely, attacks against exact username and password pairs are actively deployed in the wild. Indeed, Thomas et al. showed that users with non-stale credentials exposed by third-party breaches were ten times more likely to become hijacked than a random user [51]. Our emphasis on breached credentials helps us prioritize scarce user attention [5] and avoid potential warning fatigue similar to other warning models [2]. While migrating users to stronger passwords in general remains an important task, it is out of scope for our design.

**Near real-time:** The time that elapses between a client querying a credential and learning its breach status should be near real-time in order to facilitate integration directly with account security flows, password managers, or upon password entry. This potentially constrains the level of privacy protections provided by any protocol due to computational overhead and network latency of any cryptographic primitives involved.

### 2.3 Threat model

Democratized access hinges on mutual distrust between a client and the server involved in our breach alerting protocol. We develop our threat model with both an adversarial client and adversarial server in mind. In the case of an adversarial client with access to their own breach dataset  $D = \{(u_1, p_1), \dots, (u_n, p_n)\}$ , the attacker seeks to learn  $u \in S - D$  (e.g., a new email to spam),  $p \in S - D$  (e.g., a new password to add to a cracking dictionary), or a new credential  $(u, p) \in S - D$ . In the case of an adversarial server where a client has access to  $(u, p)$ , the threat landscape is larger. An adversarial server may learn the client’s identity  $u$  (even if  $u \in S$ , this enables tracking), a client’s password  $p$  (even if  $p \in S$ , this identifies active usage), or the credential  $(u, p)$  (even if  $(u, p) \in S$ ).

To address these threats, we outline the minimum security and privacy requirements any implementation of the abstract protocol previously outlined in Figure 1 must satisfy. In the security notions discussed below, we work with *anonymity*

*sets* (denoted  $K$ ) that describe a set of values (in our case, user credentials) that are large enough to give clients plausible deniability about their data even if their membership in  $K$  is revealed. These sets must be carefully defined to avoid trivial constructions that are insecure. At a high-level, they must have a sufficiently large support jointly over usernames and passwords (to aid in plausible deniability regarding both), should “partition” the space of credentials in a somewhat uniform manner independent of any actual usernames or passwords, and roughly all values in an anonymity set should be equally likely to be the client’s credentials. (A full discussion is deferred to Appendix A.)

**Requester credential anonymity:** A protocol provides requester credential anonymity if for every credential  $(u_1, p_1)$ , there exists a sufficiently large anonymity set  $K$  containing  $(u_1, p_1)$  such that  $\forall (u_2, p_2) \in K$ :

$$\text{CreateRequest}(u_1, p_1) \approx \text{CreateRequest}(u_2, p_2). \quad (1)$$

For two distributions  $A$  and  $B$ , we let  $A \approx B$  denote the computational indistinguishability of the two distributions—that no efficient adversary given samples from  $A$  and  $B$  can distinguish them apart much better than randomly guessing. Thus, clients with credentials from the same anonymity set create requests that are indistinguishable to the server. While a minimum  $|K|$  likely depends on the sensitivities of the client involved, we set an initial threshold at  $|K| > 50,000$ . While the IP address tied to a client’s request reduces  $|K|$ , a client can rely on a mix network such as Tor to prevent this leakage. IP address anonymity is out of scope of our threat model.

**Responses with bounded leakage:** Given a request for  $(u, p)$ , the response from a breach alerting service should bound the information leaked, denoted  $L$ , about the membership of other credentials in  $S$ . To do this, we require an efficient simulator  $\text{Sim}$  that given only  $L$  can act as the server without being noticed by the client:

$$\text{CreateResponse}(S, \text{Req}) \approx \text{Sim}(L, \text{Req}). \quad (2)$$

The presence of a successful simulator shows that the client may learn at most  $L$  by looking at responses from the server. Ideally, we want leakage to consist of only the membership of the queried credential and the anonymity set:

$$L = \{[(u, p) \in S], K\}. \quad (3)$$

We can rephrase this security notion as follows. For any  $(u_1, p_1), (u_2, p_2) \in K$  such that their membership in  $S$  is identical, i.e.,  $[(u_1, p_1) \in S] = [(u_2, p_2) \in S]$ :

$$\begin{aligned} &\text{CreateResponse}(S, \text{CreateRequest}(u_1, p_1)) \\ &\approx \text{CreateResponse}(S, \text{CreateRequest}(u_2, p_2)). \end{aligned} \quad (4)$$

In other words, our security notion implies that the responses to credentials with identical leakage will be computationally indistinguishable.

**Inefficient oracle:** Learning  $u$ ,  $p$ , or  $(u, p) \in S$  via the breach alerting service should be equally or less efficient compared to guessing attempts performed on the login portal where the account originates from. Alternatively, a pragmatic attacker should be better off finding a plaintext copy of the breach. Let  $t(f)$  denote the running time of the function  $f$ . We capture this for a remote attacker as there being a time period  $T$  such that:

$$t(\text{CreateRequest}(u_i, p_i)) > T, \quad (5)$$

for every  $(u_i, p_i)$ . This requirement extends to an attacker with direct access to  $S$  due to an insider risk, a court order, or a breach of the alerting service’s database. We frame this as merely checking the membership of a credential:

$$t([(u, p) \in S]) > T'. \quad (6)$$

Ideally,  $T = T'$ , such that local access to  $S$  provides no advantage compared to the access mediated by the protocol. We consider a protocol where  $T > 1$  second to satisfy this requirement.

**Resistance to Denial of Service:** A response from the server should not require significantly more computation than a request by a client (including bogus requests). As such, it should be difficult for an attacker to find a sequence  $(u_1, p_1), \dots, (u_n, p_n)$  such that:

$$\sum_i t(\text{CreateRequest}(u_i, p_i)) \ll \sum_i t(\text{CreateResponse}(\text{Req}_i)) \quad (7)$$

Where  $t(f(\cdot))$  denotes the running time of the function  $f$ .

**Non-threats:** Some threats are explicitly outside our threat model. These include an attacker attempting to confirm whether a breach they have access to is known to the alerting service (e.g.,  $D \subseteq S$ ), as well as an attacker learning  $|S|$ . Such information may instead be beneficial to have public, allowing the service to publicly communicate which breaches it covers.

## 2.4 Tradeoffs of existing schemes

Existing breach alerting services include HaveIBeenPwned and PasswordPing, both of which have publicly documented APIs [26, 43]. Clients for each service include the 1Password [48] and LastPass [42] password managers. GitHub relies on a local mirror of HaveIBeenPwned’s password dictionary for detection [36]. Firefox uses HaveIBeenPwned to warn users when they browse to a site that previously suffered a data breach, or if users supply their email address to Firefox [13]. We examine the tradeoffs these protocols make in terms of our design principles and threat model, with Table 1 serving as summary.

**Query by username:** HaveIBeenPwned and PasswordPing both support querying a specific plaintext username  $u$ . PasswordPing also supports querying  $H(u)$ , the SHA256 hash of a

Query by	Setup	Actionable, not informational	Breached, not weak	Near real-time	Requester credential anonymity	Inefficient oracle	Bounded leakage response	Resistant to Denial of Service
Username	Plaintext		●				●	●
	Hash		●				●	●
Password	Plaintext	●	●				●	●
	Hash	●	●				●	●
	Hash prefix	●	●	●				●
Domain	Plaintext			●	●	●	●	●
Username, then password	Plaintext, hash	●	●	●		●		●
	Hash, hash	●	●	●		●		●

**Table 1:** Summary of protocols supported by HaveIBeenPwned and PasswordPing and their tradeoffs according to our design principles and threat model.

username. In response, both services provide a list of breaches that the specified user was affected by and the class of data exposed (e.g., password, physical address). Lastpass currently relies on the username-only protocol from PasswordPing for breach alerting (after user consent).

In terms of our threat model (see Table 1),  $H(u)$  creates a unique, stable identifier of the user that is possibly reversible via a dictionary attack. This fails our requirement of requester credential anonymity. Likewise, querying  $u$  directly leaks the user’s identity. Neither  $H(u)$  or  $u$  provides a computational hurdle, thus providing an efficient oracle for performing reconnaissance on victims. Knowledge of which breaches a victim is involved in can expose the victim to extortion, similar to recent scams that include breached data to coerce victims into paying the attacker by misrepresenting wider access [31].

Revisiting our design principles, we find that username-only protocols fail to satisfy our requirement of actionable rather than informational breach warnings. Users may have changed their password, or no longer use the account involved. Likewise, isolating responses solely to the types of data exposed fails to alert users to breached passwords that they reuse across multiple sites, where just one of the sites involved might be breached.

**Query by password:** PasswordPing allows clients to send a plaintext password  $p$ , or  $H(p)$  using SHA1, SHA256, or MD5. Both PasswordPing and HaveIBeenPwned provide a more secure alternative, whereby clients supply an  $N$ -bit prefix

$H(p)_{[0:N]}$ . The server then returns all known breached passwords with that prefix, with the client performing the final exactness check locally. PasswordPing uses a 10-hex character prefix of a SHA1, SHA256, or MD5 hash; HaveIBeenPwned uses a 5-hex character prefix of a SHA1 hash. 1Password currently relies on HaveIBeenPwned and the password-prefix approach for breach alerting.

As detailed in Table 1, while supplying  $p$  explicitly exposes a client's non-breached password, revealing even  $H(p)$  leads to a potential pre-computed dictionary attack by an adversarial server. This threat is simplified by the lack of salt. As such, both schemes fail to provide requester credential anonymity. In the prefix-based variant, the same attack reduces the search space necessary by  $2^N$ , with the attacker prioritizing guesses based on a password's popularity. With a sufficiently small  $N$ , this meets our criteria for anonymity—though weakly. We provide a deeper treatment of our rationale in Appendix A. However, as the response contains multiple passwords per lookup, this does not satisfy our requirement for bounded leakage. An adversarial client can enumerate each bucket to acquire a local copy of all  $H(p)$  for offline cracking to rebuild the underlying password dictionary.<sup>1</sup> While there is a legitimate argument that an attacker could more easily acquire a plaintext copy of the data breach, ideally any such protocol should also work for more sensitive breach data that is not widely accessible.

From a design perspective, we find that password-only protocols run the risk of alerting users to merely weak passwords. If  $u_1$  in a breach shares the same password as  $u_2$  who was not in any breach, there is no way to curate the security advice to both users' circumstances.

**Query by domain:** Both HaveIBeenPwned and PasswordPing provide a protocol for determining whether a domain was part of a breach. Firefox currently uses HaveIBeenPwned to warn users when they visit a domain that's previously suffered a breach [9]. This alert specifies that if they had an account, their data may no longer be secure. While these domain-only protocols satisfy every requirement laid out in our threat model (assuming the list of insecure domains is locally cached rather than queried), they provide neither actionable advice nor specific insights into breached rather than weak passwords. For example, a site visitor may have registered an account after the breach date. Likewise, domain-only protocols cannot capture the risk of password re-use across breached and non-breached sites.

**Query by username, then password:** PasswordPing provides a protocol whereby a client first queries  $u$  or  $H(u)$  using SHA-256, in turn receiving a salt  $s$  associated with that account. The client uses this to calculate  $H(u, p, s)$  via Argon2, sending only the  $N$ -bit prefix  $H(u, p, s)_{[0:N]}$ . PasswordPing

<sup>1</sup>HaveIBeenPwned provides a direct download to every password in its corpus (hashed via SHA1), so this enumeration step is unnecessary and something the service argues is outside their threat model.

relies on a 10-hex character prefix. The server responds with all known matching credentials, allowing a client to perform the confirmation locally. This approach satisfies all of our design principles. Additionally, due to the use of Argon2, the hash complexity involved compared to SHA or MD5 satisfies our requirement of an inefficient oracle. While we can bound the leakage of this protocol, it leaks information about both a requester's identity as well as multiple  $H(u, p, s)$  per response enabling offline attacks. (The  $s$  prevents pre-computed dictionary attacks.) This protocol bears a close resemblance to ours, but we satisfy all the criteria laid out in Table 1 and show in Section 3.2 how to further protect users' password information when querying by username.

## 2.5 Alternative cryptographic protocols

Our threat model is closely related to several well-studied cryptographic primitives. These protocols offer stricter privacy guarantees, but are computationally burdensome for a network setting in practice. As such, our threat model uses a relaxed requirement of anonymity. Secure hardware enclaves would also enable stricter privacy guarantees, but current enclaves have been shown to be vulnerable to side-channel and speculative execution attacks [53, 54].

**Private Information Retrieval (PIR):** PIR protocols, introduced by Chor et al. [6], require that a user be able to query an item from a server without revealing which item was queried. While PIR protocols which are secure against computationally-bounded adversaries [32] exceed our requester anonymity and password secrecy requirements, their security guarantees are one-sided—they allow the server to leak arbitrary information about the database to the clients. Additionally, single-server PIR protocols require communication that is effectively comparable to the size of the database [22]. Multi-server PIR protocols reduce this overhead, and even offer security guarantees against adversarial clients [19], but require that users trust that there is no risk of collusion amongst servers.

**Oblivious Transfer (OT):** 1-out-of- $N$  OT protocols [8, 46] extend the PIR threat model to also require that a client learns no information about unaccessed elements of the server's database during the query. (Here  $N$  refers to the number of database entries.) While OT appears to capture the ideal requirements for a breach alerting protocol, we note that without weakening its security requirements, OT turns out to be a powerful crypto primitive [29] and requires communication overhead proportional to  $N$ .

**Private Set Intersection (PSI):** PSI protocols allow two parties with sets  $S_1$  and  $S_2$  respectively to compute some functions each of  $S_1 \cap S_2$  and learn nothing more about each other's sets. We can model our use case as PSI where the client has a singleton set and the server learns nothing (an additional requirement needed in our work not typically seen in PSI).

Early works leading to PSI [24, 38] are based off of the Diffie-Hellman assumption which we also leverage in our protocol. While PSI protocols based on OT have been shown to be the fastest in practice, they require significant communication overhead that is unsuitable for a network setting [45]. Additionally, they are designed for settings where both parties have large, balanced sets which does not map to our scenario.

## 2.6 Ethics

Providing a breach alerting service necessitates access to credentials that were illicitly obtained and then released. For our work, we exclusively rely on credential breaches that are now publicly accessible, which any sophisticated attacker is likely to already have access to. As such, we argue that making this information accessible to users and identity providers does not materially increase the potential for harm—but that any protocol should have measures in place to protect against abuse. Passwords exposed by breaches have a history of research applications including improving password strength meters [11, 39, 57] and studying password use in the wild [10]. Surveyed users have also expressed a positive attitude towards breach alerting services, particularly in the context of password resetting [28]. We believe the potential to reduce account hijacking outweighs any risk of collating already public credential data.

## 3 Breach alerting protocol

Our design for a data breach alerting protocol relies on a combination of  $k$ -anonymity, private set intersection, and computationally expensive hashing to address all the risks outlined in our threat model. Here, we detail the cryptographic primitives we use to implement our protocol and the data exchanged between a client and server. We consider two variants: one that leaks some bits of password material that is secure against a resource-constrained attacker (e.g., the attacker is unable to circumvent  $k$ -anonymity and expensive hashing); and one that leaks zero bits of password material, but where clients must spend twice as much time hashing and receive weaker bounds on requester anonymity.

### 3.1 Resource-constrained attacker variant

**CreateDatabase:** Prior to any client lookup, the server must construct a secure database containing all known breached credentials. We outline this process in Algorithm 1. The server first canonicalizes the username associated with a credential by removing any capitalization and stripping information related to email providers (e.g., `user@gmail.com` becomes `user`). This step aids in de-duplication while also enabling us to detect reuse across sites that exclusively use usernames rather than email addresses. Post-canonicalization, the server

calculates a computationally expensive hash of both the canonical username and credential password. We rely on Argon2 with a configuration that uses a single thread, 256 MB of memory, and a time cost of three.<sup>2</sup>

The server then blinds the 16-byte hash output with a 224-bit secret key  $b$  by mapping the hash to the elliptic curve `NID_secp224r1` and raising the resulting point to the power  $b$ .<sup>3</sup> The server saves only a 2-byte prefix of hash unblinded which it uses for partitioning the entire database, where we denote a partition as  $S'$ . Here, hashing satisfies our requirement for an inefficient oracle even in the event that an attacker gains direct access to the underlying database. Blinding serves as an additional layer of defense in the event of a breach, but also to prevent information leakage and ensure requester anonymity and password secrecy via private set intersection (detailed shortly). As the key  $b$  has no external dependencies, the server can rotate it regularly by first decrypting old records and then re-blinding with a new key  $b'$ .

**CreateRequest:** When generating a request, a client repeats the same hashing and blinding strategy as the server. We outline this process in Algorithm 2. In contrast to the server, the client adopts its own secret key  $a$  which it initializes per request. The resulting request includes the 2-byte hash prefix and the blinded full hash. This 2-byte prefix—while leaking some bits of password material—provides the client with  $k$ -anonymity over the universe of all username and password pairs (not just those in breaches). Previous investigations of password usage estimate that users have roughly 6–8 unique passwords [16, 44, 56]. With an estimated 3.9 billion Internet users in the world [52], if we assume each user has just one unique username, this amounts to an estimated 23.4–31.2 billion unique credential pairs. As a rough approximation then, a user will share their credential prefix with 357,000–476,000 other credentials. Even if an adversarial server were to precompute a dictionary of the most popular passwords, they would have to repeat this process for each individual username. As such, our protocol satisfies our computational requirement for requester anonymity and password secrecy. In the case of an adversarial client, any request for a guessed credential is gated on the successful computation of an expensive hash, thus satisfying our requirement for an inefficient oracle.

**CreateResponse:** A server responds to a request according to Algorithm 3. Given a hash prefix, the server returns all known unsafe credentials  $S'$  tied to the prefix. While ideally we could provide the entire blinded contents of  $S$  to a client, in practice this is too computationally expensive as  $|S|$  scales to billions of records. By partitioning  $S$ , we can limit the data downloaded to a client while ensuring membership correctness, at the cost of working with anonymity sets rather than perfect se-

<sup>2</sup>According to libsodium, this amounts to roughly 0.7 seconds on a 2.8 Ghz Core i7 CPU [34].

<sup>3</sup>We use multiplicative notation to refer to elliptic-curve group operations in the paper.

crecy. As noted in Section 2.5, the best current constructions dictate that without partitioning  $S$ , we cannot hope to deploy a scheme with reasonable limits on data downloaded by clients and computation performed by the server. By avoiding any client nonce or salt for hashing, retrieval is entirely static for the server apart from inexpensive blinding (at least compared to hashing). This satisfies our requirement for resistance to denial of service.

Providing  $S'$  absent blinding would leak information about other exposed credentials. Instead, we rely on Diffie-Hellman private set intersection [24] which is relatively efficient for a network setting on non-mobile devices [45]. The server returns all known breached credentials blinded with  $b$  while providing a client with an index into the doubly-blinded list  $H^{ab}$ . This requires the commutative properties of elliptic curve Diffie-Hellman (ECDH) such that the client can decrypt this result to recover  $H^b$  during verification, while the remaining contents of  $S'$  remain hidden.

More formally, under the random oracle model [3], with Argon2 modeled as a perfect hash function, our hash-and-blind scheme implements an oblivious pseudorandom function (OPRF) against honest-but-curious adversaries under the decisional Diffie-Hellman assumption. When  $b$  is kept secret, outputs of the hash-and-blind scheme on any user inputs  $(u_i, p_i)$  reveal no information about the hashed and blinded output on *any other*  $(u', p')$ . A more technical and detailed note is laid out in Appendix B. This achieves bounded leakage and given only the leakage  $L$  as defined in Section 2.3, we can construct a Simulator to simulate the entire response of the server.

**Verdict:** Finally, a client determines whether their credential was exposed in a breach by finishing the private set intersection protocol as detailed in Algorithm 4. This process is entirely local and, absent independent telemetry, never reveals the verdict of a match to the server.

---

**Algorithm 2 CreateRequest:** Client query to determine whether a blinded username and password with a cleartext hash prefix was exposed in a breach.

---

**Require:**  $n$ , a prefix length

```
1: function CREATEREQUEST( $u, p, n$ )
2:    $a \leftarrow \text{RAND}()$ 
3:    $u'_i \leftarrow \text{CANONCIALIZE}(u)$ 
4:    $H \leftarrow \text{HASH}(u', p)$ 
5:    $H^a \leftarrow \text{BLIND}(H, a)$ 
6:    $H_{[0:n]} \leftarrow \text{BYTESUBSTRING}(H, n)$ 
7:    $\text{LOCALSTORE}(a)$ 
8:   return  $\text{HSTSREQUEST}(H_{[0:n]}, H^a)$ 
9: end function
```

---

---

**Algorithm 3 CreateResponse:** Server response for all information known about the cleartext hash prefix.

---

**Require:**  $b = \text{rand}()$

```
1: function CREATERESPONSE( $H_{[0:n]}, H^a$ )
2:    $H^{ab} \leftarrow \text{BLIND}(H^a, b)$ 
3:    $S' \leftarrow \text{PARTITIONLOOKUP}(H_{[0:n]})$ 
4:   return  $\text{HSTSRESPONSE}(H^{ab}, S')$ 
5: end function
```

---

## 3.2 Zero-password leakage variant

Our previous approach makes a practical tradeoff between client hashing overhead and revealing some bits of a client's password. (While still protected by a computationally expensive hash and anonymity sets spanning both usernames and passwords, this information can be leaked if an attacker has auxiliary information about the username.) As an alternative, we outline a zero-password leakage variant. In Algorithm 2, a client now calculates a hash prefix of only the username  $H(u')_{[0:n]}$  along with a blinded hash of the entire credential. Algorithm 1 is modified to create a mapping between  $H(u'_i)_{[0:n]}$  to  $H(u'_i, p'_i)$  and to use it to partition the database by  $H(u'_i)_{[0:n]}$ . This variant still provides the same protection with bounded leakage, denial of service resistance, and an inefficient oracle, and modifies (and reduces) the anonymity set of credentials to only usernames. For an estimated 3.9 billion unique usernames, this amounts to  $|K| = 60,000$ .<sup>4</sup> However, this variant ensures that all password material from the client is protected by blinding. In practice, given near real-time constraints, this requires that a client spend twice as much time hashing which is non-negligible.<sup>5</sup> For the purposes of our initial deployment (detailed in Section 5), we opted for the first variant to understand the computational bounds of clients. We now plan to migrate to the zero-password leakage variant.

---

<sup>4</sup>With no password guessing required, it also enables an attacker to reasonably pre-compute the Argon2 hash of all possible usernames.

<sup>5</sup>This expense can be amortized if the client reuses their username for multiple sites with distinct passwords, or if the client regularly polls the server for the same username to obtain the most recent breach status.

---

**Algorithm 4 Verdict:** Final client-side verdict for whether a username or password was exposed in a breach.

---

**Require:**  $a$ , secret key for original request

```
1: function VERDICT( $H^{ab}, S', a$ )
2:    $H^b \leftarrow \text{UNBLIND}(H^{ab}, a)$ 
3:   return  $H^b \in S'$ 
4: end function
```

---

### 3.3 Expansion to metadata

Our protocol currently does not include information on the origin of an exposed credential as metadata (e.g., which service was compromised). In practice, we believe this is the best strategy as origin information is both untrustworthy and often unavailable. For example, large composite breaches such as Collection 1-5 and Antipublic include hundreds of millions of credentials, all of which are unattributed [21, 25]. Moreover, metadata expands the size of data downloaded as part of  $S'$ .

For completeness, our protocol can be extended to include origin information, or any metadata, by encrypting it with the output of a cryptographically secure key-derivation function such as HKDF [30] applied to  $H(u, p)$ . This approach limits access strictly to clients that prove knowledge of the associated, strongly hashed username and password. This is easy to observe; as outlined in Appendix B, the hashed-and-blinded outputs still hide information about other usernames and passwords and hence the derived keys are cryptographically strong and hide the contents of encrypted metadata. This is only done once when creating the database and adds very little overhead to the system. We note that it is crucially important that this metadata not include sensitive personally identifying information as it is not hidden from a compromised service.

### 3.4 Limitations

Our protocol requires that clients are capable of computing an expensive hash with 256MB of memory. This is a necessary requirement to hamper attackers, but it may also prove untenable for resource-constrained devices. Additionally, our approach requires that clients download a non-negligible amount of data. For context, with 1 billion credentials uniformly split into  $2^{16}$  prefixes, this equates to roughly 15,000 blinded hashes per request. At 29-bytes per item, that amounts to roughly 435KB on average. This grows linearly with the volume of newly discovered credentials.

## 4 Implementation

We implemented our protocol as a publicly accessible API hosted on Google Cloud. The API mediates access to over 4 billion unique usernames and passwords collected using an approach previously documented by Thomas et al. [51].

Canonicalization further reduces this set to 3.36 billion credentials. We also developed a Chrome extension as a proof of concept client that we could share among early testers to gather telemetry on the frequency and impact of breach notifications in the wild. In practice, other applications that handles credentials can integrate with our service by implementing the client half of our protocol.

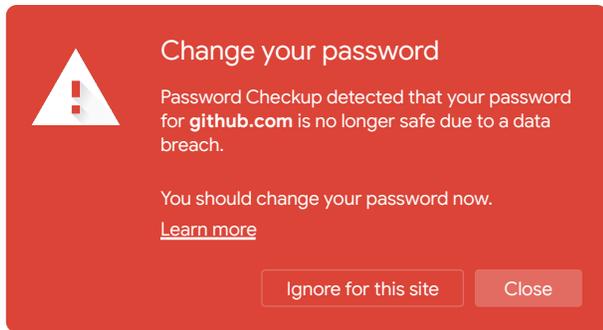

### 4.1 Client

Our Chrome extension monitors when users submit their username and password on a login page and generates a browser warning for breached credentials detected by our API. We rely on a JavaScript implementation of Argon2 from libsodium for all hashing and a web assembly compilation of OpenSSL for the elliptic curve computation required for private set intersection. Both libraries are open source with multiple years of vetting. Here, we discuss the details behind our extension, the design of our warning dialogues, and the telemetry the extension collects.

**Detecting login events:** At present, Chrome does not export an API for detecting login events. Instead, our extension registers a callback function to interpose on all `webRequests` that contain form data. When triggered, the extension relies on heuristics to detect whether the form contains a username or password field, such as matching on field names like `password` and `passwd`. If the heuristic fails to detect both a username and password, nothing is sent to our API. We manually tested our detection on the Alexa US Top 50: we successfully captured login events for 40 pages and failed for 4, while the remaining 6 did not have login forms. For the failures, login information was either obfuscated (e.g., a byte blob of all field data), or part of the payload body rather than form data. We are thus cautious when discussing data from our real world deployment in Section 6 that not every domain will be covered by our technique.

**Warning design:** Our extension modifies the DOM of the page where a user entered their breached credential to show a warning similar to Figure 2. In the browser tray, users can reach an extension popup that displays a stateful warning—similar to Figure 3. This gives users a way to see past warnings, in the event that they closed their browser tab before reviewing the warning (or due to a DOM refresh that overwrites our modifications). Additionally, this serves as a secure UI element that runs in isolation of other extensions and pages. Both styles of warning never reveal information about the username or password found in a breach. This design decision limits the context we can provide users, but allows us to avoid storing sensitive credential material that might make persistent local storage a target for attacks.

In designing our warning, we followed emerging advice about data breach notifications [20], proven terminology around data breaches [1, 28], and historical studies of browser

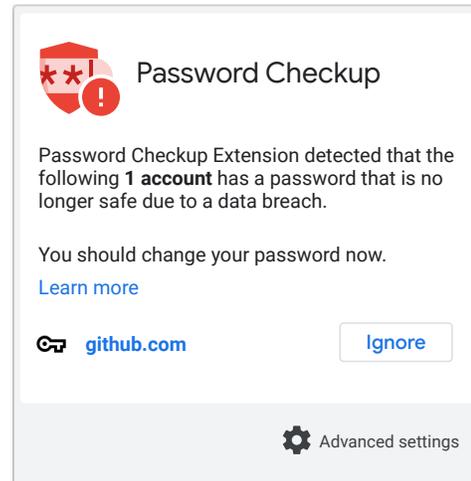

**Figure 2:** In-page warning generated by our extension when we detect that a credential is no longer secure due to a breach.

warnings related to phishing and unsafe network connections [2, 15]. In particular, we provided a clear action—"Change your password"—along with context for the danger behind the event. At the same time, we minimized unnecessary or overly technical information. We also provided a "Learn More" link that explained in greater detail the root cause of the warning and security best practices. In particular, users should (1) reset their password for the affected page; (2) reset their password wherever it was reused; (3) consider a password manager; and (4) consider adopting two-factor authentication. We collected feedback from 550 early testers from our organization before settling on the final design and language of our dialogue.

Compared to other browser warnings where the safest action is to close the tab, breached passwords require users to follow a series of unguided, proactive next steps. We emphasize unguided as there is no canonical account security page for every site to simplify password resetting. While there are industry initiatives to create common reset paths [41], these have yet to materialize. As such, we consider a more formal usability study of the warning experience—and automating the password change process—as future work. We provide a deeper treatment of the effectiveness of our warnings in terms of successful password resets later in Section 6 (in short, a quarter of warnings result in a reset during our observation period).

**Identifying user actions:** By default, our extension continuously triggers a warning each time the user authenticates with a breached credential. Given the computation and network overhead involved for each API query, if the extension detects a breached credential, it caches a 12-byte prefix of the Argon2 credential hash to avoid generating a new API query for the same credential. This also reduces the latency between a user entering a credential and observing a warning on all subsequent logins to the same domain. Conversely, if a credential was previously not present in a breach, we avoid caching any verdict and perform a new API query on each login. In the future, caching here is also possible if the cache were invalidated upon the server announcing the arrival of a new breach.

**Figure 3:** Stateful icon tray warning message to remind users which accounts need their attention. This avoids the transient nature of in-page warnings, which we use to provide better context to users.

For low-value accounts that a user might deem unnecessary to secure, we provide an option to ignore our warning on a per-domain basis as shown in Figure 2 and Figure 3. The extension manages this state by caching a local copy of the domain involved and a 12-byte prefix of the Argon2 hash of the credential that the user ignored (which is necessary in the event the user has multiple accounts on the domain).

We detect when a user resets their exposed password in order to provide a positive feedback signal to the user that their account is no longer at risk. We also purge all cached information about the now stale credential. To do this, we cache a 12-byte Argon2 prefix of an account's username (with only an 8MB memory requirement)—used only locally—along with a 12-byte prefix of the Argon2 credential hash. If the credential hash changes for the same username, this indicates the user signed in with a new password and that all local state for the credential should be reset. In the event a user merely mistyped their breached password, correct password entry will trigger a new warning and refresh the cache.

**Telemetry:** We instrument our extension to report anonymous telemetry pertaining to the volume of lookups against our API that result in a breach warning, along with whether users ignore our warnings or reset their passwords. All of these events lack any form of user identifier, precluding the possibility of correlating events or understanding per-user experiences. Each event also includes the domain of the login page involved, which we use to estimate our compatibility with popular sites and to estimate the prevalence of breached passwords across the Internet. For password changes related to breached credentials, we also report the strength of the old and new password to understand whether users as a whole migrate to stronger passwords. We use zxcvbn [57] for strength

estimation as it is entirely client-side and open source. This telemetry forms the basis of our analysis of the impact of password breach warnings in the wild, discussed in Section 6. We disclose the data we collect upfront to users in the description of our Chrome Webstore listing.<sup>6</sup> We had all of our telemetry reviewed by a group of internal experts and followed our organization’s ethics review process.

## 4.2 Storage

We partitioned our pre-computed, blinded and hashed credential corpus (totaling roughly 110GB) into  $2^{16}$  slices. We stored each slice as a static file in Google Cloud Storage. We restricted access to these files so that only the server handling requests could fetch content from storage. We also stored the key material necessary to re-blind client-blinded hashes in the same storage system.

## 4.3 Server

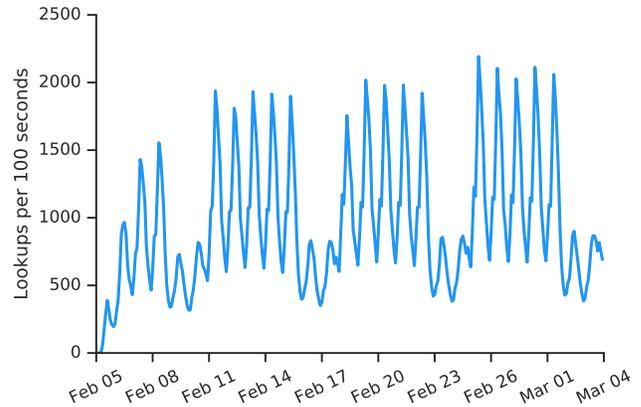

The stateless nature of our credential breach protocol allowed us to implement our serving using Google Cloud Functions. The primary benefit of this approach is that we could scale arbitrarily to the volume of incoming requests while also avoiding dormant compute cycles on pre-requisitioned cloud instances. This design also allowed us to avoid having to reason about the side-effects across requests. We implemented our Cloud Function using the same JavaScript elliptic curve library as our Chrome extension (recall that hashing is not part of the server protocol). We avoid application-layer denial of service attacks—such as sending an arbitrary length string for the server to blind—by blocking malformed requests that do not adhere to the fixed-length blinded hash we expect from a client.

## 5 Deployment

We made our extension publicly available via the Chrome Web Store and announced it through major media channels. In total, 667,716 users installed our extension over a measurement period of February 5, 2019–March 4, 2019 (UTC).

**User demographics:** Based on aggregate statistics provided by the Chrome Web Store, 48% of the users who installed our extension were from North America, 29% from Europe, 17% from Asia, and the remaining 6% from around the world. In terms of operating systems, 71% of users who installed the extension used Windows, 14% used MacOS, 13% ChromeOS, and 2% Linux. We note that extensions are unavailable on mobile devices and thus are not present in our device breakdown.

<sup>6</sup> <https://chrome.google.com/webstore/detail/password-checkup/pncabnpeffjmalckjpaodfjhijclecjno>

**Figure 4:** Volume of logins scanned by our extension every 100 seconds. Requests to our API scaled from 0.11 queries per 100 seconds in early testing, to a peak of 2,192 queries per 100 seconds at the end of our measurement window. The dips in the graph reflect lower activity during weekends.

**Scaling to requests:** Over the course of our measurement window, the lookup volume to our API scaled gracefully from 0.11 lookups per 100 seconds during early testing to a peak of 2,043 lookups per 100 seconds as shown in Figure 4. The diurnal pattern present reflects the geographic concentration of users in North America and Europe. The periodic dips reflect lower login activity over the weekend. By comparing query volume with active user metrics provided by the Chrome Web store, we estimate that an average user generates 3 API requests (e.g., logins) per weekday, and 1.5 requests per weekend. Critically, the diurnal cadence and lack of bursty behavior indicates a lack of large-scale abuse during our measurement window which might otherwise pollute our analysis later in Section 6.

**Client overhead:** We present a breakdown of the computational overhead and network latency incurred by clients that query our API in Table 2. Overall, a median query took 8.5 seconds to return a verdict, during which a user would continue browsing uninterrupted. Roughly half of this time was spent strongly hashing the user’s credential, while the remaining time was spent downloading potential credential matches. Our username hash (used for locally caching state) took a median of 100ms and was a negligible part of this delay. For 10% of users, the overall query time exceeded 18 seconds, half of which was spent in network latency. While part of this lookup overhead can be optimized—credential hashing in native code takes an average of 0.7 seconds—the only way to reduce network latency would be to download fewer breached records, thus reducing the k-anonymity set of our protocol. As such, our current privacy constraints likely remain out of reach for resource-constrained devices, at least for near real time detection.

Duration	Median	90%	95%
Argon2 username hash	0.1s	0.3s	0.3s
Argon2 credential hash	4.4s	9.8s	12.7s
End-to-end API query	8.5s	18.8s	26.9s

**Table 2:** Time spent performing API operations including hashing and downloading potentially matching breached credentials.

**Cost modeling:** A practical reality of running a breach detection service is cost. In our case, cost is intrinsically tied to the k-anonymity privacy that we provide. Every 1,000 invocations of our API costs approximately \$0.19 at the current volume of credentials in our storage and for a 2-byte k-anonymity prefix. Data serving makes up 94% of this cost, while the CPU and memory necessary to field requests and to re-encrypt client credentials makes up only 5%. Based on our query volume per user, operating our service for an estimated 500,000 users would cost \$85,500 a year. Caching the status of negative breach verdicts would substantially reduce expenses. Our goal in documenting these details is to provide other members of the community a benchmark for the costs of any improved privacy scheme. For our protocol, adding a single bit of privacy nearly doubles our operating expenses while also doubling the network latency for clients.

## 6 Analysis

We analyzed the anonymous telemetry reported during our measurement window to understand the state of breached passwords across the Internet. Facets we consider include the frequency that users log in with a breached password, the types of sites where reuse is most common, and ultimately whether displaying warnings helps users to address the risk of credential stuffing. We provide a high-level statistical summary of our telemetry in Table 3. We note that our telemetry is biased towards the users who installed our extension, which is a non-random sample of the Internet population.

### 6.1 Credential stuffing risk and remediation

**Frequency of breached credential reuse:** Overall, our API fielded 21,177,237 lookup requests, where a lookup maps to a single login attempt performed by an anonymous user. We detected that 316,531 logins involved breached credentials—roughly 1.5% of all logins. We caution this is a lower bound as we only generate telemetry for breached credentials once before caching the result locally, whereas lookups to non-breached credentials generate telemetry upon each new login. Our detection rate is lower than the 6.9% reported by Thomas et al. [51] for 751 million Google accounts and 1.9 billion breached credentials. Possible reasons include the user popu-

Metric	Value
Extension users	667,716
Logins analyzed	21,177,237
Domains covered	746,853
Breached credentials found	316,531
Warnings ignored	81,368 (26%)
Passwords reset	82,761 (26%)

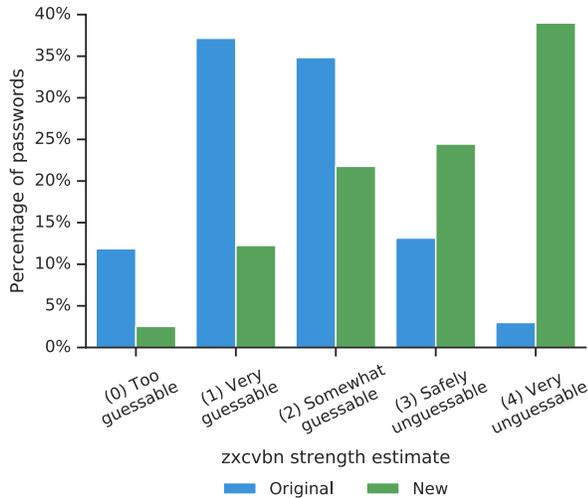

**Table 3:** Summary of the anonymous telemetry data reported over the course of our analysis window from February 5–March 4, 2019.

lation that adopted our extension is more security conscious—thus avoiding reuse as a behavior—or that dormant accounts have a higher reuse rate, which by nature our extension cannot observe as we perform checks at login time. During our 28 day measurement window, if we assume that logins and warnings are uniformly distributed across users, 47.3% of our users received a warning. Our anonymous reporting precludes more detailed per-user statistics. Taken as a whole, our results reveal that global Internet users regularly access accounts that are vulnerable to credential stuffing.

**Ignoring breached credentials:** Users opted to ignore 81,368—or 25.7%—of the breach warnings we surfaced. We consider three possible explanations. Users may be making an explicit risk assessment that the value of their account is not worth the effort of adopting a new password. Alternatively, users may not be in full control of the account (e.g., a shared household account) [37]. Finally, as our extension does not automate the process of password resetting, users may ignore our warning out of frustration due to a lack of guidance. Regardless of the underlying cause, ignored warnings leave accounts vulnerable to credential stuffing. That said, there is an opportunity here for identity providers to take action and guide users through the password resetting process.

**Remediation of breached passwords:** Our warnings resulted in users resetting 82,761—or 26.1%—of their breached passwords. Critically, we find that users used this opportunity to migrate to stronger passwords. On average, the passwords we detected as breached had a zxcvbn strength of 1.6. After remediation, this score increased to an average of 2.9. We present a more detailed summary of strength before and after resetting in Figure 5. For context, a score of one indicates a “weak password” that an attacker can guess in under  $10^6$  attempts. A score of two reflects a password that an attacker can guess in under  $10^8$  attempts, and a score of three  $10^{10}$  attempts and is considered “strong”.

Overall, 94% of password changes led to a stronger or equal zxcvbn score, while just 6% of changes resulted in a regression to a weaker password. Our results indicate that users of our extension understand stronger password compo-

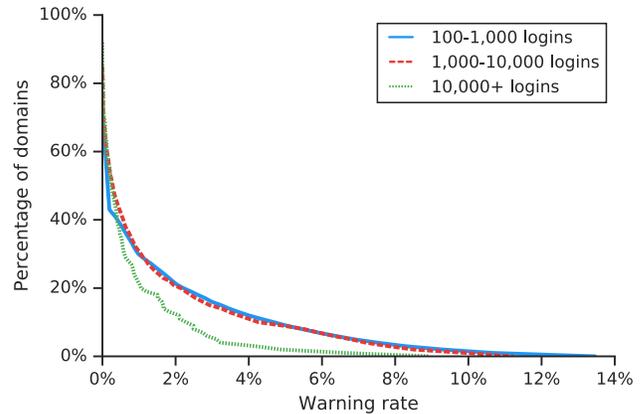

**Figure 5:** Histogram of zxcvbn password strength for passwords detected as breached and the password adopted by users after remediation. Users migrated towards stronger passwords overall as a result of our warnings.
