sition strategies. Equally important, 39% of new passwords achieved the highest possible strength score (up from 3% for the original passwords), a potential sign of the growing prevalence of password managers that automatically compose strong passwords. Our results highlight how surfacing actionable security information can help mitigate the risk of account hijacking.

## 6.2 Influence of domains on account security

**Category:** We examine whether the perceived value of an account influences the rate that users rely on reused, breached credentials. To do this, we manually labeled the top 332 domains that received more than 5,000 logins during our measurement period into one of thirteen categories (e.g., finance, email and messaging, and social networking). We used a catch all “Other” category for domains that fell outside this categorization. Combined, logins to these domains accounted for 41% of lookups against our API.

We present a breakdown of the aggregate warning rates and ignore rates across all domains per category in Table 4. Domains that we categorized as related to finance or governments exhibited the lowest rate of reused, breached credentials (0.2–0.3%). Possible explanations include the password composition policies of these domains, the fact that users adhere to popular security advice to have one strong password for their bank, or that the sites actively identify breaches and previously forced password resets. In contrast, entertainment sites like streaming video platforms and adult websites had the highest warning rate for breached credentials (3.6–6.3%). Users may adopt disposable passwords due to perceived lack

**Figure 6:** CCDF of the percentage of logins per domain that result in a warning across. We group domains by the volume of logins we observed, including 100-1,000, 1,000–10,000, and 10,000+. Popular sites tend to face less of a threat from credential stuffing, while the long tail of domains remain at risk.

of risk, or in the case of streaming sites, they may use shared accounts. Surprisingly, users ignored our breach warnings nearly uniformly across categories, with the exception of adult websites. For the latter, users ignored nearly twice as many of our warnings—potentially to hide the domain from our persistent warning tray (see Figure 3 earlier).

**Popularity:** We also consider whether more popular sites are less vulnerable to credential stuffing. We present a CCDF of the frequency of warnings per domain versus the volume of logins to the domain during our analysis window in Figure 6. We find that just 6% of domains with 10,000+ logins have a warning rate higher than 3%, compared to 15% of domains with fewer than 10,000+ logins. We believe this gap in security results from larger security investments on the part of popular domains towards proactively resetting passwords and helping users avoid “weak” passwords. While large identity providers can equally take advantage of our API, addressing the long tail of domains affected by credential stuffing likely requires relying on in-browser warnings.

## 7 Related Work

**Account hijacking threats:** Credential stuffing represents just one dimension of account hijacking threats. Other risks include large-scale phishing [7, 51], credential or token theft from local machines [50], and even targeted attacks [35, 40]. Users have internalized these risks and adopted a security model of joint responsibility between themselves and identity providers [47]. The most prominent solutions to these threats include users adopting two-factor authentication, or identity providers expanding authentication to include other passive

Category	Domains	Total visits	Breakdown	Warning rate	Ignore rate
Finance	90	1,684,851	8.0%	0.3%	18.6%
Email, messaging	47	1,519,795	7.2%	0.5%	14.0%
Social networking	15	1,191,546	5.6%	0.8%	17.8%
Shopping	29	1,007,103	4.8%	1.2%	16.4%
Technology	34	624,702	2.9%	0.7%	16.9%
Business	12	585,797	2.8%	0.7%	20.3%
Education	16	261,563	1.2%	0.9%	26.5%
Gaming	11	201,646	1.0%	0.5%	18.6%
Entertainment	9	168,565	0.8%	6.3%	27.1%
Travel	14	138,968	0.7%	1.8%	19.6%
Government	5	60,967	0.3%	0.2%	16.9%
News	5	54,864	0.3%	1.9%	20.7%
Adult	3	50,408	0.2%	3.6%	38.5%
Other	42	429,786	2.0%	1.0%	17.8%

**Table 4:** Breakdown of reused, breached passwords for domains receiving more than 5,000 logins, aggregated by business sector. Finance and govt. domains had the lowest usage of breached passwords, compared to entertainment and adult-related domains.

factors such as a user’s device and location [12, 17]. The protections we propose in this work are complementary to a defense in depth authentication model, where breach detection represents one additional factor in risk modeling.

**Password reuse behaviors:** Text passwords continue to be the prevailing mechanism for online authentication. Given the human constraints of memorizing a large number of unique text strings, people have adopted various strategies—including reuse and weak patterns—for managing their growing number of online identities [18, 23, 49, 55]. Florencio and Herley published the first large-scale study of password behavior, where they found both weak and reused passwords were a frequent flaw [16]. More recently, Wash et al. [56] and Pearman et al. [44] observed the password usage behaviors of hundreds of participants over multiple weeks. They estimated that 32% of all entered passwords involved exact reuse. Wash et al. found that users reused their most popular password on an average of 9 sites. Examining breach data directly, Das et al. found that 43–51% of users reused the same password on multiple sites [10]. While automated password filling has become more commonplace—participants used these means 57% of the time [44]—both Pearman et al. and Wash et al. found password managers have yet to be adopted as a tool for password generation. All of these factors compound the threat of credential stuffing, where inverting a single weak password hash can grant an attacker access to multiple sites.

**Improving breach alerting protocols:** In a contemporaneous work, Li et al. presented a framework for reasoning about leakages resulting from the password-based prefixes used by our protocol and HaveIBeenPwned [33]. The authors show how a password-only prefix (or an attacker with access to the plaintext username in a username-password prefix) can leverage a partition’s underlying password distribution to reduce the number of guesses necessary to potentially learn a user’s

password. To address this, the authors outline a zero-password leakage variant that relies on private set membership in conjunction with a username hash prefix for partitioning, akin to our own model from Section 3.2. Their work provides further motivation for a zero-password leakage protocol, despite its additional computational complexity as we outlined.

## 8 Conclusion

In this paper, we demonstrated the feasibility of a privacy-preserving protocol that allows a client to query whether their login credentials were exposed in a breach, without revealing the information queried. Our protocol relies on a combination of computationally expensive hashing, k-anonymity, and private set intersection. Our approach improves on existing protocols by taking into account both an adversarial client and server, while also minimizing the chance of false positives. We envision this service being used by end users, password managers, and by identity providers. As a proof-of-concept, we created a cloud service that mediates access to 4 billion usernames and passwords publicly exposed by breaches. We then released a Chrome extension that would query credentials entered at login time against our service. Based on telemetry produced by nearly 670,000 users, we estimated that 1.5% of credentials used across the web are vulnerable to credential stuffing (based on a sample of 21 million logins).

Addressing this problem requires action from both users and identity providers. In the context of our study, 26% of the warnings we generated for breached passwords resulted in users adopting a new password—94% of which were stronger or as strong as the original. Both the volume of user interest and response rate surfaced during our study demonstrate that there is an appetite on the part of users to secure their accounts from credential stuffing. We hope that by making

our protocol public, other researchers can improve on the privacy protections, computational bounds, and cost models that we establish. Our protocol is a first step in democratizing access to breach alerting in order to mitigate one dimension of account hijacking.

## 9 Acknowledgements

We would like to thank Oxana Comanescu, Sunny Consolvo, Ali Zand, and our anonymous reviewers for their feedback and support in designing our breach alerting protocol. This work was partially supported by funding from the NSF.

## A Anonymity Sets

In this section, we describe properties of anonymity sets (from Section 2.3) in more detail. Recall that anonymity sets are large sets of user credentials that provide plausible deniability about client data even if information about their membership in this set is revealed. Defining and arguing with anonymity sets is challenging and must be done carefully so as to avoid some trivialities. To avoid constructions with vacuous security, we require anonymity sets to have the following properties.

**Large marginal supports:** Our anonymity sets containing tuples  $(u, p)$  must additionally have sufficiently large marginal supports over both usernames and passwords. This ensures that despite there being several possible tuples  $(u, p)$ , there is sufficiently large ambiguity about whether membership implies a specific username or password. A trivial anonymity set, for example, might have several possible credentials with different passwords all tied to the same username.

More mathematically, given an anonymity set  $K$  of size  $|K|$ , we require that the size of the following sets:

$$\begin{aligned} \text{SuppUser}(K) &:= \{u : (u, p) \in K\}, \\ \text{SuppPwd}(K) &:= \{p : (u, p) \in K\}, \end{aligned}$$

both have large cardinalities comparable to that of  $|K|$ . Observe that  $|\text{SuppUser}(K)|$  indicates how many bits of information about the username is leaked (smaller sets narrow the set of possible users and leak a lot of information). This is similarly true for  $|\text{SuppPwd}(K)|$  for passwords.

Hashing both usernames and passwords with cryptographically strong hash functions satisfies these requirements. In fact, it is possible that both sets have cardinalities as large  $|K|$  itself which would imply that for every possible common password there might be a username such that  $(u, p) \in K$ . This is true in our scheme modeling Argon2 as a random oracle.

Schemes that only hash passwords, as noted previously in Section 2.4, might still satisfy a weaker anonymity property. They hide usernames, but depending on how they truncate hashes, password-only schemes might allow for small or large SuppPwd sets. Thus, they might satisfy these requirements, but only weakly at least with respect to passwords. Furthermore, it is not true that for every password there is a username which might be part of the client’s credentials, unlike our scheme. We also note that our trivial example, of having several passwords all tied to the same username, violates our requirement by having  $|\text{SuppUser}(K)| = 1$ .

**Uniformity requirement:** This is a more challenging requirement to model mathematically. Intuitively, however, it states that anonymity sets should partition the space of usernames and passwords in a somewhat uniform manner. In other words, over random choices of the system parameters, it should be equally likely for any  $(u, p)$  to end up in any anonymity set. A trivial anonymity set violating this requirement would, as an example, only truncate usernames, thereby trivially leaking some information about the username. Truncation does not make it equally likely that any  $(u, p)$  can end up in any anonymity set.

Under the reasonable assumption that our hash function is independent of the domain of typical usernames and passwords and does not have any “weak inputs”—domains of inputs where it does not behave like an ideal hash function—this condition is easily satisfied. It is highly improbable that related credentials such as `username`, `username0`, `username123`, will all end up in the same anonymity set.

## B Security of the Hash-and-Blind operation

In this section, we outline the security properties satisfied by the hash-and-blind operation, which is an important part of our protocol. Consider a keyed function  $F(k, x) := H(x)^k$  where  $H : \{0, 1\}^* \rightarrow \mathbb{G}$  is a hash function mapping strings to a group element. In our construction,  $H$  is Argon2, and  $\mathbb{G}$  is the elliptic curve NID\_secp224r1.

The work of Jarecki et al. [27] shows that  $F(k, \cdot)$  implements an *oblivious* pseudorandom function in the random oracle model assuming the hardness of the decision Diffie-Hellman assumption in  $\mathbb{G}$ . In this section, we do not elaborate on the details of the proof, but we state what is meant by a pseudorandom function and how  $F(k, \cdot)$  can be evaluated obliviously—without the secret key  $k$  holder knowing which input they’re evaluating on. Pseudorandomness helps us achieve bounded leakage and protects the credentials not queried by the user; obliviousness enables us to implement the Diffie-Hellman blinding based private set intersection within our protocol.

**Pseudorandomness:** Informally, a function  $F(k, \cdot)$  with outputs in  $\mathbb{Y}$  is said to be pseudorandom if the function behaves like a random function when evaluated on new inputs. More formally, given outputs  $F(k, x_1), \dots, F(k, x_Q)$  for

$Q$  queries  $x_1, \dots, x_Q$  of an adversary’s choice, for any other  $x' \notin \{x_1, \dots, x_Q\}$ , we require that  $F(k, x')$  be computationally indistinguishable from a random element in  $\mathbb{Y}$  as long as  $k$  is chosen uniformly at random and remains hidden.

When applied to our construction, it implies that a client that sees several possible  $H(u_i, p_i)^b$  still cannot distinguish  $H(u', p')^b$  from a random element in  $\mathbb{G}$  if  $b$  is hidden. Hash-and-blind therefore protects the contents of the server database when interacting with clients. For the sake of completeness, we add that this protocol is only secure against honest-but-curious adversaries which assumes that a client might be curious to learn more than it is allowed to, but chooses to honestly follow the protocol.

**Obliviousness:** A function is said to be evaluated in an oblivious manner if there is a protocol between a client holding an input  $x$  and a server holding a function  $f$  such that at the end of the protocol, the client learns  $f(x)$  and the server learns nothing. In our construction,  $f(x) = H(x)^b$  for some value  $b$ . The protocol between the client and server is fairly straightforward (and somewhat implicit in our construction): the client chooses a uniform random value  $a$ , sends  $H(x)^a$ , receives  $H(x)^{ab}$ , and reconstructs

$$f(x) = \left( H(x)^{ab} \right)^{1/a} = H(x)^b.$$

Correctness is fairly straightforward. To see why this is oblivious, observe that for any two inputs  $x_1$  and  $x_2$ , the distributions  $H(x_1)^r$  and  $H(x_2)^s$  for uniformly drawn values  $r$  and  $s$  are identical. This implies that the server learns nothing about the client’s input  $x$ .

When applied to our construction, it states that the component  $H(u, p)^a$  computed in Algorithm 2 allows the client to obliviously evaluate the PRF without revealing to the server information about the credential  $(u, p)$ .

We end this section with a couple of notes. First, a caveat noting that some information about  $(u, p)$  does end up being leaked via the anonymity set, which we capture through our notion of leakage. A direct composition of proofs of security involving anonymity sets and obliviousness might be tricky and will require careful work. Deriving keys from these PRF outputs will additionally require careful applications of KDFs with the right domain separators to avoid re-use of crypto components.

Second, Everspaugh et al. [14] propose an OPRF service that is closely related to our construction here. Our requirements out of an OPRF differs on a couple of key points which does not enable us to use such a service directly: 1) we do not require the notion of *partial* obliviousness in their construction which adds significant computational overheads to their service, and 2) our clients use of an OPRF does not require an immediate evaluation of the PRF, but rather its application to a database to obliviously evaluate its inputs and return potential matches.

# Probability Model Transforming Encoders Against Encoding Attacks

## Abstract

Honey encryption (HE) is a novel encryption scheme for resisting brute-force attacks even using low-entropy keys (e.g., passwords). HE introduces a *distribution transforming encoder (DTE)* to yield plausible-looking decoy messages for incorrect keys. Several HE applications were proposed for specific messages with specially designed *probability model transforming encoders (PMTEs)*, DTEs transformed from probability models which are used to characterize the intricate message distributions.

We propose attacks against three typical PMTE schemes. Using a simple machine learning algorithm, we propose a distribution difference attack against genomic data PMTEs, achieving 76.54%–100.00% accuracy in distinguishing real data from decoy one. We then propose a new type of attack—*encoding attacks*—against two password vault PMTEs, achieving 98.56%–99.52% accuracy. Different from distribution difference attacks, encoding attacks do not require any knowledge (statistics) about the real message distribution.

We also introduce a generic conceptual probability model—*generative probability model (GPM)*—to formalize probability models and design a generic method for transforming an arbitrary GPM to a PMTE. We prove that our PMTEs are information-theoretically indistinguishable from the corresponding GPMs. Accordingly, they can resist encoding attacks. For our PMTEs transformed from existing password vault models, encoding attacks cannot achieve more than 52.56% accuracy, which is slightly better than the randomly guessing attack (50% accuracy).

## 1 Introduction

Password-based encryption (PBE) is a fundamental scheme in many real-world systems for file encryption or authentication. However, due to the limitations of human memory, users often use weak passwords [26, 43] and reuse them [11, 30]. This leads to the vulnerability of traditional PBEs (e.g., PKCS #5 [22]) against brute-force attacks (so-called password guess-

ing attacks), including trawling guessing attacks [25, 42] and targeted guessing attacks [29, 41].

Several methods were proposed to address this threat. We summarize these countermeasures into three types. The first type is to increase the complexity of decryption for attackers, including: 1) salting, which pressurizes attackers into enumerating passwords for every user (salt); 2) using special password-hashing functions (e.g., iterated hash functions [22, 33] and memory-hard functions [6, 31]) as the key derivation function (KDF) in PBE, which increases attackers' cost of computing and memory by a constant factor but also consumes legitimate users' extra cost by the same factor. For example, LastPass, a password vault software, utilizes these methods, including salting, 5,000 rounds of PBKDF2-SHA256 on clients and 100,000 rounds on servers [38].

The second type of countermeasures is to harden passwords with other factors (e.g., servers [12, 23], devices [19, 35, 37], biometrics [9, 28]) to generate high-entropy keys. These methods are widely used in authentication protocols, for example, two-factor authentication [20, 36]. Note that LastPass also supports YubiKey devices to secure password vaults [2]. However, these methods need additional devices (servers, biometric readers) and do worse than single password methods on deployability [8]. Besides, if the additional factor gets stolen or lost (without a backup), the message encrypted cannot be recovered (e.g., [23]).

The last type of countermeasures is to generate plausible-looking decoy messages for wrong keys to confuse attackers. Several specific encryption schemes for specific data used this method [5, 17], and Juels and Ristenpart proposed a generic method called Honey Encryption (HE) [21]. HE introduces a distribution-transforming encoder (DTE) and encodes a message following a known distribution to a uniform seed before encrypting. Therefore, plausible-looking decoy messages are generated by DTE decoding incorrect seeds when decrypting a ciphertext under wrong keys. If the DTE is perfectly secure, i.e., decoy messages are indistinguishable from real ones, then attackers enumerating all passwords only get many messages and cannot distinguish the right one. This countermeasure

achieves information-theoretic security without declining on deployability and bringing legitimate users' extra cost.

Owing to the security of HE, several applications of HE [10, 14, 18] were proposed. In this paper, we focus on three typical ones, including two password vault schemes [10, 14] and one genomic data protection scheme [18]. A password vault contains an individual user's multiple passwords on websites or services and is usually encrypted under a user-chosen password, called master password. Passwords stored in password vaults are of great value (e.g., PINs of credit cards, passwords of virtual currency accounts) and hence greatly attract attackers' attention. Similar to password vaults, genomic data is sensitive and needs long-term protection, as it is unchangeable during one's lifetime and correlated with his relatives.

The key of a HE scheme is to design a secure DTE. It is easy for messages following a simple distribution, for example, a uniform distribution, a normal distribution. Juels and Ristenpart [21] designed a generic purpose DTE *IS-DTE* and several specific DTEs for RSA secret keys. Notwithstanding, it is still a great challenge to design a secure DTE for messages following intricate distributions, e.g., natural language texts, passwords, password vaults, and genomic data. Probability models are usually needed to characterize the message distributions. We call these DTEs *probability model transforming encoders (PMTEs)*, which are transformed from probability models instead of distributions. Note that Chatterjee et al. [10] named DTEs for natural language texts as *natural language encoders (NLEs)*, which are a subset of PMTEs. Though all the existing PMTE schemes [10, 14, 18] are designed for specific messages, it is still of necessity to propose a generic PMTE designing method.

In addition, the security evaluations of PMTEs are not comprehensive. The designers of password vault PMTEs [10, 14] tried to use machine learning algorithms and Kullback-Leibler divergence to distinguish real and decoy vaults, without considering the difference between the real and decoy seeds. For the PMTEs in [18], it evaluated the goodness of probability models with chi-square goodness-of-fit tests, but did not study the influence of their goodness on the security of PMTEs. These issues on PMTE study hinder the widespread use of HE.

## 1.1 Our Contribution

In order to evaluate the security of PMTEs, we propose a framework with encoding attacks and distribution difference attacks. We show that password vault PMTEs [10, 14] suffer from encoding attacks while genomic data PMTEs [18] cannot resist distribution difference attacks. *Encoding attacks*, which are a new type of attack we propose, do not require any knowledge of real message distributions. The strong encoding attack achieves 98.56%–99.52% accuracy (in distinguishing a real vault from a decoy one) against password vault PMTEs. Meanwhile, using a principal component analysis (PCA) and

a support vector machine (SVM) with a radial basis function (RBF) kernel, a distribution difference attack achieves 76.54%–100.00% accuracy against genomic data PMTEs.

We also propose a generic PMTE designing method for arbitrary probability models, by introducing a generic conceptual probability model—*generative probability model (GPM)*—to formalize probability models. We prove that our PMTEs are information-theoretically indistinguishable from corresponding GPMs, which means that they can resist encoding attacks. For our proposed PMTEs of existing password vault models, encoding attacks cannot capture more than 52.56% accuracy, compared with the randomly guessing attack (50% accuracy).

## 2 Background and Related Works

We introduce the basic concepts of HE as well as three typical HE applications with their specific PMTEs.

### 2.1 Honey Encryption

Honey Encryption (HE) [21], proposed by Juels and Ristenpart, is a novel encryption scheme using low-entropy keys (e.g., passwords) which resists brute-force attack through generating a plausible decoy message for every incorrect key. To produce decoy messages, HE introduces a randomized encoder, called *distribution transforming encoder (DTE)*.

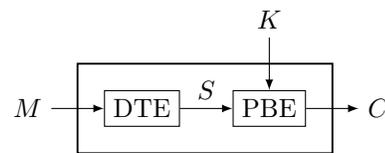

Figure 1: Honey Encryption

Figure 1 shows the encryption progress for a message  $M$ . The encryption first encodes  $M$  into a seed  $S$  by DTE, then encrypts  $S$  using PBE with the key  $K$  and finally outputs the ciphertext  $C$ . The PBE used in HE is a traditional PBE but must satisfy that decrypting any ciphertext under any key yields a valid seed (e.g., AES in CTR-mode with PBKDF). Therefore, decrypting  $C$  under an incorrect key  $K'$  will yield a wrong seed  $S'$  and a decoy message  $M'$  by decoding  $S'$ . The key of HE is designing a secure DTE which generates indistinguishable decoy messages. Juels and Ristenpart [21] proposed a general purpose DTE *IS-DTE*, for the messages following a simple distribution, such as a uniform distribution.

### 2.2 Password Vault Schemes

Two HE-based password vault schemes [10, 14] were proposed to resist brute-force attack in the literature. A password vault contains several passwords encrypted under a master

password and hence is a rich target for attackers due to the value of passwords. Using HE, attackers who have stolen an encrypted password vault will get many vaults by enumerating master passwords offline and need to verify the correctness of these vaults online. In contrast to offline guessing, online guessing is more resource-consuming, because it is easily blocked by remote servers with diversities of methods (e.g., login rate limiting [16,32] and malicious login detection [13]). Hence, HE-based password vault schemes have great improvements in security. Moreover, user surveys [11, 24, 30] and empirical experiments on real data [7, 11, 41, 42] showed that users often use weak passwords and reuse passwords on different services and websites. Therefore, designing a PMTE for password vaults needs to characterize the single-password distribution and the similarity between passwords in a vault.

Chatterjee et al. [10] proposed the first HE-based password vault scheme *NoCrack*. They improved a kind of password model—PCFG model [42]—and put forward a sub-grammar approach for the password similarity based on PCFG models. We denote this improved PCFG model as *Chatterjee-PCFG* in this paper. By designing PMTEs for PCFG models and sub-grammars respectively, they presented a PMTE for password vaults. Also, Chatterjee et al. [10] designed PMTEs for another kind of password models—Markov models.

Golla et al. [14] put forward a new PMTE for password vaults. In contrast to Chatterjee et al. [10], Golla et al. used a Markov model [25] for the single-password distribution and a reuse-rate approach for the password similarity. Their PMTE for password vaults combines Chatterjee et al.’s PMTEs for Markov models and IS-DTEs for normal distributions (assuming reuse-rates follow normal distributions). In addition, Golla et al. [14] brought in the concept of adaptive PMTEs (Golla et al. used the word *adaptive NLEs*). By adjusting the Markov model according to the real vault, an adaptive PMTE can generate decoy vaults which are more similar to the real vault. Therefore, these decoy vaults are more difficult to be distinguished from the real one. In this paper, we call adjusted probability models according to the real message *adaptive probability models*, in contrast to *static probability models*.

Chatterjee et al.’s [10] and Golla et al.’s [14] PMTEs for password vaults have the same form named *encode-then-concatenate*. Taking the Chatterjee et al.’s PMTE for a PCFG model as an example, when encoding a password, this PMTE: 1) parses the derivation of the password; 2) encodes each production rule in the derivation to a seed respectively; 3) concatenates these seeds of production rules in order and pads the concatenation to a fix length. Other PMTEs are similar, which encode each character or reuse-rate and then concatenate these seeds.

## 2.3 Genomic Data Protection Scheme

Genomic data is more sensitive than password vault and needs long-term protection. Once a person’s genomic data is com-

promised, it will affect him during his lifetime and even his relatives, because of the correlation between relatives’ genomic data. Huang et al. [18] proposed a genomic data protection scheme called *GenoGuard* based on HE. The genomic data protected by *GenoGuard* is represented by a sequence of single nucleotide variants (SNVs), which can be viewed as a string of the alphabet  $\{0, 1, 2\}$ .

To fit genomic data, Huang et al. [18] evaluated four types of models with chi-square goodness-of-fit tests, including a uniform distribution model, a public LD (linkage disequilibrium) model, three Markov models, and a recombination model. Since the recombination model delivers the best performance, they chose it for *GenoGuard*. Furthermore, Huang et al. [18] proposed a novel PMTE for these sequences with a different form named *shrink-then-encode*. When encoding, this PMTE shrinks the seed interval for each character in the string according to the probability of the character and randomly picks a seed in the final seed interval.

## 3 Attacks Against Typical PMTEs

A PMTE is secure (i.e., decoy messages generated by a PMTE are indistinguishable from real ones), if and only if the probability model is accurate for the real message distribution and the PMTE is secure for the probability model. Based on that, we propose a framework to evaluate the security of PMTEs with two types of attacks: 1) *distribution difference attacks* exploiting the difference between the real message distribution and the message probability model (i.e., the decoy message distribution); 2) *encoding attacks* exploiting the difference between the probability model and the PMTE.

### 3.1 Attacker Model

Attackers that we study in this paper have stolen ciphertext of a message and further want to recover it. Based on the Kerckhoffs’s principle, we assume that attackers know the HE algorithm, including DTEs, but do not know the key or any information of the message. It is reasonable because the program shipped to users usually contains the encryption/decryption module. Moreover, this is an essential assumption for an attacker to carry out decrypting. More advanced attackers (e.g., attackers in [10]) may equip themselves with some knowledge about the real message distribution (e.g., the character distribution of messages). However, encoding attackers we employed do not need any information about the real message distribution. Merely relying on the DTEs, such attackers can distinguish real and decoy messages with high accuracy.

To recover the message, attackers: 1) decrypt the ciphertext under  $N$  keys  $\{k_i\}_{i=1}^N$  and get  $N$  messages  $\{M_i\}_{i=1}^N$ ; 2) choose the most likely message. For some special types of messages which can be verified online, for example, authentication certificates (passwords, password vaults or authentication keys),

---

**Algorithm 1:** The attack process to recover a stolen ciphertext.

---

**Input:** a stolen ciphertext  $c$ ,  $N$  keys/passwords  $\{k_i\}_{i=1}^N$  for decryption, and a weight function  $p$ .  
**Output:** a guessing list for messages (in decreasing order of  $p$ ).

```

1 for  $i \leftarrow 1$  to  $N$  do
2    $S_i \leftarrow \text{decrypt}_{k_i}(c)$ 
3    $M_i \leftarrow \text{decode}(S_i)$ 
4 end
5 Sort  $\{M_i\}_{i=1}^N$  in decreasing order of  $p(M_i)$  (or  $p(S_i)$ ), then output the list. /* Different attacks are equipped with different weight functions  $p$ , where  $p(M_i)$  usually reflects the probability that  $M_i$  is real. */

```

---

attackers need to sort these  $N$  messages to minimize the number of online verifications. To characterize attackers in a unified form, we consider an attacker only picking one message also as a sorting attacker who picks the first one in his order. Assuming an attacker sorts the messages in decreasing order of a weight function  $p$ , the attack process can be represented as Algorithm 1.

The efficiency of an attacker depends on 1) the guessing order of keys and 2) the sorted order of messages. These two orders correspond to two factors—keys and DTEs, affecting the security of HE schemes. The stronger the keys are, the harder they are to be cracked. Keys used by HE are usually human-memorable passwords. Password researches have attracted great attention recently, such as password guessing [25, 41, 42], password strength meter [15, 39, 40], password generation policy [3, 34]. However, same as previous literature [10, 14], we ignore the influence of keys on the security of HE schemes and only focus on the security of DTEs, i.e., the indistinguishability of decoy messages.

### 3.2 Analyses of Password Vault PMTEs

Chatterjee et al.’s PMTE [10] for password vaults uses a sub-grammar approach to model the similarity of passwords in one vault. Specifically, the sub-grammar (based on Chatterjee-PCFG) of vault  $V = (\text{password}, \text{password1})$  is  $\{S \rightarrow W, S \rightarrow WD, W \rightarrow \text{password}, D \rightarrow 1\}$ , where  $W$  represents an English word and  $D$  represents a digit string. In fact, Chatterjee-PCFG is more comprehensive. We simplify it for ease of explanation. To encode a vault, this PMTE 1) first parses the sub-grammar of the vault, 2) then encodes the sub-grammar, and 3) finally encodes the passwords in the vault according to the sub-grammar. Decoding is in the opposite direction.

Because sub-grammars are parsed from the real vaults when encoding, all production rules in sub-grammars are used by passwords in the real vaults. Unfortunately, it may not hold when decoding a random seed. For example, decoding a random seed, the sub-grammar may be  $SG = \{S \rightarrow W, S \rightarrow WD, W \rightarrow \text{password}, D \rightarrow 1\}$ , and the vault may be  $V = (\text{password}, \text{password})$ . As passwords are generated inde-

pendently based on sub-grammars when decoding, production rules (e.g.,  $S \rightarrow WD$ ) in the sub-grammar may not be used by any password in the vault. In addition, decoded sub-grammars may contain identical rules, but encoded ones do not, because the rules are also independently generated when decoding a random seed.

Similar phenomena also appear in Golla et al.’s PMTEs [14]. They used a reuse-rate approach to model password similarity. Given  $V = (\text{password1}, \text{password1}, \text{password@})$ , Golla et al.’s PMTEs take “password1” as the base password of  $V$  and “password@” as a password modified from the base password. When encoding, they 1) encode the base password (“password1”) and the reuse-rate of the base password ( $\frac{2}{3}$ ), 2) encode reuse-rates of modified passwords ( $\frac{1}{3}$ ) and the modified characters (“@”). More specifically, Golla et al.’s PMTEs divide the vault into six subsets  $\{V_i\}_{i=0}^5$ : passwords with an edit distance of  $i$  to the base passwords  $V_i$  ( $0 \leq i \leq 4$ ) and the remaining passwords  $V_5$ . Assuming the proportion (reuse-rate) of  $V_i$  in  $V$  follow a normal distribution with a small variance,  $|V_i|$  (the cardinality of  $V_i$ ) is encoded by the DTE of the normal distribution, for  $0 \leq i \leq 4$ . In addition, the base password, modified characters (of passwords in  $V_i$  for  $1 \leq i \leq 4$ ) and remaining passwords in  $V_5$  are encoded by PMTEs of Markov models.

The sum of  $|V_i|$  for  $0 \leq i \leq 4$  (without  $|V_5|$ ) is less than or equal to  $|V|$  when encoding. However, it may not hold when decoding a random seed, because proportions of  $V_i$  are generated independently. Further, the modified character of password  $pw$  in  $V_i$  may be the same as the original character of the base password when decoding a random seed, which means  $pw$  actually belongs to  $V_j$  with  $j < i$ . But this is not possible when encoding a real vault.

### 3.3 Attacks Against Password Vault PMTEs

In the above analyses of password vault PMTEs, we dig out some features that real seeds (encoding from real vaults) must have but decoy seeds (random seeds) may not have. Therefore, an attacker is able to exclude some decoy seeds if they do not have these features. Let  $p_F$  denote the weight function based on the feature  $F$ :

$$p_F(S) = \begin{cases} 1, & \text{if the seed } S \text{ has feature } F, \\ 0, & \text{otherwise.} \end{cases}$$

We now present four features for exploration, the first two features for the Chatterjee et al.’s PMTE [10] and the last two features for Golla et al.’s PMTEs [14]:

1. Feature UR (unused rule): there is no unused rule in the sub-grammar decoded from the seed.
2. Feature DR (duplicate rule): there is no duplicate rule in the sub-grammar decoded from the seed.
3. Feature ED (edit distance): every password in the vault has the same value of  $i$  as the one decoded from the seed.

---

**Algorithm 2:** The weight function  $p_{\text{PCA+SVM}}$  of the PCA+SVM attack

---

```
1 training:
   Input: a dataset smsList containing the same number of real
           and decoy SNV sequences with the label (0 for decoy
           and 1 for real) list labelList.
   Output: a PCA model pca and a SVM model svm.
2 /* The classes SVC and PCA we use are svm.SVC and
   decomposition.PCA in Scikit-learn, a machine
   learning library for Python. */
3 pca ← PCA(n_components = 10) /* We use the default
   parameters except n_components as 10. */
4 pca.fit(smsList)
5 reducedSNVsList ← pca.transform(smsList)
6 svm ← SVC(probability = True)
7 svm.fit(reducedSNVsList, labelList)
8 end
9 function  $p_{\text{PCA+SVM}}(s)$ 
   Input: an SNV sequence s.
   Output: the SVM-estimated probability that s is real.
10 reducedSNVs ← pca.transform([s])[0]
11 p ← svm.predict_proba([reducedSNVs])[0, 1]
12 return p
13 end
```

---

4. Feature PN (password number): the sum of  $|V_i|$  ( $0 \leq i \leq 4$ ) is no larger than  $V$ .

To evaluate the security of PMTEs, Chatterjee et al. [10] used a Support Vector Machine (SVM) to distinguish the real and decoy vaults, and Golla et al. [14] used Kullback-Leibler (KL) divergence. These attacks only exploit the difference between the real and decoy vault distributions but neglect the seeds. We call this type of attack *distribution difference attack*. These attacks cannot exploit the features discussed above. In contrast, our proposed feature attacks only exploit seeds with PMTEs and do not require any knowledge of the real vault distribution. We call this new type of attack *encoding attack*.

### 3.4 Attacks Against Genomic Data PMTEs

Huang et al. [18] provided a formal proof for the security of their PMTEs. They proved that their PMTEs are indistinguishable from probability models, but did not consider the difference between the real message distribution and probability models. This means their PMTEs resist encoding attacks but have not been evaluated by distribution difference attacks. Although Huang et al. evaluated six probability models with chi-square goodness-of-fit tests, they did not study the influence of their goodness on the security of PMTEs.

In order to evaluate the security, we propose a simple machine learning algorithm to distinguish the real and decoy data (i.e., SNV sequences). As shown in Algorithm 2, we use a training set to train a principal component analysis (PCA) model and a support vector machine (SVM) with a radial basis function (RBF) kernel, where the training set contains the same number of real and decoy SNV sequences, the real

sequences are randomly picked from the real dataset, and the decoy sequences are generated by decoding random seeds with the corresponding PMTEs. Specifically, the PCA model is trained and used to reduce the 1000-dimensional sequences in training set to 10 dimensions, and the SVM is trained with the 10-dimensional sequences and the “real/decoy” labels. To estimate the probability that a test sequence  $s$  is real, we first use the trained PCA model to reduce  $s$  to 10 dimensions, then resort to the trained SVM to classify the reduced sequence and output the probability of it being real. All parameters of the PCA and the SVM are default except “ $n\_components$ ” as 10. Since the default parameters deliver good performance, we do not adjust them. We denote the SVM-estimated probability of  $s$  as  $p_{\text{PCA+SVM}}(s)$  and propose a PCA+SVM attack with the weight function  $p_{\text{PCA+SVM}}$ .

## 4 Generative Probability Models and Generic Encoding Attacks

In this section, we propose a generic conceptual probability model—*Generative Probability Model (GPM)*—to formalize all the existing probability models. This formalization uncovers the principle of encoding attacks. Based on this principle, we propose two generic encoding attacks—a *weak encoding attack* and a *strong encoding attack*.

### 4.1 Definition

Simple models (e.g., uniform distribution models) assign every message a probability directly, but other complex models cannot. Most complex models (e.g., PCFG models [42]) design a generative method for messages and assign every message a probability with the generated probability of the message. By assigning probabilities to the generating rules, one can get a probability model for the messages. From this point of view, we give a formal definition of *Generative Probability Model*.

**Definition 1.** A Generative Probability Model (GPM) is a 5-tuple  $(\mathcal{M}, \mathcal{R}, \mathcal{RS}, G, P)$ , where  $\mathcal{M}$  is the message space,  $\mathcal{R}$  is the set of generating rules,  $\mathcal{RS} \subset \mathcal{R}^*$  is the set of valid generating sequences,  $G$  is the generating function mapping a generating sequence  $RS$  in  $\mathcal{RS}$  to a message  $M$  in  $\mathcal{M}$ , and  $P$  is the probability density function on  $\mathcal{RS}$ . Here  $\mathcal{M}, \mathcal{R}, \mathcal{RS}$  are finite sets and  $G$  is surjective. Then the GPM gives  $\mathcal{M}$  a probability distribution by

$$P(M) = \sum_{RS \in G^{-1}(M)} P(RS). \quad (1)$$

In addition, if  $G$  is bijective (i.e., for every message in  $\mathcal{M}$ , there is only one generating sequence which can generate it), the GPM is unambiguous, and otherwise, it is ambiguous.

Usually, the probability density function  $P$  on  $\mathcal{RS}$  is given by the conditional probability distribution as follows:

$$P(RS) = \prod_{i=1}^n P(r_i | r_1 r_2 \dots r_{i-1}), \quad (2)$$

where  $RS = (r_1, r_2, \dots, r_n)$ . The conditional probability  $P(r_i | r_1 r_2 \dots r_{i-1})$  is usually given in a simple form. Note that the generating sequences in  $\mathcal{RS}$  have variable lengths, therefore, the above equation requires that  $\mathcal{RS}$  is *prefix-free*, i.e., no sequence in  $\mathcal{RS}$  is a prefix of another sequence. Otherwise, the function  $P$  defined by Equation 2 is not a probability density function on  $\mathcal{RS}$ , because  $\sum_{RS \in \mathcal{RS}} P(RS) > 1$ . Fortunately, if  $\mathcal{RS}$  is not prefix-free, it can easily be converted to a prefix-free sequence space  $\mathcal{RS}'$  by two simple methods: 1) add a special rule at the beginning of the sequence to represent the length of the sequence; 2) add a special rule at the end of the sequence to represent the end of the sequence. Therefore, without loss of generality, we assume generating sequence spaces of GPMs are all prefix-free.

## 4.2 Formalization of Existing Models

For a Markov model of order  $n$ , a generating rule is a character, and a valid generating sequence is a string. The conditional probability of a rule only depends on last  $n$  rules, formally

$$P(a_i | a_1 a_2 \dots a_{i-1}) = P(a_i | a_{i-n} a_{i-n+1} \dots a_{i-1}),$$

where  $i > n$  and  $P(a_i | a_{i-n} a_{i-n+1} \dots a_{i-1})$  is trained on a training set (RockYou for password vault schemes). The Markov model with distribution-based normalization adds some extra rules  $\{L = l\}_{l=1}^{l_{\max}}$  to  $\mathcal{R}$ ,  $L = l$  represents that the password length is equal to  $l$ , where  $1 \leq l \leq l_{\max}$  and  $l_{\max}$  is the max password length (e.g., 30). A valid generating sequence has the form  $(L = l, a_1, a_2, \dots, a_l)$  which means generating the length first and then generating the characters.  $P(L = l, a_1, a_2, \dots, a_l) = P(L = l)P(a_1, a_2, \dots, a_l)$ , where  $P(a_1, a_2, \dots, a_l)$  can be calculated as the ordinary Markov model and  $P(L = l)$  represents the probability that the length of a password is  $l$ . Note that  $l_{\max} < \infty$ , because the message space  $\mathcal{M}$  is finite (the seed space  $\mathcal{S}$  is finite).

For a PCFG model, a generating rule is a production rule of the PCFG, a valid generating sequence is a leftmost derivation of a string. The conditional probability of a rule does not depend on any previous rule, formally

$$P(r_i | r_1 r_2 \dots r_{i-1}) = P(r_i),$$

where  $P(r_i)$  is also trained on a training set.

For the Golla et al.'s model [14] of password vaults, a generating rule is a character or a value of  $|V_i|$  for  $0 \leq i \leq 4$ . A valid generating sequence of a vault consists of the following rules: 1) characters of the base password, 2)  $|V_i|$ , 3) modified characters of passwords in  $V_i$  and 4) characters of passwords

in  $V_5$ . In this case, the conditional probabilities of characters are calculated as the Markov model and  $|V_i|$  is calculated by normal distributions.

For the Chatterjee et al.'s model [10] of password vaults, a generating rule is a production rule of the PCFG or a number of production rules with a certain lefthand-side in a vault, a valid generating sequence contains a generating sequence of a sub-grammar and leftmost derivations of passwords based on the sub-grammar. More specifically, a valid generating sequence of the sub-grammar  $\{S \rightarrow D, S \rightarrow W, D \rightarrow 123456, W \rightarrow \text{password}\}$  is ( $\#S = 2, S \rightarrow D, S \rightarrow W, \#D = 1, D \rightarrow 123456, \#W = 1, W \rightarrow \text{password}$ ). The rule  $\#X = i$  represents that there are  $i$  rules with the lefthand-side  $X$  in sub-grammar, it is for the sake of the prefix-free property of  $\mathcal{RS}$ . The conditional probability of the rule  $\#X = i$  only depends on the rule itself, denoted as  $P(\#X = i)$ , which is trained on a password vault dataset (Pastebin). The conditional probability of the rule  $X \rightarrow str$  is the same as that in PCFG models.

For Huang et al.'s models [18] for genomic data, a generating rule is a character of  $\{0, 1, 2\}$  (representing an SNV), a valid generating sequence is a string. The conditional probability of a rule relies on the genomic data model: for the uniform distribution model, it is equal to  $\frac{1}{3}$  for each rule; for the public LD model (as discussed above), it depends on the last rule; for Markov model of order  $n$ , it depends on the last  $n$  rules; for the recombination model, it is calculated by the forward-backward algorithm with a hidden Markov model.

Up to this point, the existing models are all formalized with our proposed GPMs and the distributions of generating sequences are defined by the conditional distributions of generating rules. Beyond that, more probability models can be formalized. For example, neural networks for passwords [27] can be formalized as the same as Markov models except that condition probabilities are calculated by neural networks.

## 4.3 Generating Graphs

To represent a GPM visually, we propose a *generating graph*, which is a connected directed acyclic graph with a single source and with edges labeled by generating rules. In a generating graph, a generating sequence is illustrated by a path whose edges denote the corresponding generating rules in order. Moreover, a message is figured by a sink (because the generating sequence space is prefix-free) and a path from the source to the sink illustrates one generating sequence of the message. Hence, the path is called a *generating path* of the message. Note that the generating graph of a model is an arborescence, if and only if the model is unambiguous. (Note an arborescence is a directed graph in which there is only one single source and each other vertex has only one directed path from the source.)

As shown in Figure 2, in Chatterjee-PCFG model, there are two generating paths for "password". These two generating paths correspond to two generating sequences:  $\{S \rightarrow W, W \rightarrow$

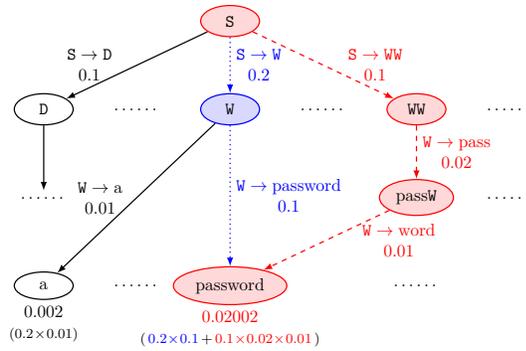

Figure 2: Generating graph of Chatterjee-PCFG

password} and  $\{S \rightarrow WW, W \rightarrow \text{pass}, W \rightarrow \text{word}\}$ . Further, the probability of the first sequence is  $0.2 \times 0.1 = 0.02$  and that of the second one is  $0.1 \times 0.02 \times 0.01 = 0.00002$ . This makes the probability of “password” be  $0.02 + 0.00002 = 0.02002$ . Since “password” has two generating sequences, Chatterjee-PCFG model is ambiguous.

#### 4.4 The Principle of Encoding Attacks

The features used by encoding attacks in Section 3 are all based on heuristic analyses of specific PMTEs. Some other features are still neglected due to the lack of a systematic analysis. For example, on Chatterjee et al.’s password vault PMTE [10], the order of rules in the sub-grammar is deterministic for real vaults, but not for decoy seeds. When encoding the vault  $V = (123456, \text{password})$ , the first two rules in the sub-grammar are  $S \rightarrow D, S \rightarrow W$  in order. But if the vault  $V$  is decoded by a decoy seed, the first two rules may be  $S \rightarrow W, S \rightarrow D$  in a different order from the real vault.

Fortunately, with the formalizations by GPMs and the visual representations by generating graphs, the principle of encoding attacks is uncovered: *existing PMTEs neglect the ambiguity of GPMs. More specifically, in an ambiguous GPM, there may exist multiple generating paths for a message, but the existing PMTEs only select one deterministic path when encoding.* We name these paths *encoding paths* which can be selected when encoding and meanwhile name these corresponding generating sequences *encoding sequences*. The generating sequence of a seed can be obtained by decoding the seed. Due to the determinacy of encoding paths, encoding attacks can exclude some decoy seeds by checking if the generating path of a seed is an encoding path, without any information of the real message distribution.

We then take Chatterjee et al.’s PMTE [10] for Chatterjee-PCFG as an example. As shown in Figure 2, this PMTE only uses the blue dotted path when encoding “password”, but the generating path of a decoy seed may be the red dashed one. In fact, Chatterjee et al. [10] noticed the ambiguity of Chatterjee-PCFG and briefly mentioned that the PMTE needs to choose one parse tree randomly in all parse trees

---

#### Algorithm 3: The weight function $p_{\text{WEA}}$ ( $= p_{\text{EC}}$ ) of the weak encoding attack

---

```

1 function  $p_{\text{WEA}}(S)$ 
  Input: a seed  $S$ .
  Output: the weight of  $S$  (for sorting in Algorithm 1).
2 Obtain the generating sequence  $RS$  and the message  $M$  of  $S$  by decoding  $S$ 
3  $S' \leftarrow \text{encode}(M)$  /* Since encode is a randomized algorithm,  $S'$  is probably not equal to  $S$ . */
4 Obtain the generating sequence  $RS'$  of  $S'$  by decoding  $S'$ 
5 if  $RS = RS'$  then return 1 /*  $S$  may be a real seed. */
6 else return 0 /*  $S$  is definitely a decoy seed. */
7 end

```

---

when encoding. However, in Chatterjee et al.’s code [10], they have not implemented the random selection method until now (June 1, 2019) and only one parse tree is selected when encoding. Moreover, Chatterjee et al. [10] completely neglected the ambiguity of the sub-grammar approach. For example, a vault  $V = (123456, \text{password})$  is encoded only with the sub-grammar  $SG = \{S \rightarrow D, S \rightarrow W, D \rightarrow 123456, W \rightarrow \text{password}\}$ , but  $V$  can be generated by multiple sub-grammars as long as they contain  $SG$ . Therefore, the encoding paths definitely have feature UR while other generating paths may not.

Similarly, Golla et al. [14] also did not consider the ambiguity of the reuse-rate approach. For example,  $V = (\text{password1}, \text{password1}, \text{password}@)$  can be generated by “password1” as the base password with reuse-rates  $|V_0| = \frac{2}{3}$  and  $|V_1| = \frac{1}{3}$ . It also can be generated by “password1” as the base password with reuse-rates  $|V_0| = \frac{1}{3}$  and  $|V_1| = \frac{2}{3}$ . In addition, Golla et al.’s GPMs [14] allow modifying the character of the base password to the same character. Therefore, “password@” may be in  $V_2$  (with “@” modified from “1” and “d” modified from itself). This brings ambiguity to the GPM, i.e., a huge number of generating paths for a vault. Only one deterministic path (the first one for  $V$ ) is chosen when encoding. Therefore, the encoding paths definitely have feature ED while other generating paths may not.

Any feature utilized by any encoding attack, including features proposed in Section 3.3, the rule-order feature or the base-password feature discussed above, can be seen as a feature of encoding paths.

#### 4.5 Generic Encoding Attacks

Due to the determinacy of encoding paths, we further propose two generic encoding attacks—a *weak encoding attack* and a *strong encoding attack*.

The weak encoding attack is accordance with feature EC (encoding consistency) that the generating path is an encoding path, i.e., the weight function  $p_{\text{WEA}} = p_{\text{EC}}$ . We use the abbreviation of the attack as the subscript of  $p$  for convenience. More specifically,  $p_{\text{WEA}}$  (i.e., whether a seed  $S$  has feature

EC) can be calculated as Algorithm 3.

In contrast to the feature attacks (proposed in Section 3.3) based on some features of encoding path, the weak encoding attack is based on feature EC. Therefore, the seeds having feature EC certainly have other features proposed in Section 3.3. In other words, the weak encoding attack excludes all decoy vaults which are excluded by any feature attack.

As the seeds with feature EC are sorted randomly by the weak encoding attack, we propose a *strong encoding attack* to sort them. Let  $RS$  denote the generating sequence of the seed  $S$ , then the weight function  $p_{SEA}$  is defined as

$$p_{SEA}(S) = \frac{1}{P(RS)} \times p_{WEA}(S).$$

## 4.6 Efficiency of Encoding Attacks

These two generic encoding attacks are efficient for PMTEs with significantly ambiguous GPMs and deterministic encoding paths, such as all existing PMTEs for password vaults. In other words, these attacks recover the encrypted real vaults with a high probability but a small number of online verifications. To make it clear, the weak encoding attack excludes the seeds whose generating paths are not encoding paths, e.g., the red dashed path in Figure 2. Namely, the excluded proportion of the weak encoding attack is equal to the total probability of all generating paths except encoding paths. This means that *the more ambiguous the GPM is, the more efficiency the weak encoding attack can achieve*. As discussed in Section 4.4, in the existing GPMs for password vaults [10, 14], every vault has countless generating paths. Due to the great ambiguity of these GPMs, the weak encoding attack is efficient for the corresponding existing PMTEs with deterministic encoding paths. On the other hand, if a GPM is unambiguous (e.g., the models of genomic data [18]), the PMTE for it can resist encoding attacks naturally. Besides, the strong encoding attack excludes all decoy seeds which are excluded by the weak encoding attacks. Therefore, the strong encoding attack is always more efficient than the weak encoding attack.

## 5 Probability Model Transforming Encoders

We propose a *generic transforming method* which transforms an arbitrary GPM to a secure PMTE. Further, we give a formal proof that the PMTE transformed by our method is indistinguishable from the GPM.

### 5.1 Conditional DTEs

Inspired by the way Chatterjee et al.'s PMTEs [10] encoding password character by character or rule by rule, we propose a fundamental concept of PMTE—*conditional distribution transforming encoder (CDTE)*—to encode message rule by rule. A DTE is an encoder transformed from a probability

distribution, while a CDTE is an encoder transformed from a conditional probability distribution. Unlike a DTE, a CDTE needs not only the message  $M$  but also the condition  $X$  to encode  $M$  (denoted as  $\text{encode}(M|X)$ ) by the conditional probability distribution  $P(\cdot|X)$ . It also needs the condition  $X$  to decode the seed  $S$  (denoted as  $\text{decode}(S|X)$ ). In this aspect, for every condition  $X$ , the CDTE ( $\text{encode}(\cdot|X), \text{decode}(\cdot|X)$ ) is a DTE. Interestingly, if the condition  $X$  and the message  $M$  are mutually independent (i.e., the conditional probability distribution  $P(\cdot|X)$  is the same for every condition  $X$ ), a CDTE degenerates into a DTE. Therefore, we state that DTEs can be seen as a special case of CDTEs. Juels and Ristenpart [21] proposed a generic method to transform a distribution to a DTE and named the DTE *IS-DTE*. For the general conditional distribution, we get a DTE **IS-DTE** $_X$  for each condition  $X$  by means of Juels-Ristenpart method and thus we give a general CDTE scheme *IS-CDTE* by the combination  $\{\text{IS-DTE}_X\}_X$ .

In the following, we give the details of our IS-CDTE. Let  $X$  denote the condition,  $\mathcal{X}$  denote the condition space, and  $\mathcal{M}_X = \{M_i\}_i$  denote the message space under the condition  $X$ . The corresponding conditional probability is  $P(M_i|X)$ , and the cumulative distribution function is  $F_i = \sum_{i'=1}^i P(M_{i'}|X)$ . When encoding the message  $M$  under the condition  $X$ , the IS-CDTE randomly generates a real number  $S$  in the interval  $[F_{i-1}, F_i)$  as a seed of  $M$ . When decoding the seed  $S$  under condition  $X$ , the IS-CDTE searches the interval  $[F_{i-1}, F_i)$  containing  $S$  and then outputs the corresponding message  $M_i$ . Encoding or decoding only requires a binary search of the corresponding CDF (cumulative distribution function) table  $\{(M_i, F_i)\}_i$  under the condition. Therefore, the space complexity and the time complexity of the IS-CDTE are  $O(|\mathcal{X}| \cdot |\mathcal{M}|)$  and  $O(\log(|\mathcal{M}|))$ , respectively.

For implementing with encryption, real-number seeds are usually represented as bit strings of length  $l$ , i.e., integers in  $[0, 2^l)$ , where  $l$  is a storage overhead parameter. IS-DTEs use the function  $\text{round}_l(x)$  converting a real-number seed to an integer seed, where  $\text{round}_l(x) = \text{round}(2^l x)$  and  $\text{round}$  represents rounding function. We use the same method for IS-CDTEs. In such case, the integer seed interval of  $M_i$  is  $[\text{round}(2^l F_{i-1}), \text{round}(2^l F_i))$ . Hence, to ensure that each message has at least one integer seed,  $l$  must be greater than or equal to  $-\log_2(\min_i P(M_i|X))$ . The loss of precision by the discretization with  $\text{round}_l$  causes a slight difference between these two conditional distributions  $\text{Pr}_{\text{IS-CDTE}}(M|X) = \text{Pr}[M = M' : S \leftarrow_s S; M' \leftarrow \text{decode}(S|X)]$  and  $P(M|X)$ , where **IS-CDTE** = ( $\text{encode}(\cdot|\cdot), \text{decode}(\cdot|\cdot)$ ). Fortunately, the difference is negligible in  $l$  (see Theorem 4). For convenience, we let  $P^{(d)}$  denote the discretization  $\text{Pr}_{\text{IS-CDTE}}$  of  $P$ .

### 5.2 Probability Model Transforming Encoder

Combining IS-CDTEs for the conditional distributions of generating rules, we present a PMTE for the messages, which we call an *IS-PMTE*. Let  $l$  denote the storage overhead parameter,

then the IS-PMTE encodes the message  $M$  as follows:

1. Parse  $M$  and get all generating sequences  $G^{-1}(M)$ .
2. Calculate the probability  $P^{(d)}(RS)$  for each generating sequence  $RS$  in  $G^{-1}(M)$ , where  $P^{(d)}(r_1 r_2 \dots r_n) = \prod_{i=1}^n P^{(d)}(r_i | r_1 r_2 \dots r_{i-1})$  and  $P^{(d)}(r_i | r_1 r_2 \dots r_{i-1})$  is the discretization of  $P(r_i | r_1 r_2 \dots r_{i-1})$ .
3. Choose a generating sequence  $RS$  in  $G^{-1}(M)$  with the probability  $P^{(d)}(RS|M)$ , where  $P^{(d)}(RS|M) = \frac{P^{(d)}(RS)}{\sum_{RS' \in G^{-1}(M)} P^{(d)}(RS')}$ .
4. Encode each rule  $r_i$  in  $RS = (r_i)_i$  by the IS-CDTE  $\text{encode}(\cdot | r_1 r_2 \dots r_{i-1})$  to a  $l$ -bit string  $S_i$ .
5. Concatenate  $(S_i)_i$ , pad the concatenation to a string  $S$  of length  $ln_{\max}$  with random bits and then output  $S$  as a seed for  $M$ , where  $n_{\max}$  is the maximum length of generating sequences in  $\mathcal{RS}$  (i.e., the depth of the generating graph).

In opposite, the IS-PMTE decodes the seed  $S$  as follows:

1. Split  $S$  into  $n_{\max}$   $l$ -bit strings  $(S_i)_{i=1}^{n_{\max}}$ .
2. Decode  $S_i$  to the rule  $r_i$  by  $\text{decode}(\cdot | r_1 r_2 \dots r_{i-1})$  in turn and ignore the padding bits.
3. Generate the message  $M$  from the generating sequence  $RS = (r_i)_{i=1}^n$  by  $M = G(RS)$ , then output  $M$  as the message of  $S$ .

Note that generating sequences vary in length. Because seeds in  $S$  are of fixed length, padding is necessary for some sequences when encoding. Furthermore, as the sequence space  $\mathcal{RS}$  is prefix-free, padding bits can be ignored unambiguously when decoding. In addition, note that in Step 2) of encoding the probabilities of sequences are calculated as the discretization  $P^{(d)}$  of  $P$ , which is necessary to guarantee the uniformity of seeds (see Theorem 3).

Due to the generality of GPMs, IS-PMTEs not only apply to probability models discussed in this paper, but also apply to general probability models, such as neural networks for passwords [27].

Figure 3 depicts how “password” is encoded by our IS-PMTE for the Chatterjee-PCFG model. First, parse all generating sequences of “password”. Corresponding to Figure 2, “password” has two generating sequences  $\{S \rightarrow \bar{W}, \bar{W} \rightarrow \text{password}\}$  and  $\{S \rightarrow \bar{W}\bar{W}, \bar{W} \rightarrow \text{pass}, \bar{W} \rightarrow \text{word}\}$ . Second, choose a sequence with the probability  $(0.02/0.02002 \approx 0.999$  for the first one and  $0.001$  for the second one). Here we take the second one as an example. Third, encode each generating rule in the sequence by searching the CDF table and translate real-number seeds to bit-string seeds with  $\text{round}_l$ . Note that in the PCFG models, the conditional probabilities of generating rules do not depend on the previous rules and the rules with the same lefthand-side have the same CDF table. Therefore, the same CDF table is searched for generating rules  $\bar{W} \rightarrow \text{pass}$  and  $\bar{W} \rightarrow \text{word}$ . Finally, concatenate seeds of rules, pad the concatenation to a fixed length with random bits and get a seed for “password”.

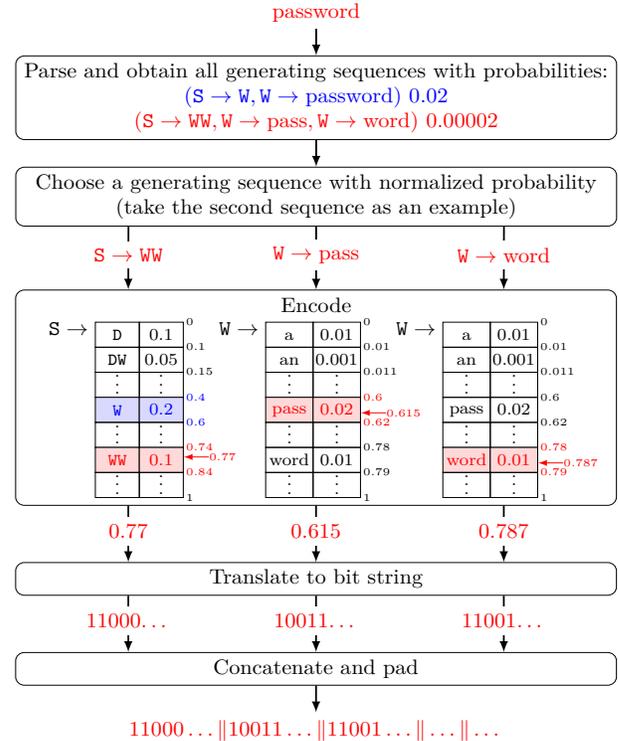

Figure 3: Encode “password” by our IS-PMTE for the Chatterjee-PCFG model

### 5.3 Difference Between IS-PMTEs and Existing PMTEs

It is easy to get IS-PMTEs from existing GPMs of password vaults and genomic data by our proposed generic transforming method. The following are the differences between the IS-PMTEs and the existing PMTEs [10, 14] for password vaults:

1. IS-PMTEs randomly choose a generating sequence, while the existing PMTEs only choose a deterministic generating sequence. This is the key to resist encoding attacks. Note that the random selection may have high time complexity, fortunately there is a method to reduce it. We leave the details in Appendix C.
2. IS-PMTEs use  $\text{round}_l(x)$  to convert a real-number seed to an integer seed, while Chatterjee et al. [10] designed another method to convert a rational-number seed to an integer seed. Unfortunately, Chatterjee et al.’s method cannot be applied to some distributions, e.g., normal distribution. This is because probabilities may be irrational numbers. The method we use (proposed by Juels and Ristenpart [21]) is applicable to arbitrary distributions.

In addition, IS-PMTEs have the same form as the existing PMTEs for password vaults, which is *encode-then-concatenate*. At the same time, the existing PMTEs [18] for genomic data use another *shrink-then-encode* form. When

encoding a string, these genomic data PMTEs shrink the seed interval for each character in the string and further pick a random seed in the final seed interval as the seed for the string. Unfortunately, each interval-shrinking needs to complete large integer arithmetic of length  $ln$  to calculate the interval boundary, where  $l$  is the storage overhead parameter, and  $n$  is the length of the string. This arithmetic costs  $\Omega(ln)$  time for each character and  $\Omega(ln^2)$  time for the string. In contrast, our IS-PMTEs only need to do integer arithmetic of length  $l$  for each character with lower time complexity  $\Theta(ln)$  for a string.

## 5.4 Security of IS-PMTEs

The weak and strong encoding attacks have more generic forms for the PMTEs such as IS-PMTEs who may randomly choose a generating path when encoding. If the PMTE chooses a deterministic generating path when encoding, these generic forms will degenerate to the given forms in Section 4.5. For the weak encoding attack, the more generic form of feature EC is

$$S \in \text{encode}(\text{decode}(S)),$$

where  $\text{encode}(M)$  represents all encoded seeds from  $M$ . If the seed  $S$  does not have feature EC, then  $S$  can be decoded to the message  $M = \text{decode}(S)$  but cannot be encoded from the message  $M$ . Therefore,  $S$  is a decoy seed. In order to resist weak encoding attack, it is necessary to ensure that  $\text{encode}(M) = \text{decode}^{-1}(M)$  for every message  $M \in \mathcal{M}$ , where  $\text{decode}^{-1}(M)$  represents all seeds which can be decoded into  $M$ . In PMTEs with deterministic encoding paths, the generating paths for all seeds in  $\text{encode}(M)$  are the same one. In this case, the weak encoding attack degenerates to the given form in Section 4.5.

For the strong encoding attack, the more generic form of the weight function is

$$\text{Pr}_{\text{encode}}(S|\text{decode}(S)),$$

where  $\text{Pr}_{\text{encode}}(S|M)$  represents the probability that  $M$  is encoded as  $S$  under the condition of message  $M$ . We denote it as  $p_{\text{GSEA}}(S)$ . In order to resist strong encoding attack, it is necessary to ensure that  $\text{Pr}_{\text{encode}}(S|M)$  are equal for every  $S \in \text{decode}^{-1}(S)$ , i.e., all valid seeds are uniformly chosen when encoding. We call this property *seed uniformity*. Further, if a DTE has this property, attackers cannot get any useful information except the message from a seed (see Theorem 2). This well explains why our IS-PMTEs choose a generating sequence  $RS$  in  $G^{-1}(M)$  with the probability  $P^{(d)}(RS|M)$  when encoding—it precisely guarantees that seeds are uniform (see Theorem 3). In addition, for PMTEs with deterministic encoding path, the strong encoding attack degenerates to the form in Section 4.5, because  $p_{\text{GSEA}} \propto p_{\text{SEA}}$ . Let  $M$  denote the message,  $RS = (r_i)_i$

denote the deterministic generating sequence of  $M$ ,  $S$  denote the seed of  $M$ , then we have: 1) if  $S \in \text{encode}(M)$ ,  $p_{\text{GSEA}}(S) = \frac{1}{|\text{encode}(M)|} = \frac{1}{|\text{encode}(RS)|} = \frac{1}{|S|P(RS)} = \frac{1}{|S|} p_{\text{SEA}}(S)$ ; 2) otherwise,  $p_{\text{GSEA}}(S) = 0 = p_{\text{SEA}}(S)$ .

In the following, we prove the security of IS-PMTEs, i.e., decoy seeds/messages are indistinguishable from real ones by any adversary. Let  $\mathcal{M}$  denote the message space,  $\text{Pr}_{\text{real}}$  denote the probability density function of real messages,  $\mathcal{S}$  denote the seed space, and **DTE** = (encode, decode) denote the DTE. Juels and Ristenpart [21] used the advantage of an attacker  $\mathcal{A}$  who distinguishes between the real and decoy message-seed pairs to evaluate the security of a DTE, where the advantage is  $\text{Adv}_{\text{DTE,real}}^{\text{dte}}(\mathcal{A}) = |\text{Pr}[\mathcal{A}(S, M) = 1 : M \leftarrow_{\text{Pr}_{\text{real}}} \mathcal{M}; S \leftarrow_s \text{encode}(M)] - \text{Pr}[\mathcal{A}(S, M) = 1 : S \leftarrow_s \mathcal{S}; M \leftarrow \text{decode}(S)]|$ . This advantage can be simplified, if **DTE** has some properties. *Correctness* is the most basic property of a DTE, which means seeds encoded from the message  $M$  can be decoded to  $M$  correctly for every message  $M$ , i.e.,  $\text{encode}(M) \subseteq \text{decode}^{-1}(M)$  for every  $M \in \mathcal{M}$ . If **DTE** is correct, attackers can get the message  $M$  from the seed  $S$ . Therefore,  $\text{Adv}_{\text{DTE,real}}^{\text{dte}}(\mathcal{A})$  can be simplified to the advantage of attacker  $\mathcal{B}$ , who distinguishes between the real and decoy seeds, where the advantage is  $\text{Adv}_{\text{DTE,real}}^{\text{dte}, S}(\mathcal{B}) = |\text{Pr}[\mathcal{B}(S) = 1 : M \leftarrow_{\text{Pr}_{\text{real}}} \mathcal{M}; S \leftarrow_s \text{encode}(M)] - \text{Pr}[\mathcal{B}(S) = 1 : S \leftarrow_s \mathcal{S}]|$  (see Theorem 1). Moreover, if **DTE** is correct and seed-uniform,  $\text{Adv}_{\text{DTE,real}}^{\text{dte}}(\mathcal{A})$  can be further simplified to the advantage of an attacker  $\mathcal{B}$ , who distinguishes between the real and decoy messages, where the advantage is  $\text{Adv}_{\text{DTE,real}}^{\text{dte}, M}(\mathcal{B}) = |\text{Pr}[\mathcal{B}(M) = 1 : M \leftarrow_{\text{Pr}_{\text{real}}} \mathcal{M}] - \text{Pr}[\mathcal{B}(M) = 1 : S \leftarrow_s \mathcal{S}; M \leftarrow \text{decode}(S)]|$  (see Theorem 2). The proof details are given in Appendix A.

**Theorem 1.** *If DTE is correct, then for any attacker  $\mathcal{A}$ , who distinguishes between the real and decoy message-seed pairs, there exists an attacker  $\mathcal{B}$  (as follows), who distinguishes between the real and decoy seeds with  $\text{Adv}_{\text{DTE,real}}^{\text{dte}, S}(\mathcal{B}) = \text{Adv}_{\text{DTE,real}}^{\text{dte}}(\mathcal{A})$ .*

```

 $\mathcal{B}(S)$ 
-----
 $M \leftarrow \text{decode}(S)$ 
return  $\mathcal{A}(S, M)$ 
```

**Theorem 2.** *If DTE is correct and seed-uniform, for any attacker  $\mathcal{A}$ , who distinguishes between the real and decoy seeds, there exists an attacker  $\mathcal{B}$  (as follows), who distinguishes between the real and decoy messages with  $\text{Adv}_{\text{DTE,real}}^{\text{dte}, M}(\mathcal{B}) = \text{Adv}_{\text{DTE,real}}^{\text{dte}, S}(\mathcal{A})$ .*

```

 $\mathcal{B}(M)$ 
-----
 $S \leftarrow_s \text{encode}(M)$ 
return  $\mathcal{A}(S)$ 
```

Our proposed IS-PMTEs have the above two properties, thus we neglect the difference between these three types of attackers. Let **GPM** denote the GPM and **IS-PMTE** denote the IS-PMTE of **GPM**. The message generated by **IS-PMTE** (decoding random seed) is indistinguishable from the message generated by **GPM**. Formally, the advantage  $\max_{\mathcal{A}} \text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A})$  is negligible in  $l$  (Theorem 5), where  $\text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) = |\Pr[\mathcal{A}(M) = 1 : M \leftarrow \text{Pr}_{\text{IS-PMTE}} \mathcal{M}] - \Pr[\mathcal{A}(M) = 1 : M \leftarrow \text{Pr}_{\text{GPM}} \mathcal{M}]|$ ,  $\text{Pr}_{\text{GPM}}$  is the probability density function  $P$  of **GPM** and  $\text{Pr}_{\text{IS-PMTE}}(M) = P^{(d)}(M) = \Pr[M = M' : S \leftarrow_{\mathcal{S}} \mathcal{S}; M' \leftarrow \text{decode}(S)]$ . This means that we design a secure PMTE for a GPM. In addition,  $\text{Adv}_{\text{IS-PMTE}, \text{real}}^{\text{dte}}(\mathcal{A}) \leq \text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) + \text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A})$ . If **GPM** is an accurate probability model for real messages, i.e.,  $\text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A})$  is negligible, then  $\text{Adv}_{\text{IS-PMTE}, \text{real}}^{\text{dte}}$  is negligible, i.e., **IS-PMTE** is secure for the real message distribution.

**Theorem 3.** *IS-PMTE is correct and seed-uniform.*

**Theorem 4.** *IS-CDTE is transformed from the conditional probability  $\text{Pr}_{\text{real}}(M|X)$ , the seed length is  $l$  and  $m = |\mathcal{M}|$ . Then for any condition  $X$  and any distinguishing attacker  $\mathcal{A}$ ,  $\text{Adv}_{\text{IS-CDTE}_X, \text{real}_X}^{\text{dte}}(\mathcal{A}) \leq \frac{m}{2^l}$ , where  $\text{Pr}_{\text{IS-CDTE}_X}(M) = \text{Pr}_{\text{IS-CDTE}}(M|X)$  and  $\text{Pr}_{\text{real}_X}(M) = \text{Pr}_{\text{real}}(M|X)$ .*

**Theorem 5.** *Assume the maximum length of generating paths is  $n$  and each vertex has at most  $m$  children in the generating graph of **GPM**, then  $\text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) \leq \frac{nm}{2^l}$  for any attacker  $\mathcal{A}$ . Further,  $\text{Adv}_{\text{IS-PMTE}, \text{real}}^{\text{dte}}(\mathcal{A}) \leq \text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A}) + \text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) \leq \text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A}) + \frac{nm}{2^l}$ .*

In summary, we propose a generic method for transforming a GPM to a PMTE. The PMTE is secure for the GPM, which means the PMTE is able to resist encoding attacks. To resist distribution difference attacks, an appropriate GPM is needed, for example, statistical language models for natural language texts. Designing such a GPM, however, needs professional knowledge of the real messages, we leave it to experts in related fields.

## 6 Experimental Results

In this section, we evaluate the security of the existing PMTEs on real datasets under the attacks we propose. In the literature, none of the PMTEs for password vaults can resist encoding attacks as well as none of the PMTEs for genomic data can resist the PCA+SVM attack. But here, we show that our proposed IS-PMTEs for existing password vault models [10, 14] achieve the expected security against encoding attacks as stated in Section 5.4.

### 6.1 Security Metrics

The ranks of real messages in the order sorted by attackers reflect the security of DTEs. If a DTE is perfectly secure, the real message ranks are evenly distributed under any attack. Accordingly, we use the real message rank distribution as a security metric like [10, 14].

More specifically, we calculate the rank of the message  $M$  as follows: 1) generate  $N$  decoy messages  $\{M_i\}_{i=1}^N$  (by decoding random seeds); 2) calculate the proportion  $\hat{r}^-(M)$  (resp.  $\hat{r}^+(M)$ ) of decoy messages with greater (resp. greater or equal) weight than  $M$  in  $\{M_i\}_{i=1}^N$ ; 3) pick a random real number in  $[\hat{r}^-(M), \hat{r}^+(M)]$  as the rank  $\hat{r}(M)$ . Same as [10, 14], we set  $N = 999$ . But different from [10, 14] using average rank  $\bar{r}$  (of real messages) and accuracy  $\alpha$  (of distinguishing a real message from a decoy one), we use rank cumulative distribution functions (RCDFs)  $F(x)$  of real messages to represent attack results. This presentation is more comprehensive than  $\bar{r}$  and  $\alpha$ . For example,  $F^{-1}(1)$  indicates the max rank of real messages, and  $F(0)$  indicates the proportion of real messages of rank 0 (i.e., ranking the first). In other words, the attacker excludes  $1 - F^{-1}(1)$  proportion decoy messages for all real messages and excludes all decoy messages for  $F(0)$  proportion of real messages. In addition,  $\bar{r}$  and  $\alpha$  can be calculated from  $F(x)$  as:

$$\bar{r} = 1 - \int_0^1 F(x) dx, \quad (3)$$

$$\alpha = 1 - \bar{r}. \quad (4)$$

### 6.2 Datasets

For a fair comparison, we use the same datasets as the previous literature [10, 14, 18]: a password dataset RockYou and a password vault dataset Pastebin for password vault schemes [10, 14], real genomic datasets from HapMap [1] for the genomic data protection scheme [18]. RockYou is a password dataset widely used in password security research, some notable ones like [4, 25, 27, 41], which includes 32.6 million passwords. To the best of our knowledge, Pastebin is the only publicly available dataset for real password vaults so far, and it contains 276 real vaults. Because RockYou and Pastebin are already public and no further harm will be caused, we believe *it is ethical to use them for experiments*. Multiple types of genomic datasets from HapMap are used, including a diploid genotype dataset, a haploid genotype dataset, allele frequency (AF) and linkage disequilibrium (LD) datasets, and recombination rates. The diploid genotype dataset contains 165 persons' SNV sequences. For other details of the above datasets, please refer to [10, 18].

### 6.3 Evaluating Password Vault PMTEs

As shown in Figure 4a and Table 1, in Chatterjee et al.'s PMTE [10], the average ranks  $\bar{r}$  of real vaults under the feature

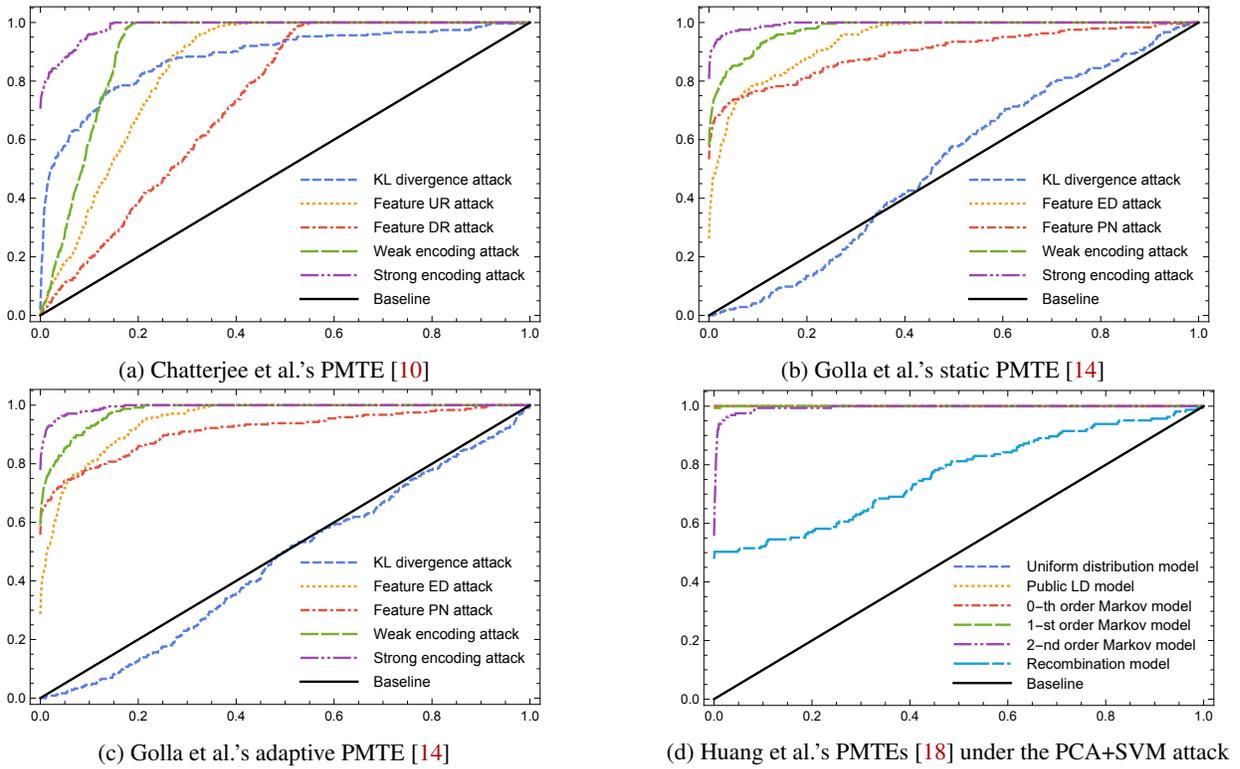

Figure 4: Rank cumulative distribution functions (RCDFs)  $F(x)$  of the existing PMTEs

Table 1: The existing PMTEs under encoding attacks or distribution difference attacks

Application	PMTE/Probability model	Attack	$\bar{r}$	$\alpha$	$F(0)$	$F^{-1}(1)$
Password vault	Chatterjee et al.'s PMTE [10]	KL divergence attack	11.83%	88.17%	1.82%	98.80%
		Feature UR attack	15.14%	84.86%	0.36%	42.24%
		Feature DR attack	26.96%	73.04%	0.00%	54.95%
		Weak encoding attack	8.74%	91.26%	0.36%	19.42%
		Strong encoding attack	1.44%	98.56%	70.55%	15.02%
	Golla et al.'s static PMTE [14]	KL divergence attack	48.26%	51.74%	0.00%	98.70%
		Feature ED attack	6.04%	93.96%	26.23%	41.14%
		Feature PN attack	10.03%	89.97%	53.28%	99.20%
		Weak encoding attack	2.25%	97.75%	58.20%	26.03%
		Strong encoding attack	0.48%	99.52%	80.74%	16.12%
	Golla et al.'s adaptive PMTE [14]	KL divergence attack	53.58%	46.42%	0.00%	100.00%
		Feature ED attack	5.18%	94.82%	28.69%	35.44%
		Feature PN attack	8.60%	91.40%	55.74%	91.79%
		Weak encoding attack	2.01%	97.99%	59.02%	21.22%
	Genomic data protection [18]	Uniform distribution model Public LD model 0-th order Markov model 1-st order Markov model 2-nd order Markov model Recombination model	PCA+SVM attack	0.00%	100.00%	100.00%
0.00%			100.00%	99.39%	0.20%	
0.00%			100.00%	100.00%	0.00%	
0.01%			99.99%	99.39%	1.30%	
0.53%			99.47%	55.76%	23.92%	
23.46%			76.54%	47.88%	99.90%	

UR attack and the feature DR attack are 15.14% and 26.96% respectively, the accuracies  $\alpha$  are 84.86% and 73.04%. Moreover, under the feature UR attack, the max rank (i.e.,  $F^{-1}(1)$ ) is 42.24%; under the feature DR attack, this number is 54.95%. This means the feature UR attack can exclude at least 57.76% (i.e.,  $1 - F^{-1}(1)$ ) decoy vaults for every real vault and the feature DR attack can exclude at least 45.05%. Figures 4b, 4c and Table 1 show the performance of Golla et al.'s static PMTE and adaptive PMTE [14], the average ranks under the feature ED attack are 6.04% and 5.18%, while under the feature PN attack are 10.03% and 8.60%. Further, in Golla et al.'s static PMTE, the feature ED attack excludes all decoy vaults for 26.23% (i.e.,  $F(0)$ ) real vaults and meanwhile, it excludes at least 58.86% decoy vaults for each real vault.  $F(0)$  and  $1 - F^{-1}(1)$  under the feature PN attack are 53.28% and 0.8% respectively. In Golla et al.'s adaptive PMTE, these numbers are 28.69%, 64.56% under the feature ED attack, and 55.74%, 8.21% under the feature PN attack.

Compared to the above feature attacks, the weak encoding attack has a significant improvement, where the average ranks  $\bar{r}$  of Chatterjee et al.'s PMTE [10] and Golla et al.'s (static and adaptive) PMTEs [14] are 8.74%, 2.25%, and 2.01% respectively. The excluded proportions  $1 - F^{-1}(1)$  are 80.58%, 78.78%, and 73.97%. The strong encoding attack has a further significant improvement compared to the weak encoding attack. The average ranks  $\bar{r}$  of these three PMTEs are 1.44%, 0.48%, and 0.57% respectively, which decrease by 84.99%, 83.88%, and 82.78%. Excluded proportions  $1 - F^{-1}(1)$  are 84.99%, 83.88%, and 82.78% respectively, which also slightly increase by 5.47%, 13.40%, and 5.08%.

Because the KL divergence attack performs better than SVM attacks on all existing PMTEs for password vaults [14], we use it for comparison. As shown in Figures 4a, 4b, 4c and Table 1, the KL divergence attack performs well on the Chatterjee et al.'s PMTE [10], achieving 88.17% accuracy, but it performs almost the same as the randomly guessing attack on Golla et al.'s PMTEs [14], only achieving 46.42%–51.74% accuracy. Further, the RCDFs on Golla et al.'s PMTEs under the KL divergence attack are close to the baseline (the RCDFs under the randomly guessing attack).

For all the existing PMTEs, the curves of RCDFs under the strong encoding attack are all above those under the KL divergence attack. This means that every metric in Table 1 under the strong encoding attack is better than that of the KL divergence attack. More specifically, the average ranks of these three PMTEs under the KL divergence attack are 11.83%, 48.26%, and 53.58%, the accuracies  $\alpha$  are 88.17%, 51.74%, and 46.42%. In contrast, the accuracies of the strong encoding attack are 98.56%, 99.52%, and 99.43%, which are 11.78%, 92.35%, and 114.20% higher than those of the KL divergence attack.

In addition, metric values in Table 1 under the KL divergence attack are different from those given in [14], owing to a couple of reasons: 1) for Chatterjee et al.'s PMTE [10], the

version of NoCrack used by Golla et al. [14] cannot decode some seeds correctly, therefore have to remedy and reimplement it in the experiments; 2) for Golla et al.'s PMTEs [14], we set the pseudocount of Markov for Laplace smoothing as 1, because under this setting the PMTEs achieve the best security (see Appendix B).

*To conclude, the Chatterjee et al.'s PMTE [10] and Golla et al.'s PMTEs [14] are all vulnerable to encoding attacks; meanwhile, Golla et al.'s PMTEs [14] are perfectly secure against the best-reported distribution difference attack.*

## 6.4 Evaluating Genomic Data PMTEs

Different from encoding attacks, the PCA+SVM attack is a distribution difference attack which needs a training set consisting of real and decoy data. We randomly pick 83 individual's SNV sequences in the real dataset<sup>1</sup>, generate a decoy sequence for each real sequence, and use them to train our PCA and SVM in the PCA+SVM attack. Then we use remaining 82 individual's sequences in the real dataset and generate  $N$  ( $= 999$ ) decoy sequences for each of them as the test set to compute the RCDF  $F(x)$  with the weight function  $p_{\text{PCA+SVM}}$ . To avoid the impact of randomness on results, we repeat the attack 10 times with different random divisions of the real SNV sequences and newly generated decoy sequences for training/testing, and calculate the average of  $F(x)$ .

As shown in Figure 4d and Table 1, the PCA+SVM attack achieves more than 99.47% accuracy for all probability models except the recombination model. Even for the recombination model, this attack achieves 76.54% accuracy. This is consistent with Huang et al.'s result [18] that the recombination model performs best. However, it still falls short of the desired security, as our attack excludes all decoy data for 47.88% persons.

*To summarize, Huang et al.'s PMTEs for all six models [18] resist encoding attacks but none of them can resist distribution difference attacks. Even the recombination model cannot be rejected at the significance level of 0.2. This means the chi-square goodness-of-fit test is unable to correctly evaluate the security of probability models for generating decoy data.*

## 6.5 Evaluating IS-PMTEs

As stated in Section 5.4, IS-PMTEs resist any encoding attack in theory, we confirm that in practice with IS-PMTEs transformed from existing password vault models. Formally, Theorem 5 demonstrates that the IS-PMTE of an accurate GPM resists arbitrary attacks including encoding attacks. In fact, the IS-PMTE for an arbitrary GPM resists the weak encoding attack. The weight function of the weak encoding attack is constant because every generating path has a chance to be chosen when encoding. This means the weak encoding

<sup>1</sup>We use the small dataset published with the code of GenoGuard on GitHub, which includes 165 persons' SNV sequences of length 1000.

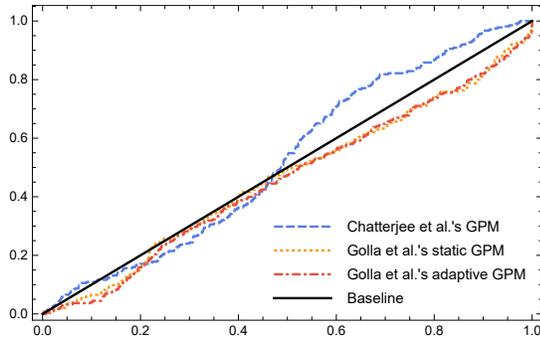

Figure 5: RCDFs of our proposed IS-PMTEs under the strong encoding attack. Note that RCDFs of IS-PMTEs under the weak encoding attack are all equal to the baseline and these under the KL divergence attack are the same as those of the corresponding existing PMTEs in Figure 4.

Table 2: Our IS-PMTEs under the strong encoding attack

Probability model	$\bar{r}$	$\alpha$	$F(0)$	$F^{-1}(1)$
Chatterjee et al.'s GPM	47.44%	52.56%	0.00%	97.60%
Golla et al.'s static GPM	53.62%	46.38%	0.41%	100.00%
Golla et al.'s adaptive GPM	54.25%	45.75%	0.00%	100.00%

Note: RCDFs of IS-PMTEs under the KL divergence attack are the same as those of existing PMTEs, therefore these metrics under this attack are the same as those in Table 1. RCDFs of IS-PMTEs under the weak encoding attack are the same as those under the randomly guessing attack, therefore these metrics are trivial (50% for  $\bar{r}$ , 50% for  $\alpha$ , 0% for  $F(0)$  and 100% for  $F^{-1}(1)$ ).

attack degenerates to the randomly guessing attack (with a constant weight function). In contrast, the weight function  $p_{\text{GSEA}}$  of the strong encoding attack is inconstant, therefore, RCDFs under the strong encoding attack depend on GPMs.

To evaluate the security of IS-PMTEs for existing vault models under the strong encoding attack, it is necessary to implement the random selection method for generating paths with the parsing function  $G^{-1}$ . However, in existing GPMs for password vaults, there are numerous generating paths for messages (as discussed in Section 4.4), therefore, it has high time complexity to parse all generating paths (see the discussion in Appendix C). For example, in Chatterjee et al.'s GPM [10], a vault  $V = (123456, \text{password})$  can be generated by any sub-grammar containing  $SG = \{S \rightarrow D, S \rightarrow W, D \rightarrow 123456, W \rightarrow \text{password}\}$ . It has high time complexity to enumerate all these sub-grammars and calculate the probabilities of generating  $V$  by them. Instead, we carry out simulation experiments under the degenerated form of the strong encoding attack with the weight function  $p_{\text{SEA}}$ . Because all generating paths are encoding paths, there is no seed  $S$  with  $p_{\text{SEA}}(S) = 0$ , i.e.,  $p_{\text{SEA}}(S) = \frac{1}{P(RS)}$  for every seed  $S$ . Accordingly, we use this weight function to sort the seeds in simulation experiments.

Compared to the existing PMTEs, IS-PMTEs transformed

from the existing GPMs have a significant improvement on security. As shown in Figure 5 and Table 2, all RCDFs of the IS-PMTEs under the strong encoding attack are approaching to the baseline, i.e., the RCDF under the randomly guessing attack. Average ranks  $\bar{r}$  are all near to the expected value of 50%, which are 47.44%, 53.62%, and 54.25%, respectively. Meanwhile, the accuracies are 52.56%, 46.38%, and 45.75%, respectively. Recall that accuracies of existing PMTEs under the strong encoding attacks are 98.56%, 99.52%, and 99.42%, respectively.

Note that our IS-PMTEs have the same decoy message distributions with the corresponding GPMs. This means our IS-PMTEs achieve the same security as the existing PMTEs for the same GPMs under distribution difference attacks. Due to the good performance of Golla et al.'s PMTEs [14] against the best-reported distribution difference attack, our IS-PMTEs for Golla et al.'s GPMs achieve the expected security under both encoding attacks and distribution difference attacks.

## 7 Conclusion

With encoding attacks and distribution difference attacks, we evaluate three typical existing PMTEs, including two for password vaults and one for genomic data. Using a PCA and an SVM, a distribution difference attack can distinguish real and decoy genomic data with high accuracy. Different from distribution difference attacks exploiting the difference between real and decoy message distributions, encoding attacks are a new type of attack we propose, which exploit the difference between probability models and PMTEs. Encoding attacks can exclude most decoy password vaults/seeds, without any knowledge of real vault distributions.

Further, we introduce a generic conceptual probability model—*generative probability model (GPM)*—to formalize probability models. With the formalization by GPMs, the principle of encoding attacks is uncovered. Based on this principle, we propose two generic and more efficient encoding attacks. In addition, we propose a generic method for transforming an arbitrary GPM to a PMTE. We prove that PMTEs transformed by this method are information-theoretically indistinguishable from the corresponding GPMs, thus can resist encoding attacks. Using this transforming method, we simplify the task of designing a secure PMTE to the task of designing an accurate GPM. Designing such a GPM needs professional knowledge of real messages, we leave it to experts in related fields for future work.

## Acknowledgment

The authors are grateful to the anonymous reviewers and the shepherd, Prof. Vincent Bindschaedler, for their invaluable comments that highly improve the completeness of the paper. We also give our special thanks to Prof. Kaitai Liang and

Qianchen Gu for their insightful suggestions and invaluable help. This research was supported by the National Key R&D Program of China under Grant No.2017YFB1200700, and by the National Natural Science Foundation of China (NSFC) under Grant No.61672059.

&= \text{Adv}_{\text{DTE,real}}^{\text{dte},S}(\mathcal{A}). \quad \square
\end{aligned}$$

*Proof of Theorem 3.* **IS-DTE** is correct, therefore, the combination **IS-CDTE** =  $\{\text{IS-DTE}_X\}_{X \in \mathcal{X}}$  is correct. In addition, because  $\mathcal{RS}$  is prefix-free, the padding bits can be ignored unambiguously when decoding. Thus, **IS-PMTE** is correct.

Let  $S$  be a seed of the message  $M$ ,  $RS = (r_i)_{i=1}^n$  be the generating sequence of  $S$ , then the length of padding bits is  $ln_{\max} - ln$  and

$$\Pr_{\text{encode}}(S|M)$$

$$\begin{aligned}
&= \frac{P^{(d)}(RS)}{P^{(d)}(M)} \cdot \frac{1}{2^{ln_{\max} - ln}} \prod_{i=1}^n \frac{1}{|\text{encode}(r_i|r_1r_2\dots r_{i-1})|} \\
&= \frac{P^{(d)}(RS)}{P^{(d)}(M)} \cdot \frac{1}{2^{ln_{\max} - ln}} \prod_{i=1}^n \frac{1}{2^l P^{(d)}(r_i|r_1r_2\dots r_{i-1})} \\
&= \frac{P^{(d)}(RS)}{P^{(d)}(M)} \cdot \frac{1}{2^{ln_{\max}}} \prod_{i=1}^n \frac{1}{P^{(d)}(r_i|r_1r_2\dots r_{i-1})} \\
&= \frac{P^{(d)}(RS)}{P^{(d)}(M)} \cdot \frac{1}{2^{ln_{\max} P^{(d)}(RS)}} \\
&= \frac{1}{2^{ln_{\max} P^{(d)}(M)}}.
\end{aligned}$$

Therefore, **IS-PMTE** is seed-uniform.  $\square$

*Proof of Theorem 4.* According to the definition of **IS-CDTE<sub>X</sub>**,  $\Pr_{\text{IS-CDTE}_X}(M_i) = \Pr_{\text{real}_X}^{(d)}(M_i) = \text{round}_l(F_i) - \text{round}_l(F_{i-1})$  and  $\Pr_{\text{real}_X}(M_i) = F_i - F_{i-1}$ , so that  $|\Pr_{\text{IS-CDTE}_X}(M_i) - \Pr_{\text{real}_X}(M_i)| \leq \frac{1}{2^l}$ . To summarize,  $\text{Adv}_{\text{IS-CDTE}_X, \text{real}_X}^{\text{dte}}(\mathcal{A}) \leq \sum_{M \in \mathcal{M}} |\Pr_{\text{IS-CDTE}_X}(M) - \Pr_{\text{real}_X}(M)| \leq \frac{m}{2^l}$ .  $\square$

*Proof of Theorem 5.*  $\Pr_{\text{IS-PMTE}}$  is the discretization of  $\Pr_{\text{GPM}}$ . Similarly, discretizing the first  $i$  levels of the generating graph (and keeping the rest levels unchanged) gets a GPM, denoted as  $\text{GPM}_i$ . Therefore,  $\Pr_{\text{GPM}_i}(r_j|r_1r_2\dots r_{j-1}) = \Pr_{\text{GPM}_{i-1}}(r_j|r_1r_2\dots r_{j-1})$  for  $j \neq i$  and by Theorem 4  $|\Pr_{\text{GPM}_i}(r_i|r_1r_2\dots r_{i-1}) - \Pr_{\text{GPM}_{i-1}}(r_i|r_1r_2\dots r_{i-1})| \leq \frac{1}{2^l}$ , then

$$\begin{aligned}
&\text{Adv}_{\text{GPM}_i, \text{GPM}_{i-1}}^{\text{gpm}}(\mathcal{A}) \\
&\leq \sum_{M \in \mathcal{M}} |\Pr_{\text{GPM}_i}(M) - \Pr_{\text{GPM}_{i-1}}(M)| \\
&\leq \sum_{RS \in \mathcal{R}_S} |\Pr_{\text{GPM}_i}(RS) - \Pr_{\text{GPM}_{i-1}}(RS)| \\
&= \sum_{(r_j)_{j \in \mathcal{R}_S}} \left| \prod_j \Pr_{\text{GPM}_i}(r_j|r_1r_2\dots r_{j-1}) \right. \\
&\quad \left. - \prod_j \Pr_{\text{GPM}_{i-1}}(r_j|r_1r_2\dots r_{j-1}) \right| \\
&= \sum_{(r_j)_{j \in \mathcal{R}_S}} \prod_{j \neq i} \Pr_{\text{GPM}_i}(r_j|r_1r_2\dots r_{j-1}) \times \\
&\quad |\Pr_{\text{GPM}_i}(r_i|r_1r_2\dots r_{i-1}) - \Pr_{\text{GPM}_{i-1}}(r_i|r_1r_2\dots r_{i-1})| \\
&\leq \sum_{(r_j)_{j \in \mathcal{R}_S}} \prod_{j \neq i} \Pr_{\text{GPM}_i}(r_j|r_1r_2\dots r_{j-1}) \frac{1}{2^l} \\
&= \frac{m}{2^l}.
\end{aligned}$$

Because  $\Pr_{\text{GPM}_0} = \Pr_{\text{GPM}}$  and  $\Pr_{\text{GPM}_n} = \Pr_{\text{IS-PMTE}}$ ,  $\text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) \leq \sum_{i=1}^n \text{Adv}_{\text{GPM}_i, \text{GPM}_{i-1}}^{\text{gpm}}(\mathcal{A}) \leq \frac{nm}{2^l}$ . Moreover,  $\text{Adv}_{\text{IS-PMTE}, \text{real}}^{\text{dte}}(\mathcal{A}) \leq \text{Adv}_{\text{IS-PMTE}, \text{GPM}}^{\text{gpm}}(\mathcal{A}) + \text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A}) \leq \text{Adv}_{\text{GPM}, \text{real}}^{\text{gpm}}(\mathcal{A}) + \frac{nm}{2^l}$ .  $\square$

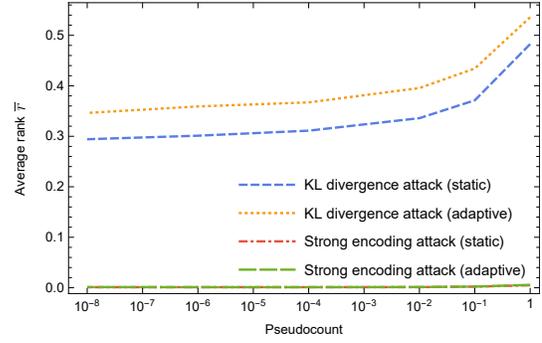

Figure 6: Average rank vs. pseudocount for Golla et al.'s PMTEs [14]

## B The Security of Golla et al.'s PMTEs [14] with Different Pseudocounts

We find out that pseudocounts (smoothing parameter) of Markov models with Laplace smoothing in Golla et al.'s PMTEs [14] have a significant influence on the security of PMTEs. As shown in Figure 6 and Table 3, the average rank  $\bar{r}$  increases as pseudocount increases under both the KL divergence attack and the strong encoding attacks, and meanwhile, the accuracy  $\alpha$  decreases. This means that Golla et al.'s PMTEs [14] achieve the best security when pseudocount is 1. Other metrics in Table 3 also support this conclusion.

Further, when pseudocount is 1,  $\alpha$  of the KL divergence attacks are 51.74% and 46.42% on Golla et al.'s static and adaptive PMTEs, respectively. This means Golla et al.'s PMTEs/GPMs almost achieve the expected security ( $\alpha = 50\%$ ) under the best-reported distribution difference attacks.

## C The Complexity of IS-PMTEs and Optimization for Encoding

The complexity of an IS-PMTE is of the same order as that of the corresponding GPM. The IS-PMTE stores the CDF table as well as the GPM stores the PDF (probability density function) table. These two tables are of the same size, which means the PMTE and the GPM have the same order of space complexity. When encoding a message, the IS-PMTE needs to obtain all generating sequences for the message and calculate the probability of each sequence, which also needs to be done when the GPM calculates the (total) probability of the message. Moreover, encoding/decoding a sequence needs to do binary search on CDF tables, and meanwhile, calculating the probability of the sequence needs to do binary search on PDF tables. Therefore, the IS-PMTE and the GPM have the same order of time complexity (for encoding messages and calculating message probabilities, respectively).

However, it suffers from high time complexity to obtain all generating paths for some GPMs with great ambiguity. As

Table 3: Golla et al.’s PMTEs [14] with different pseudocounts

Pseudo-count	Attack	Golla et al.’s static PMTE [14]				Golla et al.’s adaptive PMTE [14]			
		$\bar{r}$	$\alpha$	$F(0)$	$F^{-1}(1)$	$\bar{r}$	$\alpha$	$F(0)$	$F^{-1}(1)$

$10^{-8}$		0.11%	99.89%	91.80%	8.61%	0.13%	99.87%	92.62%	9.51%

discussed in Section 4.4, in Chatterjee et al.’s GPM [10], a vault can be generated by numerous sub-grammars in Chatterjee et al.’s GPMs. In Golla et al.’s [14] GPMs, a vault can be generated by different base passwords, different cardinalities of subsets and different modified characters. Fortunately, some generating paths can be pruned to reduce the time complexity of encoding. In some models, the dependency of some rules is ignored (by assuming the rules are independent). This triggers some unnecessary paths which can be pruned. For example, in Golla et al.’s GPMs [14], the modified character  $b_i$  of passwords in  $V_i$  ( $1 \leq i \leq 4$ ) and the corresponding character  $a_i$  of the base password are assumed to be independent. In other words, the character of the base password can be modified to itself, i.e.,  $a_i = b_i$ . This yields significant ambiguity. By prohibiting this, we can prune the branch of the original character  $a_i$  when generating the modified character  $b_i$ . More specifically, the steps of the pruned encoding are as follows: 1) copy a CDF table and delete  $a_i$  in the new table; 2) renormalize remaining characters; 3) encode  $b_i$  through the renormalized CDF table; 4) abandon the copied CDF table (use the original table for encoding other characters). From the view of the generating graph, the branch of  $a_i$  on the node of generating  $b_i$  are pruned, resulting in a decrease of time complexity. Besides, the following branches can also be pruned: 1) the character of passwords in  $V_5$  which is the same as the corresponding character of the base password; 2) the cardinality of  $V_i$  which is larger than the number of rest passwords. By pruning unnecessary branches on some nodes in the generating graph, we greatly reduce the ambiguity of Golla et al.’s GPMs [14]. For the vaults  $V$ , there are only  $n'$  generating paths left, where  $n'$  is the number of unique passwords in  $V$ . Each path corresponds to a different password for generating the vault as the base password.

In Chatterjee et al.’s GPM [10], some unnecessary branches can also be pruned efficiently, e.g., the branches of duplicate rules. However, the branches of unused rules are difficult to be pruned. For example, a vault  $V$  of size 2 is generated

by the sub-grammar  $SG = \{S \rightarrow D, S \rightarrow W, D \rightarrow 123456, W \rightarrow \text{password}\}$ . If the first password in  $V$  is “123456”, then the second one must be “password” to avoid unused rules, i.e., the branch of the rule  $S \rightarrow D$  should be pruned when generating the second password. In addition, some sub-grammars cannot generate a vault of size 2 without unused rules, for example, the sub-grammars consist of three rules with the lefthand-side  $S$ . It also needs to be pruned the branches of all these sub-grammars and renormalize the rest branches. Therefore, in order to prune the branches of unused rules, it is necessary to prune and renormalize branches on almost all nodes in the generating graph. This pruning is difficult because of the high time complexity, especially for the vaults of large sizes. Another simple and straightforward method is to add extra rules in the sub-grammar randomly when encoding. It seems to address this problem. However, the Chatterjee et al.’s GPM [10] with this rule-adding method resists the weak encoding attack but still suffers from the strong encoding attack unless the probability of adding extra rules is equal to the probability of the generating path. This is because the DTE must be seed-uniform in order to resist the strong encoding attack. Moreover, calculating the probability of adding extra rules has the same order of time complexity as calculating the probability of the generating path. Therefore, if this rule-adding method guarantees the property of seed-uniformity, it is equivalent to our method which randomly chooses a generating path with its probability. In other words, the rule-adding method does not perform efficiently in resisting the strong encoding attack. To conclude, we state that a secure DTE of the sub-grammar approach does have high time complexity.

To get rid of the high time complexity of encoding sub-grammars, we propose a design principle for GPMs—*minimizing the ambiguity of the GPM*—to reduce the time complexity of encoding in the corresponding PMTEs. Instead of optimizing the encoding algorithm after designing a GPM with great ambiguity, it may be better to minimize the ambiguity when designing the GPM.

# The Art of The Scam: Demystifying Honeypots in Ethereum Smart Contracts

## Abstract

Modern blockchains, such as Ethereum, enable the execution of so-called *smart contracts* – programs that are executed across a decentralised network of nodes. As smart contracts become more popular and carry more value, they become more of an interesting target for attackers. In the past few years, several smart contracts have been exploited by attackers. However, a new trend towards a more proactive approach seems to be on the rise, where attackers do not search for vulnerable contracts anymore. Instead, they try to lure their victims into traps by deploying seemingly vulnerable contracts that contain hidden traps. This new type of contracts is commonly referred to as *honeypots*. In this paper, we present the first systematic analysis of honeypot smart contracts, by investigating their prevalence, behaviour and impact on the Ethereum blockchain. We develop a taxonomy of honeypot techniques and use this to build HONEYBADGER – a tool that employs symbolic execution and well defined heuristics to expose honeypots. We perform a large-scale analysis on more than 2 million smart contracts and show that our tool not only achieves high precision, but is also highly efficient. We identify 690 honeypot smart contracts as well as 240 victims in the wild, with an accumulated profit of more than \$90,000 for the honeypot creators. Our manual validation shows that 87% of the reported contracts are indeed honeypots.

## 1 Introduction

The concept of blockchain has been introduced in 2009 with the release of Satoshi Nakamoto’s Bitcoin [26] and has greatly evolved since then. It is regarded as one of the most disruptive technologies since the invention of the Internet itself. In recent years, companies across the globe have poured value into blockchain research, examining how it can make their existing business more efficient and secure. A blockchain is essentially a verifiable, append-only list of records in which all transactions are recorded in so-called

*blocks*. Every block is linked to its previous block via a cryptographic hash, thus forming a chain of blocks or a so-called “*blockchain*”. This list is maintained by a distributed peer-to-peer network of untrusted nodes, which follow a consensus protocol that dictates the appending of new blocks. Trust is obtained via the assumption that the majority acts faithfully and going against the protocol is too costly.

A broad range of different blockchain implementations have emerged since the inception of Bitcoin. However, all of these implementations pursue a common goal, namely, the decentralisation of control over a particular asset. Bitcoin’s asset is its cryptocurrency and the trusted centralised entities it attempts to decentralise are traditional banks. Modern blockchains such as Ethereum [46] aim to decentralise the computer as a whole through so-called *smart contracts*. Smart contracts are programs that are stored and executed across the Ethereum blockchain via the Ethereum Virtual Machine (EVM). The EVM is a purely stack-based virtual machine that supports a Turing-complete instruction set of opcodes. Smart contracts are deployed, invoked and removed from the blockchain via transactions. Each operation on the EVM costs a specified amount of *gas*. When the total amount of gas assigned to a transaction is exceeded, program execution is terminated and its effects are reversed. In contrast to traditional programs, smart contracts are immutable. Thus, programming mistakes that were never intended by the developer, become now irreversible. Developers usually write smart contract code in a high-level language which compiles into EVM bytecode. At the time of writing, Solidity [47] is the most prevalent high-level language for developing smart contracts in Ethereum.

In 2018, Ethereum reached a market capitalisation of over \$133 billion [9]. As it becomes more and more valuable, attackers become more and more incentivised to find and exploit vulnerable contracts. In fact, Ethereum already faced several devastating attacks on vulnerable smart contracts. The most prominent ones being the DAO hack in 2016 [34] and the Parity Wallet hack in 2017 [29], together causing a loss of over \$400 million. In response to these attacks,

academia proposed a plethora of different tools that allow to scan contracts for vulnerabilities, prior to deploying them on the blockchain (see e.g. [21, 25, 38]). Unfortunately, these tools may also be used by attackers in order to easily find vulnerable contracts and exploit them. This potentially enables attackers to follow a reactive approach by actively scanning the blockchain for vulnerable contracts.

Alternatively, attackers could follow a more proactive approach by luring their victims into traps. In other words: *Why should I spend time on looking for victims, if I can just let the victims come to me?* This new type of fraud has been introduced by the community as “*honeypots*” (see e.g. [32, 33]). Honeypots are smart contracts that appear to have an obvious flaw in their design, which allows an arbitrary user to drain *ether* (Ethereum’s cryptocurrency) from the contract, given that the user transfers a priori a certain amount of ether to the contract. However, once the user tries to exploit this apparent vulnerability, a second, yet unknown, trapdoor unfolds which prevents the draining of ether to succeed. The idea is that the user solely focuses on the apparent vulnerability and does not consider the possibility that a second vulnerability might be hidden in the contract. Similar to other types of fraud, honeypots work because human beings are often easily manipulated. People are not always capable of quantifying risk against their own greed and presumptions.

In this paper, we investigate the prevalence of such honeypot smart contracts in Ethereum. To the best of our knowledge this is the first work to provide an in depth analysis on the inner workings of this new type of fraud. Moreover, we introduce HONEYBADGER – a tool that uses a combination of symbolic execution and precise heuristics to automatically detect various types of honeypots. Using HONEYBADGER, we are able to provide interesting insights on the plethora, anatomy and popularity of honeypots that are currently deployed on the Ethereum blockchain. Finally, we investigate whether this new type of scam is profitable and we discuss the effectiveness of such honeypots. In summary, we present the following main contributions:

- We conduct the first systematic analysis of an emerging new type of fraud in Ethereum: *honeypots*.
- We identify common techniques used by honeypots and organise them in a taxonomy.
- We present HONEYBADGER, a tool that automatically detects honeypots in Ethereum smart contracts.
- We run HONEYBADGER on 151,935 unique smart contracts and confirm the prevalence of at least 282 unique honeypots.

## 2 Background

In this section, we provide the required background for understanding the setting of our work, including a description

of smart contracts, the Ethereum virtual machine, and the Etherscan blockchain explorer.

### 2.1 Smart Contracts

The notion of smart contracts has been introduced by Nick Szabo in 1997 [35]. He described the concept of a trustless system consisting of self-executing computer programs that would facilitate the digital verification and enforcement of contract clauses contained in legal contracts. However, this concept only became a reality with the release of Ethereum in 2015. Ethereum smart contracts are different from traditional programs in several aspects. For example, as the code is stored on the blockchain, it becomes immutable and its execution is guaranteed by the blockchain. Nevertheless, smart contracts may be destroyed, if they contain the necessary code to handle their destruction. Once destroyed, a contract can no longer be invoked and its funds are transferred to another address. Smart contracts are usually developed using a dedicated high-level programming language that compiles into low-level bytecode. The bytecode of a smart contract is then deployed to the blockchain through a transaction. Once successfully deployed, a smart contract is identified by a 160-bit address. Despite a large variety of programming languages (e.g. Vyper [44], LLL [19] and Bamboo [6]), Solidity [47] remains the most prominent programming language for developing smart contracts in Ethereum. Solidity’s syntax resembles a mixture of C and JavaScript. It comes with a multitude of unique concepts that are specific to smart contracts, such as the transfer of funds or the capability to call other contracts.

### 2.2 Ethereum Virtual Machine

The Ethereum blockchain consists of a network of mutually distrusting nodes that together form a decentralised public ledger. This ledger allows users to create and invoke smart contracts by submitting transactions to the network. These transactions are processed by so-called *miners*. Miners execute smart contracts during the verification of blocks, using a dedicated virtual machine denoted as the Ethereum Virtual Machine [46]. The EVM is a stack-based, register-less virtual machine, running low-level bytecode, that is represented by an instruction set of opcodes. To guarantee termination of a contract and thus prevent miners to be stuck in endless loops of execution, the concept of *gas* has been introduced. It associates costs to the execution of every single instruction. When issuing a transaction, the sender has to specify the amount of gas that he or she is willing to pay to the miner for the execution of the smart contract. The execution of a smart contract results in a modification of the world state  $\sigma$ , a data structure stored on the blockchain mapping an address  $a$  to an account state  $\sigma[a]$ . The account state of a smart contract consists of two main parts: a balance  $\sigma[a]_b$ , that holds

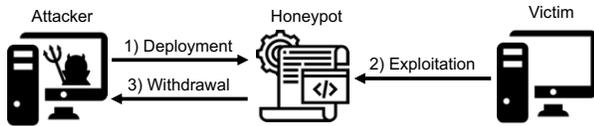

Figure 1: Actors and phases of a honeypot.

the amount of ether owned by the contract, and storage  $\sigma[a]_s$ , which holds the persistent data of the contract. Storage is organised as a key-value store and is the only way for a smart contract to retain state across executions. Besides the world state  $\sigma$ , the EVM also holds a transaction execution environment  $I$ , which contains the address of the smart contract that is being executed  $I_a$ , the transaction input data  $I_d$ , the transaction sender  $I_s$  and the transaction value  $I_v$ . The EVM can essentially be seen as a transaction-based state machine, that takes as input  $\sigma$  and  $I$ , and outputs a modified world state  $\sigma'$ .

### 2.3 Etherscan Blockchain Explorer

Etherscan<sup>1</sup> is an online platform that collects and displays blockchain specific information. It acts as a blockchain navigator allowing users to easily lookup the contents of individual blocks, transactions and smart contracts on Ethereum. It offers multiple services on top of its exploring capabilities. One of these services is the possibility for smart contract creators to publish their source code and confirm that the bytecode stored under a specific address is the result of compilation of the specified source code. It also offers users the possibility to leave comments on smart contracts.

## 3 Ethereum Honeypots

In this section, we provide a general definition of a honeypot and introduce our taxonomy of honeypots.

### 3.1 Honeypots

**Definition 1 (Honeypot)** *A honeypot is a smart contract that pretends to leak its funds to an arbitrary user (victim), provided that the user sends additional funds to it. However, the funds provided by the user will be trapped and at most the honeypot creator (attacker) will be able to retrieve them.*

Figure 1 depicts the different actors and phases of a honeypot. A honeypot generally operates in three phases:

1. The attacker deploys a seemingly vulnerable contract and places a bait in the form of funds;
2. The victim attempts to exploit the contract by transferring at least the required amount of funds and fails;

<sup>1</sup><https://etherscan.io/>

3. The attacker withdraws the bait together with the funds that the victim lost in the attempt of exploitation.

An attacker does not require special capabilities to set up a honeypot. In fact, an attacker has the same capabilities as a regular Ethereum user. He or she solely requires the necessary funds to deploy the smart contract and place a bait.

### 3.2 Taxonomy of Honeypots

We grasped public sources available on the Internet, in order to have a first glimpse at the inner workings of honeypots [45, 22, 32, 31, 33]. We were able to collect a total of 24 honeypots (see Table 5 in Appendix A) and distill 8 different honeypot techniques. We organise the different techniques in a taxonomy (see Table 1), whose purpose is twofold: (i) as a reference for users in order to avoid common honeypots in Ethereum; (ii) as a guide for researchers to foster the development of methods for the detection of fraudulent smart contracts. We group the different techniques into three different classes, according to the level on which they operate:

1. *Ethereum Virtual Machine*
2. *Solidity Compiler*
3. *Etherscan Blockchain Explorer*

The first class tricks users by making use of the unusual behaviour of the EVM. Although the EVM follows a strict and publicly known set of rules, users can still be misled or confused by devious smart contract implementations that suggest a non-conforming behaviour. The second class relates to honeypots that benefit from issues that are introduced by the Solidity compiler. While some compiler issues are well known, others still remain undocumented and might go unnoticed if a user does not analyse the smart contract carefully or does not test it under real-world conditions. The final and third class takes advantage of issues that are related to the limited information displayed on Etherscan's website. Etherscan is perhaps the most prominent Ethereum

Level	Technique
Ethereum Virtual Machine	Balance Disorder
Solidity Compiler	Inheritance Disorder
	Skip Empty String Literal
	Type Deduction Overflow
Etherscan Blockchain Explorer	Uninitialised Struct
	Hidden State Update
	Hidden Transfer
	Straw Man Contract

Table 1: A taxonomy of honeypot techniques in Ethereum smart contracts.

```

1 contract MultiplierX3 {
2     ...
3     function multiply(address adr) payable {
4         if (msg.value >= this.balance)
5             adr.transfer(this.balance+msg.value);
6     }
7 }

```

Figure 2: An example of a balance disorder honeypot.

blockchain explorer and many users fully trust the data displayed therein. In the following, we explain each honeypot technique through a simplified example. We also assume that: 1) the attacker has placed a bait in form of ether into the smart contract, as an incentive for users to try to exploit the contract; 2) the attacker has a way of retrieving the amount of ether contained in the honeypot.

### 3.2.1 Ethereum Virtual Machine

**Balance Disorder.** Every smart contract in Ethereum possesses a balance. The contract in Figure 2 depicts an example of a honeypot that makes use of a technique that we denote as *balance disorder*. The function `multiply` suggests that the balance of the contract (`this.balance`) and the value included in the transaction to this function call (`msg.value`) are transferred to an arbitrary address, if the caller of this function includes a value that is higher than or equal to the current balance of the smart contract. Hence, a naive user will believe that all that he or she needs to do, is to call this function with a value that is higher or equal to the current balance, and that in return he or she will obtain the “invested” value plus the balance contained in the contract. However, if a user tries to do so, he or she will quickly realise that line 5 is not executed because the condition at line 4 does not hold. The reason for this is that the balance is already incremented with the transaction value, before the actual execution of the smart contract takes place. It is worth noting that: 1) the condition at line 4 can be satisfied if the current balance of the contract is zero, but then the user does not have an incentive to exploit the contract; 2) the addition `this.balance+msg.value` at line 5, solely serves the purpose of making the user further believe that the balance is updated only after the execution.

### 3.2.2 Solidity Compiler

**Inheritance Disorder.** Solidity supports inheritance via the `is` keyword. When a contract inherits from multiple contracts, only a single contract is created on the blockchain, and the code from all the base contracts is copied into the created contract. Figure 3 shows an example of a honeypot that makes use of a technique that we denote as *inheritance disorder*. At first glance, there seems to be nothing special

```

1 contract Ownable {
2     address owner = msg.sender;
3     modifier onlyOwner {
4         require(msg.sender == owner);
5     };
6 }
7 }
8 contract KingOfTheHill is Ownable {
9     address public owner;
10    ...
11    function() public payable {
12        if(msg.value>jackpot)owner=msg.sender;
13        jackpot += msg.value;
14    }
15    function takeAll() public onlyOwner {
16        msg.sender.transfer(this.balance);
17        jackpot = 0;
18    }
19 }

```

Figure 3: An example of an inheritance disorder honeypot.

about this code, we have a contract `KingOfTheHill` that inherits from the contract `Ownable`. We notice two things though: 1) the function `takeAll` solely allows the address stored in variable `owner` to withdraw the contract’s balance; 2) the `owner` variable can be modified by calling the fallback function with a message value that is greater than the current jackpot (line 12). Now, if a user tries to call the function in order to set themselves as the owner, the transaction succeeds. However, if he or she afterwards tries to withdraw the balance, the transaction fails. The reason for this is that the variable `owner`, declared at line 9, is not the same as the variable that is declared at line 2. We would assume that the `owner` at line 9 would be overwritten by the one at line 2, but this is not the case. The Solidity compiler will treat the two variables as distinct variables and thus writing to `owner` at line 9 will not result in modifying the `owner` defined in the contract `Ownable`.

**Skip Empty String Literal.** The contract illustrated in Figure 4 allows a user to place an investment by sending a minimum amount of ether to the contract’s function `invest`. Investors may withdraw their investment by calling the function `divest`. Now, if we have a closer look at the code, we realise that there is nothing that prohibits the investor from divesting an amount that is greater than the originally invested amount. Thus a naive user is led to believe that the function `divest` can be exploited. However, this contract contains a bug known as *skip empty string literal*<sup>2</sup>. The empty string literal that is given as an argument to the function `loggedTransfer` (line 14), is skipped by the encoder of the Solidity compiler. This has the effect that the encoding of all arguments following this argument are shifted to the left by 32 bytes and thus the function call argument

<sup>2</sup><https://github.com/ethereum/solidity/blob/develop/docs/bugs.json>

```

1 contract DividendDistributorv3 {
2   ...
3   function loggedTransfer(uint amount, bytes32
4     msg, address target, address currentOwner){
5     if (!target.call.value(amount)()) throw;
6     Transfer(amount, msg, target, currentOwner);
7   }
8   function invest() public payable {
9     if (msg.value >= minInvestment)
10      investors[msg.sender].investment += msg.
11        value;
12   }
13   function divest(uint amount) public {
14     if (investors[msg.sender].investment == 0
15       || amount == 0) throw;
16     investors[msg.sender].investment -= amount;
17     this.loggedTransfer(amount, "", msg.sender,
18       owner);
19   }
20 }

```

Figure 4: An example of a skip empty string literal honeypot.

```

1 contract For_Test {
2   ...
3   function Test() payable public {
4     if (msg.value > 0.1 ether) {
5       uint256 multi = 0;
6       uint256 amountToTransfer = 0;
7       for (var i = 0; i < 2*msg.value; i++) {
8         multi = i*2;
9         if (multi < amountToTransfer) {
10          break;
11          amountToTransfer = multi;
12        }
13        msg.sender.transfer(amountToTransfer);
14      }
15    }
16  }

```

Figure 5: An example of a type deduction overflow honeypot.

msg receives the value of target, whereas target is given the value of currentOwner, and finally currentOwner receives the default value zero. Thus, in the end the function loggedTransfer performs a transfer to currentOwner instead of target, essentially diverting all attempts to divest from the contract to transfers to the owner. A user trying to use the smart contract's apparent vulnerability thereby effectively just transfers the investment to the contract owner.

**Type Deduction Overflow.** In Solidity, when declaring a variable as type var, the compiler uses type deduction to automatically infer the smallest possible type from the first expression that is assigned to the variable. The contract in Figure 5 depicts an example of a honeypot that makes use of a technique that we denote as *type deduction overflow*. At first, the contract suggests that a user will be able to double the in-

```

1 contract GuessNumber {
2   uint private randomNumber=uint256(keccak256(
3     now))%10+1;
4   uint public lastPlayed;
5   uint public minBet=0.1ether;
6   struct GuessHistory {
7     address player;
8     uint256 number;
9   }
10  function guessNumber(uint256 _number) payable{
11    require(msg.value >= minBet && _number <= 10);
12    GuessHistory guessHistory;
13    guessHistory.player = msg.sender;
14    guessHistory.number = _number;
15    if (_number == randomNumber)
16      msg.sender.transfer(this.balance);
17    lastPlayed = now;
18  }

```

Figure 6: An example of an uninitialised struct honeypot.

vestment. However, since the type is only deduced from the first assignment, the loop at line 7 will be infinite. Variable i will have the type uint8 and the highest value of this type is 255, which is smaller than  $2 * msg.value^3$ . Therefore, the loop's halting condition will never be reached. Nevertheless, the loop can still be stopped, if the variable multi is smaller than amountToTransfer. This is possible, since amountToTransfer is assigned the value of multi, which eventually will be smaller than amountToTransfer due to an integer overflow happening at line 8, where i is multiplied by 2. Once the loop exits, the contract performs a value transfer back to the caller, although with an amount that will be at most 255 wei (smallest sub-denomination of ether, where 1 ether =  $10^{18}$  wei) and therefore far less than the value the user originally invested.

**Uninitialised Struct.** Solidity provides means to define new data types in the form of structs. They combine several named variables under one variable and are the basic foundation for more complex data structures in Solidity. An example of an *uninitialised struct* honeypot is given in Figure 6. In order to withdraw the contract's balance, the contract requires a user to place a minimum bet and guess a random number that is stored in the contract. However, any user can easily obtain the value of the random number, since every data stored on the blockchain is publicly available. The first thought suggests that the contract creator simply made a common mistake by assuming that variables declared as private are secret. An innocent user simply reads the random number from the blockchain and calls the function guessNumber by placing a bet and providing the correct number. Afterwards, the contract creates a struct that seems to track the participation of the user. However, the struct

<sup>3</sup>  $2 * 0.1 \text{ ether} = 2 * 10^{17} \text{ wei}$

```

1 contract Gift_1_ETH {
2     bool passHasBeenSet = false;
3     ...
4     function SetPass(bytes32 hash) payable {
5         if (!passHasBeenSet && (msg.value >= 1 ether))
6             hashPass = hash;
7     }
8     function GetGift(bytes pass) returns (bytes32) {
9         if (hashPass == sha3(pass))
10            msg.sender.transfer(this.balance);
11        return sha3(pass);
12    }
13    function PassHasBeenSet(bytes32 hash) {
14        if (hash == hashPass) passHasBeenSet = true;
15    }
16 }

```

Figure 7: An example of a hidden state update honeypot.

is not properly initialised via the `new` keyword. As a result, the Solidity compiler maps the storage location of the first variable contained in the struct (`player`) to the storage location of the first variable contained in the contract (`randomNumber`), thereby overwriting the random number with the address of the caller and thus making the condition at line 14 fail. It is worth noting that the honeypot creator is aware that a user might try to guess the overwritten value. The creator therefore limits the number to be between 1 and 10 (line 10), which drastically reduces the chances of the user generating an address that fulfils this condition.

### 3.2.3 Etherscan Blockchain Explorer

**Hidden State Update.** In addition to normal transactions, Etherscan also displays so-called *internal messages*, which are transactions that originate from other contracts and not from user accounts. However, for usability purposes, Etherscan does not display internal messages that include an empty transaction value. The contract in Figure 7 is an example of a honeypot technique that we denote as *hidden state update*. In this example, the balance is transferred to whoever can guess the correct value that has been used to compute the stored hash. A naive user will assume that `passHasBeenSet` is set to `false` and will try to call the unprotected `SetPass` function, which allows to rewrite the hash with a known value, given that at least 1 ether is transferred to the contract. When analysing the internal messages on Etherscan, the user will not find any evidence of a call to the `PassHasBeenSet` function and therefore assume that `passHasBeenSet` is set to `false`. However, the filtering performed by Etherscan can be misused by the honeypot creator in order to silently update the state of the variable `passHasBeenSet`, by calling the function `PassHasBeenSet` from another contract and using an empty transaction value. Thus, by just looking at the internal messages displayed on Etherscan, unaware users will believe that the variable is set to `false` and confidently

```

1 contract TestToken {
2     ...
3     function withdrawAll() payable {
4         require(0.5 ether < total);

5         if (block.number > 5040270) {if (
6             _owner == msg.sender) {_owner.transfer(
7                 this.balance);} else {throw;}}
8         msg.sender.transfer(this.balance);
9     }
10 }

```

Figure 8: An example of a hidden transfer honeypot.

transfer ether to the `SetPass` function.

**Hidden Transfer.** Etherscan provides a web interface that displays the source code of a validated smart contract. Validated means that the provided source code has successfully been compiled to the associated bytecode. For quite a while, Etherscan presented the source code within an HTML textarea element, where larger lines of code would only be displayed up to a certain width. Thus, the rest of the line of code would be hidden and solely visible by scrolling horizontally. The contract in Figure 8 takes advantage of this “feature” by introducing, at line 4 in function `withdrawAll`, a long sequence of white spaces, effectively hiding the code that follows. The hidden code throws, if the caller of the function is not the owner and thereby prevents the subsequent balance transfer to any caller of the function. Also note the check at line 4, where the block number must be greater than 5,040,270. This ensures that the honeypot solely steals funds when deployed on the main network. Since the block numbers on the test networks are smaller, testing this contract on a such a network would transfer all the funds to the victim, making him or her believe that the contract is not a honeypot. We label this type of honeypot as *hidden transfer*.

**Straw Man Contract.** In Figure 9 we provide an example of a honeypot technique that we denote as *straw man contract*. At first sight, it seems that the contract’s `CashOut` function is vulnerable to a reentrancy attack [2] (line 14). In order to be able to mount the reentrancy attack, the user is required to first call the `Deposit` function and transfer a minimum amount of ether. Eventually, the user calls the `CashOut` function, which performs a call to the contract address stored in `TransferLog`. As shown in the Figure 9, the contract called `Log` is supposed to act as a logger. However, the honeypot creator did not initialise the contract with an address containing the bytecode of the shown logger contract. Instead it has been initialised with another address pointing to a contract that implements the same interface, but throws an exception if the function `AddMessage` is called with the string “CashOut” and the caller is not the honeypot creator.

```

1  contract Private_Bank {
2    ...
3    function Private_Bank(address _log) {
4      TransferLog = Log(_log);
5    }
6    function Deposit() public payable {
7      if (msg.value >= MinDeposit) {
8        balances[msg.sender] += msg.value;
9        TransferLog.AddMessage("Deposit");
10     }
11  }
12  function CashOut(uint _am) {
13    if(_am <= balances[msg.sender]){
14      if(msg.sender.call.value(_am)()){
15        balances[msg.sender] -= _am;
16        TransferLog.AddMessage("CashOut");
17      }
18    }
19  }
20 }
21 contract Log {
22  ...
23  function AddMessage(string _data) public {
24    LastMsg.Time = now;
25    LastMsg.Data = _data;
26    History.push(LastMsg);
27  }
28 }

```

Figure 9: An example of a straw man contract honeypot.

Thus, the reentrancy attack performed by the user will always fail. Another alternative, is to use a `delegatecall` right before the transfer of the balance. `Delegatecall` allows a callee contract to modify the stack of the caller contract. Thus, the attacker would simply swap the address of the user contained on the stack with his or her own address and when returning from the `delegatecall`, the balance would be transferred to the attacker instead of the user.

## 4 HONEYBADGER

In this section, we provide an overview on the design and implementation of HONEYBADGER<sup>4</sup>.

### 4.1 Design Overview

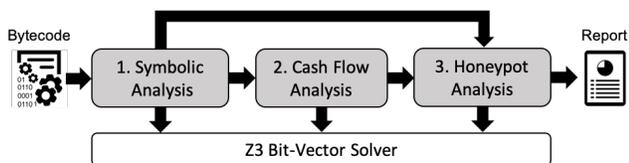

Figure 10: An overview of the analysis pipeline of HONEYBADGER. The shaded boxes represent the main components.

<sup>4</sup><https://github.com/christofortres/HoneyBadger>

Figure 10 depicts the overall architecture and analysis pipeline of HONEYBADGER. HONEYBADGER takes as input EVM bytecode and returns as output a detailed report regarding the different honeypot techniques it detected. HONEYBADGER consists of three main components: *symbolic analysis*, *cash flow analysis* and *honeypot analysis*. The symbolic analysis component constructs the control flow graph (CFG) and symbolically executes its different paths. The result of the symbolic analysis is afterwards propagated to the cash flow analysis component as well as the honeypot analysis component. The cash flow analysis component uses the result of the symbolic analysis to detect whether the contract is capable to receive as well as transfer funds. Finally, the honeypot analysis component aims at detecting the different honeypots techniques studied in this paper using a combination of heuristics and the results of the symbolic analysis. Each of the three components uses the Z3 SMT solver [10] to check for the satisfiability of constraints.

## 4.2 Implementation

HONEYBADGER is implemented in Python, with roughly 4,000 lines of code. We briefly describe the implementation details of each main component below.

### 4.2.1 Symbolic Analysis

The symbolic analysis component starts by constructing a CFG from the bytecode, where every node in the CFG corresponds to a basic block and every edge corresponds to a jump between individual basic blocks. A basic block is a sequence of instructions with no jumps going in or out of the middle of the block. The CFG captures all possible program paths that are required for symbolic execution. Symbolic execution represents the values of program variables as symbolic expressions. Each program path consists of a list of path conditions (a formula of symbolic expressions), that must be satisfied for execution to follow that path.

We reused and modified the symbolic execution engine proposed by Luu et al. [21, 20]. The engine consists of an interpreter loop that receives a basic block and symbolically executes every single instruction within that block. The loop continues until all basic blocks of the CFG have been executed or a timeout is reached. Loops are terminated once they exceed a globally defined loop limit. The engine follows a depth first search approach when exploring branches and queries Z3 to determine their feasibility. A path is denoted as feasible if its path conditions are satisfiable. Otherwise, it is denoted as infeasible. Usually, symbolic execution tries to detect and ignore infeasible paths in order to improve their performance. However, our symbolic execution does not ignore infeasible paths, but executes them nevertheless, as they can be useful for detecting honeypots (see Section 4.2.3).

The purpose of the symbolic analysis is to collect all kinds of information that might be useful for later analysis. This information includes a list of storage writes, a list of execution paths  $P$ , a list of infeasible as well as feasible basic blocks, a list of performed multiplications and additions, and a list of calls  $C$ . Calls are extracted through the opcodes CALL and DELEGATECALL, and either represent a function call, a contract call or a transfer of Ether. A call consists of the tuple  $(c_r, c_v, c_f, c_a, c_t, c_g)$ , where  $c_r$  is the recipient,  $c_v$  is the call value,  $c_f$  is the called contract function,  $c_a$  is the list of function arguments,  $c_t$  is the type of call (i.e. CALL or DELEGATECALL) and  $c_g$  is the available gas for the call.

## 4.2.2 Cash Flow Analysis

Given our definition in Section 3.1, a honeypot must be able to *receive* funds (e.g. the investment of a victim) and *transfer* funds (e.g. the loot of the attacker). The purpose of our *cash flow* analysis is to improve the performance of our tool, by safely discarding contracts that cannot receive or transfer funds.

**Receiving Funds.** There are multiple ways to receive funds besides direct transfers: as a recipient of a block reward, as a destination of a selfdestruct or through the call of a payable function. Receiving funds through a block reward or a selfdestruct makes little sense for a honeypot as this would not execute any harmful code. Also, the compiler adds a check during compilation time, that reverts a transaction if a non-payable function receives a transaction value that is larger than zero. Based on these observations, we verify that a contract is able to receive funds, by first iterating over all possible execution paths contained in  $P$  and checking whether there exists an execution path  $p$ , that does not terminate in a REVERT. Afterwards, we use Z3 to verify if the constraint  $I_v > 0$  can be satisfied under the given path conditions of the execution path  $p$ . If  $p$  satisfies the constraint, we know that funds can flow into the contract.

**Transferring Funds.** There are two different ways to transfer funds: either explicit via a *transfer* or implicit via a *selfdestruct*. We verify the former by iterating over all calls contained in  $C$  and checking whether there exists a call  $c$ , where  $c_v$  is either symbolic or  $c_v > 0$ . We verify the latter by iterating over all execution paths contained in  $P$  and checking whether there exists an execution path  $p$  that terminates in a SELFDESTRUCT. Finally, we know that funds can flow out of the contract, if we find at least one call  $c$  or execution path  $p$ , that satisfies the aforementioned conditions.

## 4.2.3 Honeypot Analysis

Our honeypot analysis consists of several sub-components. Each sub-component is responsible for the detection of a particular honeypot technique. Every honeypot technique is identified via heuristics. We describe the implementation of each sub-component below. The honeypot analysis can easily be extended to detect future honeypots by simply implementing new sub-components.

- **Balance Disorder.** Detecting a balance disorder is straightforward. We iterate over all calls contained in  $C$  and report a balance disorder, if we find a call  $c$  within an infeasible basic block, where  $c_v = I_v + \sigma[I_a]_b$ .
- **Inheritance Disorder.** Detecting an inheritance disorder at the bytecode level is rather difficult since bytecode does not include information about inheritance. Therefore, we leverage on implementation details that are specific to this honeypot technique: 1) there exists an  $I_s$  that is written to a storage location which is never used inside a path condition, call or suicide; and 2) there exists a call  $c$ , whose path conditions contain a comparison between  $I_s$  and a storage variable, whose storage location is different than the storage location identified in 1).
- **Skip Empty String Literal.** We start by iterating over all calls contained in  $C$  and checking whether there exists a call  $c$ , where the number of arguments in  $c_a$  is smaller than the number of arguments expected by  $c_f$ . We report a skip empty string literal, if we can find another call  $c'$ , that is called within function  $c_f$  and where  $c'_r$  originates from an argument in  $c_a$ .
- **Type Deduction Overflow.** We detect a type deduction overflow by iterating over all calls contained in  $C$  and checking whether there exists a call  $c$ , where  $c_v$  contains the result of a multiplication or an addition that has been truncated via an AND mask with the value `0xff`, which represents the maximum value of an 8-bit integer.
- **Uninitialised Struct.** We use a regular expression to extract the storage location of structs, whose first element is pointing at storage location zero within a basic block. Eventually, we report an uninitialised struct, if there exists a call  $c \in C$ , where either  $c_v$  contains a value from a storage location of a struct or the path condition of  $c$  depends on a storage location of a struct.
- **Hidden State Update.** We detect a hidden state update by iterating over all calls contained in  $C$  and checking whether there exists a call  $c$ , whose path conditions depend on a storage value that can be modified via another function, without the transfer of funds.

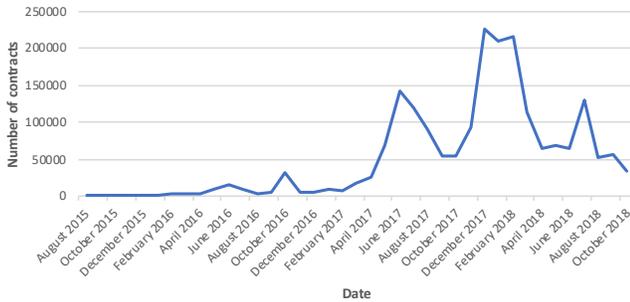

Figure 11: Number of monthly deployed smart contracts in Ethereum.

- **Hidden Transfer.** We report a hidden transfer, if two consecutive calls  $c$  and  $c'$  exist along the same execution path  $p$ , where  $c_r \in \sigma[I_a]_s \wedge c_v = \sigma[I_a]_b$  and  $c'_r = I_s \wedge c'_v = \sigma[I_a]_b$ .
- **Straw Man Contract.** First, we verify if two consecutive calls  $c$  and  $c'$  exist along the same execution path  $p$ , where  $c_r \neq c'_r$ . Finally, we report a straw man contract if one of the two cases is satisfied: 1)  $c$  is executed after  $c'$ , where  $c'_i = DELEGATECALL \wedge c_v = \sigma[I_a]_b \wedge c_r = I_s$ ; or 2)  $c$  is executed before  $c'$ , where  $c'_i = CALL \wedge I_s \in c'_a$ .

## 5 Evaluation

In this section, we assess the correctness and effectiveness of HONEYBADGER. We aim to determine the reliability of our tool and measure the overall prevalence of honeypots currently deployed on the Ethereum blockchain.

**Dataset.** We downloaded the bytecode of 2,019,434 smart contracts, by scanning the first 6,500,000 blocks of the Ethereum blockchain. The timestamps of the collected contracts range from August 7, 2015 to October 12, 2018. Figure 11 depicts the number of smart contracts deployed on Ethereum per month. We state a sudden increase in the number of smart contracts deployed between December 2017 and February 2018. We suspect that this inflation is related to the increase of the price of ether and other cryptocurrencies such as Bitcoin [9]. In 2016, 50,980 contracts were deployed on average per month, whereas in 2017 this number increased almost tenfold, with 447,306 contracts on average per month. Interestingly, a lot of contracts share the same bytecode. Out of the 2,019,434 contracts, solely 151,935 are unique in terms of exact bytecode match. In other words, 92.48% of the contracts deployed on the Ethereum blockchain are duplicates.

**Experimental Setup.** All experiments were conducted on our high-performance computing cluster using 10 nodes with 960 GB of memory, where every node has 2 Intel Xeon

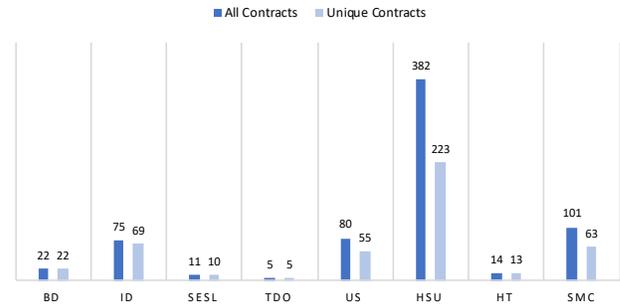

Figure 12: Number of detected honeypots per technique.

L5640 CPUs with 12 cores each and clocked at 2,26 GHz, running 64-bit Debian Jessie 8.10. We used version 1.8.16 of Geth's EVM as our disassembler and Solidity version 0.4.25 as our source-code-to-bytecode compiler. As our constraint solver we used Z3 version 4.7.1. We set a timeout of 1 second per Z3 request for the symbolic execution. The symbolic execution's global timeout was set to 30 minutes per contract. The loop limit, depth limit (for DFS) and gas limit for the symbolic execution were set to 10, 50 and 4 million, respectively.

## 5.1 Results

We run HONEYBADGER on our set of 151,935 unique smart contracts. Our tool took an average of 142 seconds to analyse a contract, with a median of 31 seconds and a mode of less than 1 second. Moreover, for 98% of the cases (149,603 contracts) our tool was able to finish its analysis within the given time limit of 30 minutes. The number of explored paths ranges from 1 to 8,037, with an average of 179 paths per contract and a median of 105 paths. Finally, during our experiments, HONEYBADGER achieved a code coverage of about 91% on average.

Out of the 151,935 analysed contracts, 48,487 have been flagged as cash flow contracts. In other words, only 32% of the analysed contracts are capable of receiving as well as sending funds. Figure 12 depicts for each honeypot technique the number of contracts that have been flagged by HONEYBADGER. Our tool detected a total of 460 unique honeypots. It is worth mentioning that 24 out of the 460 honeypots were part of our initial dataset (see Table 5 in Appendix A) and that our tool thus managed to find 436 new honeypots. Moreover, as mentioned earlier, many contracts share the same bytecode. Thus, after correlating the results with the bytecode of the 2 million contracts currently deployed on the blockchain, a total of 690 contracts were identified as honeypots<sup>5</sup>. Our tool therefore discovered a total of 22 balance disorders (BD), 75 inheritance disorders (ID), 11

<sup>5</sup><https://honeybadger.uni.lu/>

	Balance Disorder	Inheritance Disorder	Skip Empty String Literal	Type Deduction Overflow	Uninitialised Struct	Hidden State Update	Hidden Transfer	Straw Man Contract
TP	20	41	9	4	32	134	12	30
FP	0	7	0	0	0	30	0	4
$p$	100	85	100	100	100	82	100	88

Table 2: Number of true positives (TP), false positives (FP) and precision  $p$  (in %) per detected honeypot technique for contracts with source code.

skip empty string literal (SESL), 5 type deduction overflows (TDO), 80 uninitialised structs (US), 382 hidden state updates (HSU), 14 hidden transfers (HT) and finally 101 straw man contracts (SMC). While many contracts were found to be HSU, SMC and US honeypots, only a small number were found to be TDO honeypots.

## 5.2 Validation

In order to confirm the correctness of HONEYBADGER, we performed a manual inspection of the source code of the contracts that have been flagged as honeypots. We were able to collect through Etherscan the source code for 323 (70%) of the flagged contracts. We verified the flagged contracts by manually scanning the source code for characteristics of the detected honeypot technique. For example, in case a contract has been flagged as a balance disorder, we checked whether the source code contains a function that transfers the contract’s balance to the caller if and only if the value sent to the function is greater than or equal to the contract’s balance.

Table 2 summarises our manual verification in terms of true positives (TP), false positives (FP) and precision  $p$ , where  $p$  is computed as  $p = TP / (TP + FP)$ . A true positive means that the contract is indeed a honeypot with respect to the reported technique and a false positive means that the contract is *not* a honeypot with respect to the reported technique. Overall our tool shows a very high precision and a very low false positive rate. Our tool achieves a false positive rate of 0% for 5 out of the 8 analysed honeypot techniques. For the remaining 3 techniques, our tool achieves a decent false positive rate, where the highest false positive rate is roughly 18% for the detection of hidden state updates, followed by 15% false positive rate for the detection of inheritance disorder and finally 12% false positive rate for the detection of straw man contracts.

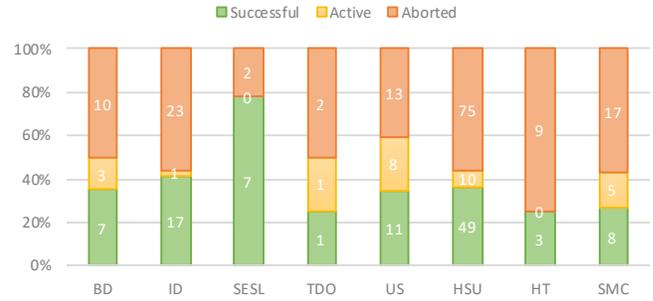

Figure 13: Number of successful, active and aborted honeypots per honeypot technique.

## 6 Analysis

In this section, we analyse the true positives obtained in Section 5, in order to acquire insights on the *effectiveness, liveness, behaviour, diversity* and *profitability* of honeypots.

### 6.1 Methodology

We crawled all the transactions of the 282 true positives using Etherchain’s<sup>6</sup> API, in order to collect various information about the honeypots, such as the amount of spent and received ether per address, the deployment date and the balance. Afterwards, we used simple heuristics to label every address as either an *attacker* or a *victim*. An address is labeled as an attacker if it either: 1) created the honeypot; 2) was the first address to send ether to the honeypot; or 3) received more ether than it actually spent on the honeypot. An address is labeled as a victim if it has not been labeled as an attacker and if it received less ether than it actually spent on the honeypot. Finally, using this information we were able to tell if a honeypot, was either *successful, aborted* or still *active*. A honeypot is marked as successful if a victim has been detected, as aborted if the balance is zero and no victim has been detected or as active if the balance is larger than zero and no victim has been detected.

### 6.2 Results

**Effectiveness.** Figure 13 shows the number of successful, aborted and active honeypots per honeypot technique. Our results show that *skip empty string literal* is the most effective honeypot technique with roughly 78% success rate, whereas *hidden transfer* is the least effective technique with solely 33% success rate. The overall success rate of honeypots seems rather low with roughly 37%, whereas the overall abortion rate seems quite high with about 54%. At the time of writing, solely 10% of the analysed honeypots are still active. Figure 14 illustrates the number of monthly deployed

Table 3: Bytecode similarity (in %) per honeypot technique.

their bytecode might still be very diverse.

**Profitability.** Table 4 lists the profitability per honeypot technique. The profitability is computed as *received amount* - (*spent amount* + *transaction fees*). No values are provided for TDO, because for the single true positive that we analysed, the transaction fees spent by the attacker were higher than the amount that the attacker gained from the victim. The smallest and largest profit were made using a hidden state update honeypot, with 0.00002 ether being the smallest and 11.96 ether being the largest. The most profitable honeypots are straw man contract honeypots, with an average value of 1.76 ether, whereas the least profitable honeypots are uninitialised struct honeypots, with an average value of 0.46 ether. A total profit of 257.25 ether has been made through honeypots, of which 171.22 ether were solely made through hidden state update honeypots. However, the exchange rate of cryptocurrencies is very volatile and thus their value in USD may vary greatly on a day-to-day basis. For example, although 11.96 ether is the largest profit made in ether, its actual value in USD was solely 500 at the point of withdrawal. Thus, we found that the largest profit in terms of USD, was actually a honeypot with 3.10987 ether, as it was worth 2,609 USD at the time of withdrawal. Applying this method across the 282 honeypots, results in a total profit of 90,118 USD.

## 7 Discussion

In this section we summarise the key insights gained through our analysis and we discuss the ethical considerations as well as the challenges and limitations of our work.

	Min.	Max.	Mean	Mode	Median	Sum

## 7.1 Honeypot Insights

Although honeypots are capable of trapping multiple users, we have found that most honeypots managed to take the funds of only one victim. This indicates that users potentially look at the transactions of other users before they submit theirs. Moreover, the low success rate of honeypots with comments, suggests that users also check the comments on Etherscan before submitting any funds. We also found that the bytecode of honeypots can be vastly different even if using the same honeypot technique. This suggests that the usage of signature-based detection methods would be rather ineffective. HONEYBADGER is capable of recognising a variety of implementations, as it specifically targets the functional characteristics of each honeypot technique. More than half of the honeypots were successful within the first 24 hours. This suggests that honeypots become less effective the older they become. This is interesting, as it means that users seem to target rather recently deployed honeypots than older ones. We also note that most honeypot creators withdraw their loot within 24 hours or abort their honeypots if they are not successful within the first 24 hours. We therefore conclude that honeypots have in general a short lifespan and only a small fraction remain active for a period longer than one day.

## 7.2 Challenges and Limitations

The amount of smart contracts with source code available is rather small. At the time of writing, there are only 50,000 contracts with source code available on Etherscan. This highlights the necessity of being able to detect honeypots at the bytecode level. Unfortunately, this turns out to be extremely challenging when detecting certain honeypot techniques. For example, while detecting inheritance disorder at the source code level is rather trivial, detecting it at the bytecode level is rather difficult since all information about the inheritance is lost during compilation and not available anymore at the bytecode level. The fact that certain information is solely available at the source code level and not at the bytecode level, obliges us to make use of other less precise information that is available in the bytecode in order to detect honeypot techniques such as inheritance disorder. However, as Section 5 shows, this approach reduces the precision of our detection and introduces some false positives. Finally, another limitation of our tool is that it is currently limited to the detection of the eight honeypot techniques described in this paper. Thus other honeypot techniques are not detected. Nevertheless, we designed HONEYBADGER with modularity in mind, such that one can easily extend the honeypot analysis component with new heuristics in order to detect more honeypot techniques.

### 7.3 Ethical Considerations

In general, honeypots have two participants, the creator of the honeypot, and the user whose funds are trapped by the honeypot. However, the ethical intentions of both participants are not always clear. For instance, a honeypot creator might deploy a honeypot with the intention to scam users and make profit. In this case we clearly have a malicious intention. However, one could also argue that a honeypot creator is just attempting to punish users that behave maliciously. Similarly, the intentions of a honeypot user can either be malicious or benign. For example, if a user tries to intentionally exploit a reentrancy vulnerability, then he or she needs to be knowledgeable and mischievous enough to prepare and attempt the attack, and thus clearly showing malicious behaviour. However, if we take the example of an uninitialised struct honeypot that is disguised as a simple lottery, then we might have the case of a benign user who loses his funds under the assumption that he or she is participating in a fair lottery. Thus, both honeypot creators and users cannot always be clearly classified as either malicious or benign, this depends on the case at hand. Nevertheless, we are aware that our methodology may serve malicious attackers to protect themselves from other malicious attackers. However, with HONEYBADGER, we hope to raise the awareness of honeypots and save benign users from potential financial losses.

## 8 Related Work

Honeypots are a new type of fraud that combine security issues with scams. They either rely on the blockchain itself or on related services such as Etherscan. With growing interest within the blockchain community, they have been discussed online [31, 32, 33] and collected within public user repositories [22, 45]. Frauds and security issues are nothing new within the blockchain ecosystem. Blockchains have been used for money laundering [24] and been the target of several scams [42], including mining scams, wallet scams and Ponzi schemes, which are further discussed in [4, 43]. In particular, smart contracts have been shown to contain security issues [2]. Although not performed directly on the blockchain, exchanges have also been the target of fraud [23].

Several different methods have been proposed to discover fraud as well as security issues. Manual analysis is performed on publicly available source code to detect Ponzi schemes [3]. [49] introduces ERAYS, a tool that aims to produce easy to analyse pseudocode from bytecode where the source code is not available. However, manual analysis is particularly laborious, especially considering the number of contracts on the blockchain. Machine learning has been used to detect Ponzi schemes [8] and to find vulnerabilities [36]. The latter relies on [27] to obtain a ground truth of vulnerable smart contracts for training their model. Fuzzing techniques have been employed to detect security vulnera-

bilities in smart contracts [15] and in combination with symbolic execution to discover issues related to the ordering of events or function calls [17]. However, fuzzing often fails to create inputs to enter specific execution paths and therefore might ignore them [40]. Static analysis has been used to find security [7, 39, 37] and gas-focused [11] vulnerabilities in smart contracts. [7] requires manual interaction, while [39] requires both the definition of violation and compliance patterns. [37] requires Solidity code and therefore cannot be used to analyse the large majority of the smart contracts deployed on the Ethereum blockchain. [11] considers gas-related issues which is not necessary for the purpose of this work. In order to use formal verification, smart contracts can, to some extent, be translated from source code or bytecode into F\* [5, 12] where the verification can more easily be performed. Other work operates on high-level source code available for Ethereum or Hyperledger [16]. [13, 14] propose a formal definition of the EVM, that is extended in [1] towards more automated smart contract verification and the consideration of gas. Formal verification often requires (incomplete) translations into other languages or manual user interaction (e.g.: [30]). Both of these reasons make formal verification unsuitable to be used on a large number of contracts, as it is required in this work.

Symbolic execution has been used on smart contracts to detect common [28, 25, 21, 38] vulnerabilities. This technique also allows to find specific kinds of misbehaving contracts [27]. It can further provide values that can serve to generate automated exploits that trigger vulnerabilities [18]. The same technique is used in this paper. Symbolic execution has the advantage of being capable to reason about all possible execution paths and states in a smart contract. This allows for the implementation of precise heuristics while achieving a low false positive rate. Another advantage is that symbolic execution can be applied directly to bytecode, thus making it well suited for our purpose of analysing more than 2 million smart contracts for which source code is largely not available. The disadvantage is the large number of possible paths that need to be analysed. However, in the case of smart contracts this is not an issue, as most are not very complex and very short. Moreover, smart contract bytecode cannot grow arbitrarily large due to the gas limit enforced by the Ethereum blockchain.

To the best of the authors' knowledge, this paper is the first to consider and discuss honeypot smart contracts, a new type of fraud, and to propose a taxonomy as well as an automated tool using symbolic execution for their detection.

## 9 Conclusion

In this work, we investigated an emerging new type of fraud in Ethereum: *honeypots*. We presented a taxonomy of honeypot techniques and introduced a methodology that uses symbolic execution and heuristics for the automated detec-

tion of honeypots. We showed that HONEYBADGER can effectively detect honeypots in the wild with a very low false positive rate. In a large-scale analysis of 151,935 unique Ethereum smart contracts, HONEYBADGER identified 460 honeypots. Moreover, an analysis on the transactions performed by a subset of 282 honeypots, revealed that 240 users already became victims of honeypots and that attackers already made more than 90,000 USD profit with honeypots. It is worth noting that these numbers solely provide a lower bound and thus might only reflect the tip of the iceberg. Nonetheless, tools such as HONEYBADGER may already help users in detecting honeypots before they can cause any harm. In future work, we plan to further generalise our detection mechanism through the use of machine learning techniques. We also plan to extend our analysis with a larger subset and eventually detect new honeypots by looking at other contracts that are linked to the newly discovered honeypot contracts.

## Acknowledgments

We would like to thank Hugo Jonker and Sjouke Mauw as well as the anonymous reviewers for their valuable feedback and comments. The experiments presented in this paper were carried out using the HPC facilities of the University of Luxembourg [41] – see <https://hpc.uni.lu>. This work is partly supported by the Luxembourg National Research Fund (FNR) under grant 13192291.

# The Anatomy of a Cryptocurrency Pump-and-Dump Scheme

Jiahua Xu

## Abstract

While pump-and-dump schemes have attracted the attention of cryptocurrency observers and regulators alike, this paper represents the first detailed empirical query of pump-and-dump activities in cryptocurrency markets. We present a case study of a recent pump-and-dump event, investigate 412 pump-and-dump activities organized in Telegram channels from June 17, 2018 to February 26, 2019, and discover patterns in crypto-markets associated with pump-and-dump schemes. We then build a model that predicts the pump likelihood of all coins listed in a crypto-exchange prior to a pump. The model exhibits high precision as well as robustness, and can be used to create a simple, yet very effective trading strategy, which we empirically demonstrate can generate a return as high as 60% on small retail investments within a span of two and half months. The study provides a proof of concept for strategic crypto-trading and sheds light on the application of machine learning for crime detection.

## 1 Introduction

While pump-and-dump schemes are a well-trodden ruse in conventional financial markets, the old-fashioned ploy has found a new playground to thrive — cryptocurrency exchanges.

The relative anonymity of the crypto space has led to it becoming a fertile ground for unlawful activities, such as currency theft (e.g. the DAO hack [1]), Ponzi schemes [26], and pump-and-dump schemes that have each risen in popularity in cryptocurrency markets over the last few years. Due to their end-to-end encryption, programmability, and relative anonymity, new social media tools such as Telegram<sup>1</sup> and Discord have become cryptocurrency enthusiasts' preferred communication vehicles. While pump-and-dump schemes have been discussed in the press [29], we are not aware of a comprehensive study of this phenomenon to date.

<sup>1</sup>Note that not all Telegram traffic is end-to-end encrypted.

**Regulation:** In February 2018, the CFTC (Commodity Futures Trading Commission) issued warnings to consumers [8] about the possibility of cryptocurrency pump-and-dump schemes. It also offered a substantial reward to whistleblowers around the same time [12].

In October 2018, the SEC (Securities and Exchange Commission) filed a subpoena enforcement against an investment company trust and trustee for an alleged pump-and-dump ICO scheme [27].

Clearly, regulators are aiming to find perpetrators of pump-and-dump schemes and to actively prosecute them.

**This paper:** In this paper, we trace the message history of over 300 Telegram channels from June 17, 2018 to February 26, 2019, and identify 412 *pump events* orchestrated through those channels. We analyze features of pumped coins and market movements of coins before, during, and after pump-and-dump. We develop a predictive random forest model that provides the likelihood of each possible coin being pumped *prior* to the actual pump event. With an AUC (area under curve) of the ROC (receiver operating characteristic) curve of over 0.9, the model exhibits high accuracy in predicting pump-and-dump target coins.

**Contributions:** This paper makes the following contributions:

- **Longitudinal study:** This paper is the *first* research study that examines routinely organized pump-and-dump events in the cryptocurrency space. We use a unique dataset of pump-and-dump records from June 17, 2018 to February 26, 2019 across multiple crypto-exchanges and analyze crypto-market movements associated with those pump-and-dump events.
- **Analysis:** Our analysis shows that pump-and-dump activities are a lot more prevalent than previously believed. Specifically, around 100 organized Telegram pump-and-dump channels coordinate on average 2 pumps a day, which generates an aggregate artificial trading volume of 6 million USD a month. We discover that some ex-

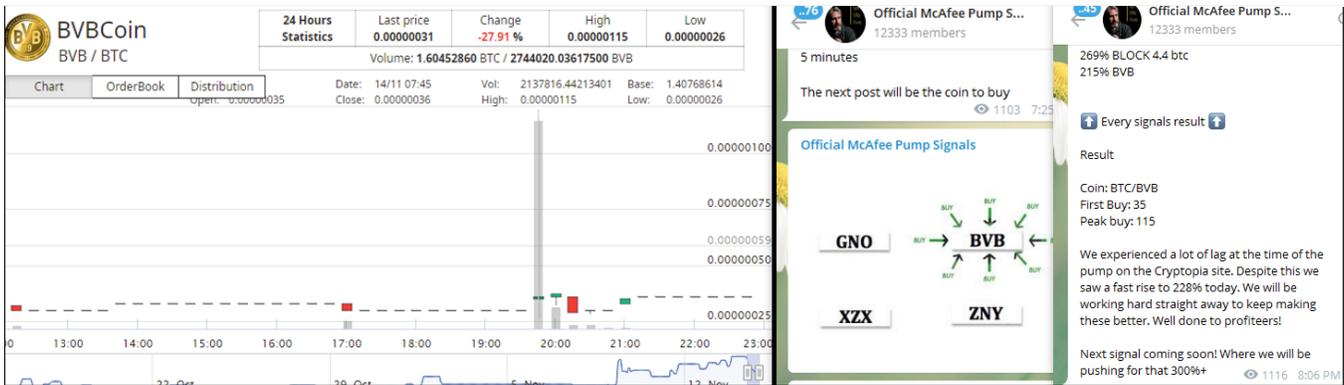

Figure 1: A successfully organized pump event. On the right hand side of the screenshot is the message history of a Telegram channel. The first message is the final countdown; the second message is the coin announcement; the last message presents the pump result. On the left hand side is the market movement of the corresponding coin around the pump time.

changes are also active participants in pump-and-dump schemes.

- **Prediction:** We develop machine learning models that, given pre-pump market movements, can predict the likelihood of each coin being pumped with an AUC (Area Under Curve) of over 0.9 both in-sample and out-of-sample. The models confirm that market movements contain hidden information that can be utilized for monetary purposes.
- **Trading strategy:** We formulate a simple trading strategy which, when used in combination with a calibrated prediction model, demonstrates a return of 60% over a period of three weeks, even under strict assumptions.

**Paper organization:** The paper is structured as follows. In [Section 2](#) we provide background information on pump-and-dump activities organized by Telegram channels. In [Section 3](#) we present a pump-and-dump case study. In [Section 4](#) we investigate a range of coin features. In [Section 5](#) we build a prediction model that estimates the pump likelihood of each coin for each pump, and propose a trading strategy along with the model. In [Section 6](#) we summarize the related literature. In [Section 7](#) we outline our conclusions. Finally, the Appendix specifies parameters of the models we have used in this paper.

## 2 Background

A pump is a coordinated, intentional, short-term increase in the demand of a market instrument — in our study, a cryptocurrency — which leads to a price hike. With today’s chat applications such as Telegram and Discord offering features of encryption and anonymity, various forms of misconduct in cryptocurrency trading are thriving on those platforms.

### 2.1 Pump-and-Dump Actors

**Pump organizer:** Pump organizers can be individuals, or, more likely, organized groups, typically who use encrypted chat applications to coordinate pump-and-dump events. They have the advantage of having insider information and are the ultimate beneficiaries of the pump-and-dump scheme.

**Pump participants:** Pump participants are cryptocurrency traders who collectively buy a certain coin immediately after receiving the instruction from the pump organizer on which coin to buy, causing the price of the coin to be “pumped”. Many of them end up buying coins at an already inflated price and are the ultimate victim of the pump-and-dump scheme.

**Pump target exchange:** A pump target exchange is the exchange selected by the pump organizer where a pump-and-dump event takes place. Some exchanges are themselves directly associated with pump-and-dump. Yobit, for example, has openly organized pumps multiple times (see [Figure 2](#)). The benefits for an exchange to be a pump organizer are threefold:

1. With coins acquired before a pump, it can profit by dumping those coins at a higher, pumped price;
2. It earns high transaction fees due to increased trading volume driven by a pump-and-dump;
3. Exchanges are able to utilize their first access to users’ order information for front-running during a frenzied pump-and-dump.

### 2.2 A Typical Pump-and-Dump Process

**Set-up:** The organizer creates a publicly accessible group or channel, and recruits as many group members or channel subscribers as possible by advertising and posting invitation links on major forums such as Bitcointalk, Steemit, and Reddit.

Telegram *channels* only allow subscribers to receive messages from the channel admin, but not post discussions in the channel. In a Telegram *group*, members can by default post messages, but this function is usually disabled by the group admin to prohibit members’ interference. We use the terms *channel* and *group* interchangeably in this paper.

**Pre-pump announcement:** The group is ready to pump once it obtains enough members (typically above 1,000). The pump organizer, who is now the group or channel admin, announces details of the next pump a few days ahead. The admins broadcast the exact time and date of the announcement of a coin which would then precipitate a pump of that coin. Other information disclosed in advance includes the exchange where the pump will take place and the pairing coin<sup>2</sup>. The admins advise members to transfer sufficient funds (in the form of the pairing coin) into the named exchange beforehand.

While the named pump time is approaching, the admin sends out countdowns, and repeats the pump “rules” such as: 1) buy fast, 2) “shill”<sup>3</sup> the pumped coin on the exchange chat box and social media to attract outsiders, 3) “HODL”<sup>4</sup> the coin at least for several minutes to give outsiders time to join in, 4) sell in pieces and not in a single chunk, 5) only sell at a profit and never sell below the current price. The admin also gives members a pep talk, quoting historical pump profits, to boost members’ confidence and encourage their participation.

**Pump:** At the pre-arranged pump time, the admin announces the coin, typically in the format of an OCR (optical character recognition)-proof image to hinder machine reading (Figure 1). Immediately afterwards, the admin urges members to buy and hold the coin in order to inflate the coin price. During the first minute of the pump, the coin price surges, sometimes increasing several fold.

**Dump:** A few minutes (sometimes tens of seconds) after the pump starts, the coin price will reach its peak. While the admin might shout “buy buy buy” and “hold hold hold” in the channel, the coin price keeps dropping. As soon as the first fall in price appears, pump-and-dump participants start to panic-sell. While the price might be re-boosted by the second wave of purchasers who buy the dips (as encouraged by channel admins), chances are the price will rapidly bounce back to the start price, sometimes even lower. The coin price declining to the pre-pump proximity also signifies the end of the dump, since most investors would rather hold the coin than sell at a loss.

**Post-pump review:** Within half an hour, after the coin price and trading volume recover to approximately the pre-pump levels, the admin posts a review on coin price change, typically including only two price points – start price (or low price) and peak price, and touts how much the coin price increased by

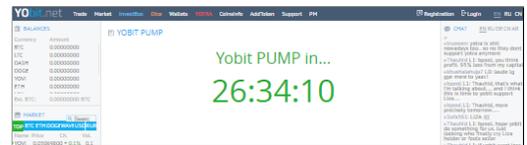

<sup>2</sup>A pairing coin is a coin that is used to trade against other coins. Bitcoin (BTC) is a typical pairing coin.

<sup>3</sup>Crypto jargon for “advertise”, “promote”.

<sup>4</sup>Crypto jargon for “hold”.

(a) Tweets from @YobitExchange.

(b) Pump timer from the Yobit website.

Figure 2: The screen-shots demonstrate that the exchange Yobit was actively involved in pump-and-dump activities.

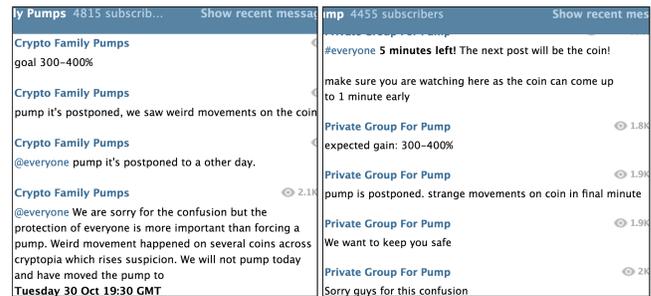

Figure 3: A pump attempt coordinated by multiple channels not executed due to unanticipated price movement of the to-be-pumped coin.

the pump (Section 2). Information such as trading volume and timescale is only selectively revealed: if the volume is high, and the pump-and-dump lasts a long time (over 10 minutes, say, would be considered “long”), then those stats will be “proudly” announced; if the volume is low or the time between coin announcement and price peak is too short (which is often the case), then the information is glossed over. Such posts give newcomers, who can access channel history, the illusion that pump-and-dumps are highly profitable.

**Failed pump-and-dump attempts:** Note that not every pump attempt is successful. Figure 3 shows that the admins decided not to carry through a pre-announced pump due to unanticipated price movements of the to-be-pumped coin.

While it is unknown what caused these movements, the case evidences that the admin is aware of the coin choice before the pump (as opposed to the coin being randomly selected and immediately announced at the pump time purely by algorithm), and hence has the time advantage of hoarding the coin at a low price before the coin announcement, whereas group members only purchase the coin after the coin announcement and slow buyers risk acquiring the coin at an

already (hyper)inflated price. It is generally known to pump participants that admins benefit the most from a pump. So why are there still people enthusiastic about partaking a pump, given the risk of being ripped off by the admins? Because people believe that they can sell those coins at an even higher price to other “greater fools”. The greater fool theory also forms the foundation of many other schemes, such as pyramid scams or Ponzi games [5].

One may also hypothesize that in this case, someone might have worked out the pattern of the coin selection and pre-purchased a basket of coins with high pump likelihood that happens to contain the actual to-be-pumped coin, which might explain why the admin observed peculiar movements of the coin. In the next section, we study the features of pumped coins and their price movements to understand if it is indeed possible to predict the to-be-pumped coin.

### 2.3 Regulatory and Ethical Considerations

Pump-and-dumps in the stock market nowadays typically involve penny stock manipulation employing deceptive campaigns on social media to amass gains and are deemed criminal [27]. However, since many cryptocurrencies cannot be neatly classified as investment or consumer products [22], the applicability of certain securities laws might be ambiguous, and to date, regulation of pump-and-dumps in the cryptocurrency market is still weak [23].

Yet, the crypto-market is likely to be considered subject to common law and general-purpose statues even though it has not been clearly regulated as either a securities market or a currency market. While offenses of market manipulation can depend on a defined market, outright fraud and deception do not. As pump-and-dump admins create information asymmetry by not showing investors the full picture of their scheme, they intentionally mislead investors for their own financial benefit. As a consequence, when it comes to US legislation, for instance, admins might be committing false advertising under the FTC (Federal Trade Commission) Act (15 USC §45) [15] or fraudulent misrepresentation. Of course, practically speaking, these admins are frequently outside of the US jurisdiction.

Pump-and-dump admins, aiming to profit from price manipulation, are certainly unethical. Nevertheless, other pump-and-dump participants are also culpable since their behaviour enables and reinforces the existence of such schemes; ironically, most participants become the victim of their own choices.

## 3 A Pump-and-Dump Case Study

We further study in depth the pump-and-dump event associated with Figure 1. The pump-and-dump was organized by at least four Telegram channels, the largest one being **Official McAfee Pump Signals**, with a startling 12,333 members. Prior to the coin announcement, the members were notified

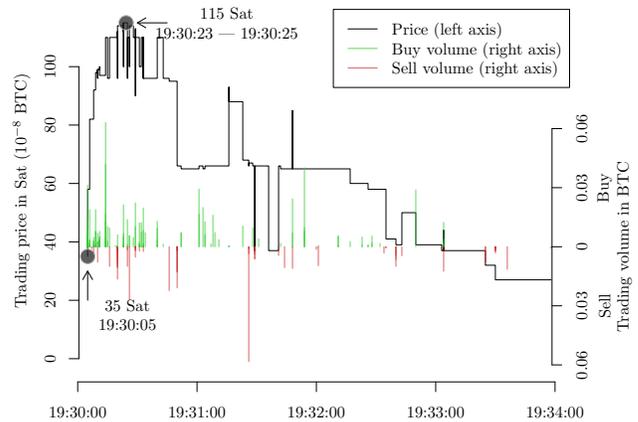

Figure 4: Tick-by-tick movement of the BVB/ BTC market during the first four minutes after the coin announcement.

that the pump-and-dump would take place on one of the Cryptopia’s BTC markets (i.e., BTC is the pairing coin).

**Announcement:** At 19:30 GMT, on November 14, 2018, the channels announced the target coin in the form of a OCR-proof picture, but not quite simultaneously. **Official McAfee Pump Signals** was the fastest announcer, having the announcement message sent out at 19:30:04. **Bomba bitcoin “cryptopia”** was the last channel that broadcast the coin, at 19:30:23.

The target coin was BVB, a dormant coin that is not listed on CoinMarketCap. The launch of the coin was announced on Bitcointalk on August 25, 2016.<sup>5</sup> The coin was claimed to be have been made by and for supporters of a popular German football club, Borussia Dortmund (a.k.a. BVB). The last commit on the associated project’s source code on GitHub was on August 10, 2017.<sup>6</sup>

Although it has an official Twitter account, @bvbcoin, its last Tweet dates back to 31 August, 2016. The coin’s rating on Cryptopia is a low 1 out of possible 5. This choice highlights the preference of pump-and-dump organizers for coins associated with unserious projects.

During the first 15 minutes of the pump, BVB’s trading volume exploded from virtually zero to 1.41 BTC (illustrated by the tall grey bar towards the right end of the price/volume chart), and the coin price increased from 35 Sat<sup>7</sup> to its three-fold, 115 Sat (illustrated by the thin grey vertical line inside the tall grey bar).

**Price fluctuations:** Further dissecting the tick by tick transactions (Figure 4), we note that the first buy order was placed and completed within 1 second after the first coin announcement. With this lightning speed, we conjecture that such an order might have been executed by automation. After a mere 18

<sup>5</sup><https://bitcointalk.org/index.php?topic=1596932.0>

<sup>6</sup><https://github.com/bvbcoin/bvbcoin-source>

<sup>7</sup>One Satoshi (Sat) equals 10<sup>-8</sup> Bitcoin (BTC).

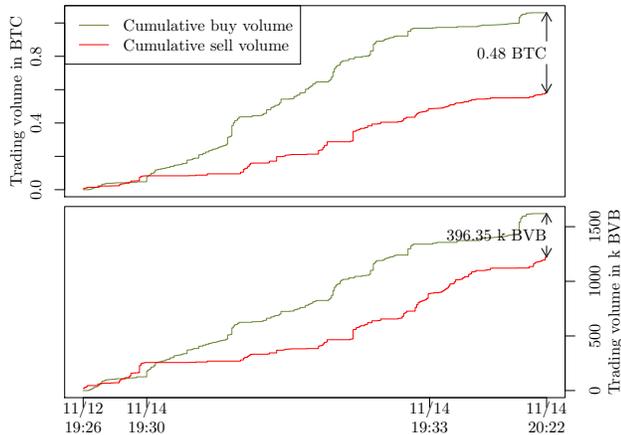

Figure 5: Gap between buy volume and sell volume caused by the BVB pump-and-dump. The figure shows a timeline from 48 hours before up to 1 hour after the pump-and-dump. For the illustration purposes, the timeline is scaled with non-linear transformation to better display the development of volume gaps during the pump-and-dump.

seconds of a manic buying wave, the coin price already skyrocketed to its peak. Note that **Bomba bitcoin “cryptopia”** only announced the coin at the time when the coin price was already at its peak, making it impossible for investors who solely relied on the announcement from the channel to make any money.

Not being able to remain at this high level for more than a few seconds, the coin price began to decrease, with some resistance in between, and then plummeted. Three and half minutes after the start of the pump-and-dump, the coin price had dropped below its open price. Afterwards, transactions only occurred sporadically.

**Volume:** Figure 5 shows that the pump-and-dump induces fake demand and inflates buy volume. While every pump-and-dump participant would hope for a quick windfall gain during a minute-long pump, the majority would not manage to act fast enough to sell at a high price. Those investors would either end up selling coins at a loss, or, if reluctant to sell low, would hold the virtually worthless coins. This is demonstrated by Figure 5, which shows that the buy volume exceeds the sell volume, whether measured by the target coin BVB or by BTC. The figure also shows small volume movements shortly before the pump-and-dump, also observable in Figure 4(a), which can be indicative of organizers’ pre-purchase conduct. As the BVB blockchain is not being actively maintained and the coin itself is extremely illiquid, any market movement may be deemed unusual.

Figure 5 illustrates that the total buy volume (also including the pre-purchased volume, though negligible) in BTC associated with the pump-and-dump amounts to 1.06 BTC, the sell volume only 0.58 BTC; the total buy volume measured in BVB is 1,619.81 thousand BVB, the sell amount 1,223.36 thousand BVB. This volume discrepancy between the sell and

Exchange	Volume (30d)	No. markets	Launch	Country
Binance	\$21,687,544,416	385	Jul 2017	China
Bittrex	\$1,168,276,090	281	Feb 2014	U.S.A.
Cryptopia	\$107,891,577	852	May 2014	New Zealand
YoBit	\$797,593,680	485	Aug 2014	Russia

Figure 6: Exchanges involved in pump-and-dump schemes, sorted by 30-day volume: No. markets is the number of trading pairs (eg. DASH/BTC, ETC/USDT) in the exchange. Volume and No. markets were extracted from CoinMarketCap on November 5, 2018.

the buy sides indicates a higher trading aggressiveness on the buy side.<sup>8</sup> This further suggests that many investors may be “stuck” with BVB which they are unwilling to liquidate at the low market price after the pump-and-dump. Those coin holders can only expect to reverse the position in the next pump, which might never come.

**Low participation ratio:** It is worth noting that the total count of trading transactions associated with this pump-and-dump is merely 322. That number appears very low compared to the 1,376 views of the coin announcement message, let alone the over 10,000 channel members. This indicates that the majority of group members are either observers, who want no skin in the game, or have become aware of the difficulty in securing profit from a pump-and-dump.

## 4 Analyzing Pump-and-Dump Schemes

In this section we explain how we obtain data from both Telegram and the various exchanges, which allows us to analyze and model pump-and-dump schemes.

### 4.1 Collecting Pump-and-Dump Events

In this study, we examine routinely organized pump-and-dump events that follow the pattern of “set-up → pre-pump announcement → pump → dump → post-pump review” as described in Section 2. This type of pump-and-dump involves live instructions from organizers (see Figure 1 and Figure 3), so encrypted chat applications such as Telegram and Discord are ideal for broadcasting those events.

We are confident that it suffices to focus solely on pump-and-dump events orchestrated on Telegram as every active pump-and-dump group we found on Discord was also on Telegram.<sup>9</sup> Telegram is among the primary media for pump-and-dump activities and announcements, and it would be both unreasonable and unlikely for any pump-and-dump organizer

<sup>8</sup>Note that Cryptopia is a peer-to-peer trading platform which lets users trade directly with each other; the exchange takes no risk position and only profits from charging trading fees. Therefore, buying volume implies that the trade is initiated by the buyer, which typically drives the market price up; similarly, sale volume is initiated by the sell side and would drive the price down.

<sup>9</sup>This observation has also been confirmed by the PumpOlymp team, an online information provider specialized in cryptocurrency pump-and-dump.

to restrict the platform to only Discord, since the key to the success of a pump-and-dump is the number of participants.

**Telegram channels:** Our primary source on pump-and-dump Telegram channels and events is provided by PumpOlymp,<sup>10</sup> a website that hosts a comprehensive directory of hundreds of pump-and-dump channels.

PumpOlymp discovers those channels by searching pump-related keywords — e.g. “pump”, “whales”, “vip” and “coin” — on Telegram aggregators such as <https://tgstat.com/> and <https://telegramcryptogroups.com/>. Another source for new pump-and-dump channels is cross-promotion on the known channels.<sup>11</sup> To validate the incoming data from PumpOlymp, we conduct an independent manual search for pump-and-dump channels. We are not able to add new channels to the existing channel list from PumpOlymp, and we are not aware of any other, more comprehensive pump-and-dump channel list. Therefore, we believe the channel list from PumpOlymp is a good starting point.

Next, we use the official Telegram API to retrieve message history from those channels, in total 358, to check their status and activity. Among those channels, 43 have been deleted from the Telegram sever, possibly due to inactivity for an extended period of time. Among the existing ones, over half (168/315) have not been active for a month, possibly because cautious admins delete pump-and-dump messages to eviscerate their traces. This might also imply that the Telegram channels have a “hit-and-run” characteristic. As described in the section above, one learns from participation in pump-and-dump activities that quick bucks are not easy to make. Therefore, curious newcomers might be fooled by pump-and-dump organizers’ advertising and lured into the activity. After losing money a few times, participants may lose faith and interest, and cease partaking. This forms a vicious circle, since with fewer participants, it would be more difficult to pump a coin. Therefore, channel admins might desert their channel when the performance declines, and start new ones to attract the inexperienced.

**Pump-and-dump history:** Starting June 2018, PumpOlymp has been gleaning pump-and-dump events organized on Telegram. Using their API,<sup>12</sup> we acquire an initial list of historical pump-and-dump activities over the period of June 17, 2018 and February 26, 2019. For each listed pump-and-dump event, the data set contains the pumped coin, the target exchange, the organizing Telegram channel, the coin announcement time, plus the price and volume data on the tick-by-tick level from coin announcement up to 15 minutes afterwards.

We run plausibility checks to validate each record’s qualification as a pump-and-dump. For example, if an alleged pump-and-dump is recorded to have started at a time that is

<sup>10</sup><https://pumpolymp.com>

<sup>11</sup>This is based on a conversation with a PumpOlymp staff member.

<sup>12</sup><https://pumpolymp.com:5001/api/allPumps> and <https://pumpolymp.com:5001/api/PumpMarketHistory/raw>, only available for premium users.

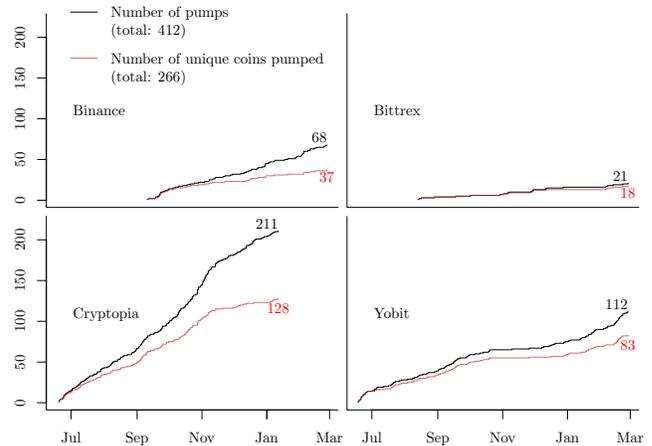

Figure 7: Cumulative counts of pumps and pumped coins on four exchanges from June 2018 to February 2019.

far from a full hour (6:00, 7:00, etc.) or a half hour, then we would be suspicious, because an organizer would normally not choose a random time for a pump-and-dump. If there is no significant increase in volume or high price around the pump time, we would also be skeptical. In such a circumstance, we manually check the message history to make a final judgment. In most cases, the message either discusses the potential of a coin or the record is simply a mistake. Note that we exclusively consider message series with count-downs (e.g. “3 hours left”, “5 mins left”) and coin announcement; messages on pump signal detection are eliminated from our sample.

In the end, we trace 429 pump-and-dump coin announcements from June 17, 2018 to February 26, 2019, each of which is characterized by a series of messages similar to those presented in Figure 1. One pump-and-dump can be co-organized by multiple channels; if two coin announcements were broadcast within 3 minutes apart from each other and they target the same coin at the same exchange, then we consider them to be one pump-and-dump event. In total, we collected 412 unique pump-and-dump events.

**Excluded data points:** All the pumped coins in our sample were paired with BTC. We also observed and manually collected a few ETH-paired pumps, most of which took place in other exchanges.<sup>13</sup> Inclusion of those cases would require data collection with other methods and resources. Due to their rarity, we do not consider ETH-paired pump-and-dumps in our study.

## 4.2 Obtaining Coin Data

Apart from consulting the online pump-and-dump information center PumpOlymp, we retrieve additional information on features and price movements of coins from other sources,

<sup>13</sup>For example, PLX on October 10, 2018 in CoinExchange, ETC on April 22, 2018 in Bibox.

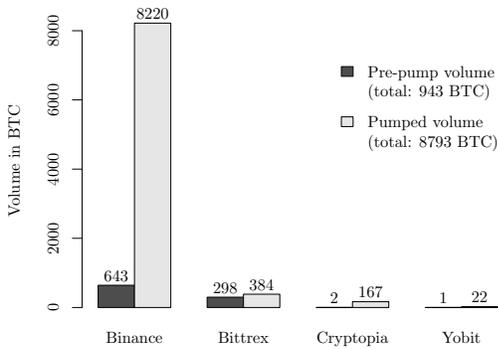

Figure 8: Aggregate trading volume of pumped coins before and during a pump.

in order to establish a connection between the information and the pump-and-dump pattern.

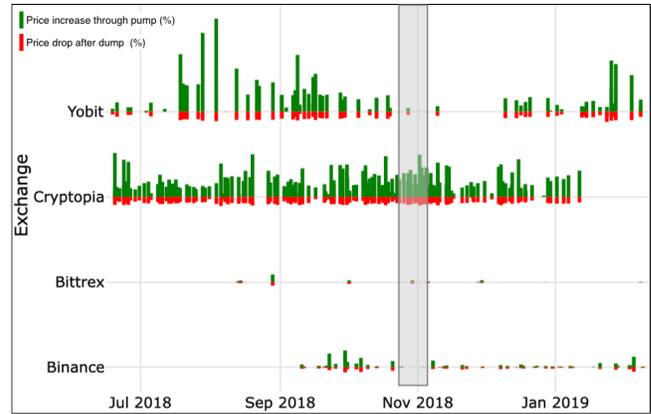

Specifically, we use the public API from CryptoCompare<sup>14</sup> for coins’ hourly OHLC (open, high, low, close) and volume data on 189 exchanges, including Binance, Bittrex, Cryptopia and Yobit. The API provides live data, which means users are able to obtain price information up to the time point of data retrieval. While historical minute-level data are also available on CryptoCompare, they are restricted to a 7-day time window and thus not utilized.

In the conventional stock market, pump-and-dump operators favor microcap stocks due to high manipulability of their price [3]; we expect to observe a similar phenomenon in the crypto-market. To collect coins’ market cap data, we use the public API from CoinMarketCap. Because we are interested in coins’ “true” market cap that is uninfluenced by any maneuver, we purposefully chose to retrieve the data at 08:42 GMT, November 5. We believe the market cap data retrieved are not contaminated by Telegram organized pump-and-dumps, since they typically start on the hour or the half hour and last only a few minutes.

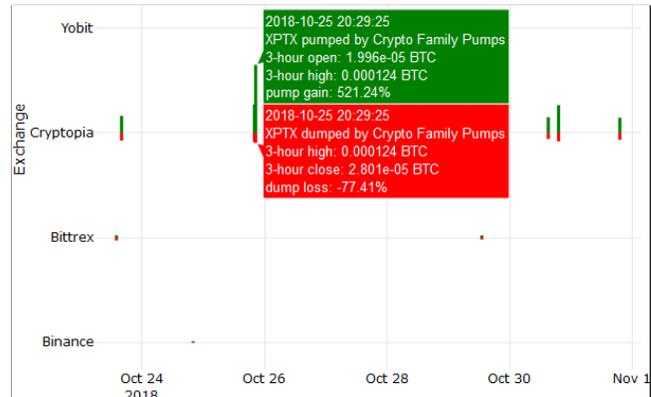

In addition to market trading data, we also retrieve coins’ non-financial features. Specifically, we use exchanges’ public API<sup>15</sup> to collect information on coins’ listing status, algorithm, and total supply. We also collect coins’ launch dates using CryptoCompare’s public API. For information that is not contained in the API but viewable online (such as coins’ rating data on Cryptocurrency), we use either page source scraping or screen scraping, depending on the design of the desired webpage. All our data on coin features are from publicly accessible sources.

Figure 9: Pump and dump timeline. A green bar represents price increase through pump, calculated as  $\frac{\text{high price} - \text{open price}}{\text{open price}}$ ; a red bar represents price drop after pump, calculated as  $\frac{\text{close price} - \text{high price}}{\text{close price}}$ . All prices are denominated in BTC, and from a 3-hour window around pump activities. Visit <http://rpubs.com/xujiahuyz/pd> for the full, interactive chart.

### 4.3 Role of Exchanges

Pump-and-dump schemes take place within the walled gardens of crypto-exchanges. Binance, Bittrex, Cryptopia, and Yobit are among the most popular exchanges used by pumpers (see Figure 6). While those exchanges differ vastly in terms of their volume, markets, and user base, each of them has its own appeal to pumpers. Large exchanges such as Binance and Bittrex have a large user base, and abnormal price hype caused by pump activities can quickly attract a large number of other users to the exchange. Smaller exchanges such as Cryptopia and Yobit tend to host esoteric coins with low liquidity, whose price can be more easily manipulated compared to mainstream coins such as Ether (ETH) or Litecoin (LTC).

In general, larger exchanges are more reliable than smaller ones. While both Binance and Cryptopia were hacked recently,<sup>16</sup> the former managed to remain operative, while the

<sup>16</sup><https://www.bloomberg.com/news/articles/2019-05-08/crypto-exchange-giant-binance-reports-a-hack-of-7-000-bitcoin>

Exchange	Number of PD's	Admins' profit (BTC), aggregated	Admins' return, aggregated
Binance	51	148.97	15%
Bittrex	15	0.92	7%
Cryptopia	180	44.09	57%
Yobit	102	5.54	52%
<b>Total</b>	<b>348</b>	<b>199.52</b>	<b>18%</b>

Table 1: Number of pump-and-dumps (348) considered in this analysis deviates from the total number of pump-and-dumps (412) due to lack of price data for some events.

latter halted trading and fell into liquidation.

**Activity distribution by exchange:** Among the 412 pump-and-dump activities, 68 (17%) took place in Binance, 21 (5%) in Bittrex, 211 (51%) in Cryptopia and 112 (27%) in Yobit. In aggregate, 35% (146/412) of the time, the selected coin had previously been pumped in the same exchange (see Figure 7).

Figure 8 compares the aggregate three-hour trading volume in BTC of pumped coins before and during a pump-and-dump, and the artificial trading volume generated by those pump-and-dump activities is astonishing: 8,793 BTC (93% from Binance), roughly equivalent to 50 million USD,<sup>17</sup> of trading volume during the pump hours, 9 times as much as the pre-pump volume (943 BTC), and that only over a period of eight months.

Figure 9 illustrates the occurrence and the effectiveness of individual pump-and-dump activities. In terms of frequency, Bittrex is most rarely chosen; Binance started to gain traction only since September, but still witnesses far less pump-and-dump occurrence than Yobit and Cryptopia. Turning to Yobit with Cryptopia, we find that the two exchanges have complemented each other: when Yobit was inactive (most notably October 2018 to January 2019), Cryptopia experienced more traffic; when Cryptopia went silent (since the hack in mid-January 2019), Yobit regained popularity. In terms of percentage of coin price increase, pumps in both Yobit and Cryptopia appear to be more powerful than those in Bittrex and Binance. What goes hand-in-hand with price surge is price dip: coin prices also drop more dramatically during the dump in Yobit and Cryptopia compared to their peer exchanges.

**Profit for admins:** Even with tick-by-tick data for each pumped coin during their respective pump-and-dump period, due to lack of trader ID we cannot precisely match individuals' buy and sell transactions. Therefore, to estimate profit for admins, we need to make a few assumptions:

1. Admins purchase coins and enter sell orders only prior to the pump.

and [https://www.nzherald.co.nz/business/news/article.cfm?c\\_id=3&objectid=12231209](https://www.nzherald.co.nz/business/news/article.cfm?c_id=3&objectid=12231209).

<sup>17</sup>This is calculated based on the unit BTC price of 5,715 USD, which is the mean of the high price of 8,250 USD and the low price 3,180 USD during the data period.

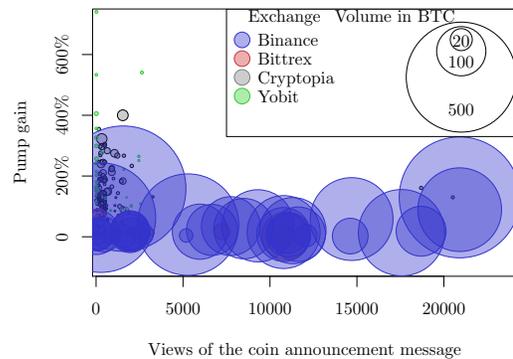

Figure 10: Views of coin announcement message versus coin price increase during the pump. The figure illustrates the relationships between coin price increase through pump, views of coin announcement message, pump volume, and pump exchange.

2. Admins purchase coins at the price immediately before the pump begins.
3. During the pump period — before the price reaches the peak, investors lift the admin's offers and push the price higher; during the dump period — when the price drops, investors transact with each other.

With those assumptions, we arrive at the estimation as presented in Table 1. We estimate that admins made a net profit of 199.52 BTC, equivalent to 1.1 million USD, through 348 pump and dump events during our sample period. The estimated return of insiders averages 18%, which aligns perfectly with Li et al. [23].

So, what is the investors' payout? Some investors win; others lose. Since trading is a zero-sum game, the aggregate investor loss would be on the equivalent scale as the aggregate admin win.

**Coin announcement views:** While investigating the degree of exposure in coin announcement messages distributed by Telegram channels, we find a negative correlation (-0.162) between number of views of coin announcement and pump gain, which is rather counter-intuitive, because one would think that more views would indicate more participation, which would result in higher pump gain. Two extreme examples: the coin announcement of the pump on MST had 325 views and the pump gain was 12.6%; another coin announcement of the pump on PARTY had only 18 views, and the pump gain was a whopping 533.3%.

This finding suggests that the number of views cannot accurately proxy number of participants, possibly because: (1) only a fraction of message viewers would actually participate in a pump-and-dump; (2) if a user reads the message history after the pump, his/her view would still be counted; (3) if a user re-views a message 24 hours after his/her first view, the user's view would be counted twice;<sup>18</sup> (4) some participants

<sup>18</sup><https://stackoverflow.com/questions/42585314/telegram-channels-post-view-count>

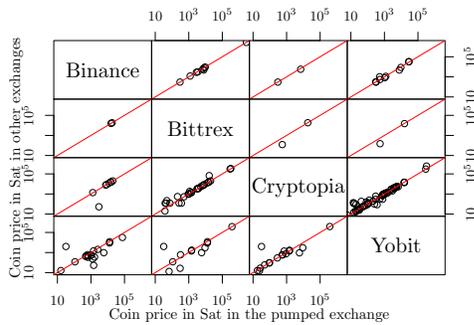

Figure 11: Arbitrage opportunities: coin price (highest during the pump hour) in pumped exchange versus price in other exchanges

might have retrieved messages via bots, which would not be counted in number of views.<sup>19</sup>

**Price increase:** We further notice that although pump-and-dumps in Binance generate more trading volume during the pump hour (Figure 8),<sup>20</sup> thanks to its large user base, coin price increase through pumps is generally at a much smaller scale than that in Cryptopia and Yobit (Figure 9 and Figure 10). This is possibly caused by high bid and sell walls on the order book that are typical for large crypto exchanges like Binance, which prevent the price from fluctuating significantly even at coordinated pump-and-dump events.

**Arbitrage:** Pump-and-dump activities not only engender abnormal returns within the pumped exchange, but also arbitrage opportunities across different exchanges. Figure 11 shows the presence of a price discrepancy of the same coin during the pump hour across different exchanges. Interestingly, coin price can sometimes be higher in exchanges other than the pumped one. It is also worth noting that most coins pumped in Cryptopia are also listed in Yobit but not in Bittrex or Binance, and vice versa. This is because the former two have more conservative coin listing strategies, which results in a different, more mainstream portfolio of listed coins compared to the latter two. While there may be trading strategies resulting from these arbitrage opportunities, they are outside the scope of this work.

## 4.4 Capturing Features

**Market cap:** Figure 12 presents the market cap distribution of coins pumped in different exchanges. Pumped coins' market cap ranges from 1 BTC (Royal Kingdom Coin (RKC), pumped in Cryptopia) to 27,600 BTC (TrueUSD (TUSD), pumped in Yobit). Half of those coins have a market cap below 100 BTC, most of which were pumped in Cryptopia.

<sup>19</sup><https://stackoverflow.com/questions/49704911/is-it-possible-for-a-telegram-bot-increase-post-view-count>

<sup>20</sup>A pump hour refers to the clock hour during which a pump occurs.

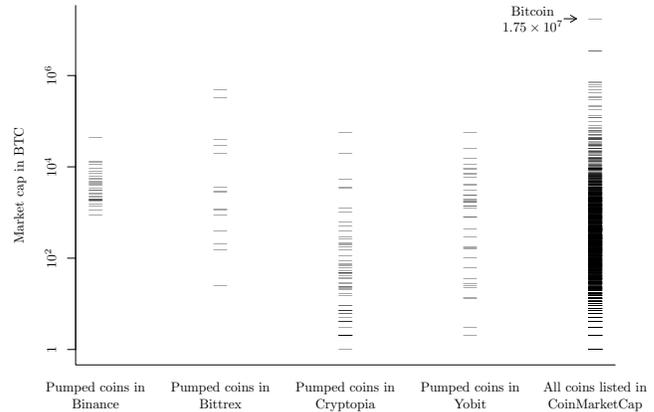

Figure 12: Distribution of coin market caps. Market cap information was extracted from CoinMarketCap on November 5, 2018.

Pump-and-dump organizers' preference for small-cap coins resembles equity market manipulators' taste for microcap stocks [3, 24], and can be explained by the empirical finding of Hamrick et al. [18] and Li et al. [23]: the smaller the market cap of the pumped coin, the more successful the pump would be.

**Price movement:** Figure 13 depicts time series of hourly log returns of pumped coins between 48 hours before and 3 hours after a pump. We detect anomalous return signals before pump-and-dump admins' announcement of the pumped coin. The signals appear most jammed one hour prior to the pump, and less so before that. This is to a certain degree in accord with Kamps et al. [20] who find that a shorter, 12-hour rolling estimation window is more suitable for anomaly detection in the crypto-market than a longer, 24-hour one.

The return signal before the pump is the strongest with Cryptopia, where in numerous pumps, coin prices were elevated to such an extent that the hourly return before the pump even exceeds the hourly return during the pump. This can be explained by the assumption that pump organizers might utilize their insider information to purchase the to-be-pumped coin before the coin announcement, causing the coin price elevation and usual return volatility before the pump. The analysis above provides grounds for predicting the pumped coin before coin announcement using coin features and market movement.

## 5 Predicting Pump-and-Dump Target Coins

### 5.1 Feature Selection

Based on the preliminary analysis in the last section, we believe pump-and-dump organizers have specific criteria for coin selection and they generally purchase the to-be-pumped coin before naming it to the investors. Thus, it should be possible to use coin features and market movements prior to a

Feature	Description	Notation
Market cap	Market cap information extracted from CoinMarketCap at 08:42 GMT, November 5, 2018 when no pump-and-dump activity in Telegram channels was observed *	<i>caps</i>
Returns before pump	$x$ -hour log return of the coin within the time window from $x + 1$ hours to 1 hour before the pump	$return[x]h^{\dagger}$
Volumes in coin before pump	Total amount of the coin traded within the time window from $x + 1$ hours to 1 hour before the pump	$volumefrom[x]h^{\dagger}$
Volumes in BTC before pump	Total trading volume of the coin measured in BTC within the time window from $x + 1$ hours to 1 hour before the pump	$volumeto[x]h^{\dagger}$
Return volatilities before pump	Volatility in the hourly log return of the coin within the time window from $y + 1$ hours to 1 hour before the pump	$returnvola[y]h^{\ddagger}$
Volume volatilities in coin before pump	The volatility in the hourly trading volume in coin within the time window from $y + 1$ hours to 1 hour before the pump	$volumefromvola[y]h^{\ddagger}$
Volume volatilities in BTC before pump	The volatility in the hourly trading volume in BTC within the time window from $y + 1$ hours to 1 hour before the pump	$volumetovola[y]h^{\ddagger}$
Last price before pump	Open price of the coin one hour before the coin announcement	<i>last price</i>
Time since existence	The time difference between the time when the first block of the is mined and the pump time	<i>age</i>
Pumped times before	Number of times the coin been pumped in Cryptopia before	<i>pumpedtimes</i>
Coin rating	Coin rating displayed on Cryptopia, 0 being the worst, 5 being the best. The rating considers the following criteria wallet on {Windows, Linux, Mac, mobile, web, paper}, premine ratio, website and block explorer	<i>rating</i>
Withdrawal fee	Amount of coin deducted when withdrawing the coin from Cryptopia	<i>WithdrawFee</i>
Minimum withdrawal	Minimum amount of coin that can be withdrawn from Cryptopia	<i>MinWithdraw</i>
Maximum withdrawal	Daily limit on the amount of coin that can be withdrawn from Cryptopia	<i>MaxWithdraw</i>
Minimum base trade	Minimum base trade size of the coin	<i>MinBaseTrade</i>

Table 2: Features included in the prediction model. \*The feature is designed to represent a coin’s market cap in a normal setting, i.e. absent market manipulation. While it might be useful to also collect coins’ historical market cap before each pump-and-dump, we have not found a public source that provides this type of data.  $\dagger x \in \{1, 3, 12, 24, 36, 48, 60, 72\}$ .  $\ddagger y \in \{3, 12, 24, 36, 48, 60, 72\}$ .

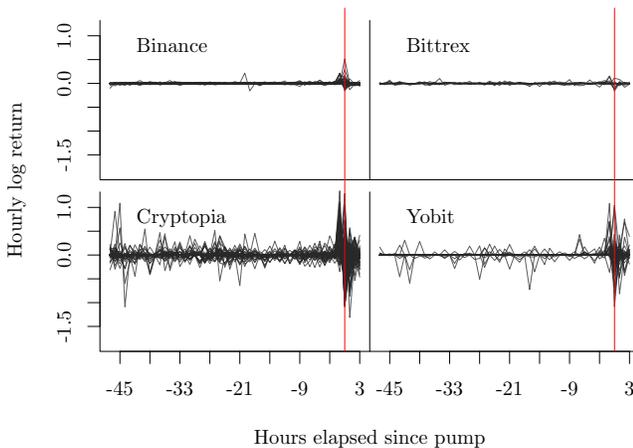

Figure 13: Time series of coin returns before and after pump. In each subplot, the hourly log return of each pumped coin before and shortly after the pump is superimposed. The vertical red line represents the pump hour during which the coin was announced.

coin announcement to predict which coin might be pumped.

In the following exercise, we focus on predicting coins pumped in one specific exchange for the ease of data harmo-

nization. We choose Cryptopia due to sufficient data collected for modelling. Although the exchange ceased to operate on May 15, 2019, our exercise demonstrates a proof of concept for strategic crypto-trading that can be adapted for any exchange.

For each coin before a pump event, we predict whether it will be pumped (TRUE) or not (FALSE). The formula for the prediction model is:

$$Pumped = M(feature_1, feature_2, \dots)$$

where the dependent variable *Pumped* is a binary variable that equals 1 (TRUE) when the coin is selected for the pump, and 0 (FALSE) otherwise. Table 2 lists the features considered in the prediction model.

Previous analyses indicate unusual market movements prior to the pump-and-dump might signal organizers’ pre-pump behavior, which could consequently give away the coin selection information. Therefore, we place great emphasis on features associated with market movements, such as price, returns and volatilities covering various lengths of time. Those features, 46 in total, account for 85% of all the features considered.

## 5.2 Model Application

**Sample specification:** We consider all the coins listed on Cryptopia at each pump-and-dump event. On average, we have 296 coin candidates at each pump, out of which one is the actual pumped coin. The number of coins considered varies for each event due to constant listing/delisting activities on the part of exchanges. The full sample contains 53,208 pump-coin observations, among which 180 are pumped cases,<sup>21</sup> accounting for 0.3% of the entire sample population. Apparently, the sample is heavily skewed towards the unpumped class and needs to be handled with care at modelling.

For robustness tests, we split the whole sample into three chronologically consecutive datasets: training sample, validation sample and and test sample:

Pumped?	Training	Validation	Test	Total
TRUE	60	60	60	180 (0.3%)
FALSE	17,078	17,995	18,135	53,028 (99.7%)
<b>Total</b>	17,138	18,055	18,195	53,208 (100.0%)

The training sample covers the period of June 19, 2018 to September 5, 2018 and consists of 17,138 data points (32.2% of full sample); the validation sample covers September 5, 2018 to October 29, 2018 and consists of 18,055 data points (33.9% of full sample); the test sample covers October 29, 2018 to January 11, 2019 and consists of 18,195 data points (34.2% of full sample).

**Model selection:** We test both classification and logit regression models for the prediction exercise. Specifically, for the classification model, we choose random forest (RF) with stratified sampling; for the logit regression model, we apply generalized linear model (GLM). Both RF and GLM are widely adopted in machine learning and each has its own quirks.

RF is advantageous in handling large quantities of variables and overcoming overfitting issues. In addition, RF is resilient to correlations, interactions or non-linearity of the features, and one can be agnostic about the features. On the flip side, RF relies upon a voting mechanism based on a large number of bootstrapped decision trees, which can be time-consuming, and thus challenging to execute. In addition, RF provides information on feature importance, which is less intuitive to interpret than coefficients in GLM.

GLM is a highly interpretable model [28] that can uncover the correlation between features and the dependent variable. It is also highly efficient in terms of processing time, which is a prominent advantage when coping with large datasets. However, the model is prone to overfitting when fed with too many features, which potentially results in poor out-of-sample performance.

<sup>21</sup>Due to missing data on several delisted coins, this number deviates from the total number of 211 pump events in Cryptopia, as presented in Figure 7.

**Hyperparameter specification:** Due to the heavily imbalanced nature of our sample, we stratify the dataset when using RF [9], such that the model always includes TRUE cases when bootstrapping the sample to build a decision tree. Specifically, we try the following three RF variations:

Model	Sample size per tree		Total	Number of trees
	TRUE	FALSE		
RF1	60	20,000	20,060	5,000
RF2	60	5,000	5,060	10,000
RF3	60	1,000	1,060	20,000

We fix the number TRUES at 60 for each RF variation, so that the model may use the majority of TRUES to learn their pattern when building each tree. Model RF1 stays loyal to our sample's original TRUE/FALSE ratio, with 0.3% of TRUES contained in each tree-sample. RF2 and RF3 raise the TRUE/FALSE ratio to 1.2% and 6%, respectively. Note that while the sample size per tree decreases from RF1 to RF2 to RF3, we are mindful to increase the number of trees accordingly to ensure that whichever model we use, every input case is predicted a sufficient number of times. We use the R package `randomForest` to model our data with RF1, RF2 and RF3.

With conventional binomial GLM, problems can arise not only when the dependent variable has a skewed distribution, but also when features are skewed. With heavy-tailed coin price distribution and market cap distribution, conventional binomial GLM can be insufficient to handle our sample. Therefore, we apply LASSO (least absolute shrinkage and selection operator) regularization to the GLM models. After preliminary testing, we choose to focus on three representative LASSO-GLM models with various shrinkage parameter values ( $\lambda$ ):

Model	Shrinkage parameter ( $\lambda$ )
GLM1	$10^{-8}$
GLM2	$10^{-3}$
GLM3	$5 \times 10^{-3}$

Higher values of  $\lambda$  causes elimination of more variables. We use the R package `glmnet` to model our data with GLM1, GLM2, and GLM3.

**Variable assessment:** By applying the specified models on the training sample, we are able to assess the features' relevance to coin prediction. Figure 17 presents features' importance based on mean decrease in Gini coefficient with RF models. We find that:

- Coin market cap *caps* and last hour return before the pump *return1h* appear to be the two most important features in predicting pumped coin using RF models.
- Features describing market movements shortly before the pump, e.g. *return1h*, *volumeto1h* and *volumefrom1h*, appear to be more important than features describing longer-term movements.

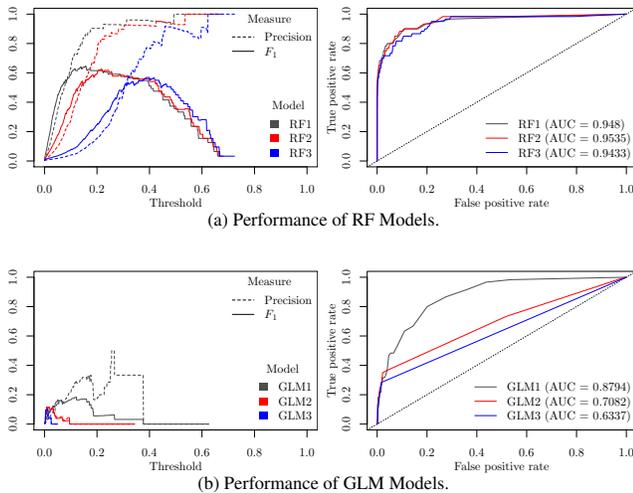

Figure 14: Model performance on the training sample measured by Precision,  $F_1$  (left) and ROC AUC (right) at different threshold levels.

- Among all the features related to market movements, return features are generally more important than volume or volatility features.
- Exchange-specific features including *MinBaseTrade*, *MinWithdraw*, *MaxWithdraw*, and *WithdrawFee* are least important.

Figure 18 presents the estimated coefficients of variables with GLM models, from which we obtain several findings in line with what is indicated by RF models above. Specifically, we notice that:

- When only one variable is included, *return1h* appears to have the highest explanatory power on coins' pump likelihood;
- The positive coefficients of return features imply that the higher the return a coin shows before the pump, the more likely the coin is to be pumped;
- The positive coefficient of *pumpedtimes* implies that pumped coins are more likely to get pumped again.

The variable assessment performed by RF and GLM is coherent in that both find features representing market movement shortly before the pump to be more important than longer-term features. This echoes our exploratory analysis illustrated in Figure 13 and aligns with Kamps et al. [20]. The finding suggests the spontaneity of admins' coin selection, and the importance for strategic traders to obtain real-time market data.

### 5.3 Assessing Prediction Accuracy

Both the random forest model and GML predict whether a given coin will be pumped as a likelihood ranging between 0

and 1. We apply thresholding to get a binary TRUE/FALSE answer.

Figure 14 depicts the in-sample fitting of model candidates with the training sample as the threshold value changes. The fitting measurements include precision, the  $F_1$  measure and area under ROC (Receiver operating characteristic) curve. Figure 14(a) describes the performance of RF models and Figure 14(b) GLM models.

Precision represents the number of true positive divided by number of predicted positive, and the precision line ends when the denominator equals zero, i.e. when no TRUE prediction is produced. Figure 14 shows that, among the three RF models, the threshold value at which the line ends is the lowest with RF1, and highest with RF3. This indicates that absent balanced bootstrapping, an RF model tends to systematically underestimate pump likelihood, leading to zero predicted TRUE cases even when the threshold value is small.

Compared to RF models, none of the GLM models is able to produce high precision.

In terms of  $F_1$  measure, RF models again appear superior to GLM models. Among the three RF models, the RF1 performs best at a low threshold range ( $< 0.2$ ), while RF3 performs best at a high threshold range ( $> 0.4$ ). RF2 resides in between.

The RF models' superiority to GLM models is further demonstrated by the ROC (Receiver operating characteristic) curve in Figure 14. Among the three RF models, no discernible difference can be found in terms of ROC AUC: all exhibit high performance with  $AUC > 0.94$ . The GLM models, in contrast, render an AUC between 0.63 and 0.88.

Due to their obvious inferiority, we eliminate GLM models from further analysis. Figure 15 illustrates the out-of-sample performance of RF models. The model performance with the validation sample resembles that of the training sample, remaining strong with regard to all three indicators (precision,  $F_1$  and AUC). This suggests that the classification model trained and calibrated on one period of data can accurately predict a later period.

Both Figure 14(a) and Figure 15 suggest that balancing the sample with various TRUE/FALSE ratios only changes the absolute value of the pump likelihood output, but not the relative one. This means the three RF models can perform similarly in terms of Precision and  $F_1$  measure, when the appropriate threshold value is chosen in correspondence with the model (specifically,  $Threshold_{RF1} < Threshold_{RF2} < Threshold_{RF3}$ ).

### 5.4 Testing an Investment Strategy

To explore the model's practical utility, we devise a simple investment strategy. At each pump, we check which coin's predicted pump likelihood surpasses a predetermined threshold, and we purchase all those coins before the actual coin announcement (if no coin's vote exceeds the threshold, we will not pre-purchase any coin). Note that if we had the ability to short or use margin trading on the exchanges we use,

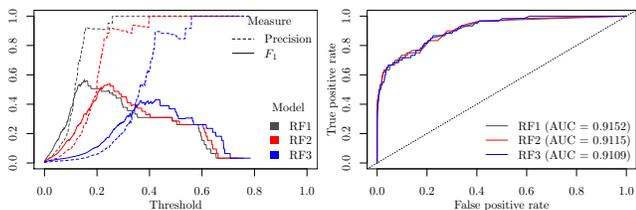

Figure 15: Performance of RF models on the validation sample measured by Precision,  $F_1$  (left) and ROC AUC (right) at different threshold levels.

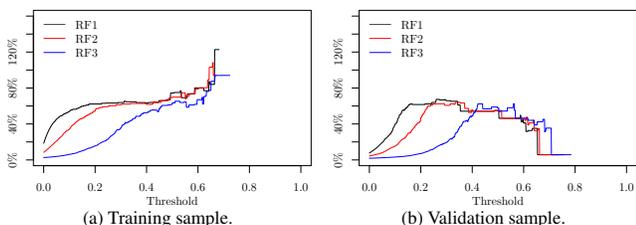

Figure 16: Investment return using different models at different threshold levels.

potentially more options would open up for us.

**Strategy:** Specifically, for each coin that we pre-purchase, we buy the coin at the open price one hour before the coin announcement with the amount of BTC equivalent to  $k$  times the vote where  $k$  is a constant. That is to say, with all the coins we purchase, the investment, measured in BTC, on each coin is proportionate to its vote supplied by the random forest model. This is logical because a higher vote implies a higher likelihood of being pumped, and thus worth a higher investment.

We further assume that among all the coins we purchased, those coins that do not get pumped (false positive, “false alarms”) will generate a return of zero, i.e. their price will remain at the same level as the purchase price; those coins that get pumped (true positive, “hits”) will be sold at an elevated price during the pump. To be conservative, we assume that with each purchased coin that gets pumped we only obtain half of the pump gain, expressed as:

$$\text{pump gain} = \frac{\text{high price} - \text{open price}}{\text{open price}}$$

**Returns:** Figure 16 presents the relationship between the aggregate return and the threshold choice.

Figure 16(a) illustrates the performance of the trading strategy with the training sample. The figure shows that, in general, the *higher* the threshold, which means we buy coins with higher pump likelihoods and disregard others, the *higher* the return.

Figure 16(b) illustrates the performance of the trading strategy with the validation sample. As the threshold increases, the return first increases and then decreases. This is because the coins with the highest predicted pump likelihood in the validation sample happen to have very low pump gain. When the threshold is high, only those coins with high likelihood but

		Predicted		Total
		TRUE	FALSE	
Actual	TRUE	9	51	60
	FALSE	0	18,135	18,135
Total		9	18,186	18,195

Table 3: Confusion matrix of RF1 with threshold value 0.3 applied to test sample.

low gain are included in the investment portfolio, resulting in a low overall return.

As already mentioned at the end of Section 5.3, every model has its own optimal threshold value. In terms of the magnitude of the profit, with the right combination of threshold and model, investors would theoretically enjoy a return of 140% with the training sample cases (RF1 with threshold of 0.7), and a return of 80% with the validation sample cases (RF1 with threshold of 0.3).

One should be mindful that if the threshold is set *too high* (e.g., greater than 0.8), then the investor might end up not buying any coins, and consequently gaining no profit. In addition, although high threshold comes with high precision, it also leads to a low number of coins being purchased, increasing the risk associated with an undiversified investment portfolio, as demonstrated in Figure 16(b).

## 5.5 Final Test

Based on the training and validation results of specified models, we need to select one model and an accompanying threshold value to apply to the test sample. Our ultimate goal to maximize the trading profit using the selected model in combination with the proposed trading strategy on a set of out-of-sample data. Therefore, we base our decision primarily on Figure 16(b). We apply RF1 and a threshold of 0.3 — the combination that delivers the highest return in Figure 16(b) — on our test sample.

To determine the investment amount in BTC for our trading strategy, we need to examine the market depth. This is particularly important for exchanges with low trading volume such as Cryptopia and Yobit. When trading in those exchanges, it has to be ensured that during the pump-and-dump, the market would provide sufficient depth for us to liquidate the coins purchased prior to the pump. For example, if the total trading volume in one event is 0.4 BTC, it would make no sense to spend 0.8 BTC on the coin.

To this end, we calculate the average trading volume per pump-and-dump at Cryptopia. We only consider “uptick” transactions, i.e. where the buyer is the aggressor. This yields a ballpark estimation of the market depth on the buy side. We use this number, 0.37 BTC, as the baseline investment quantity. This baseline amount, discounted by the predicted pump likelihood, would be the investment value in BTC.

Coin	Date	Pumped?	weight wt	BTC	Pump	Assumed	BTC
				invested $q = \bar{Q} \times wt$	gain pg	gain $ag = pg/2$	gained $q \times ag$
BVB	Nov 14	TRUE	0.30	0.11	283%	142%	0.16
CON	Nov 16	TRUE	0.44	0.16	33%	17%	0.03
FLAX	Nov 10	TRUE	0.58	0.21	135%	67%	0.14
MAGN	Nov 13	TRUE	0.37	0.14	70%	35%	0.05
MAGN	Dec 16	TRUE	0.39	0.14	85%	43%	0.06
OSC	Nov 13	TRUE	0.65	0.24	297%	148%	0.36
OSC	Nov 25	TRUE	0.52	0.19	100%	50%	0.10
SOON	Nov 01	TRUE	0.58	0.21	10%	5%	0.01
UMO	Nov 15	TRUE	0.55	0.20	60%	30%	0.06
				<b>1.61</b>			<b>0.96</b>

Table 4: Purchased coins based on pump likelihood predicted by RF1. Only coins with predicted pump likelihood of greater than 0.3 are purchased. Investment weight equals pump likelihood.  $\bar{Q} = 0.37$ , the average of total transaction volume in a pump-and-dump event in Cryptopia. Only transaction volume where the buyer is the aggressor is considered.

Table 3 displays the confusion matrix of the model prediction with the test sample. The model suggests us to purchase 9 coins in total, all of which are ultimately pumped. Table 4 lists those 9 coins, their respective investment weight and assumed profit. The return on the investment amounts to 60% (2.61/4.38) over the test sample period of two and a half months. Note that the effect of transaction fees (0.2% on Cryptopia) on the investment profitability is negligible. The result of the final test is very similar to that with both the training sample and the validation sample when the same combination of model (RF1) and threshold (0.3) is applied (Figure 16), confirming the model’s robustness.

## 5.6 Caveats and Improvement Potential

**Data:** Upon availability, order book data, tick-by-tick data before a pump and traders’ account information can also be included as features.

**Modelling method:** Random forest with unsupervised anomaly detection has the potential to improve the model performance. In addition, other classification (e.g. k-NN) and regression (e.g. ridge) models are worth considering.

**Additional considerations:** Regarding investment weights, one may consider coin price increase potential (based on e.g. historical returns) in combination with coin pump likelihood. One must beware that in liquid exchanges, the trading strategy only applies to *small* retail investment, since big purchase orders prior to a pump can move the market, such that pump organizers may cancel the pump or switch the coin last-minute. Also worth factoring in is the market risk (e.g. security risk, legal risk) associated with the nascent crypto-market.

## 6 Related Work

Over the past year, a handful of studies researching cryptocurrency pump-and-dump activities have been conducted, notably Kamps et al. [20], Li et al. [23] and Hamrick et al. [18].

Our work differs from the aforementioned studies in terms of motivation, methodology, data, and contribution. We aim for *prospective* prediction as opposed to *retrospective* investigation of pump-and-dump activities. We use a homogeneous set of data that only includes clearly announced pump-and-dump events on Telegram.<sup>22</sup> Regarding the sample period, our data cover a recent time span of June 17, 2018 to February 26, 2019 (Table 5).

Our paper is also closely linked to literature on market manipulation in non-cryptocurrency contexts. Lin [24] explains potential damage of various manipulation methods including pump-and-dump, front running, cornering and mass misinformation, and argues for swift regulatory action against those threats. Austin [3] calls for authorities’ demonstration of their ability to effectively deter market manipulation such as pump-and-dump in exchanges for small-capped companies, in order to recover investors’ confidence in trading in those markets, which would consequently foster economic growth.

Our paper is further related to research on crypto trading. Gandal et al. [17] demonstrate that the unprecedented spike in the USD-BTC exchange rate in late 2013 was possibly caused by price manipulation. Makarov et al. [25] probe arbitrage opportunities in crypto markets. Aune et al. [2] highlight potential manipulation in the blockchain market resulting from the exposure of the footprint of a transaction after its broadcast and before its validation in a blockchain, and proposes a cryptographic approach for solving the information leakage problems in distributed ledgers.

Our paper is also akin to existing literature on cryptocurrencies’ market movements. The majority of related literature still orients its focus on Bitcoin. Many scholars use GARCH models to fit the time series of Bitcoin price. Among them, Dyrberg et al. [13] explore the financial asset capabilities of Bitcoin and suggests categorizing Bitcoin as something between gold and US Dollar on a spectrum from pure medium of exchange to pure store of value; Bouoiyour et al. [7] argue that Bitcoin is still immature and remains reactive to negative rather than positive news at the time of their writing; 2 years later, Conrad et al. [10] present the opposite finding that negative press does not explain the volatility of Bitcoin; Dyrberg [14] demonstrates that bitcoin can be used to hedge against stocks; Katsiampa [21] emphasizes modelling accuracy and recommends the AR-CGARCH model for price retro-fitting. Bariviera et al. [4] compute the Hurst exponent by means of the Detrended Fluctuation Analysis method and conclude that the market liquidity does not affect the level of long-range dependence. Corbet et al. [11] demonstrate that Bitcoin shows characteristics of a speculative asset rather than a currency also with the presence of futures trading in Bitcoin.

Among the few research studies that also look into the financial characteristics of other cryptocurrencies, Fry et al. [16]

<sup>22</sup>As suggested earlier, all the coin announcements we found on Discord overlap with our Telegram data

examine bubbles in the Ripple and Bitcoin markets; Baur et al. [6] investigate asymmetric volatility effects of large cryptocurrencies and discover that in the crypto market positive shocks increase the volatility more than negative ones. Jahani et al. [19] assess whether and when the discussions of cryptocurrencies are truth-seeking or hype-based, and discover a negative correlation between the quality of discussion and price volatility of the coin.

## 7 Conclusions

This paper presents a detailed study of pump-and-dump schemes in the cryptocurrency space. We start by presenting the anatomy of a typical attack and then investigate a variety of aspects of real attacks on crypto-coins over the last eight months on four crypto-exchanges. The study demonstrates the persisting nature of pump-and-dump activities in the crypto-market that are the driving force behind tens of millions of dollars of phony trading volumes each month. The study reveals that pump-and-dump organizers can easily use their insider information to profit from a pump-and-dump event at the sacrifice of fellow pumpers.

Through market investigation, we further discover that market movements prior to a pump-and-dump event frequently contain information on which coin will be pumped. Using LASSO regularized GML and balanced random forests, we build various models that are predicated on the time and venue (exchange) of a pump-and-dump broadcast in a Telegram group. Multiple models display high performance across all subsamples, implying that pumped coins can be predicted based on market information. We further propose a simple but effective trading strategy that can be used in combination with the prediction models. Out-of-sample tests show that a return of as high as 60% over two and half months can be consistently exploited even under conservative assumptions.

In sum, we wish to raise the awareness of pump-and-dump schemes permeating the crypto-market through our study. We

show that with fairly rudimentary machine learning models, one can accurately predict pump-and-dump target coins in the crypto-market. As such, we hope our research could, on one hand, lead to fewer people falling victim to market manipulation and more people trading strategically, and on the other hand, urge the adoption of new technology for regulators to detect market abuse and criminal behavior. If such advice would be heeded, admins' schemes would crumble, which would in turn lead to a healthier trading environment, accelerating the market towards a fairer and more efficient equilibrium.

## Abstract

Since the release of a browser-based cryptominer by Coinhive in 2017, the easy use of these miners has skyrocketed illicit cryptomining in 2017 and continued in 2018. This method of monetizing websites attracted website owners, as well as criminals seeking new ways to earn a profit. In this paper, we perform two large studies into the world of cryptojacking, focused on organized cryptomining and the spread of cryptojacking on the Internet. We have identified 204 cryptojacking campaigns, an order of magnitude more than previous work, which indicates that these campaigns are heavily underestimated by previous studies. We discovered that criminals have chosen third-party software – such as WordPress – as their new method for spreading cryptojacking infections efficiently. With a novel method of using NetFlow data we estimated the popularity of mining applications, which showed that while Coinhive has a larger installation base, CoinImp WebSocket proxies were digesting significantly more traffic in the second half of 2018. After crawling a random sample of 49M domains, ~20% of the Internet, we conclude that cryptojacking is present on 0.011% of all domains and that adult content is the most prevalent category of websites affected.

## 1 Introduction

Unlike traditional currencies, such as the Euro or Dollar, cryptocurrencies are digital assets created as a medium of exchange based on cryptography and a blockchain, which are used to secure both the creation and transactions of units. In 2009, Satoshi Nakamoto released the Bitcoin [33], the first ever decentralized cryptocurrency, which made it possible to transfer monetary value to another person by creating a transaction and committing this to the blockchain, a list of blocks secured by cryptographic operations maintained by a peer-to-peer network of miners. These miners secure the blockchain by constantly collecting transaction data from the network and validating it by solving cryptographic challenges based on the previous block, the transaction and the receiver

of the transaction. After validation, the confirmed transaction is inserted into the blockchain again in the form of a validated block. As a reward, the miner gets a (part of a) cryptocurrency. This network guarantees that only the rightful owner of a Bitcoin wallet can make transactions and prevents malicious actors from inserting false information into the blockchain.

Solving these cryptographic challenges as a miner has however become so difficult that Bitcoin cannot efficiently be mined anymore on regular PCs. Over the past years, over 4,000 other cryptocurrencies have been created, so-called alt-coins. One of them is Monero (XMR), launched in 2014 and nowadays the most popular cryptocurrency in browser-based mining [34]. In contrast to Bitcoin, Monero uses a private blockchain, meaning that while anybody can use it to make transactions, nobody is allowed to view them [47]. It also builds upon a different proof-of-work algorithm to validate its transactions, called CryptoNight, a fork of CryptoNote [43]. This algorithm is designed to be memory-hard and therefore requires a large set of bytes in memory to perform frequent read and write operations on. Simple consumer-grade CPUs have exactly that memory available at their processor caches, making this kind of mining the most efficient on regular consumer-grade hardware. To speed up the mining process, mining jobs can be distributed among individual miners in a mining pool. In such a pool, miners work together to mine new blocks and share the rewards. Work is distributed among miners in the pool based on the difficulty of the cryptographic challenge. As a consequence, powerful machines solve the more difficult puzzles, while low-end machines receive the easier ones. Rewards are shared according to the same principle. Mining pools closely monitor the submissions from their miners and state that they will block any wallet address after receiving evidence that a wallet is used for malware or botnet activities [28].

The introduction of alt-coins that by design can be effectively mined on regular PCs also made them an attractive target for cybercriminals. Both the private blockchain and the ASIC-resistant mining algorithm of Monero quickly made Monero one of the preferred choices. In addition to being

included in malware [37], there also exist implementations to perform *drive-by mining* or *cryptojacking*, where cryptocurrency is mined in the user's web browser while visiting a web site. While originally developed as an alternative mechanism to donate to the upkeep of a website in presence of now ubiquitous ad-blockers, many methods exist to maliciously apply browser-based mining: for example, criminals hack vulnerable websites to install mining scripts [3] or create malicious advertisements with cryptojacking code that are displayed on benign websites [30], but actors have also compromised routers [35] or setup malicious Wi-Fi networks [38] to inject cryptominers into their users' traffic.

Previous studies have performed surveys on the use of cryptominers across the most commonly visited websites and have identified groups of criminals installing cryptominers on a large number of domains for their own profit [22, 39]. It makes sense for a cyber criminal to lure as many users as possible into such mining, which could be accomplished not only by deploying the cryptojacking code into popular websites, but hacking a large number of websites or injecting a resource such as a common library that is used by a large number of unsuspecting websites. These individual installations are working together in a coordinated campaign, thus significantly increasing the profits of the criminal, but at the same time also indicating an elevated level of knowledge and sophistication of the adversary. The presence and extent of such coordination is however largely unknown.

In this paper, we address this gap and systematically investigate the coordination and collaboration of cryptojackers on the Internet and make the following four contributions:

- We are the first to systematically analyze the relationships between websites that perform cryptomining and the actors behind them. By this campaign analysis, we find the existence of massive installations. In fact, we have identified 3 times as much cryptojacking activity as [39] and the five largest campaigns we detected exceed the *total* size of cryptomining reported in [22].
- We show that the bulk of organized mining activity is the result of compromised (parts of) third-party software and that comparatively little organized activity is the result of hacked websites or an explicit choice to mine by the website owner.
- Through a survey of 1,136 top level domains and by comparing the installation base with actual mining traffic on the Internet using NetFlow data, we find that the most prominently installed miner is actually not the one that generates the most mining activity in practice. We also see that applications and attack vectors come and go, and that different TLD zones exhibit clear differences in mining application popularity.
- Estimating cryptojacking by solely crawling the Alexa Top 1M results is an overestimation of the size, as we

see that cryptojacking activity is almost 6 times higher in that subset compared to the rest of the Internet.

To enable follow up research, we make our data and software publicly available at <https://www.cyber-threat-intelligence.com/cryptojacking-campaigns>.

## 2 Background

**WebAssembly & asm.js** To enable faster execution of code inside the browser, Mozilla developed *asm.js*, a technique for translating high-level languages, such as C and C++, into JavaScript to be used by the browser [29]. Multiple validation methods enable the JavaScript engine to compile this code ahead-of-time and improve execution speed. This technique made it possible to execute code faster inside the browser after its release in 2013.

WebAssembly (*Wasm*) is a more recently released scripting language developed by the World Wide Web consortium in 2017 and is able to compile high-level languages like C, C++ and Rust inside the browser to be used in web applications [50]. It runs in a sandbox within the browser and it aims to execute as fast as native machine code. Wasm is complementary to JavaScript, as it is being controlled by JavaScript code after its compilation.

The difference between *asm.js* and *Wasm* is the fact that the latter is compiled only once and is started directly at native speed, whereas code in *asm.js* is compiled and optimized at run time, therefore decreasing execution speed. Both techniques are supported by all four major browsers (Chrome, Firefox, Edge and Safari) and have drastically improved the execution speed of applications inside the browser, which made them very attractive for browser-based mining.

**WebSockets & Stratum** WebSockets is a HTML5 protocol providing two-way communication between the client and a server over a single TCP connection [52]. The protocol enables easy real-time data transfer without refreshing (a part of) the web page. Communication is done over the same TCP ports as the web browser, making it robust to strict firewall rules or other blocking.

Developers are free to define the format of messages sent over WebSocket connections. However, there is a protocol specifically designed for cryptomining communications: the Stratum Mining Protocol, a line-based protocol with messages encoded in plain-text JSON-RPC format [46]. Servers communicate with their clients using Stratum to authorize new miners in the pool, distribute jobs based on difficulty and retrieve found hashes from the miners. An example of a WebSocket connection using the Stratum protocol is given in Table 1.

**Browser-based mining** Triggered by the rise of CPU-mineable cryptocurrencies (such as Monero) and the rapid

Table 1: Example of a WebSocket connection using the Stratum Mining Protocol to communicate with a mining pool

development of useful web standards (e.g. WebAssembly and the Stratum protocol), browser-based cryptomining gained an enormous momentum in the autumn of 2017. Coinhive, a German company, created an easy to use browser-based mining application as an alternative to advertisements [9, 23]. They provide a JavaScript library, an API and a WebSocket proxy infrastructure to developers to easily integrate a browser-based miner into their website and let their visitors mine for Monero. 70% of the mined Monero is transferred to the owner of the account, the remaining 30% is kept by Coinhive [10]. Soon after Coinhive released their miner application, similar ones appeared, such as Cryptoloot [11] and Coin-Have [6]. Nowadays, miner applications come and go, with various capabilities and usage fees, but Coinhive still has a prominent place in the cryptojacking landscape.

**Overview of a cryptojacking attack** Although different mining applications exist, all browser-based miners show great similarities. As depicted in Figure 1, the user visits the cryptomining website (1) and receives a valid HTTP response (2). The cryptomining website requests a JavaScript file (3), which controls the mining operation. This script first explores the host system, searches for the number of CPU threads available, downloads the WebAssembly mining script

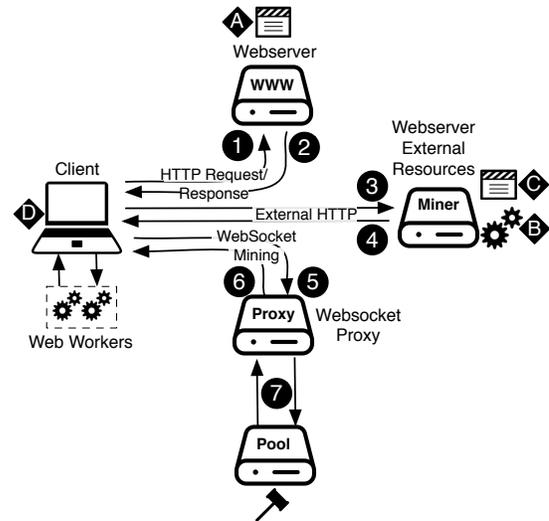

Figure 1: Browser-based cryptomining attack

for the actual mining operation (4) and distributes it over a number of WebWorkers (a JavaScript instance running in the background, without affecting the page performance). It also sets up a WebSocket connection with the mining pool through a proxy (5). The script authenticates itself to the mining pool server (in Stratum format) and, if successful, receives the first job to work on (6). The WebWorkers start working on that job and found hashes are submitted to the mining pool by the controller script (7).

**Campaign analysis** Campaign analysis is the field of research focused on discovering clusters of malicious online entities. The term originates from analysis of large volumes of SPAM or phishing emails, but can also be used in other areas, such as browser-based cryptomining. In this particular case, campaign analysis is focused on finding clusters of the same cryptominers on different domains. Since those miners always include a form of identification to which funds need to be transferred, clustering cryptojacking websites can be done relatively easily. Most mining applications define a *siteKey*, a unique (random) string used to identify the user to which earnings have to be transferred, which can be found in either the source code or the WebSocket traffic. A similar *siteKey* guarantees that the same account is rewarded for the mining that takes place. Identifying campaigns can also be done by searching for similar WebSocket proxy servers, if the website is not using a popular one, but instead hosting its own server. We have used these, and other techniques to discover campaigns as discussed in Section 6.1. We have chosen to define a cluster of websites as a campaign once they share identical features more than 5 times. E.g. a cluster of 6 websites with the same *siteKey* or private WebSocket proxy server is considered a campaign.

### 3 Attack vectors

Mining cryptocurrencies with the computing power of website visitors is not illegal, as long as users are asked permission to mine. When a user cannot consent to the mining activities their computer is involved in, it is called *cryptojacking*. Although browser-based cryptomining is a recent phenomenon, jurisdiction on cryptomining without consent already exists. In 2015, a US court settled a case with a developer of Bitcoin-mining software, in which the Attorney General stated that no website should tap into a person's computer processing power and that the user has to be informed about the cryptomining activities which take place on the visited website [18]. However, this is often not the case. In this section, we summarize the attack surface for cryptojacking on the Internet. All attack vectors are marked in Figure 1 by their corresponding characters.

**Website owner (A)** The owner of a website can add a cryptomining script to his web page without informing its users. This can be done as a replacement for advertisements, which was the case for The Pirate Bay, one of the most popular torrent websites [48]. Only a few days after the Coinhive service was launched, they added a miner to their website which started mining without user consent, as a replacement for the intrusive advertisements they would normally show. Nowadays, the website shows a disclaimer on the bottom of the homepage, notifying their visitors that their CPU will be used for cryptomining. Another major source of website owner initiated cryptojacking is parked domains [13].

**Compromised websites (A)** A cryptomining script can also be present on a web page without knowledge of the website owner. When a website gets hacked, an attacker is able to inject cryptomining scripts. Now, the attacker receives the rewards for the visitors mining on that website. There are numerous examples of this kind of attack. There have been cryptojacking scripts found on web pages of the Indian government [3], CBS Showtime [26] and many others.

**Third-party software (B)** Gaining unsolicited access to large number of domains is a time-consuming operation. As a consequence, attackers have tried different tactics to infect multiple websites at once by infecting third-party software. In the last year, we have seen attacks in which cryptojacking code is injected into popular third-party software, such as JQuery or Google Tag Manager [5]. Drupal, a widely used open-source CMS, was the victim of a large attack involving more than 100,000 websites [32] and WordPress, a similar CMS, suffered from a weather plugin [53] secretly injecting a cryptojacking script into the website it was installed on.

**Malicious advertisements (C)** Advertisement-supported websites let their advertisements be sold by advertisement networks, such as Google. The downside of this system is that attackers can attach cryptomining scripts to advertisements and distribute them through an advertisement network over a large number of websites. In January 2018, Youtube was a victim of this kind of attack, in which cryptomining scripts were injected in the ads shown on the website [30].

**Man in the middle (D)** The most effective method of gaining large groups of miners for an attacker is by being the man-in-the-middle. In August 2018, 200,000 MikroTik routers were infected by malware, which inserted a Coinhive script into every website the user visits [35]. The bug was patched within a day, but many MikroTik routers are not, leaving them still vulnerable. In our research, we are not able to detect these attacks, since they are not originating from a website.

### 4 Related Work

Academic research on browser-based cryptomining has only started in 2017 and is, due to the recent developments of the used web standards, very topical. The first explorations into this research field have been performed by Eskandari et al. [13]. In their analysis, the authors queried two large source code datasets for strings known to be part of cryptomining scripts (such as `coinhive.min.js` or `load.jsecoin.com`) and found a large number of domains. This method is only able to detect known mining applications, not the obfuscated or new ones. While calculating the profitability, the authors stumbled upon a Coinhive campaign which ran a miner on over 11,000 parked websites. This study kicked-off a number of subsequent investigations, which were all aimed at detecting browser-based cryptomining. Rauchberger et al. [39] created their *MiningHunter*, a crawler able to detect mining scripts even when their malicious activities are obfuscated. The detection method relied on analyzing executed JavaScript code and WebSocket traffic frames. After a successful crawl of the Alexa Top 1M in the beginning of December 2017, they were able to detect 3,178 websites running a cryptominer. 1,210 unique keys were retrieved and one large campaign involving 1,116 websites infected by a malicious advertisement network was identified. At the same time Parra Rodriguez et al. [40] worked on *RAPID*, a resource and API-based detection method, which is able to detect browser-based cryptomining and is resistant to JavaScript obfuscation. Their classification was able to classify mining samples with a precision of 96%. Eventually 656 actively mining websites were found in the Alexa Top 330,550. A similar classification study was performed by Carlin et al. [2], in which they demonstrated that dynamic opcode tracing is extremely effective at detecting cryptomining behavior. Liu et al. [24] proposed a novel approach for detecting browser-based mining applications by

creating *BMDetector*, a detection system based on a modified Chrome kernel. Using this modified kernel, the authors were able to perform JavaScript code block analysis on the compiled JavaScript code, which allowed them to detect heavily obfuscated miner applications as well. Hong et al. [19] built *CMTracker*, a behavior-based detector with two runtime profilers for tracking browser-based cryptomining. The first profiler monitors incoming JavaScript files for known fingerprints, the second profiler observes the call stack and searches for periodic executions. Their approach was able to detect 868 actively mining websites among the Alexa Top 100K in April 2018. More than half of the found keys were used only once and they noticed that domains hosting mining scripts were migrating faster than the mining pool domains. The authors also mentioned evasion techniques, such as code obfuscation and payload hiding inside third-party libraries. Periodic execution in mining scripts was also noticed by Wang et al. [49], who created *SEISMIC*, a monitoring service to interrupt browser-based mining scripts based on this finding.

A different view on the subject was given by Papadopoulos et al. [36], who tried to answer the question whether browser-based cryptomining could be a suitable alternative to advertisements. After crawling a dataset of 200K websites running advertisements or cryptominers, they concluded that advertisements are still more than 5 times more profitable than cryptominers. This will only change once a visitor stays on the same website for more than 5.3 minutes or when Monero becomes more valuable [36]. A broader view of the browser-based cryptomining ecosystem is given by Saad et al. [42], who researched both cryptomining code and user impact. Besides various JavaScript static code analysis clustering methods and battery drainage studies when cryptomining, they did not perform any crawling of the web. This is in great contrast to the work of R uth et al. [41], who dug deep into browser-based cryptomining by conducting two large web crawls. A first crawl using *zgrab*, which downloaded the first 256 kB of 137M *.com*, *.net*, and *.org* domains, as well as from the Alexa Top 1M websites. Consequently, the resulting HTML file was checked against the NoCoin [14] block list. A second crawl was performed on a subset of 10M websites, with a customized Chrome browser, instructed to dump WebAssembly modules for further inspection. They conclude their work by stating that 0.08% of the probed websites is actively mining [41].

Another large web crawl study is conducted by Konoth et al. [22] as a study for the creation of *MineSweeper*. Again, the Alexa Top 1M (including three internal pages) was crawled, with a crawler extracting information from all loaded JavaScript and HTML files, WebSocket traffic, and requests made while visiting the website. A total of 1,735 websites was found to be actively mining, the majority of them using Coinhive. 20 mining campaigns were discovered in their analysis, of which the largest involved 139 websites. Based on these findings, a novel detection technique was developed, which

focused on the aspects all mining scripts have in common: high CPU cache usage and WebAssembly. They developed *MineSweeper*, able to successfully identify mining scripts based on the CPU's L1 and L3 cache usage and cryptomining characteristics in WebAssembly, thus hardening it against miner obfuscation.

As shown by this summary of related work, most attention of academic investigation has been on detecting these browser-based cryptominers. Multiple studies have shown to be able to detect them with high precision [19, 22, 24, 39–41]. Academic research is less focused on finding campaigns of cryptomining websites, while the online research community (such as Badpackets [31] or Krebs on Security [23]) is particularly interested in finding those relations. The first explorations into this area have been taken by [22], [13] and [39], but campaigns have not been systematically explored in their research. This paper aims to resolve this gap, by focusing on identifying campaigns, methods used in these campaigns and their evolution. We are also interested in the spread of cryptojacking on the Web, but as previous work is mostly crawling (subsets of) the Alexa Top 1M, we will analyze a broader set of websites online. In this paper we will not try to create a new detection method, but we build upon the work of [22] to perform our crawls.

## 5 Methodology

In a measurement study like this, suitable datasets and methods are essential for conducting proper research. In this section we first discuss the datasets used or created, followed by a summary of our crawler implementation.

### 5.1 Dataset creation

In our first crawl, we focus on finding campaigns of cryptojacking websites. Previous work of [19, 22, 39, 41] mainly investigated the popular parts of the Internet by crawling the Alexa Top 1M, or subsets of it. But, as pointed out by Scheitle et al., the Alexa Top 1M is not the only list measuring the popular Internet and the method Alexa uses to create this list raises questions whether it is the most reliable list to use for research on cryptojacking [44]. To overcome this issue, we have decided to use the union of three top lists on the Internet; the Alexa Top 1M [1], the Cisco Umbrella 1M [4] and the Majestic 1M [25], all using different measurement strategies, to include the popular part of the Internet in our dataset. These last two also include subdomains and domains not serving a web page. Therefore, we have only added the domains to the list of URLs to be crawled and omitted the subdomains from the latter two. Since we are interested in finding as many cryptojacking domains as possible for our campaign analysis, we have decided to extend our list even further with a list of websites gathered from querying PublicWWW – a source code search engine – with the keywords listed in Appendix A.

Table 2: Dataset creation for the campaign focused crawl

List	No. of websites	Date (2018)
Alexa Top 1M	1,000,000	Dec 24
Cisco Umbrella 1M	233,145	Dec 24
Majestic 1M	897,767	Dec 24
Custom PublicWWW set	87,051	Nov 23 – Dec 24
<b>Total</b>	<b>1,896,503</b>	

The union of these sets formed the dataset to be crawled and consisted out of 1,896,503 websites (unique effective TLDs + 1), as listed in Table 2. To estimate the prevalence of cryptojacking on the Internet in general, we will not use a top list as the Alexa Top 1M, because it is not a random sample of the Internet. We therefor also download a random sample of ~20% of the websites in 1,136 TLDs. We discuss this crawl in more detail in Section 7.

**Operator NetFlows** While the aforementioned datasets provide insights into the landscape of cryptomining installations at a given moment, these data sources do not reveal much about the actual usage of such services. In order to bridge this gap, we analyzed NetFlow traces from the network of a Tier 1 operator from September 2017 until December 2018, which were collected at a 1:8192 sampling ratio. For our analysis, we obtained NetFlow records for all traffic from and to the various WebSocket proxy servers belonging the mining services. Although NetFlows do not reveal the actual contents of a connection, the used ports and packet sizes can indicate connection types. The identity of the source connecting to the WebSocket proxy is however irrelevant, and was anonymized to a pseudo-random value by the operator using the CryptoPan algorithm [54].

## 5.2 Crawler implementation

As mentioned in Section 4, this research builds upon the work of Konoth et al. [22]. Therefore, we have used their crawler implementation as a starting point for our crawler. The following paragraphs will highlight the major changes and additions made to their work for our research.

**Addition of new miner applications** The publicly available *Minesweeper* crawler supports 22 different mining applications. Based on previous work and online research, we have added another 9 miner applications to the crawler, in order to also identify the newest miner applications. The added applications and their keywords are listed in Appendix B. For some of the already supported miner applications we have extended the fingerprints and improved the regular expressions to find *siteKeys*.

**Active mining detection** We have instructed the crawler to never explicitly consent to any mining operation. Therefore, we define that website to be actively mining without consent when: a mining code signature is found, together with a *siteKey*, more than two WebWorkers and a WebSocket connection, or, when the Stratum protocol communication or login credentials for a mining pool are found in WebSocket traffic. If one of these conditions holds, we mark the domain as actively cryptojacking.

**WebSocket stack trace** The miner application communicates with the mining pool using WebSocket connections. WebSocket traffic was already logged in the crawler, but the initiator of the WebSocket connection was not. By inspecting the stack trace of the WebSocket initiation, we can determine which script was responsible for opening the WebSocket connection and therefore the mining initiator. Using this method, we can easily distinguish between miners started from the main HTML page or the ones hidden inside other resources. Moreover, similar stack traces are a powerful indicator for campaign analysis, since it shows what component started the mining application. We have used this method successfully in our campaign analysis to identify attack vectors. Miners hidden inside third-party software such as WordPress are easily noticed in the stack trace, as we will show in Section 6.1.

**Changed logic and exhaustive key finding** Our crawler visits every website twice. First, by using a custom Chrome build, with the `-dump-wasm-module` flag enabled to dump any WebAssembly on the page. If present, these Wasm modules are analyzed for cryptojacking code by the *MineSweeper* application. Second, by using another Chrome build, which visits the website and saves every file it encounters. Instead of visiting 3 internal pages (as Konoth et al. did), we instructed the crawler to visit just one internal page. Besides that, we have implemented a more exhaustive *siteKey* search. The crawler first searches for fingerprints of known miner applications and afterwards for the *siteKey* in the following order: WebSocket traffic, the HTML page and finally in all other HTML and JavaScript resources. A minor addition has been made to automatically decode a base64 encoded *siteKey* of the Mineralt miner [27]. This addition allowed us to retrieve more *siteKeys*, which improves the campaign analysis afterwards.

## 5.3 Infrastructure

We deployed the crawler in Docker containers on 60 servers within the university network, each running 8 Docker instances in parallel. The crawl started on the December 24, 2018 and completed on January 9, 2019. In total, 1,769,183 websites have been successfully visited in this initial crawl. Afterwards, we have performed a second crawl using the same infrastructure, which we discuss in Section 7.

Table 3: Summary of the results of the first crawl

Crawling period	24/12/2018 – 9/1/2019
# websites crawled	1,769,183 (93%)
# potential cryptojacking websites	21,022
# active cryptojacking websites	10,100
# active miner applications	22
# websites with unknown miners	323
# cryptojacking campaigns identified	204
# websites in largest campaign	987
# websites in Alexa Top 1M	648 (0.065%)
# websites in Cisco Umbrella 1M	109 (0.047%)
# websites in Majestic 1M	506 (0.056%)

## 6 Current state of cryptojacking campaigns

We have identified 21,022 websites with traces of cryptomining activities of which 10,100 websites are actively mining without the visitor’s explicit consent. Only 648 of these websites are listed in the Alexa Top 1M. 22 different miner applications have been identified among the crawled websites, most of them running at least the Coinhive miner application (71%). Also, 509 websites are deploying multiple miners. For 323 websites, the used miner application could not be detected, which indicates heavily obfuscated or unknown miner applications. The results are summarized in Table 3.

Among the identified websites, 204 campaigns have been detected, of which the largest one covers 987 websites. This number of campaigns is a magnitude larger compared to previous work [22, 39]. We have identified the use of third-party software, such as Drupal and WordPress, to be the driving factor behind the largest cryptojacking campaigns.

**Mining with consent** There are two mining applications focused on mining solely with visitor consent. JSEcoin, a mining service presenting itself as “*The future blockchain & ecosystem for ecommerce and digital advertising*”, allows website owners to let their users mine JSE tokens, after explicit opt-in consent [20]. Another consent-focused mining application is AuthedMine, the opt-in version of Coinhive, introduced after adblockers started blocking Coinhive [8]. In our crawl, we have identified 2,477 websites using the JSEcoin miner and 227 websites using AuthedMine. None of the websites using AuthedMine opened a WebSocket connection, which indicates that no mining activity took place. 143 websites using JSEcoin did however open a WebSocket connection, but never actually started mining. By analyzing the WebSocket traffic, we observed that in most cases the WebSocket connection initiation was followed by two probes sent back and forth, waiting for the user to opt-in. Since these mining applications did not started mining without consent of the visitor, we have omitted them from our results.

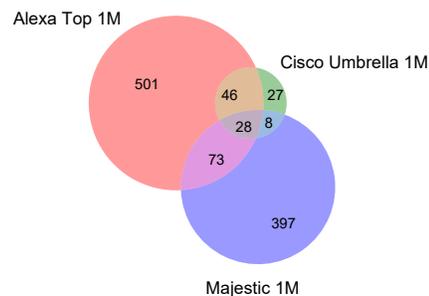

Figure 2: Venn-diagram showing the distribution of identified cryptojacking domains over the used top lists

**Identified domains in top lists** Of the 10,100 domains identified as actively cryptojacking, only 925 were found in one of the three top lists. The Alexa Top 1M contains the most cryptojacking domains (648), meaning that 0.065% of the websites in the Alexa Top 1M are cryptojacking, slightly less than previous work [22, 41]. For both other lists this number is lower. The addition of the Cisco Umbrella 1M resulted in only 27 additional findings, whereas the addition of the Majestic 1M led to the discovery of 397 new cryptojacking domains. In Figure 2, a Venn diagram depicts these differences in subsets. Only a small number of websites is shared among the Alexa Top 1M and the Majestic 1M. Also note that 9,175 (86%) of the identified websites are not listed in any of these top lists. This finding stresses the necessity of looking further than top lists while performing campaign analysis and to study the current state of cryptojacking on the Internet.

**Categorization of websites** We have discovered various sorts of cryptojacking websites on the Internet. By complementing the list of identified domains with website categorization data of Webshrinker [51], we categorized each cryptojacking website. We confirm previous work by identifying adult content (such as pornography) as the most prevailing category within our dataset, with over 2,000 websites in this category. Illegal content, a category known being home to abusive web resources, contains a lower number of cryptojacking websites compared to what we expected.

**Installation base** Coinhive is still the most popular cryptomining application installed on the identified cryptojacking websites (75%), followed by Cryptoloot (5.3%) and CoinImp (3.2%). But, there are noticeable differences between the complete crawl and the subset of domains in the Alexa Top 1M. Coinhive’s share is halved, whereas CoinImp and Cryptoloot installations are doubled in size. Nerohut and Webminerpool miners are relatively more present in the Alexa Top 1M subset, while Mineralt has a similar share in that subset. The bottom

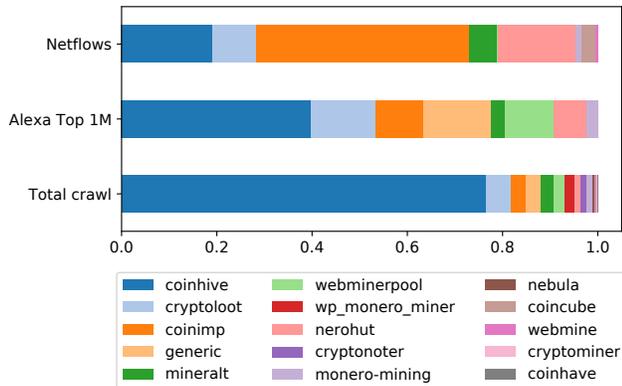

Figure 3: Distribution of cryptomining applications based on the total crawl, the Alexa Top 1M and NetFlows analysis.

two stacked bars in Figure 3 show the distribution of miners according to our analysis.

We have also discovered services which combine multiple cryptomining applications. The most popular mining combination is the set of Coinhive, Cryptoloot and Cryptonoter, which are bundled in the implementation of the WordPress Monero Miner plugin [21]. A combination of a Nerohut miner with a Cryptoloot or Webminerpool miner is also regularly encountered. Usually, only one miner starts (due to another script deciding which one to use), but we also encountered domains on which multiple miners were started concurrently.

**Actual mining activity** The distribution of mining applications installed on domains gives an insight into their popularity by actors pursuing cryptomining, but not into their actual usage. The amount of actual mining that takes place can however be estimated by tracing the connections website visitors make to the mining application’s WebSocket proxy, as explained in Figure 1. We obtained a trace of connections transported by a Tier 1 network operator in 1:8192 sampling for a period of 14 months, and followed the WebSocket proxy server IPs from these mining applications to estimate the traffic to these servers. This gives an insight into how much traffic these WebSocket proxies digest, and is therefore a more reliable source for popularity measures. The upper stacked bar chart in Figure 3 shows the distribution of NetFlows to the WebSocket proxy servers of known mining applications for the month of December. The results show a drastic difference between installation base and mining traffic: while Coinhive is found on most websites, CoinImp proxy servers handle more than twice as much traffic than the dominant application. WebSocket traffic to servers of Cryptoloot is similar in size compared to its installation base.

Table 4: Mining pools the identified domains are mining in

Mining pool	Occurrence
supportxmr.com	93
xmrpool.eu	15
greenpool.site	13
minexmr.com	6
xmr.omine.org	4
monerocean.stream	2
seollar.me	1
xmr.nanopool.org	1

**Mining pool participation** Most mining applications do not disclose the actual mining pool they are mining for in WebSocket traffic. However, on 135 identified domains, the WebSocket traffic did reveal that, as listed in Table 4. Most of these websites are participating in the supportxmr.com mining pool, which is commonly orchestrated by a Webminerpool or Nerohut mining script. Other pools are less commonly used or were not revealed in WebSocket traffic.

**Throttling of applications** Most cryptomining applications allow for a throttle value to be set, which limits the percentage of the CPU the miner can use. It is not necessary to set a throttle value, in this case the miner uses 100% of the available processing power. We have discovered that when a throttle value is set, this is often set to 0.3, meaning that 70% of the processing power can be used by the miner. Setting a throttle to use 70% of the resources seems to be balancing between gaining enough profit and not disturbing the browsing experience too much. In the identified campaigns, the throttle value is mostly set to the same value on all domains. An exception is listed in Table 5, in which a campaign involving 180 websites uses two different throttle values.

**Attack vectors encountered** We were able to retrieve the *siteKey* of actively cryptomining websites in 92% of the cases. Most of the gathered *siteKeys* are only used once (78%) and only a small portion (5%) is used on more than 5 different websites. However, the *siteKeys* in this last category are found on 4,663 different websites (46% of the total). The high number of *siteKeys* used only once suggests a large amount of website owner initiated cryptojacking, since every domain uses its own key. The fact that almost half of the websites is part of a campaign involving at least 5 websites also indicates different attack vectors. We have manually analyzed the used *siteKeys* in the latter category, and we can conclude that, besides website owner initiated cryptojacking, the use of third party software is a prevailing attack vector. Third-party applications like WordPress, Drupal or Magento are often abused to spread cryptojacking injections. These applications play a major part in campaign analysis, as discussed in Section 6.1.

**Hiding techniques** With the rise of cryptomining blocking applications such as NoCoin [17] or Minerblock [16], mining scripts are more often hidden to prevent detection. We have encountered a number of hiding techniques in our crawl and distinguish the following levels of obfuscation:

1. *No obfuscation.* The script is loaded in clear text, key and other options are visible to the user.

```
var miner = new CoinHive.Anonymous('key');
miner.start();
```

2. *Limiting CPU usage.* Script is loaded in clear text, key and other options are visible to the user, but CPU usage is throttled, so detection by the user is less likely.
3. *Renamed variables.* The script is loaded in clear text, but (some) variable names have been changed. These variable names are either replaced by random strings, or by completely different words, such as on <http://www.2001.com.ve/>:

```
startHarryPotter("boddington", "2001");
```

4. *Renamed mining script.* The loaded script is still in clear text, but hosted on the web server itself instead of fetched from a mining service. The file name is changed to prevent blacklist blocking, frequently to general names, such as `jquery.js` or `stat.js`.
  5. *Hidden inside other scripts.* The miner is appended or inserted into another script. The benign script still functions as normal, but also starts up the mining process.
  6. *Obfuscated code.* The loaded scripts are masked by a code obfuscator and contain packed or CharCode code. All application-specific strings are encoded, stored in an array and variable names are replaced by random strings.
- ```
var _0x5d02=["\x75\x73\x65\x20\x73\x74", ..]
```
7. *Obfuscated code and WebSocket traffic.* The loaded script is obfuscated by a code obfuscator and WebSocket traffic is sent encrypted to the proxy server.
  8. *Obfuscated and hidden.* Scripts are hidden inside other files and/or via multiple redirects. Every script is randomly named and obfuscated, and so is the WebSocket traffic. WebAssembly is not retrieved from the server, but included inside the script.

In our crawl, most website owner initiated cryptojacking is not obfuscated, often not even throttling CPU usage. Attacks using third-party software are usually hiding cryptomining code inside other scripts and apply some obfuscation. We have encountered multiple WordPress themes and Drupal plugins with such a hidden miner. Only 391 websites with encrypted WebSocket have been identified, whereas most websites are using plain text Stratum communication. The highest level of obfuscation is rarely encountered.

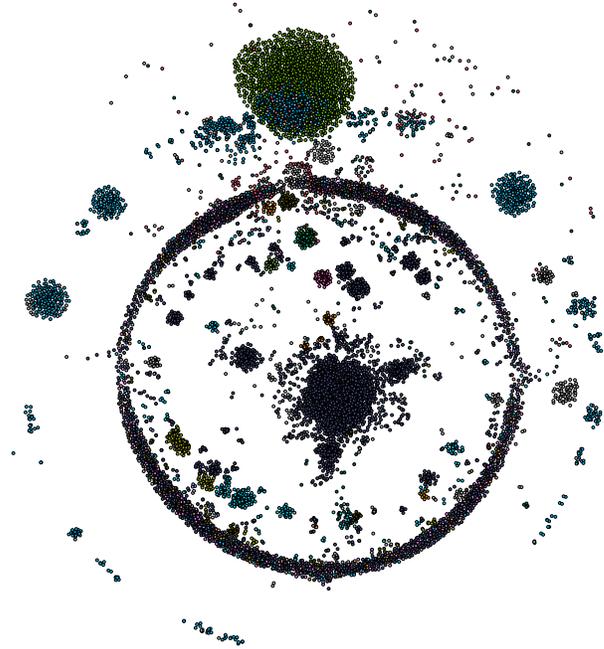

Figure 4: Relationships between the identified cryptojacking domains depicted in a force-directed graph

## 6.1 Cryptojacking campaigns

We have identified 204 cryptojacking campaigns, covering 5,733 websites, meaning that 57% of all cryptojacking websites encountered are part of a campaign. We define a cluster of more than 5 websites to be a campaign, as stated in Section 2. Figure 4 shows all the identified cryptojacking domains in a force-directed graph, where domains with similar features attract each other, colored according to the used application. Clear clusters can be distinguished, such as a Monero-Mining campaign shown in pink and a large Mineralt campaign shown in green right above it. Coinhive, the application used the most, is shown in dark blue with multiple large clusters all over the graph. The circle represents the cryptojacking domains not part of a campaign. In the following paragraphs, we highlight our findings based on different possibilities for identifying campaigns as introduced in Section 2.

**Found on shared siteKey** We were able to successfully retrieve the *siteKey* of 92% of the actively cryptojacking domains, which enabled us to cluster domains sharing the same *siteKey*. A shared *siteKey* guarantees that the rewards for mining will be transferred to the same account. We have identified 192 cryptojacking campaigns based on the same *siteKey* being installed on more than 5 different websites. As shown in Table 5, the largest campaign covers 987 websites, all using WordPress. A variety of plugins and themes include a malicious file named `jquery.js`, which is responsible for starting

a Coinhive miner. A similar attack vector is observed in a campaign involving 317 Drupal websites. This campaign is part of the Drupalgeddon 2 and 3 attacks, which took advantage of major remote code execution vulnerabilities in Drupal to inject their malicious scripts [45]. The only large campaign using the Mineralt miner, also focused on WordPress, has base64 encoded its *siteKey* inside the `script` tags. This makes them seem different, but match once decoded, since only the throttle value is changed. Not just vulnerabilities in CMS systems are used to spread cryptojacking code, also Magento, an e-commerce system, is involved in a Coinhive mining campaign targeting 175 websites in our crawl. The largest campaign using the compromised websites attack vector involved 376 Chinese websites, which share a miner script injected on the bottom of the page. A provider of The Pirate Bay proxies orchestrates the largest website owner initiated campaign on our list, with 70 proxy domains using the same Cryptoloot miner. These findings indicate that the most successful and largest cryptojacking campaigns are created by abusing third-party software.

**Found on shared WebSocket proxy server** Most cryptojacking campaigns are using the infrastructure of popular applications, such as Coinhive, to connect to a mining pool. Thus, clustering domains on these WebSocket proxy servers will not create meaningful clusters. However, when we discard these popular proxy servers, we are able to identify another 12 campaigns, which have not already been identified by shared *siteKeys*. Those are listed in Table 6. A Coincube miner campaign involving 27 websites uses `coin-services.info` as a WebSocket proxy server on a variety of ports. This campaign hosts its miner scripts on code repositories such as GitHub and BitBucket, where a number of accounts is created to host the miner files, which are all named `main.js`. On one of the GitHub accounts, even a picture of stacked Ukrainian money can be found [15]. 28 very similar websites, all offering illegal video streams, were found to be using a WebSocket proxy server on `wss://ws**.1q2w3.life/proxy` with, after manual inspection, `seriesf.lv` as the accompanied *siteKey*. This proxy server was also discovered by [22] on 5 websites in their crawl. They estimated that this campaign made a profit of \$2,012.90 per month, which is likely to be a lot more, since we have found almost 6 times as many domains involved in this campaign. We have discovered that websites using a private WebSocket proxy are more likely to hide their activities by using higher levels of obfuscation.

Additionally, we have discovered 14 WebSocket proxy servers with very similar addresses on 75 domains (e.g. `nfllying.bid`, `flightzy.bid` and `flightsy.bid`). These servers are contacted by the most obfuscated miner encountered in this crawl. The miner code is hidden inside a randomly named file, the miner code is heavily obfuscated and the WebSocket traffic is sometimes encrypted. Our efforts to reverse engineer the obfuscated miner code are so far un-

successful. Therefore, we can not cluster them as being a campaign based on the shared proxy servers, but we have added the signature to our crawler as a separate mining application for the next crawls.

**Found on shared initiator file** In our crawling process, the stack trace of an initialized WebSocket connection is saved for every website. While examining these stack traces, some file names emerged and lead to the identification of another 4 cryptojacking campaigns. The oddly named file `gnimorenomv2.js`, responsible for opening WebSocket connections on 24 websites seemed to be part of a malicious advertisement campaign, which injects cryptojacking scripts into served advertisements. As shown in Table 6, this file opens a connection to `wss://heist.thefashiontip.com:8182/` to earn the profits from the displayed mining advertisements. Another campaign was identified by grouping the websites in which `adsmine.js` was responsible for opening a WebSocket connection. These websites turned out to be 17 very similar pornography websites, which indicates that this campaign is website owner initiated. The newly discovered mining application, as described in the previous section, served obfuscated mining scripts to its miners. Although obfuscated, inspection of the random file names revealed clusters of websites injected with the same randomly named miner, which lead to the discovery of another 3 campaigns, all targeting solely WordPress websites.

**Found on shared mining pool login** Most miner applications submit their solved hashes to a WebSocket proxy server, which combines the hashes of multiple miners before forwarding it to the actual mining pool. However, we have discovered 238 websites directly submitting their hashes to a mining pool. These websites are using only six unique cryptocurrency wallet addresses. The shared wallet addresses guarantee that profits made by cryptojacking are transferred to the exact same wallet. These findings did not lead to the discovery of any new campaigns, but did confirm previous findings. E.g., proxy `wss://delagrossemerde.com:8181/` (used by 15 sites) is solely receiving traffic from domains using the same wallet. The different methods used in this section enabled us to find 204 cryptojacking campaigns. We can conclude that the largest campaigns are using third-party services like WordPress, Drupal or Magento as their method of spreading. Only one campaign using advertisements with injected cryptojacking scripts has been identified, this in contrast to previous work by [22, 39], who reported malicious advertisements as a significant attack vector. Compromised websites or website owner initiated campaigns are generally smaller in size. The obfuscation level used in most campaigns is rather low, heavily obfuscated code is encountered rarely and in more than half of the identified campaigns a miner added in plain text.

Table 5: Identified campaigns based on a shared *siteKey* (HT = hiding technique encountered)

| SiteKey                                               | #   | Type       | Attack vector                              | HT |
|-------------------------------------------------------|-----|------------|--------------------------------------------|----|
| I2OG8vG[...]coQL & hn6hNEM[...]w1hE                   | 987 | Coinhive   | Third-party software (WordPress)           | 5  |
| I8rYivhV3ph1iNrKfUjvdqNGfc7iXOEw                      | 376 | Coinhive   | Compromised websites                       | 2  |

## 6.2 A in-depth campaign search

The sizes of the campaigns identified in Section 6.1 depend on the dataset we crawled, so they could have been incomplete. To find more websites belonging to the identified campaigns, we have taken the indicators of compromise for a large number of campaigns and queried PublicWWW for domains matching these IoCs. This resulted in a dataset of 7,892 websites. Combined with the 21,022 potentially cryptojacking websites from the initial crawl, a total of 25,121 URLs was crawled on February 12, 2019, more than a month after the initial crawl. We successfully obtained 24,187 (96%) of them.

Most of the campaigns remained of similar size in this crawl, except for a campaign involving three keys, `ef937f99557277ff62a6fc0e5b3da90ea9550ebcdfac, 06d93b846706f4dca9996baa15d4d207e82d1e86676c` and `dd27d0676efdecbl2703623d6864bbe9f4e7b3f69f2e`. This advanced campaign is targeting domains using Bitrix24, a CRM platform used by a variety of organizations. The most remarkable website it has been found on is the website of the Ministry of Education of Belarus (<https://edu.gov.by/>). The malicious code is hidden as the core loader of Bitrix24 and uses both Nerohut and Cryptoloot to mine with. It has a built-in anti-detection method, since it stops mining once a developer tools window is opened. In our initial crawl, we have identified only 68 domains belonging to this campaign, which turned out to be 855 in our in-depth search, making this campaign the second largest campaign

we have identified so far. Another campaign, involving key `vPFDHk89TxmH1arysiJDrutpYGntofP`, is displaying fake loading screens on 86 websites, whereas only 47 of these have been identified in our initial crawl.

All other campaigns remained similar or slightly smaller in size. Except for the two aforementioned campaigns, we conclude that our initial crawl likely identified the correct size of campaigns, given the database of PublicWWW. Their database contains source code snapshots of over 544M websites, which should provide a proper approximation.

## 6.3 Evolution of cryptojacking

To study the evolution of cryptojacking on the Internet, data is needed from different moments in time. Fortunately, Konoth et al. [22] shared their crawling results and Hong et al. [19] shared their list of identified cryptojacking domains, which made it possible for us to crawl these exact same sets of URLs and to analyze whether these domains were still mining. Additionally, we have followed the domains identified in our crawls over a period of 3 months, and analyzed WebSocket proxy traffic over time using operator NetFlows.

**Comparison with previous crawls** Konoth et al. [22] crawled from March 12 until 19, 2018 and identified 1,735 potential cryptojacking domains. We crawled their list on January 21, 2019 and obtained 1,725 of them. 85% of the

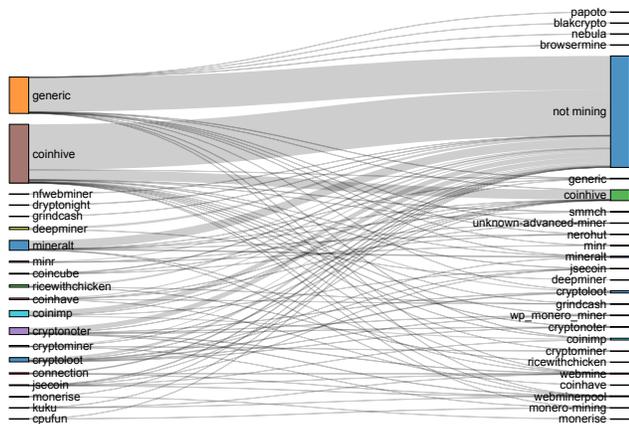

Figure 5: Usage evolution between March 2018 and January 2019 in the list of identified domains by [22]

websites are not cryptomining anymore, and only 10% is still using the same application. On 136 websites (7%), the same key was found in both crawls. As Figure 5 shows, a large number of websites using a Coinhive miner removed the miner application. Some continued using Coinhive, but also a small shift into less popular mining applications can be observed. Websites already using these miners tend to stick to their choice and are still using the same miner almost a year later. We have also seen a number of mining applications become extinct, such as Deepminer and NF Webminer. Hong et al. [19] also published the list of identified cryptojacking domains from their crawl in February 2018. A year later, on February 12, 2019, we have crawled this list of 2,770 domains. We obtained 2,435 (88%) of them and only 340 (14%) domains are still actively cryptojacking. Both crawls show that a large number of websites stopped cryptojacking themselves or removed the miner infection. After one year, approximately 85% of the domains are not actively cryptojacking anymore. We have also observed a small portion of domains switching to less popular applications. The low number of 7% of websites that are still mining with the same *siteKey* indicates the fast changes in the cryptojacking threat landscape.

**Evolution of identified domains** We have followed all previously identified cryptojacking domains for a period of 3 months (until May 5, 2019) and crawled them initially occasionally, but afterwards every other day. Within this time period, Coinhive announced to end its mining application, due to decreased Monero prices and hash rate [7]. The announcement was made on February 26, 2019 and stated that mining would not be operating anymore after March 8, 2019, and that the service would be discontinued by the end of April 2019. This led to a drastic change in the cryptojacking landscape, as Coinhive’s dominance in actively mining installations col-

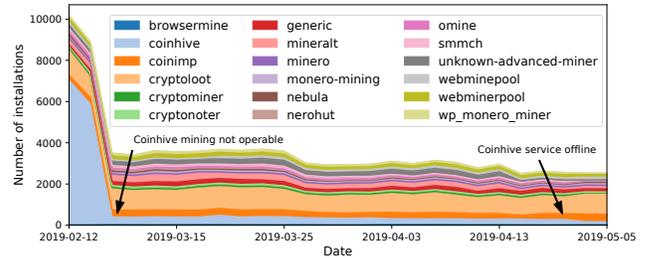

Figure 6: Evolution of the cryptojacking domains per type

lapsed when their mining service was set non-operational. Mining applications were however not massively replaced, which confirms our finding that a large portion of browser-based cryptomining is not initiated by the website owner. Only when the Coinhive mining service was actually discontinued and errors were shown while requesting the offline Coinhive mining resources, we observe a small increase in Cryptoloot and CoinImp installations.

**WebSocket proxy traffic over time** As discussed in Section 2, most miner applications use a WebSocket proxy server to forward traffic from their miners to the mining pool. Using NetFlow data mentioned earlier, we have analyzed traffic towards popular WebSocket proxies from September 2017 till December 2018, which gives an insight into the evolution of cryptomining applications usage, as shown in Figure 7. We have taken the set of WebSocket proxy IPs the miners connect to as a basis, which we extended by using passive DNS data to discover other WebSocket proxy server IPs used by these applications, but hosted on different servers, not encountered during our crawls. The same passive DNS data was used to verify whether these IP addresses were solely used as WebSocket proxy servers. To prevent other traffic to these servers from being in our dataset, we have both set the maximum packet size to 550 kB and verified that only WebSocket traffic was counted towards these servers. For most proxies, this is traffic towards port 80 or 443, and for a few servers using specific ports, this could be different. An example is the WebSocket proxy server of the WP-monero-miner which uses port 8020.

The blue line from September 2017 on shows how the web-mining ecosystem is monopolized by innovator Coinhive at the start, where after copycats like Cryptoloot and Webmine start to emerge in October. We see that CoinImp essentially starts to eclipse all other miner applications from mid April 2018 onwards in terms of mining traffic to the proxies, which is unexpected given the distribution of installations on websites and previous studies. Some mining proxies only have transient success: a remarkable example is the WP-monero-miner, released shortly after Coinhive in 2017. The applica-

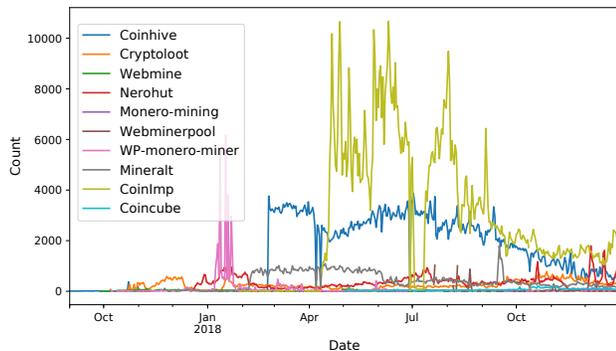

Figure 7: Number of NetFlows involving WebSocket proxy servers for popular miners between Sep 2017 and Dec 2018

tion hosts its own mining pool and digested a lot of traffic in January 2018, only to almost disappear again weeks later. Coinhive, the application used by most websites, is a constant factor in the miner landscape with over 4,000 NetFlows a day in mid 2018 (given our 1:8192 sampling, thus 32M connections per day), but not as large as one would expect from its installation base. Additionally, a clear declining trend can be observed in the NetFlow counts to all mining services after the summer of 2018. The last months of NetFlow data show a diverse set of mining applications actively used.

## 7 An Internet scale study on cryptojacking

In order to estimate the prevalence of browser-based cryptojacking on the Internet and to indicate any differences between Top Level Domains (TLDs), we have performed another crawl, in which we have crawled ~20% of the websites belonging to each of the 1,136 existing TLDs. We obtained a daily zone transfer for all generic top level domains (gTLDs) – such as *.top*, *.loan* – from the Internet Corporation for Assigned Names and Numbers (ICANN), as well as a feed of registered country code top-level domains (ccTLDs) – such as *.uk*, *.jp*, or *.ru* – from a security intelligence provider. From these lists, we randomly picked a sample of ~20% of the size of each TLD [12]. Based on the results of the previous crawl, we have added another 5 mining applications to the crawler implementation, as listed in Appendix C. From January 11 until April 3, 2019, we crawled the random sample including 48.9M domains. This yielded a total of 125 TB of network traffic.

### 7.1 General findings

After crawling a random sample of 48.9M websites in a large number of different top level domains, we are able to draw conclusions about the prevalence of browser-based cryptojacking on the Internet. We estimate that 0.011% of all domains are actively cryptomining without their visitors’ explicit consent,

Table 7: Distribution of cryptomining applications installations in the Internet scale crawl (sum of percentages is >100%, because of websites using multiple applications)

| Type                   | # of websites | Percentage |
|------------------------|---------------|------------|

| Cryptominer            | 26            | 0.501%     |
| Minero                 | 24            | 0.462%     |
| Nebula                 | 23            | 0.443%     |
| Webmine                | 19            | 0.366%     |
| Coincube               | 19            | 0.366%     |
| Project-poi            | 4             | 0.077%     |
| Adless                 | 1             | 0.019%     |

meaning that one in every 9,090 websites is cryptojacking. Comparing this number to the statistics of the top lists used in our initial crawl, we conclude that cryptojacking activity is mainly focused on the popular parts of the Internet. In the Alexa Top 1M, 0.065% of the websites was actively cryptojacking, in this random sample only 0.011% of the websites, which is almost 6 times lower. This can be explained by the lucrativeness of cryptojacking, in which a higher popularity means more visitors, yielding more potential miners and thus higher potential profits. Additionally, it shows that researching the prevalence of cryptojacking by crawling the Alexa Top 1M overestimates the problem size. However, the distribution of used applications in our random sample is fairly similar to the distribution in the Alexa Top 1M. The distribution of mining applications in this crawl is listed in Table 7.

The categories of domains identified in this crawl are very similar to the initial crawl. As depicted in Figure 8, *Adult content* remains the most prevailing category, while other large categories are *Technology* and *Under Construction*, the category involving parked, expired or yet-to-be developed domains. Based on these two very different crawls we can conclude that cryptojacking is indeed more prevailing on domains hosting adult content.

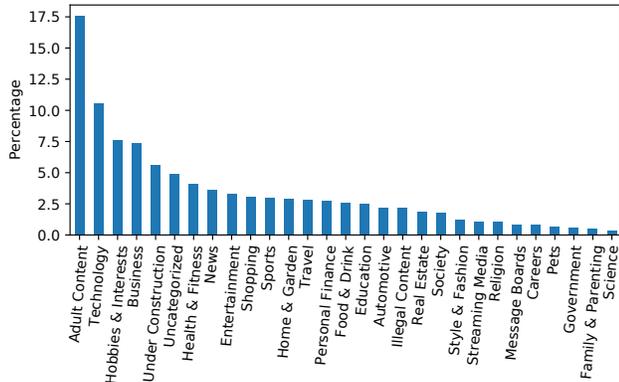

Figure 8: Categories of mining domains in the second crawl

## 7.2 Cryptojacking on different TLDs

We have crawled domains of roughly ~20% of 1,136 different TLDs in order to analyze the prevalence of cryptojacking. As Table 8 shows, cryptojacking activity varies enormously within different TLD zones. The four largest TLDs, *.com*, *.de*, *.net* and *.org* have a similar percentage of cryptojacking websites, but we have discovered almost 6 times as much cryptojacking activity in the Russian TLD. Also, domains in the Brazilian and Spanish zones are more susceptible to cryptojacking, having respectively 4 and 3 times more cryptojacking activity than average. On the contrary, the *.top*, *.us* and *.loan* zones host only a few cryptojacking websites.

Our website category analysis showed that adult content is the most prevailing category for cryptojacking activities. This triggered our attention for the *.xxx* domain, which is specially created for adult content, which we therefore crawled completely instead of ~20%. Surprisingly, the *.xxx* domain contains only one website actively cryptomining.

When comparing used mining applications on the different TLDs, large differences can be distinguished, as shown in Figure 9. Coinhive is the most popular miner in most zones, whereas Cryptoloot is preferred in the Russian zone, and French and Czech websites contain more Nerohut miners. The Russian zone is also the only TLD where browsermine is used regularly. The high number of generic miner applications in the Dutch and Belgian zone is remarkable. A large number of these domains in the *.nl* and *.be* zone are part of a campaign using expired domain names of a Dutch registrar (*Totaaldomein B.V.*) to host porn and unknown cryptominers.

Our results show a different popularity of used mining applications compared to previous work of [41]. They detected Coinhive on 85% to 90% of the *.com*, *.net* and *.org* TLDs, whereas we determine that this market share is significantly lower (~50%). This result proves that a simple solution like the NoCoin block list is unable to detect all miners and analyses with such techniques result in different outcomes.

Table 8: Results of the TLD crawl. Listed are the top 10 largest domains, followed by remarkable TLDs

| TLD             | Size        | Crawled            | Cryptojacking         |
|-----------------|-------------|--------------------|-----------------------|

## 8 Discussion

Crawling the Internet inevitably comes with its shortcomings. Limitations in the crawler implementation, network used and analysis can produce both false positives and negatives. The latter category can occur for example when extreme obfuscation is used, as we have seen in Section 6. However, we believe that due to our double crawling strategy, based on both WebAssembly and code signatures, this could not have happened very often. Finally, the use of worldwide NetFlow traffic from a Tier 1 network operator allowed us to analyze the popularity of cryptojacking services in a revolutionary way, although BGP policies, and a specific PoP and IXP footprint could lead to a bias of certain autonomous systems just as some discrepancies might arise due to 1:8192 random sampling. Additionally, since the NetFlows do not reveal the actual contents of the connection, we can never be sure about the contents. However, during our crawls we could confirm the mining applications to contact the WebSocket proxy servers in question, and passive DNS lookups did not show any other domains pointed to that IP. Furthermore, the NetFlows both revealed no traffic to other ports than those seen from our crawlers and packet sizes resembling those observed in our crawls, thus the methodology should provide valid results.

**Future work** The additional angle provided by the NetFlow data allowed us to study the evolution of cryptojacking over a longer period of time, something which has not been done be-

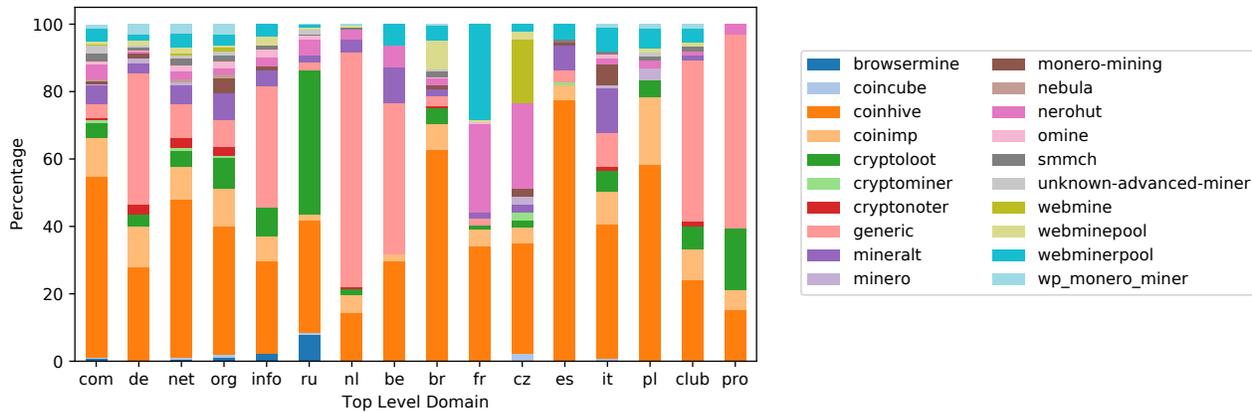

Figure 9: The distribution of used mining applications in various TLDs

fore. Regular crawls of the Internet, especially of the already identified cryptojacking domains gives more insight in this practice, as will it increase the innovation of defense mechanisms. The most influential defense against cryptojacking will nonetheless be frequent patching, as most cryptominers are installed exploiting known vulnerabilities. CMS providers, such as Drupal or WordPress, have shown agility in patching vulnerabilities, but the responsibility of installing these patches remains with the website owner. Finally, as we have seen a decline in the price of Monero (-85% in 2018), we believe that cryptojacking infections on individual websites will decrease, but that cyber criminals will search for other possibilities to exploit cryptojacking at an even larger scale. As we have mentioned in Section 3, the most effective method of collecting large groups of miners is by launching a MITM attack. Investigating the prevalence of this attack vector for cryptomining is something we preserve for future work.

## 9 Conclusions

In this paper, we have studied the prevalence of cryptojacking as well as of cryptojacking campaigns on the Internet. We have performed multiple large crawls, each with a different focus. In our first crawl, we have analyzed the 1.7M most popular domains to identify organized campaigns. We found 204 campaigns, from which we conclude that the size of cryptojacking campaigns is heavily underestimated by current academic research. Additionally, using solely the Alexa Top 1M shows significantly different results in terms of the size of organized activity and infection rate, which we found to be almost 6 times lower in a random sample compared to the Alexa Top 1M, hence overestimating the problem. Third-party software is often used by attackers to spread cryptojacking scripts over a large number of domains. The share of domains serving advertisements injected with cryptojacking scripts is lower compared to previous work, most likely because

of stricter monitoring by advertisement networks. We have seen that obfuscation of cryptojacking scripts is definitely present, but only occasionally used. Comparing our results with data from previous studies (in both February and March 2018) shows that after a year, only 15% of the websites is still actively mining. This, and our novel way of estimating miner application popularity by analyzing NetFlows, led to the conclusion that the cryptojacking landscape is constantly changing and involves a variety of actors.

A second, Internet-scale crawl involving ~20% of 1,136 TLDs (48.9M websites), which represents a truly random sample of the Internet, allows us to conclude that cryptojacking is present on 0.011% of all domains. Not unexpectedly, this percentage increases in the more popular parts of the Internet, because cryptojacking on popular domains is much more lucrative. Both of our crawls have shown that cryptojacking mostly takes place on websites hosting adult content, although the .xxx TLD is home to only one cryptojacking website. Based on the applications used within the time span of our analysis, we can conclude that Coinhive was the largest mining application in terms of installation base, but that CoinImp’s WebSocket proxy servers were digesting much more traffic in 2018. Looking at the different TLDs, we conclude that Russian, Brazilian and Spanish zones are home to a disproportionate number of cryptojacking domains.

With the discontinuation of Coinhive in March 2019, the landscape of cryptojacking has changed enormously, but based on our results, we are only expecting a further decline in individual cryptojacking activities given that the Monero value keeps diminishing. However, this only stresses the importance of organized cryptojacking campaigns, as cyber criminals will find new ways to spread their cryptojacking infections to still be profitable. Here, campaign analysis will be an important asset: as adversaries are unlikely to develop a unique approach for each infected website, the reuse of resources and methods will provide an effective angle to detect and mitigate these activities.

## D Human Subjects and Ethical Considerations

For the analysis of cryptojacking usage in the wild, this paper uses NetFlow statistics from a Tier 1 network operator. This data access was cleared by the institutional review board. The research team did not obtain direct access to the NetFlow data containing source and destination IP addresses as personally identifiable information, but instead provided a list of IP addresses of cryptomining proxies and mining pools to the data owner, based on which the corresponding flow records were provided with the connection's source IP protected by a salted hash.

# Rendered Private: Making GLSL Execution Uniform to Prevent WebGL-based Browser Fingerprinting

Shujiang Wu, Song Li, Yinzhi Cao, and Ningfei Wang<sup>†\*</sup>  
Johns Hopkins University, <sup>†</sup>Lehigh University  
{swu68, lsong18, yinzhi.cao}@jhu.edu, wangningfei7@gmail.com

## Abstract

Browser fingerprinting, a substitute of cookies-based tracking, extracts a list of client-side features and combines them as a unique identifier for the target browser. Among all these features, one that has the highest entropy and the ability for an even sneakier purpose, i.e., cross-browser fingerprinting, is the rendering of WebGL tasks, which produce different results across different installations of the same browser on different computers, thus being considered as fingerprintable.

Such WebGL-based fingerprinting is hard to defend against, because the client browser executes a program written in OpenGL Shading Language (GLSL). To date, it remains unclear, in either the industry or the research community, about how and why the rendering of GLSL programs could lead to result discrepancies. Therefore, all the existing defenses, such as these adopted by Tor Browser, can only disable WebGL, i.e., a sacrifice of functionality over privacy, to prevent WebGL-based fingerprinting.

In this paper, we propose a novel system, called UNIGL, to rewrite GLSL programs and make uniform WebGL rendering procedure with the support of existing WebGL functionalities. Particularly, we, being the first in the community, point out that such rendering discrepancies in state-of-the-art WebGL-based fingerprinting are caused by floating-point operations. After realizing the cause, we design UNIGL so that it redefines all the floating-point operations, either explicitly written in GLSL programs or implicitly invoked by WebGL, to mitigate the fingerprinting factors.

We implemented a prototype of UNIGL as an open-source browser add-on (<https://www.github.com/unigl/>). We also created a demo website (<http://test.unigl.org/>), i.e., a modified version of an existing fingerprinting website, which directly integrates our add-on at the server-side to demonstrate the effectiveness of UNIGL. Our evaluation using crowdsourcing workers shows that UNIGL can prevent state-of-the-art WebGL-based fingerprinting with reasonable FPSes.

<sup>\*</sup>The last author, Ningfei Wang, contributed to the paper when he was a master student financially supported and mentored by Dr. Yinzhi Cao.

## 1 Introduction

Browser fingerprinting [12, 13, 20, 23, 34, 45, 63], a substitute of traditional cookie-based approaches, is recently widely adopted by many real-world websites to track users' browsing behaviors potentially without their knowledge, leading to a violation of user privacy. In particular, a website performing browser fingerprinting collects a vector of browser-specific information called browser fingerprint, such as user agent, a list of browser plugins, and installed browser fonts, to uniquely identify the target browser.

Among all the possible fingerprintable vectors, the rendering behavior of WebGL, i.e., a Web-level standard that follows OpenGL ES 2.0 to introduce complex graphics functionalities to the browser, is an important factor that contributes the most, in terms of entropy, to the overall distinguishability of browser fingerprints [19]. Specifically, WebGL-based fingerprinting is first discovered by Mowery et al. [41], and then further explored by Cao et al. [19], who not only show that WebGL-based fingerprinting has the highest entropy among all fingerprinting factors, but also demonstrate the ability of WebGL-based fingerprinting for an even sneakier purpose, i.e., cross-browser fingerprinting, compared to traditional fingerprinting vectors like user agents.

In order to prevent WebGL from being used as a vector of browser fingerprinting, Tor Browser, the pioneer private browser for the Web makes WebGL click-to-play, i.e., disabling it by default, so that a website cannot use it for the tracking purpose. However, there exists a tradeoff between privacy and functionality: Tor Browser sacrifices an important functionality—i.e., all the computer graphics features brought by WebGL, which are particularly useful for modern web applications like games [10] and virtual reality [50]—for privacy. Specifically, according to a 2016 study [55], about 10% of Top 10K Alexa websites, including famous ones visited by billions of users such as Google Map and Earth [2], adopt WebGL to augment user experience—and the number keeps increasing as the WebGL community grows. Therefore, the research question that we want to ask in the paper is whether

a browser can allow Web applications to use WebGL and its abundant functionalities without violating users' privacy.

Before answering this question, we first take a look at how existing works prevent browser fingerprinting that does not use WebGL. There are two categories of approaches in defending against browser fingerprinting in general (e.g., these based on fonts, plugins, and user agent), which are randomization and uniformity. The former, adopted by PriVaricator [44] and some browser add-ons [1,9], adds noise to the fingerprinting results so that an adversary cannot obtain an accurate fingerprint each time. However, according to prior work [18,49], such randomization-based defense can be defeated if the adversary fingerprints the browser multiple times and averages the results. In addition, according to a recent work [59], inconsistencies in browser fingerprints may cause further privacy violations. Because of these concerns, Tor Browser also explicitly prefers the latter, i.e., uniformity, over randomization in its design document [49].

Therefore, our detailed research question becomes how to make uniform WebGL rendering results and prevent WebGL-based browser fingerprinting. The answer to this question is unknown in the community as indicated in Tor Browser's practice of disabling WebGL. The reason is that unlike other forms of fingerprinting (e.g., user agent and fonts), which rely on the outputs of a browser API, WebGL-based fingerprinting runs a program, i.e., a rendering task, in OpenGL Shading Language (GLSL). One possible solution, i.e., an idea floated in the design document [49] of Tor Browser without any implementation, is to adopt software rendering and make uniform WebGL rendering. However, Cao et al. [19] show that even if software rendering is enabled, WebGL rendering results are still fingerprintable.

Now, to answer the specific question of making WebGL uniform in the paper, we need to understand why a single WebGL rendering task differs much from one browser to another. From a high level, the reason is that computer graphic tasks pursue visual rather than computational uniformity. One single WebGL task on different browsers is rendered by a different combination of a variety of computer graphics rendering layers, such as browsers, graphics libraries (e.g., DirectX and OpenGL) including conversion interfaces (e.g., Almost Native Graphics Layer Engine, i.e., ANGLE), rendering mechanisms, device drivers and graphics cards. Therefore, different implementations and even versions of these various layers will lead to a computationally different rendering result. This high-level answer also partially explains the reason that software rendering cannot prevent fingerprinting: Software rendering, belonging to rendering mechanisms, is just one of the many layers that could lead to the rendering discrepancies, and it may also have different versions and implementations.

While this problem appears hard to solve unless we make uniform all the graphics layers, the root reason, after our intensive manual study and experiment, can be summarized as one surprisingly concise and abstract sentence—i.e., the

results of floating-point operations on different machines are different inside and across various graphics layers, leading to rendering differences. This one-sentence, intuitive reason can be further broken down into many sub-reasons when the WebGL rendering performs various operations in different graphics layers. Let us illustrate two examples.

First, we consider the color value, i.e., RGB, in WebGL, which semantically ranges from 0 to 255 but is represented as a floating-point from 0 to 1. Therefore, a conversion is required when WebGL renders a 0–1 color value on the screen to be a 0–255 RGB value—and most importantly the conversion, i.e., a floating-point operation, will lead to rendering difference. Say one WebGL implementation, i.e., a combination of different graphics layer, multiplies the color value with 255 and applies *floor* to convert it to the RGB value, and the other applies *round*. Then, a color value of  $\langle 0.5, 0.5, 0.5 \rangle$  will be rendered as  $\langle 127, 127, 127 \rangle$  in the former, but as  $\langle 128, 128, 128 \rangle$  in the latter. This float-to-int conversion issue can be generalized in many other representation, such as alpha value, texture size, and canvas size—and also other conversion algorithms beyond *floor* and *round*, such as linear interpolation in texture mapping.

Second, let us consider another common graphics operation involving several float multiplications and then a subtraction, i.e., we need to decide whether a given point, very close to one triangle edge, is inside the given triangle. Say, there are two WebGL implementations, one adopting 10-bit float numbers and the other a higher precision, i.e., 16-bit. The multiplication results on these two implementations differ slightly, because the former has fewer decimals than the latter. Because the given point is very close to the triangle, such slight difference will propagate to the float subtraction, leading to a positive in the former implementation but a negative the latter. Therefore, the point will be judged as either inside or outside the triangle in these two implementations, causing a rendering difference.

That said, the *key* insight of the paper is that we need to make uniform all the floating-point operations across various computer graphics layers. Specifically, we adopt two integers, one as the numerator and the other as the denominator, to simulate floating-point operations in GLSL programs so that the underlying layers, regardless of their implementation or approximation for floating-point operations, always produce the same results. When we need to feed simulated values into WebGL, we convert the value to a float based on its semantics. In the aforementioned color value example, we can use  $127/255$  to represent 127 and  $128/255$  for 128, leading to no confusions under different implementations.

While the idea is intuitively simple, the major challenge is that WebGL rendering process involves implicit floating-point operations. In order to understand this challenge, let us briefly describe the three-stage WebGL rendering process—i.e., (i) vertex rendering, (ii) rasterization and interpolation, and (iii) fragment rendering—and corresponding floating-point operations in each stage. The first stage, controlled by a

GLSL program, i.e., vertex shader, generates vertices information using graphics operations, e.g., transformation and rotation, and also associates attribute values with each vertex. These aforementioned graphics operations are all related to floating-point operations. Then, the second stage, an implicit one implemented by WebGL and not controlled by any GLSL program, generates fragments, called rasterization, and then interpolates values based on fragments using floating-point operations. Lastly, the third stage, controlled by another GLSL program, called fragment shader, colors each fragment, which also involves floating-point operations, such as texture mapping.

In this paper, we propose UNIGL, a novel system that rewrites GLSL programs and redefines all the floating-point operations in the aforementioned three stages of WebGL rendering. Specifically, UNIGL hooks JavaScript APIs—which accept GLSL programs and the corresponding parameters such as vertex and index arrays—and then rewrites both vertex and fragment shaders via three phases mapping to the three stages of WebGL rendering. First, UNIGL converts the vertex shader to a JavaScript program and executes it. During the execution, floating-point operations in vertex shader, e.g., matrix multiplication, are executed as JavaScript, thus kept with uniformity. Second, UNIGL takes the execution results of JavaScript vertex shader and feeds them into a customized rasterization and interpolation engine written as a fragment shader. In this phase, UNIGL preserves uniformity for floating-point operation implemented natively in WebGL’s rasterization and interpolation module via integer simulation. Lastly, UNIGL rewrites the original fragment shader and redefines floating-point operations, such as texture mapping, in the fragment shader via integer simulation.

In designing UNIGL, we realize the following additional challenges from the viewpoint of system building.

- **Backward Compatibility.** We want UNIGL to be backward compatible with existing commercial Web Browsers. Specifically, we deploy UNIGL as a browser add-on, easily installable, to protect Web users’ privacy.
- **Performance.** We want to keep the high-performance benefits brought by WebGL, especially when it runs on GPU. Therefore, we design UNIGL so that the rendering bottleneck, i.e., rasterization, interpolation and coloring, runs as a GLSL program on fragment shader possibly via GPU (depending on whether the underlying rendering mechanism is software or hardware rendering). Note that the vertex shader has to run as a JavaScript program because otherwise we do not have access to intermediate results between two shaders without modifying the browser. Because of this, we adopt multiple optimization techniques, such as caching, typed array, and code-data separation, to speed up UNIGL’s vertex shader.
- **Variable Number Limits.** Since we choose backward compatibility, we are constrained by the limit that is enforced by the current version of WebGL. Particularly, all current

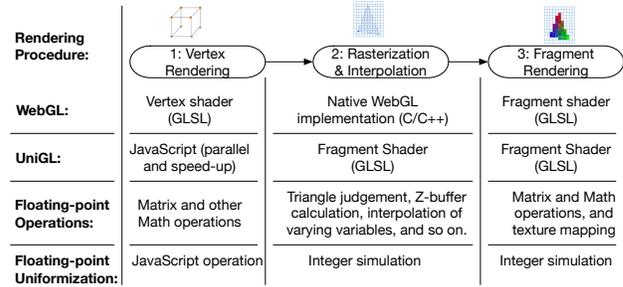

Figure 1: A High-level Overview of Rendering Procedure (i.e., the execution of GLSL programs) in both WebGL and UNIGL as well as a Description of Corresponding Floating-point Operations

implementations of WebGL have enforced a limit [26] for “uniform” variables, sometimes 256 or 1024 depending on the graphics card and operating system. Therefore, in designing UNIGL, we have to divide one rendering task iteratively until each small one can fit into and run as a fragment shader.

We implemented a prototype of UNIGL as an open-source Google Chrome add-on, which is available at the repositories of this GitHub user (<https://www.github.com/unigl/>). We also created a demo website, i.e., <http://test.unigl.org/>, which works on modern web browsers including Chrome, Firefox, and Safari. Specifically, the demo is a modified version of Cao et al.’s fingerprinting website [19], which directly integrates our add-on at the server-side, to show that UNIGL can prevent WebGL-based browser fingerprinting.

We make the following contributions in the paper:

- We are the first to point out that WebGL-based browser fingerprinting is caused by floating-point operations.
- We design UNIGL to rewrite GLSL programs and redefine all, i.e., explicit and implicit, floating-point operations embedded deeply inside WebGL.
- We show that our prototype of UNIGL can defend against WebGL-based browser fingerprinting with reasonable FPS.

## 2 Overview

We give an overview of WebGL and UNIGL rendering procedure, and then present a running example.

### 2.1 WebGL’s Rendering and Floating-point Operations

WebGL’s rendering procedure can be roughly divided into three stages as shown in Figure 1. First, the vertex shader in WebGL performs operations, e.g., rotation via a matrix multiplication, related to the vertices of a computer graphics model. Specifically, the shader accepts two types of variables, i.e., attributes and uniforms, binds attributes, such as texture coordinates, to vertices, and then outputs transformed vertices, i.e., *gl\_Position*, and varyings. Many operations in the vertex shader, such as matrix multiplication and Math functions like *sqrt*, have floating-point values involved.

Second, the outputs of the vertex shader are fed into the rasterization and varying interpolation module implemented

natively by WebGL. The module maps a computer graphics model to each pixel on the canvas and interpolates each varying variable based on the attribute values on each vertex. Let us illustrate three major floating-point related operations in this module. (i) The module decides whether a given pixel is inside a triangle. (ii) The module calculates the z-buffer of each point, i.e., determining whether a point is in front of or behind another on the canvas. (iii) The module interpolates a varying variable based on attributes.

Lastly, the outputs of the rasterization and varying interpolation module are fed into the fragment shader in WebGL, which paints all pixels on the canvas by assigning a value to `gl_FragColor`. All the floating-point related operations in the vertex shader, such as matrix operations, also exist in the fragment shader. Additionally, color lookup operations, such as texture mapping, need to fetch a color from a texture, which involve floating-point operations as well.

### 2.1.1 An Explanation of Floating-point Operation and Rendering Discrepancies

We now explain that floating-point operations will cause rendering discrepancies. Figure 2 shows a classic computer graphics model, i.e., a 3D monkey head, covered with a random texture. We render this WebGL task in Google Chrome browser on two different machines, one iMac and the other Dell with Windows system—the rendering results, though being visually the same (Left and Middle of Figure 2), are quite different if we compare them pixel by pixel (Right of Figure 2).

This model is complex with many floating-point operations and thus hard to explain the discrepancies. We now decompose the complex model into several small experiments with only one or a few types of floating-point operations for explanation.

- A Varying Experiment. We setup a thin  $3 \times 100$  rectangle and then specify a varying variable spanning along the long edge from 0 to 100. The variable starts from a color  $\langle 0, 0, 0 \rangle$  at position 0 and ends to a color  $\langle 0, 0, 255 \rangle$  at position 100. That is, we are rendering a simple spectrum on a canvas with only one type of floating-point operation, i.e., the interpolation of a varying variable between 0 and 100.

When we perform this varying experiment on different machines and compare the rendering results, we find that the result differences are several single-pixel lines orthogonal to the long edge. This explains that floating-point operations for interpolating varying variable will lead to rendering discrepancies.

- A Triangle Experiment. We setup a triangle on a  $255 \times 255$  canvas: two vertices at  $\langle 127, 0 \rangle$  and  $\langle 0, 128 \rangle$ , and the third movable along the line from  $\langle 255, 0 \rangle$  to  $\langle 255, 255 \rangle$ . We then color the triangle with only a single color, such as black. By doing so, we create a rendering task with another

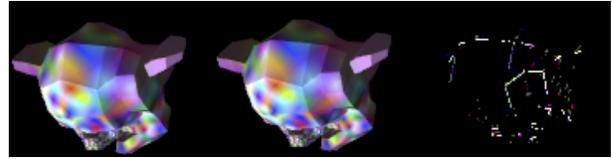

Figure 2: An Illustration of Rendering Task Difference for Browser Fingerprinting Purpose (Left: A classic monkey head model rendered in Google Chrome on an iMac, Middle: the same model rendered in Google Chrome on a Windows machine, Right: The pixel difference between these two rendering results.)

type of floating-point operation, i.e., determining whether a pixel is inside a triangle.

When we perform this triangle experiment on different machines and move the point along the edge, we find that the result difference is a single pixel close to the triangle edge for a special third vertex position. This explains that floating-point operations for triangle judgement will lead to rendering discrepancies.

- A Texture Experiment. We setup a triangle and then map a random texture onto the triangle. That is, we create a rendering task with a texture mapping operation, which has floating-point operations in color interpolation. When we perform this texture experiment on different machines, we find that the result differences are several pixels within the triangle. This explains that floating-point operations for texture mapping will lead to rendering discrepancies.

## 2.2 UNIGL’s Rendering and Floating-point Operations

Now let us go over the three-stage rendering procedure (Figure 1) again in UNIGL and show how to make uniform floating-point operations in aforementioned steps. First, UNIGL moves the vertex shader from GLSL to JavaScript, i.e., all the floating-point operations are executed on JavaScript interpreter and thus handled by CPU without any discrepancies. Note that we need to adopt parallel workers and many other speed-up techniques to run the JavaScript version of vertex shader fast.

Second, UNIGL implements a customized rasterization and varying interpolation module via GLSL in which all the floating-point values are represented via integer simulation, and therefore, all the aforementioned floating-point operations in this module are made uniform. It is worth noting that theoretically we can also implement the module via JavaScript for uniformization, but the performance is unacceptable.

Lastly, UNIGL executes the fragment shader in GLSL, but rewrites all the floating-point operations via integer simulation. Additionally, UNIGL also implements a customized texture mapping algorithm using integers so that the color lookup operation in texture mapping is also made uniform.

## 2.3 A Running Example

After a high-level overview of UNIGL rendering, we now present a detailed running example to illustrate our target problem and how UNIGL solves the problem via uniformity.

#### JavaScript:

```
1 vers=[...]; // vertices information
2 inds=[...]; // indices information
3 ...
4 var versBufferObject = gl.createBuffer();
5 gl.bindBuffer(gl.ARRAY_BUFFER, versBufferObject);
6 gl.bufferData(gl.ARRAY_BUFFER, new Float32Array(vers),
  gl.STATIC_DRAW);
7 var indexBufferObject = gl.createBuffer();
8 gl.bindBuffer(gl.ELEMENT_ARRAY_BUFFER, indexBufferObject
  );
9 gl.bufferData(gl.ELEMENT_ARRAY_BUFFER, new Uint16Array(
  inds), gl.STATIC_DRAW);
10 ...
11 gl.bindBuffer(gl.ARRAY_BUFFER, versBufferObject);
12 var posAttr=gl.getAttribLocation(program, 'aVersPos');
13 ...
14 var uMVLoc=gl.getUniformLocation(program, "uMVMMatrix");
15 gl.uniformMatrix4fv(uMVLoc, [...]);
16 ...
17 // bind other attributes and uniforms
18 gl.drawElements(gl.TRIANGLES, length, gl.UNSIGNED_SHORT
  ,0);
```

#### Vertex Shader:

```
1 attribute vec3 aVersPos, aVersNormal;
2 attribute vec2 aTextureCoord;
3 uniform mat4 uMVMMatrix, uPMatrix;
4 uniform mat3 uNMatrix;
5 uniform vec3 uAmbColor, uLtDir, uDirColor;
6 varying vec2 vTextureCoord;
7 varying vec3 vLightWeighting;
8 void main(void) {
9   gl_Position=uPMatrix * uMVMMatrix * vec4(aVersPos.xyz,
  1.0);
10  vTextureCoord=aTextureCoord;
11  vLightWeighting=uAmbColor + uDirColor * max(dot(
  uNMatrix * aVersNormal, uLtDir), 0.0);
12 }
```

#### Fragment Shader:

```
1 varying vec2 vTextureCoord;
2 varying vec3 vLightWeighting;
3 uniform sampler2D uSampler;
4 void main(void) {
5   vec4 texColor=texture2D(uSampler, vTextureCoord);
6   gl_FragColor=vec4(texColor.rgb * vLightWeighting,
  texColor.a);
7 }
```

#### JavaScript:

```
1 vers = [...]; // vertices information
2 inds = [...]; // indices information
3 ... // hook JS APIs to obtain arguments
4 var UniGL_aVersPos=UniGLAttr('aVersPos');
5 var UniGL_uMVMMatrix=UniGLUniform('uMVMMatrix');
6 ...
7 for (UniGL_I=0;UniGL_I<AttrLen;UniGL_I++) {
8   // Transformed JS vertex shader
9   aVersPos=UniGL_aVersPos[UniGL_I];
10  uMVMMatrix=UniGL_uMVMMatrix;
11  ...
12  UniGL_Position=UniGLMultiply(UniGLMultiply(uPMatrix,
  uMVMMatrix), UniGLVec4(UniGLExtract(aVersPos,
  [1,1,1]), 1.0));
13  vTextureCoord=aTextureCoord;
14  vLightWeighting=UniGLAdd(uAmbColor, UniGLMultiply(
  uDirColor, UniGLMax(UniGLDot(UniGLMultiply(uNMatrix,
  aVersNormal), uLtDir), 0.0));
15  // end of transformation
16  UniGL_vTextureCoord.push(vTextureCoord);
17  UniGL_vLightWeighting.push(vLightWeighting);
18 }
19 UniGL_CallFragmentShader(UniGL_Position,
  UniGL_vTextureCoord, UniGL_vLightWeighting);
```

#### Fragment Shader:

```
1 #define N AttributeNumber
2 uniform ivec3 UniGL_Position[N];
3 uniform ivec2 UniGL_vTextureCoord[N];
4 uniform ivec3 UniGL_vLightWeighting[N];
5 uniform sampler2D uSampler;
6 void main(void) {
7   for (UniGL_I=0;UniGL_I<N;UniGL_I+=3) {
8     if (UniGL_InTriangleZBuffer(gl_FragCoord, UniGL_I)) {
9       vTextureCoord = UniGL_Interpolate(gl_FragCoord,
  UniGL_I, UniGL_vTextureCoord[UniGL_I],
  UniGL_vTextureCoord[UniGL_I+1], UniGL_vTextureCoord[
  UniGL_I+2]);
10      vLightWeighting = ...;
11      // Transformed fragment shader
12      ivec4 texColor=UniGL_texture2D(uSampler,
  vTextureCoord);
13      gl_FragColor=UniGL_i2f(ivec4(UniGL_Multiply(texColor
  .rgb, vLightWeighting), texColor.a));
14      // end of transformation
15    }
16  }
17 }
```

Figure 3: A Running Example (Left: The original code, Right: The code rewritten by UNIGL—JavaScript WebGL APIs are hooked, the vertex shader is rewritten as JavaScript code, and the fragment shader is still as fragment shader with floating-point operations redefined.)

We now show the source code of this rendering task of Figure 2 in Figure 3 (Left). The source code contains three parts: JavaScript, Vertex Shader and Fragment Shader. First, the JavaScript code prepares data, such as attributes, uniforms, and texture, for both vertex and fragment shaders. Lines 4–13 (Left, JavaScript) show an example of passing attributes to the vertex shader. Next, Lines 14–16 (Left, JavaScript) show another example of passing uniforms to the vertex shader. Second, the vertex shader code accepts attribute and uniform values from the JavaScript and then performs operations, i.e., Lines 9–11 (Left, Vertex Shader), on each attribute in a parallel manner. The outputs of the vertex shader to the fragment shader are a special variable, *gl\_position*, which indicates the transformed vertices, and multiple varyings. Third, the fragment shader accepts outputs, i.e., vertices and varying, from the vertex shader, performs rasterization and interpolation, and then runs the code (i.e., Line 5–6, Left, Fragment Shader).

Now, let us describe the floating-point related operations that cause the rendering result difference. First, the vertices, i.e., *gl\_position*, and the varyings, i.e., *vTextureCoord* and *vLightWeighting*, are passed and interpolated between the vertex and the fragment shader. Such interpolation and accompanied rasterization involve floating-point operations and may cause difference. Second, WebGL functions, such as *dot* at Line 11 (Left, Vertex Shader) and *texture2D* at Line 5 (Left, Fragment Shader), include floating-point operations and may cause difference. Lastly, floating-point operations, such as Lines 9–10 (Left, Vertex Shader) and Line 6 (Left, Fragment Shader), may cause difference.

Next, we use Figure 3 (Right) to illustrate how UNIGL rewrites the original code and prevents such differences caused by floating-point operations. First, UNIGL will hook all the JavaScript APIs, such as *bindBuffer* and *bufferData*, to obtain vertices and indices information and associate them with attributes and uniforms in the vertex shader. Then, UNIGL rewrites the original vertex shader by replacing

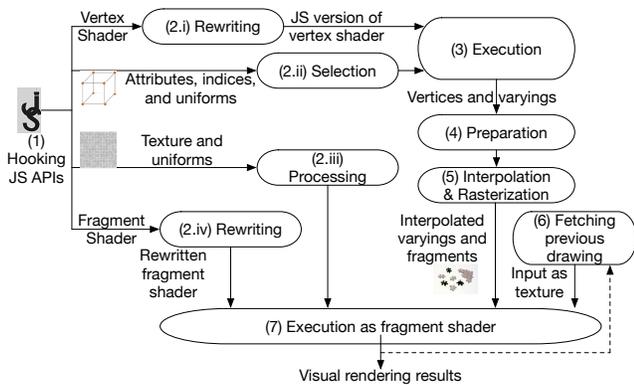

Figure 4: Overall Architecture of UNIGL (Steps 1–4 are executed as JavaScript, and Steps 5–7 as a fragment shader in a GLSL program). floating-point operations like *dot* with JavaScript functions like *UniGLDot*, and executes it as JavaScript at Line 9–15 (Right, JavaScript). Second, UNIGL collects the execution results from JavaScript-based vertex shader (Lines 16–17, Right, JavaScript) and then feeds them into a rewritten fragment shader as uniforms (Line 2–4, Right, Fragment Shader). Third, UNIGL rewrites the original fragment shader and execute it with customized rasterization and interpolation. The rasterization process at Lines 7–8 (Right, Fragment Shader) goes through all the triangles for each pixel on the canvas and determines whether a given pixel lies inside a triangle. If yes, UNIGL calculates the z-buffer of the given pixel for the triangle, decides whether the triangle is in the front and needs to be rendered, and also calculates pixel values based on alpha. Then, the interpolation process (Lines 9–10, Right, Fragment Shader) interpolates varyings based on vertices and attributes passed from JavaScript as uniforms. Lastly, UNIGL executes a rewritten fragment shader at Lines 12–13.

### 3 Design

We present the design of UNIGL in this section.

#### 3.1 System Architecture

In this subsection, we show and describe the overall architecture of UNIGL. The main function of UNIGL is encapsulated as JavaScript files executed directly in the website runtime context. The add-on part is a thin layer used to inject UNIGL into the runtime context of the target website with WebGL tasks. That is, the purpose of the add-on is to ensure the injected UNIGL JavaScript code is executed before any website code. Once the injected scripts are running, the add-on code is disposable. We make this design choice so that UNIGL can be easily transferred between browsers.

Once the main part of UNIGL is injected into the target website, UNIGL performs seven detailed steps to render a WebGL task on a canvas as shown in Figure 4. First, UNIGL needs to perform some preparation tasks outside the three stages in Figure 1. In Step (1), UNIGL hooks WebGL related JavaScript APIs to obtain four types of information: (i) vertex shader (via *shaderSource* API), (ii) inputs to vertex

shader, such as attributes, indices and uniforms (via APIs, such as *bufferData* and *bindBuffer*), (iii) fragment shader (via *shaderSource* API), and (iv) inputs to fragment shader, such as texture and uniforms (via APIs, such as *texImage2D* and *texParameteri*). Then, in Step (2), UNIGL processes all the information obtained in Step (1). Particularly, UNIGL rewrites both vertex and fragment shaders in Step (2.i) and (2.iv), and extracts and prepares inputs in Step (2.ii) and (2.iii). For example, UNIGL reads indices and attributes, associates each attribute buffer with corresponding attribute variable in the vertex shader, and then prepares data based on the drawing mode (e.g., *drawElements* vs. *drawArray*, and *gl.POINTS* vs. *gl.LINES* vs. *gl.TRIANGLES*). Similarly, UNIGL also extracts texture information, such as image width and height, and texture mapping algorithm (e.g., *GL\_LINEAR* vs. *GL\_NEAREST*).

After that, in Step (3), UNIGL executes the rewritten vertex shader and generates outputs, i.e., vertices and varyings, which also belongs to Stage 1 in Figure 1. Next, in Step (4), UNIGL prepares inputs to the fragment shader by processing the outputs in Step (3), i.e., Stage 2 in Figure 1. Specifically, UNIGL performs backface culling on the triangles and iteratively divides the visible triangles by half so that each rendering task only contains uniforms within the limit enforced by WebGL. Then, in Step (5), UNIGL loops through all the pixels on canvas and determines whether each pixel falls inside the triangles or on the lines depending on the drawing mode. If yes, UNIGL interpolates all the varyings based on the given pixel and vertices. If no, UNIGL fetches previous drawing results from a special texture and uses the pixel color in Step (6). Lastly, UNIGL executes the rewritten fragment shader to calculate the pixel color in Step (7), i.e., performing Stage 3 in Figure 1.

#### 3.2 Floating-point Operation Simulation

In this subsection, we present how to simulate floating-point operations using integers, i.e., the integer simulation method in Figure 1 for fragment shader. Such method is used in both Stage 2: Rasterization&Interpolation and Stage 3: Fragment Rendering, i.e., Step (5) and (7) in Figure 4.

##### 3.2.1 Floating-point Representation and Operation

UNIGL adopts two integers, i.e., one numerator ( $p$ ) and the other denominator ( $q$ ), to represent an arbitrary floating-point value in the fragment shader. In this paper, we also refer the denominator as a *base*, because UNIGL can easily perform operations, such as addition and subtraction, on two values with the same base. Note that such representation also aligns well with the physical meaning of WebGL floating-point values. Take coordinates for example. The original vertices or texture coordinates are specified as an integer in terms of the canvas or texture size, which can serve as the numerator, and then the canvas or texture size can serve as the base. For

another example, 255 will be the base for all the color values, because all RGB colors are within the range of 255.

One important operation for UNIGL’s floating-point numbers is to change base for a given number. Such operation will be used when UNIGL converts simulated floating-point values to real ones represented by WebGL, such as the specification of texture coordinates at Line 12 and color values at Line 13 of Figure 3 (Right, Fragment Shader). The choice of a base depends on the underlying physical meaning of the WebGL functions, e.g., UNIGL adopts 255 as the base for *gl\_FragColor*.

We now explain why the base representation can make uniform rendering results across browsers. Specifically, although a color value is represented as a float value internally in WebGL, WebGL has to convert it back to an integer when rendering the color on canvas. That is, if WebGL accepts a value  $p$  in between  $1/255$  and  $2/255$ , it may render  $p$  as 1 or 2 depending on the underlying conversion algorithm. At contrast, if WebGL accepts a value as either  $1/255$  or  $2/255$ , the ambiguity disappears and the results are uniform across browsers. In sum, UNIGL adopts different bases according to the physical meaning when UNIGL passes the floating-point value back to WebGL.

Next, we describe how to change base for a given number especially when it does not have the required base. Intuitively, we can multiply the value with the new base and divide the product with the old base. However, such intuitive approach does not work, because the division of one integer over another involves floating-point operations in some WebGL implementations. That is, the division result differs from one browser to another. Therefore, after obtaining the quotient, UNIGL needs to search within a range (i.e.,  $\pm 1$ ) of the quotient for the real quotient. Other than the base change operation, UNIGL also supports basic arithmetic operations, which follow fraction operations. Due to simplicity, we skip details here. One thing worth noting is that UNIGL needs to avoid result overflows—if so, UNIGL needs to increase the base to accommodate a larger value.

In the next two subsections, we show how to use such base representation of floating-point values and replace existing ones in two important types of WebGL functions.

### 3.2.2 Floating-point Operations in Rasterization and Interpolation

Rasterization and interpolation are automatically performed in between the vertex and fragment shaders. Specifically, for all pixels on the canvas and all triangles, rasterization needs to decide whether the given pixel is inside the triangle and, if so, calculate the z-buffer. Note that both procedures involve floating-point values and operation, which need to adopt the base representation during calculation. Then, the interpolation calculates weights for three vertices at a given triangle and then outputs the interpolated varying, i.e., a weighted sum

of the attribute values at three vertices. All the weights and calculations are in the aforementioned base representation.

Another thing here, being different from normal rasterization and interpolation, is that UNIGL divides the entire, rectangle canvas into two triangles with four vertices as shown in Figure 5a instead of using the original vertices. The usage of such vertices is necessary to design a GLSL-version of rasterization, because the fragment shader will only expose a pixel to the GLSL program when the pixel is inside one triangle. Therefore, if we adopt the original vertices as the inputs to the fragment shader, some pixels, especially when they are on the edge, may be considered as inside a triangle by one browser but outside by another. The division shown in Figure 5a will consider all pixels on the canvas as being within either of these two triangles on any browser. This will give UNIGL the capability to go through all the pixels and decide whether a pixel, such as  $(x, y)$  in Figure 5a, is inside triangles consisted of the original vertices, i.e.,  $(x_1, y_1) \dots (x_4, y_4)$ .

### 3.2.3 Floating-point Operations in Fragment Shader

The fragment shader uses many float-point related functions, such as “texture2D”, “normalize” and “sqrt”. In this subsection, we use texture mapping, i.e., “texture2D”, as an example to show the procedure of adopting integer simulation and replacing floating-point operations.

Texture mapping, in its normal definition, is a method of applying a two-dimensional surface upon a three-dimensional graphics model. There are many variations of texture mapping algorithms, such as linear interpolation (i.e., `GL_LINEAR`) and nearest neighbor (`GL_NEAREST`). Sometimes, mipmaps are also generated to process the texture before mapping. In this paper, we use linear interpolation as a proof of concept algorithm to show how to redefine texture mapping in UNIGL.

One of the major tasks in redefining texture mapping is to pass texture data from JavaScript to the fragment shader. The naïve method is to utilize “uniforms” just as vertices. However, because there exists a limit for the number of “uniform” variables and texture cannot be divided in multiple draws, we have to rely on existing texture information stored in WebGL.

Here is how UNIGL redefines a linear interpolation algorithm for texture mapping. UNIGL stores texture information using the default WebGL method with a nearest neighbor algorithm—therefore, WebGL will just directly fetch color values from the texture instead of performing any computation. When UNIGL has a texture coordinate, say, for example,  $1/base$  in Figure 5c, UNIGL will first change the base to the size of the texture. Note that we use a square-shape texture as an example and a rectangle-shape will be similar.

Then, UNIGL fetches the colors, i.e.,  $c_1 \dots c_4$ , of four texture points in Figure 5c, which locate around the target texture coordinate. Because UNIGL uses the texture size as the new base, the ambiguity among browsers will disappear. Next, UNIGL calculates two weights, i.e.,  $w_1$  and  $w_2$ , based on the distance between the target texture coordinate and four texture

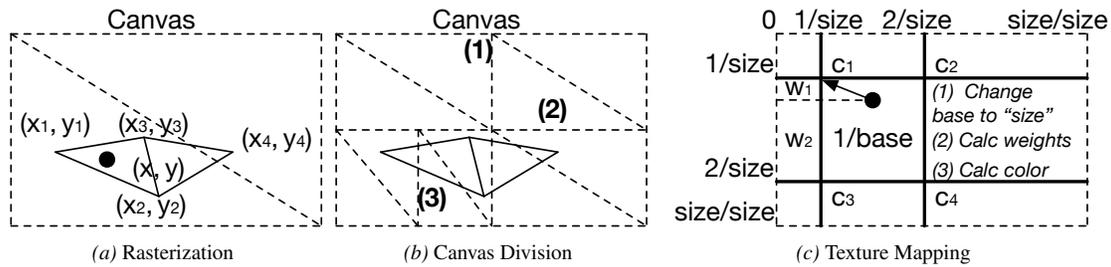

Figure 5: Explanation of Different UNIGL Operations. In subfigure (a), during rasterization, UNIGL needs to determine the triangle that each point belongs to. Specifically, Point  $(x, y)$  is inside the triangle consisting of vertices  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$ , but outside the other triangle consisting of vertices  $(x_2, y_2)$ ,  $(x_3, y_3)$ , and  $(x_4, y_4)$ . Therefore, UNIGL will interpolate the values of all the varyings at  $(x, y)$  based on  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$ . In subfigure (b), UNIGL first divides the entire canvas into two parts, i.e. left and right, and then top and bottom. After that, because the number of vertices in some divided parts is small enough to be handled by WebGL, UNIGL will not further divide such parts, like top right and top left. If the number of vertices in a part is still larger than the minimum number of allowed uniform variables, UNIGL will further divide the canvas, like cut (3). Subfigure (c) adopts a square texture as an example to show how the linear interpolation algorithm of texture mapping works in UNIGL. UNIGL calculates an interpolated color value for a given point based on four color values around this point.

Table 1: WebGL Data and Corresponding JavaScript APIs that Intercept such Data

| Intercepted WebGL Data | JavaScript APIs               |
|------------------------|-------------------------------|
| GLSL Program           | createProgram, attachShader   |
| Shader                 | attachShader, getShaderSource |
| Buffer                 | bufferData                    |
| Attribute              | vertexAttribPointer           |
| Attribute Location     | getAttribLocation             |
| Uniform                | uniform*** (e.g., uniform1f)  |
| Uniform Location       | getUniformLocation            |

fetches points—these two weights can be in any base. Lastly, UNIGL calculates the color for the target texture coordinate using these two weights, i.e.,  $color = w_2w_2c_1 + w_1w_2c_2 + w_2w_1c_3 + w_1w_1c_4$ .

### 3.3 Rendering Preparation

In this subsection, we introduce how to prepare inputs to both rewritten vertex and fragment shaders, i.e., Steps (1), (4), and (6). These steps do not have direct involvement with floating-point values, but are essential in preparing the vertex and fragment shaders in UNIGL.

**JavaScript Hooking and Data Extraction.** UNIGL hooks WebGL-related JavaScript APIs in Step (1) of Figure 4. Specifically, UNIGL utilizes the dynamic feature of JavaScript to redefine such JavaScript APIs, intercepts all arguments, i.e., parameters to WebGL, processes the arguments, and stores them in an internal data structure of UNIGL. Table 1 shows a list of WebGL data and corresponding JavaScript APIs. Such data can be roughly divided into two major categories: programs and inputs. “GLSL program” and “shader data” in Table 1 are intercepted by UNIGL for rewriting purpose. All others, such as “attribute” and “uniform”, are inputs to the program—UNIGL intercepts them and then feeds them to the rewritten programs. Both “attribute” and “uniform” refer to the data, e.g., colors and vertices, and “at-

tribute location” and “uniform location” are the corresponding variables defined in the shaders.

**Backface Culling.** UNIGL adopts backface culling [11] in Step (4) of Figure 4 to determine whether a polygon, such as a triangle, of a graphical object is visible. Specifically, UNIGL calculates the normal vector of all the triangles and filters these triangles of which the normal vector does not face the camera.

**Rendering Task Division.** Rendering task division, part of Step (4), is designed specifically in UNIGL to overcome the limit of the uniform variable numbers in fragment shader. Figure 5b shows an illustration of such division. UNIGL first divides the canvas vertically by half, e.g., division (1) in Figure 5b, and then horizontally, e.g., division (2). Such vertical or horizontal division will be performed alternatively in each iteration on a small region until the number of vertices in that region is smaller than the limit enforced by WebGL implemented in a specific browser. Note that if a triangle is partially inside a region, e.g., the right corner region in Figure 5b, UNIGL will count all three vertices towards the limit. The reason is that all three vertices are required to determine whether a given pixel lies inside a triangle.

**Reading Previous Draw Results.** In this part, we describe how UNIGL handles multiple draws in Step (6). For example, a WebGL program may first draw a triangle by calling one GLSL program and then a rectangle by calling another. In such multiple draws, the rendering results are treated as a background in the latest draw. Because UNIGL goes through all the pixels in the fragment shader each time, UNIGL needs to read previous draw results. Specifically, UNIGL relies on the readPixels API to obtain the canvas contents, constructs a texture based on the contents and then passes the texture to the fragment shader. Then, in the fragment shader, UNIGL first reads the color value from the texture, and assigns the color to  $gl\_FragColor$ . Later on, if the current drawing renders a

```

1  attribute vec2  vertPosition;
2  void main() {
3    gl_Position =  vec4(vertPosition, 0.0, 1.0);
4    gl_PointSize = 1.0;
5  }

```

Figure 6: Dummy Vertex Shader (The vertex shader performs a self-mapping with a z-value as 0.0 and a w-value as 1.0. The point size is also set to be 1.0.)

color on this pixel, the assigned color will be overwritten; otherwise, the assigned color is treated as the background.

### 3.4 Rewriting and Rendering

In this subsection, we describe UNIGL’s rewriting and rendering process, i.e., Step (2). In both Steps (2.i) and (2.iv), UNIGL preprocesses the GLSL program, i.e., replacing pre-processor directives with a hash symbol at the beginning, and then parses the processed program into Abstract Syntax Tree (AST). We then discuss how to rewrite vertex and fragment shaders separately.

- **Vertex Shader.** UNIGL traverses through the AST, redefines corresponding node, e.g., replacing the operator plus with a function `UniGL_Plus`, and then converts the AST back to either JavaScript or GLSL code. All the type information is kept the same because UNIGL has redefined all the types in JavaScript to be the same as in GLSL. Note that one additional step is that UNIGL needs to divide the  $w$  value of `gl_Position` from the  $x$ ,  $y$  and  $z$  values so that UNIGL can switch the rendering results from an orthographic view to a perspective view. This step was performed implicitly in the original WebGL, and UNIGL needs to do so as well.
- **Fragment Shader.** UNIGL traverses through the AST and redefines the following three types of nodes: (i) operators, (ii) constant float number, and (iii) type information related to floating point values. First, UNIGL redefines all the existing operations, such as multiply, with the corresponding GLSL function, such as `UniGL_Multiply`. Second, UNIGL converts all the constant floating point values, e.g., 0.32 as an alpha value, to our base representation, e.g., 32 as the value and 100 as the base for all alphas. Lastly, UNIGL need to convert all the types related to floating point values, such as float and `vec3`, to the corresponding integer type, such as int and `ivec3`.

Note that WebGL requires that all GLSL programs have both vertex and fragment shaders. Therefore, UNIGL executes a dummy vertex shader as shown in Figure 6. The dummy vertex shader needs to set `gl_PointSize`, because the default value also differs on different OSes, e.g., Mac vs. Windows.

### 3.5 Execution of JavaScript Vertex Shader and Corresponding Floating-point Operations

In this subsection, we describe the execution of JavaScript vertex shader in Step (3). All the floating-point operations in

the vertex shader are thus executed on CPUs. We adopt five runtime optimizations to speed up the execution as shown below.

- **Multiple Web Workers.** Once one frame comes in, UNIGL puts the vertex rendering tasks of the frame into a queue. Then, multiple workers keep fetching the tasks from the queue, and run them in parallel.
- **Caching.** UNIGL adopts a caching mechanism for matrix operations, e.g., `UniGLAdd` and `UniGLMultiply` at Lines 12 and 14 of Figure 3 (Right, JavaScript), in Step (3). That is, UNIGL will cache the calculation results of a matrix operation, e.g., the multiplication of two matrices. If the rewritten vertex shader asks for the results of an operation upon the same matrices, UNIGL will directly return the result directly instead of calculating it again.
- **Typed, fixed-size Array.** UNIGL adopts typed arrays, such as `Float32Array`, instead of the normal JavaScript array to store data. The reason is that typed array are stored in a contiguous memory region can fast accessed by the browser. In addition, UNIGL needs to specify the length to avoid array resizing. The reason is that array resizing may involve additional memory allocation and data copy. Note that we also need to avoid using some heavy JavaScript array operations, such as `Array.map()`.
- **Code and Data Separation.** UNIGL separates the code and the data for the rewritten shader. That is, the code will be prepared in the hooked `useProgram` API, which does not have an influence on the runtime performance, and JIT-ed for performance speed-up. Note that UNIGL triggers the JIT engine by executing the code once with initial data. Then, further data will be prepared in the draw stage.
- **WebAssembly.** UNIGL executes some heavyweight operations, such as matrix multiplication, using native code like `WebAssembly`.

## 4 Implementation

We implemented a prototype of the core function of UNIGL with around 8,500 lines of JavaScript code, around 650 lines of GLSL code, and around 3,000 lines of code for auxiliary components such as `WebAssembly` and add-on. The rewriting component of UNIGL is modified from one open-source GitHub repository (namely, <https://github.com/stackgl/glsl-transpiler>). Other than this repository, we also use several other libraries, such as `glMatrix`.

UNIGL is open-source, available at repositories under this GitHub user (<https://www.github.com/unigl/>). We also provide a demo at this url (<http://test.unigl.org/>), a modified version of Cao et al. [19]’s fingerprinting websites, to demonstrate that UNIGL can prevent state-of-the-art WebGL-based browser fingerprinting. All rendering results are the same in this new, UNIGL rewritten version.

## 5 Evaluation

We evaluate UNIGL prototype on three metrics: anti-fingerprinting capability, performance, compatibility, and CPU energy consumption.

### 5.1 Anti-fingerprinting Capability

We adopt a state-of-the-art WebGL-based browser fingerprinting work [19] as our benchmark to evaluate the anti-fingerprinting capability and performance of UNIGL. Specifically, the benchmark contains 17 different WebGL rendering tasks including plain WebGL tasks and these relying on three.js, a WebGL library, to explore various WebGL features, such as varyings, light and texture. The first column of Table 2 shows the names of all the rendering tasks and the second column a rendering result example on a dell desktop installed with Windows 10.

We evaluate UNIGL by asking Amazon Mechanical Turks to visit our website—including a demo site of UNIGL together with the original fingerprinting site from Cao et al.—using Firefox, Chrome and Safari. In total, we have collected 656 fingerprints from these three types of browsers. Among all the 656 fingerprints, UNIGL only renders one unique fingerprint for each rendering task across different browsers. This unique fingerprint, being visually the same to the original rendering result, is shown in the “Example” column under UNIGL of Table 2. As a comparison, we also show the number of unique fingerprints of Cao et al. in the “# Unique Results” column under “Original” of Table 2—this confirms Cao et al.’s findings that WebGL is a high-entropy vector for browser fingerprinting. We also list some more statistics in Appendix A.

In addition to the Amazon Mechanical Turk experiment, we also perform a local experiment that enumerates a large varieties of factors across the graphics layers. Specifically, we test UNIGL with the following different settings: OS (Windows 7, 8, 10, iOS 10.14.1, and Ubuntu 18.04), graphics card (Nvidia Geforce GTX 1070, Intel Iris plus Graphics 640, AMD Radeon R9 M390, and AMD Radeon HD 6770m), drivers (Nvidia, Intel, and AMD drivers), screen resolution (all these provided by the OS, such as 2560x1440 and 1920x1080), and DPI scaling (100%, 125%, 150%, 175%, 200%, and 225%). UNIGL only produces one unique result, which is the same as the Amazon Mechanical Turk experiment.

### 5.2 Performance

We test the performance of UNIGL by using both micro- and macro-benchmarks. All the experiments, except for the crowdsourced results in Table 2, are performed on an iMac – the machine has an Intel Core i5, 3.2 Hz, 4-core CPU, 24 GB memory, and an AMD Radeon R9 M390 GPU with 2048 MB VRAM.

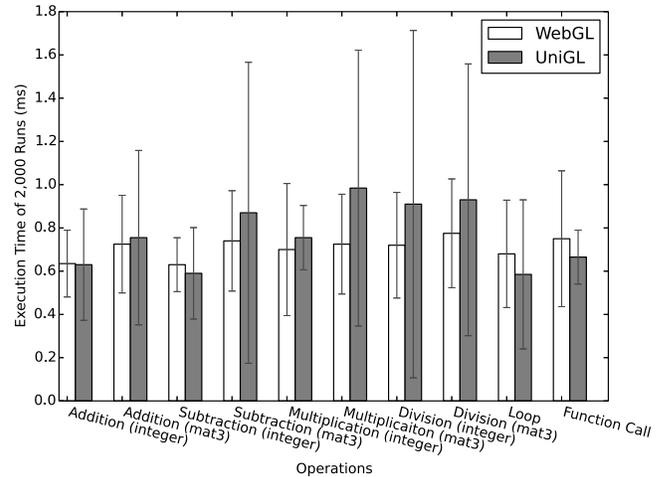

Figure 7: Micro-benchmark of Vertex Shader.

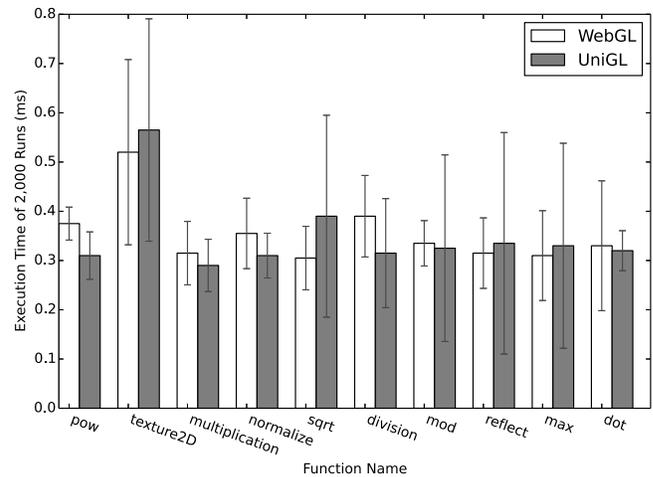

Figure 8: Micro-benchmark of Fragment Shader (all the operations in WebGL are using floating-point values; these in UNIGL adopts integer simulation).

#### 5.2.1 Micro-benchmark

In the micro-benchmark, we test several atomic WebGL operations and compare the original version with the one defined in UNIGL. Specifically, we run each operation in either fragment or vertex shader for 2,000 times and calculate the interval between two draws. Each experiment is performed 20 times to obtain a standard deviation. Note that we adopt a simple model, i.e., a cube, in the micro-benchmark experiment. When we are testing one shader, the other shader will contain a one-line, dummy statement, i.e., the assignment of either `gl_Position` or `gl_FragColor`.

Figure 7 shows the micro-benchmark performance of the vertex shader. The vertex shader of UNIGL outperforms the one written in GLSL in some aspects, such as these operations that have integers involved. The reason is that CPU is well designed for integer operation when compared with GPU. On the contrary, the original shader written in GLSL is better at matrix operations, because such operations can be performed in parallel using shading languages.

Table 2: Macro-benchmark WebGL Tasks [19] and Corresponding Rendering Results with UNIGL (“# Vertices” means the number of vertices in the model, which are two per line segment in a 2D model and three per triangle in a 3D model. “Example” is one rendering example collected from users. In “# Unique Results” columns, X/Y means the number of unique fingerprints collected from all the users out of the total number of fingerprints. “FPS” means frames per second—which is around 60 Hz due to the screen refresh rate. )

| WebGL Task                    | # Vertices | Example                                                                             | Original         |         |        |            | UNIGL                                                                                 |                  |            |
|-------------------------------|------------|-------------------------------------------------------------------------------------|------------------|---------|--------|------------|---------------------------------------------------------------------------------------|------------------|------------|
|                               |            |                                                                                     | # Unique Results |         |        | FPS        | Example                                                                               | # Unique Results | FPS        |
|                               |            |                                                                                     | Chrome           | Firefox | Safari |            |                                                                                       |                  |            |
| Curve and Line                | 262        |    | 74/496           | 23/108  | 18/52  | 60.32±0.38 |    | 1/656            | 61.77±0.54 |
| Curve and Line (AA)           | 262        |    | 83/496           | 32/108  | 21/52  | 60.78±0.54 |    | 1/656            | 61.83±0.97 |
| Cube                          | 36         |    | 4/496            | 2/108   | 5/52   | 60.67±0.49 |    | 1/656            | 62.50±0.80 |
| Cube (AA)                     | 36         |    | 55/496           | 20/108  | 23/52  | 60.46±0.15 |    | 1/656            | 62.39±1.36 |
| Cube (Camera)                 | 36         |    | 56/496           | 18/108  | 7/52   | 60.02±0.22 |    | 1/656            | 61.75±1.32 |

| Bubble (three.js)             | 974        |  | 49/496           | 17/108  | 22/52  | 60.20±1.52 |  | 1/656            | 60.07±1.43 |
| Compressed Texture (three.js) | 98         |  | 72/496           | 21/108  | 19/52  | 60.04±0.56 |  | 1/656            | 59.59±0.73 |
| Shadow (three.js)             | 156        |  | 53/496           | 17/108  | 19/52  | 59.84±0.35 |  | 1/656            | 60.12±1.02 |
| Combined fingerprint          |            |                                                                                     | 123/496          | 41/108  | 26/52  |            |                                                                                       | 1/656            |            |

Figure 8 shows the micro-benchmark performance of the fragment shader. Similar to the vertex shader, while UNIGL is slower than the original WebGL in some cases, such as “texture2D” as UNIGL redefines the function, it is worth noting that UNIGL is faster than the original WebGL in many other cases, such as “pow” and “multiplication”. The reason is that an integer operation is indeed sometimes cheaper than a floating-point one. For example, it takes less time to multiply two integers than two floating-point values. Note that we are referring to integer operations that exist in the original vertex shader during this discussion. Floating-point values are still represented as floats in the vertex shader of UNIGL.

### 5.2.2 Macro-benchmark

In this subsection, we use the WebGL tasks provided by Cao et al. [19] as our macro-benchmark to measure the FPS of

these rendered by UNIGL. The column “FPS” under UNIGL of Table 2 shows the FPS of each rendering task and we also show the FPS without UNIGL, i.e., these rendered directly by WebGL in the same table. The performance of UNIGL can satisfy the required screen refresh rate, i.e., 60 Hz. The FPS of UNIGL for all the tasks are similar to the original one rendered by WebGL alone.

There are two things worth noting. First, the FPS of UNIGL is even sometimes a little bit higher than the one of WebGL. The reason is that when the model is simple, our highly optimized vertex shader with the help of WebAssembly is faster than the original one. Second, the FPSes of both UNIGL and WebGL are a little bit higher than 60 Hz in some tasks, because modern browsers reduce the precision of *performance.now* to prevent timing attacks [7], which may

Table 3: Overhead Breakdown for the “Two models (Complex light)” Task

| Procedure               | Overhead     |
|-------------------------|--------------|
| Data Preparation        | 0.08±0.07ms  |
| Backface Culling        | 2.16±0.06ms  |
| Vertex Shader           | 2.26±0.18ms  |
| Rendering Task Division | 5.34±0.73ms  |
| Fragment Shader         | 6.51±0.85ms  |
| Total                   | 16.35±0.74ms |

Table 4: Vertex Shader Optimization (all numbers are averaged from 10 experiments and rounded to ms)

|                                    |        |
|------------------------------------|--------|
| Unoptimized Vertex Shader          | 110 ms |
| Result Caching of Matrix Operation | -24 ms |
| Typed, Fixed-size Array for Data   | -22 ms |
| Code and Data Separation           | -39 ms |
| Parallelization                    | -19 ms |
| WebAssembly                        | -4 ms  |
| Optimized Vertex Shader            | 2 ms   |

lead to a small measurement error. Such measurement errors are consistent across UNIGL and WebGL.

We further look at one specific task, i.e., “Two models (Complex light)”, and analyze the overhead brought by UNIGL. Table 3 shows the overhead breakdown by different procedures of UNIGL. The rendering task division and fragment shader are the most time-consuming procedures, i.e., each taking one third of the entire overhead. Both data preparation and backface culling are lightweight, taking up a small portion of the overhead.

We then look at how our optimization reduces overhead of UNIGL, especially the vertex shader, using the same task. Specifically, we evaluate five optimizations and their impact on the performance in Table 4. The unoptimized vertex shader in JavaScript takes 110ms and each optimization reduces the overhead to some degree. Code and data separation is the most effective one, i.e., about 40ms reduction, because JIT engine will execute code natively rather than on an interpreter. Then, both caching and typed, fixed-size array speed up the shader by reducing around 20ms, and parallelization also reduces the overhead by around 19ms. Lastly, if we apply WebAssembly optimization, the overhead can also be reduced by 4 ms.

### 5.3 Compatibility

In this section, we evaluate the compatibility of UNIGL with existing WebGL applications. Specifically, in addition to the WebGL tasks from Cao et al. [19], we run UNIGL using two other real-world WebGL applications shown below:

- **Zygote Body.** Zygote Body (<https://www.zygotebody.com/>), formerly known as Google Body, is created by Zygote Media Group to renders a manipulable 3D model of human body from outside, such as skins, muscle tissues and hairs, to inside, such as blood vessels and skeletons.

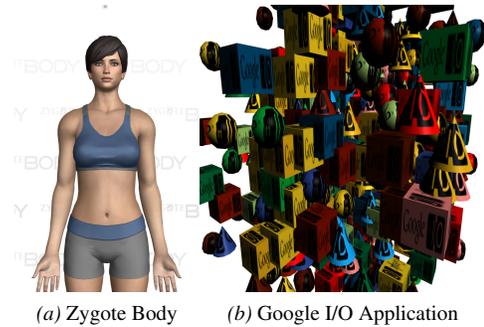

Figure 9: Two Screenshots of Zygote (Google) Body and Google I/O Application Rendered by UNIGL

- **Google I/O 2011 Applications.** Google has presented WebGL applications (<https://webgl.samples.org/google-io/2011/index.html>) at its I/O event in 2011 to show the new technique and performance.

Our evaluation result shows that UNIGL is compatible with both applications. First, we run UNIGL with Zygote Body—the human body is rendered correctly with no visual difference. We can also manipulate it by looking at different layers, such as skeleton and muscle. Second, we run UNIGL with Google I/O applications—all the objects are shown and displayed correctly with the right texture, moving on the canvas the same as ones with WebGL directly. Two screenshots of both applications are also shown in Figure 9: Figure 9a shows the front page of Zygote Body, a default rendering of a human, and Figure 9b a screenshot of one Google I/O application after it runs for two seconds.

### 5.4 CPU Energy Consumption

In this section, we evaluate the CPU package power of our macro-benchmark. Specifically, we use CPUID’s HWMonitor [3], a program that monitors PC systems’ main health sensors, to calculate the CPU package power consumption for each macro-benchmark task. Note that our experiment is performed on a Dell Desktop because HWMonitor is only available on PC systems.

Figure 10 shows our evaluation results, i.e., CPU package power consumption when each macro-benchmark task is rendered by WebGL (hardware rendering), WebGL (software rendering), and UNIGL. The power consumption for WebGL (hardware rendering) is the smallest for all the tasks because hardware rendering relies on GPU to perform computation. UNIGL is the second, because UNIGL relies on CPU for rendering vertex shader, but GPU for fragment shader. WebGL (software rendering) is the highest as all the rendering tasks are performed on CPU.

It is also worth noting that CPU package powers for “thousands of rings” and “clipping plane” are the highest compared with other tasks. The reason is that the vertex shader for both tasks are computationally heavy. Take “thousands of rings” for example. The position and shapes for all the rings are calculated in the vertex shader.

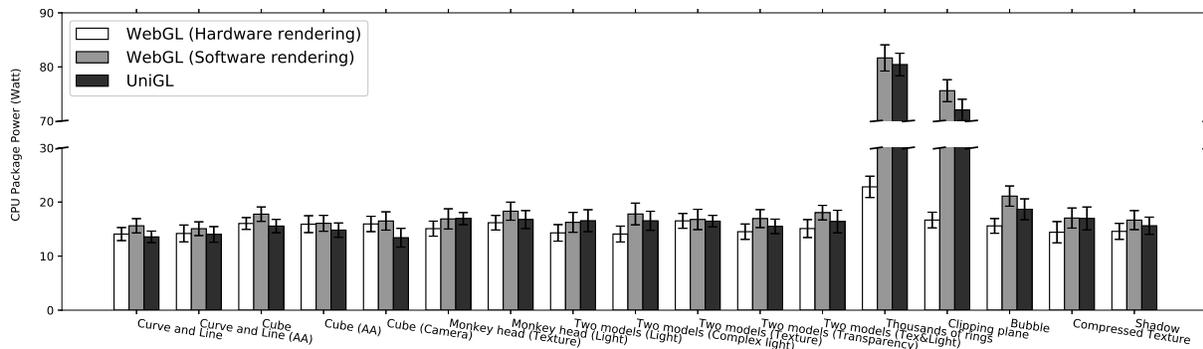

Figure 10: CPU Package Power Comparison among WebGL (hardware rendering), WebGL (software rendering), and UNIGL. (Note that all other WebGLs mentioned in the paper except for this figure and corresponding texts refer to the default hardware rendering.)

## 6 Discussion

We discuss several issues regarding UNIGL in this section.

- **Timing side-channel attacks.** Timing information, such as the rendering speed of WebGL tasks, may also be used for fingerprinting. For example, Naghibijouybari et al. [43] shows that timing side channels exist in GPU, e.g., WebGL rendering tasks. Similarly, the execution time of floating-point operations can also be used as a timing side channels [29, 51]. Many existing works, such as Deterministic Browser [18], JavaScript Zero [54], and CTFP [14], are proposed to defend against such timing channels, and therefore we would consider such timing-based fingerprinting out of scope of the paper.
- **Self-modifying code (i.e., an strong adversary aware of UNIGL).** There are three techniques used to prevent self-modifying code that is aware of the existence of UNIGL from tampering the UNIGL code and logics. First, UNIGL adopts anonymous closure to encapsulate all the core code of UNIGL from access by any potentially malicious website JavaScript. Specifically, anonymous closure makes sure that all the private variables and original WebGL functions, such as drawElements, are securely protected. Second, UNIGL obtains all the system object, such as “undefined”, to avoid tampering from an adversary. Lastly, the add-on code injects the main function of UNIGL as the first script to execute before any other website JavaScript. It is worth noting that we are aware that there exists an active Chrome bug [4] at the time when we write the paper, which is about “document\_start” hook on child frames. We believe that this bug should be fixed to follow the specification of Chrome extension.
- **WebGL Vulnerability.** WebGL may expose some low-level vulnerabilities in device drivers to web applications [62]. As discussed in Milkomeda [62], WebGL has already imported security checks to prevent an attacker exploiting such vulnerabilities.
- **Fingerprinting via WebGL meta-information.** We realize that not only the rendering behaviors of WebGL tasks but also the meta-information of WebGL engine and implementation can be used for fingerprinting. For example, as shown

by this website (<https://browserleaks.com/webgl>), different WebGL meta-information, such as vendor, renderer, and shader parameters, can all be used as part of browser fingerprinting.

We would like to point out that such fingerprinting relying on WebGL meta-information is relatively easy to prevent as shown by Tor Browser’s in uniformization of the reported values of such meta-information. Specifically, Tor Browser changes and makes uniform the return values of WebGL meta-information functions, such as `getParameter()`, `getSupportedExtensions()`, and `getExtension()`. Therefore, we encourage one to rely on Tor Browser for prevention of such fingerprinting.

- **Floating-point Value Precision.** We now discuss the precision of floating-point values used in UNIGL. Our integer simulation of floating-point values can meet the needs of graphics tasks, because WebGL does not need a high-precision definition of floating-point variables. Specifically, the semantic meaning of many WebGL variables only requires a relatively low-precision value. Take color values for example: Each color value only ranges from 0 to 255 and thus a high-precision, 16-bit floating-point value will not represent more colors. In fact, many WebGL implementation only support a medium (10 bits) or low (8 bits) for float variables.
- **Future WebGL-based fingerprinting.** State-of-the-art WebGL fingerprinting is based on differences in floating-point operations. We empirically verify this via carefully-designed experiments following WebGL specifications in Section 2.1.1 and our evaluation of UNIGL against Cao et al.’s WebGL fingerprinting [19]. Future WebGL fingerprinting techniques and those that do not rely on WebGL are out of scope of the paper.
- **Ethic concerns.** We discussed with our Institutional Review Board (IRB) about the ethics of the proposed research and experiment, because we require a human to run our experiment on their machines. The conclusion is that the proposed research does not require IRB approval. The reason is that although browser fingerprinting may be used to collect private information, the fingerprint itself, just like

cookies, is just an identifier, which does not contain any private information. Our experiment only collects fingerprints but not any private information associated with the fingerprint.

## 7 Related Work

We discuss related work in this section.

**Browser Fingerprinting.** Browser fingerprinting is a second-generation web tracking that goes beyond cookies or super cookies [30–33, 35, 53] to utilize inherent features inside web browsers. For example, there are many works [12, 13, 20, 23, 45, 63] performing measurement works on browser fingerprinting. Browser fingerprinting can rely on many features. Laperdrix et al. [34], i.e., AmIUnique, is a comprehensive study on 17 features of browser fingerprinting. Then, Vastel et al. studied the dynamics of fingerprints [59], i.e., how browser fingerprints change over time, and the privacy implication of browser fingerprint inconsistencies [60]. Researchers also study specific features of browser fingerprinting, such as fonts [23], AudioContext [20], and JavaScript engine [40, 42]. The defense target of the paper is WebGL-based fingerprinting, which was first proposed by Mowery et al. [41] and then thoroughly examined by Cao et al. [19].

**Floating-point Timing Channel.** A floating-point timing channel [29, 51] of web browser refers to that the duration of a floating-point operation can be used to break same-origin policy. Other than floating-point timing channel, many other timing channels [16, 22, 24, 25, 28, 39, 46, 57, 58, 64, 65] have also been studied. As a comparison, the side channel studied in the paper is caused by the different results of floating-point operations, such as conversion from low resolution to high resolution, but not the different duration of floating-point operations. Therefore, we consider that floating-point timing channels are out of scope of the paper, and one should refer to existing works [18] for solutions.

**Defense against Fingerprinting.** To the best of knowledge, none of existing works can defend against WebGL-based browser fingerprinting while still preserving its functionality. The reason is that we believe we are the first to point out floating-point operations are the root cause for WebGL-based browser fingerprinting. UNIGL is also the first system to find out and then redefines such floating-point operations that cause rendering discrepancies.

In the related work, Tor Browser [48], as discussed, is the pioneer work in defending against browser fingerprinting, but it disables WebGL for privacy. PriVaricator [44] adds noises to browser fingerprinting, which can be defeated if the adversary runs the fingerprinting multiple times. Similarly, Multilogin Browser [5] also creates a virtual browser profile with a random fingerprint. TrackingFree [47] only defends against the first-generation web tracking, i.e., these based on cookies or super cookies, but not browser fingerprinting.

**Rewriting Technique.** In the past, both academia [21, 27, 38] and industry [6, 8] have adopted rewriting techniques in dif-

ferent scenarios. In academia, WebShield [38] and BrowserShield [52] rewrite webpages in a proxy to enable web defense techniques. Erlingsson et al. [21] enforce cyber security policies by rewriting binaries. In industry, ShapeSecurity [8], a commercial company, provide products to rewrite websites and prevent bots and malware. Google’s PageSpeed Module [6] also rewrites webpages to improve their performance.

As a comparison, there are unique challenges in rewriting GLSL languages in UNIGL, because it contains two shaders and many internal variables, such as varyings and uniforms. Specifically, UNIGL not only redefines floating-point operations, but also implements rasterization and interpolation in fragment shader so that corresponding floating-point operations in these two procedures can be made uniform.

**Determinism.** Determinism is a technique used to defend against side-channel attacks. For example, StopWatch [36, 37], Deterministic Browser [18], and DeterLand [61] adopt determinism to defend against timing channels. Burias et al. [17] design a deterministic information-flow control system to defend against cache attacks and then Stefan et al. [56] prove that such cache attacks are still possible given a reference clock. Aviram et al. [15] use provider-enforced deterministic execution to prevent timing channels within a shared cloud domain. As a comparison, UNIGL makes the execution results the same but not the execution time across different browsers.

## 8 Conclusion

In this paper, we propose UNIGL, a novel system that rewrites GLSL programs and renders them uniformly across different browsers, thus preventing WebGL-based browser fingerprinting. UNIGL redefines all the floating-point operations, either explicitly written in the shader, or implicitly invoked by the WebGL system.

We implemented an open-source prototype of UNIGL as a browser add-on. Our evaluation shows that UNIGL can defend against state-of-the-art WebGL-based fingerprinting, i.e., there exists only one rendering result when Amazon Mechanical Turks visit our demo website from different browsers on different machines. Our evaluation also shows that the performance of UNIGL can satisfy the needs for the screen refresh rate, i.e., the FPSes of graphics tasks rendered by UNIGL are around 60 Hz.

In the future, we believe that browser vendors should integrate UNIGL natively into browsers. If they choose to do so, they can directly use integer simulation for all the components including vertex shader, rasterization & interpolation engine, and fragment shader, because the outputs from vertex shader, though unavailable in the JavaScript-level, are accessible and can be made uniform directly in native browser. Additionally, a native implementation does not need the rendering task division step in UNIGL because there will be no “uniform” variable limit in the low-level.

## Acknowledgment

We would like to thank our shepherd, Ben Stock, and anonymous reviewers for their helpful comments and feedback. This work was supported in part by National Science Foundation (NSF) grant CNS-18-12870 and an Amazon Research Award. The views and conclusions contained herein are those of the authors and should not be interpreted as necessarily representing the official policies or endorsements, either expressed or implied, of NSF or Amazon.

## Appendix

### A Statistics of Collected Fingerprints

In the appendix, we show some statistics about collected fingerprints using the WebGL tasks provided by the original Cao et al.'s website. Figure 11 shows the anonymous set for the collected data, which is broken down into three different browsers. The size of anonymous set is relatively small—if we limit it to be three, we include 77% of all the collected fingerprints. The largest anonymous set is just with about 10 fingerprints. Among all the browsers, Safari is the most fingerprintable as compared with others: It is probably also because the number of Safari users is relatively small.

## Abstract

Current production web browsers are multi-process but place different web sites in the same renderer process, which is not sufficient to mitigate threats present on the web today. With the prevalence of private user data stored on web sites, the risk posed by compromised renderer processes, and the advent of transient execution attacks like Spectre and Meltdown that can leak data via microarchitectural state, it is no longer safe to render documents from different web sites in the same process. In this paper, we describe our successful deployment of the *Site Isolation* architecture to all desktop users of Google Chrome as a mitigation for process-wide attacks. Site Isolation locks each renderer process to documents from a single site and filters certain cross-site data from each process. We overcame performance and compatibility challenges to adapt a production browser to this new architecture. We find that this architecture offers the best path to protection against compromised renderer processes and same-process transient execution attacks, despite current limitations. Our performance results indicate it is practical to deploy this level of isolation while sufficiently preserving compatibility with existing web content. Finally, we discuss future directions and how the current limitations of Site Isolation might be addressed.

## 1 Introduction

Ten years ago, web browsers went through a major architecture shift to adapt to changes in their workload. Web content had become much more active and complex, and monolithic browser implementations were not effective against the security threats of the time. Many browsers shifted to a multi-process architecture that renders untrusted web content within one or more low-privilege sandboxed processes, mitigating attacks that aimed to install malware by exploiting a rendering engine vulnerability [43, 51, 70, 76].

Given recent changes in the security landscape, that multi-process architecture no longer provides sufficient safety for visiting untrusted web content, because it does not provide similar mitigation for attacks between different web sites. Browsers load documents from multiple sites within the same renderer process, so many new types of attacks target rendering engines to access cross-site data [5, 10, 11, 33, 53]. This is increasingly common now that the most ex-

ploitable targets of older browsers are disappearing from the web (e.g., Java Applets [64], Flash [1], NPAPI plugins [55]).

As others have argued, it is clear that we need stronger isolation between security principals in the browser [23, 33, 53, 62, 63, 68], just as operating systems offer stronger isolation between their own principals. We achieve this in a production setting using *Site Isolation* in Google Chrome, introducing OS process boundaries between web site principals.

While Site Isolation was originally envisioned to mitigate exploits of bugs in the renderer process, the recent discovery of *transient execution attacks* [8] like Spectre [34] and Meltdown [36] raised its urgency. These attacks challenge a fundamental assumption made by prior web browser architectures: that software-based isolation can keep sensitive data protected within an operating system process, despite running untrustworthy code within that process. Transient execution attacks have been demonstrated to work from JavaScript code [25, 34, 37], violating the web security model *without requiring any bugs in the browser*. We show that our long-term investment in Site Isolation also provides a necessary mitigation for these unforeseen attacks, though it is not sufficient: complementary OS and hardware mitigations for such attacks are also required to prevent leaks of information from other processes or the OS kernel.

To deploy Site Isolation to users, we needed to overcome numerous performance and compatibility challenges not addressed by prior research prototypes [23, 62, 63, 68]. Locking each sandboxed renderer process to a single site greatly increases the number of processes; we present process consolidation optimizations that keep memory overhead low while preserving responsiveness. We reduce overhead and latency by consolidating painting and input surfaces of contiguous same-site frames, along with parallelizing process creation with network requests and carefully managing a spare process. Supporting the entirety of the web presented additional compatibility challenges. Full support for *out-of-process iframes* requires proxy objects and replicated state in frame trees, as well as updates to a vast number of browser features. Finally, a privileged process must filter sensitive cross-site data without breaking existing cross-site JavaScript files and other subresources. We show that such filtering requires a new type of confirmation sniffing and can protect not just HTML but also JSON and XML, beyond prior discussions of content filtering [23, 63, 68].

With these changes, the privileged browser process can keep most cross-site sensitive data out of a malicious document's renderer process, making it inconsequential for a web attacker to access and exfiltrate data from its address space. While there are a set of limitations with its current implementation, we argue that Site Isolation offers the best path to mitigating the threats posed by compromised renderer processes and transient execution attacks.

In this paper, Section 2 introduces a new browser threat model covering *renderer exploit attackers* and *memory disclosure attackers*, and it discusses the current limitations of Site Isolation's protection. Section 3 presents the challenges we overcame in fundamentally re-architecting a production browser to adopt Site Isolation, beyond prior research browsers. Section 4 describes our implementation, consisting of almost 450k lines of code, along with critical optimizations that made it feasible to deploy to all desktop and laptop users of Chrome. Section 5 evaluates its effectiveness against compromised renderers as well as Spectre and Meltdown attacks. We also evaluate its practicality, finding that it incurs a total memory overhead of 9-13% in practice and increases page load latency by less than 2.25%, while sufficiently preserving compatibility with actual web content. Given the severity of the new threats, Google Chrome has enabled Site Isolation by default. Section 6 looks at the implications for the web's future and potential ways to address Site Isolation's current limitations. We compare to related work in Section 7 and conclude in Section 8.

Overall, we answer several new research questions:

- Which parts of a web browser's security model can be aligned with OS-level isolation mechanisms, while preserving compatibility with the web?
- What optimizations are needed to make process-level isolation of web sites feasible to deploy, and what is the resulting performance overhead for real users?
- How well does process-level isolation of web sites upgrade existing security practices to protect against compromised renderer processes?
- How effectively does process-level isolation of web sites mitigate Spectre and Meltdown attacks, and where are additional mitigations needed?

## 2 Threat Model

We assume that a *web attacker* can lure a user into visiting a web site under the attacker's control. Multi-process browsers have traditionally focused on stopping web attackers from compromising a user's computer, by rendering untrusted web content in sandboxed renderer processes, coordinated by a higher-privilege browser process [51]. However, current browsers allow attackers to load victim sites into the same renderer process using iframes or popups, so the browser must trust security checks in the renderer process to keep sites isolated from each other.

In this paper, we move to a stronger threat model emphasizing two different *types* of web attackers that each aim to steal data across web site boundaries. First, we consider a *renderer exploit attacker* who can discover and exploit vulnerabilities to bypass security checks or even achieve arbitrary code execution in the renderer process. This attacker can disclose any data in the renderer process's address space, as well as lie to the privileged browser process. For example, they might forge an IPC message to retrieve sensitive data associated with another web site (e.g., cookies, stored passwords). These attacks imply that the privileged browser process must validate access to all sensitive resources without trusting the renderer process. Prior work has shown that such attacks can be achieved by exploiting bugs in the browser's implementation of the Same-Origin Policy (SOP) [54] (known as universal cross-site scripting bugs, or UXSS), with memory corruption, or with techniques such as data-only attacks [5, 10, 11, 33, 53, 63, 68].

Second, we consider a *memory disclosure attacker* who cannot run arbitrary code or lie to the browser process, but who can disclose arbitrary data within a renderer process's address space, even when the SOP would disallow it. This can be achieved using transient execution attacks [8] like Spectre [34] and Meltdown [36]. Researchers have shown specifically that JavaScript code can manipulate microarchitectural state to leak data from within the renderer process [25, 34, 37].<sup>1</sup> While less powerful than renderer exploit attackers, memory disclosure attackers are not dependent on any bugs in web browser code. Indeed, some transient execution attacks rely on properties of the hardware that are unlikely to change, because speculation and other transient microarchitectural behaviors offer significant performance benefits. Because browser vendors cannot simply fix bugs to mitigate cases of these attacks, memory disclosure attackers pose a more persistent threat to the web security model. It is thus important to reason about their capabilities separately and mitigate these attacks architecturally.

### 2.1 Scope

We are concerned with isolating sensitive web site data from execution contexts for other web sites within the browser. Execution contexts include both *documents* (in any frame) and *workers*, each of which is associated with a *site* principal [52] and runs in a renderer process. We aim to protect many types of content and state from the attackers described above, including the HTML contents of documents, JSON or XML data files they retrieve, state they keep within the browser (e.g., cookies, storage, saved passwords), and permissions they have been granted (e.g., geolocation, camera).

Site Isolation is also able to strengthen some existing security practices for web application code, such as upgrading clickjacking [30] protections to be robust against com-

<sup>1</sup>In some cases, transient execution attacks may access information across process or user/kernel boundaries. This is outside our threat model.

promised renderers, as discussed in Section 5.1. Not all web security defenses are in scope, such as mitigations for XSS [46].

## 2.2 Limitations

For both types of attackers we consider, Site Isolation aims to protect as much site data as possible, while preserving compatibility. Because we isolate *sites* (i.e., scheme plus registry-controlled domain name [52]) rather than *origins* (i.e., scheme-host-port tuples [54]) per Section 3.1, cross-origin attacks within a site are not mitigated. We hope to allow some origins to opt into origin-level isolation, as discussed in Section 6.3.

Cross-site subresources (e.g., JavaScript, CSS, images, media) are not protected, since the web allows documents to include them within an execution context. JavaScript and CSS files were already somewhat exposed to web attackers (e.g., via XSS attacks that could infer their contents [26]); the new threat model re-emphasizes not to store secrets in such files. In contrast, cross-site images and media were sufficiently opaque to documents before, suggesting a need to better protect at least some such files in the future.

The content filtering we describe in Section 3.5 is also a best-effort approach to protect HTML, XML, and JSON files, applying only when it can confirm the responses match the reported content type. This confirmation is necessary to preserve compatibility (e.g., with JavaScript files mislabeled as HTML). Across all content types, we expect this filtering will protect most sensitive data today, but there are opportunities to greatly improve this protection with headers or web platform changes [21, 71, 73], as discussed in Section 6.1.

Finally, we rely on protection domains provided by the operating system. In particular, we assume that the OS's process isolation boundary can be trusted and consider cross-process and kernel attacks out of scope for this paper, though we discuss them further in Sections 5.2 and 6.2.

## 3 Site Isolation Browser Architecture

The *Site Isolation* browser architecture treats each web site as a separate security principal requiring a dedicated renderer process. Prior production browsers used rendering engines that predated the security threats in Section 2 and were architecturally incompatible with putting cross-site iframes in a different process. Prior research browsers proposed similar isolation but did not preserve enough compatibility to handle the full web. In this section, we present the challenges we overcame to make the Site Isolation architecture compatible with the web in its entirety.

### 3.1 Site Principals

Most prior multi-process browsers, including Chrome, Edge, Safari, and Firefox, did not assign site-specific security principals to web renderer processes, and hence they did not enforce isolation boundaries between different sites at

the process level. We advance this model in Chrome by partitioning web content into finer-grained principals that correspond to web *sites*. We adopt the *site* definition from [52] rather than *origins* as proposed in research browsers [23, 62, 63, 68]. For example, an origin `https://bar.foo.example.com:8000` corresponds to a site `https://example.com`. This preserves compatibility with up to 13.4% of page loads that change their origin at runtime by assigning to `document.domain` [12]. Site principals ensure that a document's security principal remains constant after `document.domain` modifications.

For each navigation in any frame, the browser process computes the site from the document's URL, determining its security principal. This is straightforward for HTTP(S) URLs, though some web platform features require special treatment, as we discuss in Appendix A (e.g., `about:blank` can inherit its origin and site).

### 3.2 Dedicated Processes

Site Isolation requires that renderer processes can be dedicated to documents, workers, and sensitive data from only a single site principal. In this paper, we consider only the case where *all* web renderer processes are locked to a single site. It would also be possible for the browser to isolate only some sites and leave other sites in shared renderer processes. In such a model, it is still important to limit a dedicated renderer process to documents and data from its own site, but it is also necessary to prevent a shared process from retrieving data from one of the isolated sites. When isolating all sites, requests for site data can be evaluated solely on the process's site principal and not also a list of which sites are isolated.

The browser's own components and features must be also partitioned in a way that does not leak cross-site data. For example, the network stack cannot run within the renderer process, to protect `HttpOnly` cookies and so that filtering decisions on cross-site data can be made before the bytes from the network enter the renderer process. Similarly, browser features must not proactively leak sensitive data (e.g., the user's stored credit card numbers with autofill) to untrustworthy renderer processes, at least until the user indicates such data should be provided to a site [49]. These additional constraints on browser architecture may increase the amount of logic and state in more privileged processes. This does not necessarily increase the attack surface of the trusted browser process if these components (e.g., network stack) can move to separate sandboxed processes, as in prior microkernel-like browser architectures [23, 62].

### 3.3 Cross-Process Navigations

When a document in a frame navigates from site A to site B, the browser process must replace the renderer process for site A with one for site B. This requires maintaining state in the browser process, such as session history for the tab, related window references such as openers or parent frames,

and tab-level session storage [74]. Due to web-visible events such as `beforeunload` and `unload` and the fact that a navigation request might complete without creating a new document (e.g., a download or an HTTP “204 No Content” response), the browser process must coordinate with both old and new renderer processes to switch at the appropriate moment: after `beforeunload`, after the network response has proven to be a new document, and at the point that the new process has started rendering the new page. Note that cross-site server redirects may even require selecting a different renderer process before the switch occurs.

Session history is particularly challenging. Each stop in the back/forward history can contain information about multiple cross-site documents in various frames in the page, and it can include sensitive data for each document, such as the contents of partially-filled forms. To meet the security goals of Site Isolation, this site-specific session history state can only be sent to renderer processes locked to the corresponding site. Thus, the browser process must coordinate session history loads at a frame granularity, tracking which data to send to each process as cross-site frames are encountered in the page being loaded.

### 3.4 Out-of-process iframes

The largest and most disruptive change for Site Isolation is the requirement to load cross-site iframes in a different renderer process than their embedding page. Most widely-used browser rendering engines were designed and built before browsers became multi-process. The shift to multi-process browsers typically required some changes to these existing engines in order to support multiple instances of them. However, many core assumptions remained intact, such as the ability to traverse all frames in a page for tasks like painting, messaging, and various browser features (e.g., find-in-page). Supporting *out-of-process iframes* is a far more intrusive change that requires revisiting such assumptions across the entire browser. Meanwhile, prior research prototypes that proposed this separation [23, 63, 68] did not address many of the challenges in practice, such as how to ensure the iframe’s document knows its position in the frame tree. This section describes the challenges we overcame to make out-of-process iframes functional and compatible with the web platform.

**Frame Tree.** To support out-of-process iframes, multi-process browser architectures must change their general abstraction level from *page* (containing a tree of frames) to *document* (in a single frame). The browser process must track which document, and thus principal, is present in each frame of a page, so that it can create an appropriate renderer process and restrict its access accordingly. The cross-process navigations described in Section 3.3 must be supported at each level of the frame tree to allow iframes to navigate between sites.

Each process must also keep a local representation of documents that are currently rendered in a different process,

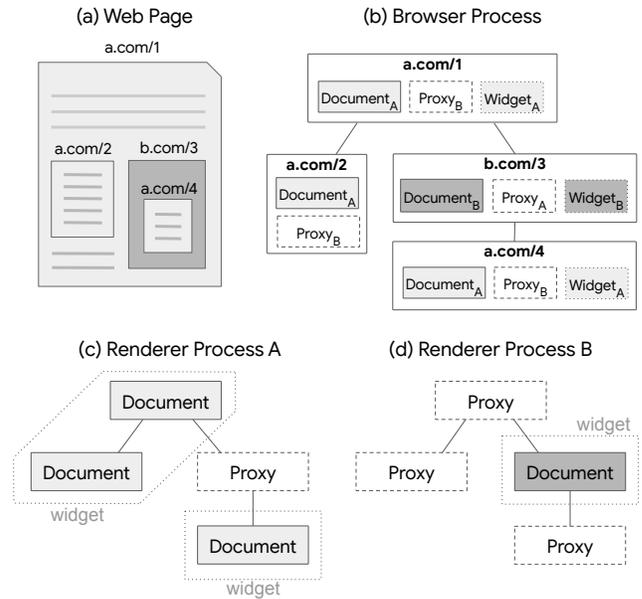

Figure 1: **An example of out-of-process iframes.** To render the web page shown in (a), the browser process (b) coordinates two renderer processes, shown in (c) and (d).

which we call *proxies*. Proxies offer cross-process support for the small set of cross-origin APIs that are permitted by the web platform, as described in [52]. These APIs may be accessed on a frame’s window object and are used for traversing the frame hierarchy, messaging, focusing or navigating other frames, and closing previously opened windows. Traversing the frame hierarchy must be done synchronously within the process using proxies, but interactions between documents can be handled asynchronously by routing messages. Note that all same-site frames within a frame tree (or other reachable pages) must share a process, allowing them to synchronously script each other.

An example of a page including out-of-process iframes is shown in Figure 1 (a), containing three documents from `a.com` and one from `b.com`, and thus requiring two separate renderer processes. Figure 1 (b) shows the browser process’s frame tree, with representations of each document annotated by which site’s process they belong to, along with a set of proxy objects for each frame (one for each process which might reference the frame). Figure 1 (c-d) shows the corresponding frame trees within the two renderer processes, with proxy objects for any documents rendered in a different process. Note that the actual document and proxy objects live in renderer processes; the corresponding browser-side objects are stubs that track state and route IPC messages between the browser and renderer processes.

For example, suppose the document in `a.com/2` invokes `window.parent.frames["b"].postMessage("msg", "b.com")`. Renderer Process A can traverse its local frame tree to find the parent frame and then its child frame named “b”, which is a proxy. The renderer process will send the message to the corresponding `ProxyA` object for `b.com/3` in

the browser process. The browser process passes it to the current `DocumentB` object in this frame, which sends the message to the corresponding `Document` object in `Renderer Process B`. Similar message routing can support other cross-origin APIs, such as focus, navigation, or closing windows.

**State Replication.** The renderer process may need synchronous access to some types of state about a frame in another process, such as the frame’s current name (to find a frame by name, as in the example above) or `iframe` sandbox flags. As this state changes, the browser process broadcasts it to all proxies for a frame across affected processes. Note that this state should never include sensitive site-specific data (e.g., full URLs, which may have sensitive URL parameters), only what is necessary for the web platform implementation.

**Painting and Input.** To preserve the Site Isolation security model, the rendered appearance of each document cannot leak to other cross-site renderer processes. Otherwise, an attacker may be able to scrape sensitive information from the visible appearance of frames in other processes. Instead, each renderer process is responsible for the layout and paint operations within each of its frames. These must be sent to a separate process for compositing at the granularity of *surfaces*, to form the combined appearance of the page. The compositing process must support many types of transforms that are possible via CSS, without leaking surface data to a cross-site renderer process.

Often, many frames on a page come from the same site, and separate surfaces for each frame may be unnecessary. To reduce compositing overhead, we use a *widget* abstraction to combine contiguous same-site frames into the same surface. Figure 1 shows how `a.com/1` and `a.com/2` can be rendered in the same widget and surface without requiring compositing. `b.com/3` requires its own widget in `Renderer Process B`. Since `a.com/4` is not contiguous with the other two `a.com` frames and its layout may depend on properties assigned to it by `b.com/3` (e.g., CSS filters), it has a separate widget within `Renderer Process A`, and its surface must be composited within `b.com/3`’s surface.

Widgets are also used for input event routing, such as mouse clicks and touch interactions. In most cases, the compositing metadata makes it possible for the browser process to perform sufficient hit testing to route input events to the correct renderer process. In some cases, though, web platform features such as CSS transforms or CSS `pointer-events` and `opacity` properties may make this difficult. Currently, the browser process uses *slow path hit testing* over out-of-process iframes, i.e., asking a parent frame’s process to hit-test a specific point to determine which frame should receive the event, without revealing any further details about the event itself. This is only used for mouse and touch events; keyboard events are reliably delivered to the renderer process that currently has focus.

Note that images and media from other sites can be included in a document. The Site Isolation architecture does not try to exclude these from the renderer process, for multiple reasons. First, moving cross-origin image handling out of the renderer process and preventing renderers from reading these surfaces would require a great deal of complexity in practice. Second, this would substantially increase the number of surfaces needed for compositing. This decision is consistent with other research browsers [23, 62, 63], including Gazelle’s implementation [68]. Thus, we leave cross-site images and media in the renderer process and rely on servers to prevent unwanted inclusion, as discussed in Section 6.1.

**Affected Features.** In a broad sense, almost all browser features that interact with the frame tree must be updated to support out-of-process iframes. These features could traditionally assume that all frames of a page were in one process, so a feature like find-in-page could traverse each frame in the tree in the renderer process, looking for a string match. With out-of-process iframes, the browser process must coordinate the find-in-page feature, collecting partial results from each frame across multiple renderer processes. Additionally, the feature must be careful to avoid leaking information to renderer processes (e.g., whether there was a match in a cross-site sibling frame), and it must be robust to renderer processes that crash or become unresponsive.

These updates are required for many features that combine data across frames or that perform tasks that span multiple frames: supporting screen readers for accessibility, compositing PDFs for printing, traversing elements across frame boundaries for focus tracking, representations of the full page in developer tools, and many others.<sup>2</sup>

### 3.5 Cross-Origin Read Blocking

Loading each site’s documents in dedicated renderer processes is not sufficient to protect site data: there are many legitimate ways for web documents to request cross-site URLs within their own execution context, such as JavaScript libraries, CSS files, images, and media. However, it is important not to give a renderer process access to cross-site URLs containing sensitive data, such as HTML documents or JSON files. Otherwise, a document could access cross-site data by requesting such a URL from a `<script>`, `<style>`, or `<img>` tag. The response may nominally fail within the requested context (e.g., an HTML file would produce syntax errors in a `<script>` tag), but the data would be present in the renderer process, where a compromised renderer or a transient execution attack could leak it.

Unfortunately, it is non-trivial to perfectly distinguish which cross-site URLs must be allowed into a renderer process and which must be blocked. It is possible to categorize content types into those needed for subresources and those that are not (as in Gazelle [68]), but content types of re-

<sup>2</sup>A list of these features is included in Appendix B.

sponses are often inaccurate in practice. For example, many actual JavaScript libraries have content types of `text/html` rather than `application/javascript` in practice. Changing the browser to block these libraries from cross-site documents would break compatibility with many existing sites.

It may be desirable to require sites to correct their content types or proactively label any resources that need protection (e.g., with a new `Cross-Origin-Resource-Policy` header [21]), but such approaches would leave many existing resources unprotected until developers update their sites.

Until such shifts in web site behavior occur, browsers with Site Isolation can use a best effort approach to protect as many sensitive resources as possible, while preserving compatibility with existing cross-site subresources. We introduce and standardize an approach called *Cross-Origin Read Blocking (CORB)* [17, 20], which prevents a renderer process from receiving a cross-site response when it has a *confirmed* content type likely to contain sensitive information. CORB focuses on content types that, when used properly, cannot be used in a subresource context. Subresource contexts include scripts, CSS, media, fetches, and other ways to include or retrieve data within a document, but exclude iframes and plugins (which can be loaded in separate processes). CORB filters the following content types:

- HTML, which is used for creating new documents with data that should be inaccessible to other sites.
- JSON, which is used for conveying data to a document.
- XML, which is also often used for conveying data to a document. An exception is made for SVG, which is an XML data type permitted within `<img>` tags.

Since many responses have incorrect content types, CORB requires additional confirmation before blocking the response from the renderer process. In other contexts, web browsers perform MIME-type sniffing when a content type is missing, looking at a prefix of the response to guess its type [4]. OP2 and IBOS use such sniffing to confirm a response is HTML [23, 63], but this will block many legitimate JavaScript files, such as those that begin with HTML comments (i.e., “`<!--`”). In contrast, CORB relies on a new type of *confirmation sniffing* that looks at a prefix of the response to confirm that it matches the claimed content type and not a subresource [17]. For example, a response labeled as `text/html` starting with “`<!doctype`” would be blocked, but one starting with JavaScript code would not. (CORB attempts to scan past HTML comments when sniffing.) This is a default-allow policy that attempts to protect resources where possible but prioritizes compatibility with existing sites. For example, CORB allows responses through when they are polyglots which could be either HTML or JavaScript, such as:

```
<!--/--><html><body><script type="text/javascript"><!--/**/  
var x = "This is both valid HTML and valid JavaScript.";  
/--></script></body></html>
```

CORB skips confirmation sniffing in the presence of the existing `X-Content-Type-Options: nosniff` response header, which disables the browser’s existing MIME sniffing logic. When this header is present, responses with incorrect content types are already not allowed within subresource contexts, making it safe for CORB to block them. Thus, we recommend that web developers use this header for CORB-eligible URLs that contain sensitive data, to ensure protection without relying on confirmation sniffing.

If a cross-site response with one of the above confirmed content types arrives, and if it is not allowed via CORS headers [18], then CORB’s logic in the network component prevents the response data from reaching the renderer process.

### 3.6 Enforcements

The above architecture changes are sufficient to mitigate *memory disclosure attackers* as described in Section 2. For example, transient execution attacks might leak data from any cross-site documents present in the same process, but such attacks cannot send forged messages to the browser process to gain access to additional data. However, a *renderer exploit attacker* that compromises the renderer process or otherwise exploits a logic bug may indeed lie to the browser process, claiming to be a different site to access its data.

The browser process must be robust to such attacks by tracking which renderer processes are locked to which sites, and thus restricting which data the process may access. Requests for site data, actions that require permissions, access to saved passwords, and attempts to fetch data can all be restricted based on the site lock of the renderer process. In normal execution, a renderer process has its own checks to avoid making requests for such data, so illegal requests can be interpreted by the browser process as a sign that the renderer process is compromised or malfunctioning and can thus be terminated before additional harm is caused. The browser process can record such events in the system log, to facilitate audits and forensics within enterprises.

These enforcements may take various forms. If the renderer process sends a message labeled with an origin, the browser process must enforce that the origin is part of the process’s site. Alternatively, communication channels can be scoped to a site, such that a renderer process has no means to express a request for data from another site.

The CORB filtering policy in Section 3.5 also requires enforcements against compromised renderers, so that a renderer exploit attacker cannot forge a request’s initiator to bypass CORB. One challenge is that extensions had been allowed to request data from extension-specified sites using scripts injected into web documents. Because these requests come from a potentially compromised renderer process, CORB cannot distinguish them from an attacker’s requests. This weakens CORB by allowing responses from any site that an active extension can access, which in many cases is all sites. To avoid having extensions weaken the security

of Site Isolation, we are changing the extension system to require these requests to be issued by an extension process instead of by extension scripts in a web renderer process, and we are helping extension developers migrate to the new approach [9].

## 4 Implementation

With the Chrome team, we implemented the Site Isolation architecture in Chrome's C++ codebase. This was a significant 5-year effort that spanned approximately 4,000 commits from around 350 contributors (with the top 20 contributors responsible for 72% of the commits), changing or adding approximately 450,000 lines of code in 9,000 files.

We needed to re-architect a widely deployed browser without adversely affecting users, both during development and when deploying the new architecture. This section describes the steps we took to minimize the impact on performance and functionality, while Section 5 evaluates that impact in practice.

### 4.1 Optimizations

Fundamentally, Site Isolation requires the browser to use a larger number of OS processes. For example, a web page with four cross-site iframes, all on different sites, will require five renderer processes versus one in the old architecture. The overhead of additional processes presents a feasibility risk, due to extra memory cost and process creation latency during navigation. To address these challenges, we have implemented several optimizations that help make Site Isolation practical.

#### 4.1.1 Process Consolidation

Our security model dictates that a renderer process may never contain documents hosted at different sites, but a process may still be shared across separate instances of documents from the same site. Fortunately, many users keep several tabs open, which presents an opportunity for process sharing across those tabs.

To reduce the process count, we have implemented a process consolidation policy that looks for an existing *same-site* process when creating an out-of-process iframe. For example, when a document embeds an `example.com` iframe and another browser tab already contains another `example.com` frame (either an iframe or a main frame), we consolidate them in the same process. This policy is a trade-off that avoids process overhead by reducing performance isolation and failure containment: a slow frame could slow down or crash other same-site frames in the process. We found that this trade-off is worthwhile for iframes, which tend to require fewer resources than main frames.

The same policy could also be applied to main frames, but doing this unconditionally is not desirable: when resource-heavy documents from a site are loaded in several tabs, using a single process for all of them leads to bloated processes

that perform poorly. Instead, we use process consolidation for same-site main frames only after crossing a *soft process limit* that approximates memory pressure. When the number of processes is below this limit, main frames in independent tabs don't share processes; when above the limit, all new frames start reusing same-site processes when possible. Our threshold is calculated based on performance characteristics of a given machine. Note that Site Isolation cannot support a hard process limit, because the number of sites present in the browser may always exceed it.

#### 4.1.2 Avoiding Non-essential Isolation

Some web content is assigned to an opaque origin [29] without crossing a site boundary, such as iframes with `data:URLs` or sandboxed *same-site* iframes. These could utilize separate processes, but we choose to keep these cases in-process as an optimization, focusing our attention on true cross-site content.

Other design decisions that help reduce process count include isolating at a site granularity rather than origin, keeping cross-site images in-process, and allowing extensions to share processes with each other. Section 6.3 discusses improving isolation in these cases in the future.

#### 4.1.3 Reducing the Cost of Process Swaps

Section 3.3 implies that many more navigations must create a new process. We mask some of this latency by (1) starting the process in parallel with the network request, and (2) running the old document's `unload` handler in the background after the new document is created in the new process.

However, in some cases (e.g., back/forward navigations) documents may load very quickly from the cache. These cases can be significantly slowed by adding process creation latency. To address this, we maintain a warmed-up *spare* renderer process, which may be used immediately by a new navigation to any site. When a spare process is locked to a site and used, a new one is created in the background, similar to process pre-creation optimizations in OP2 [23]. To control memory overhead, we avoid spare processes on low memory devices, when the system experiences memory pressure, or when the browser goes over the soft process limit.

## 4.2 Deployment

Shipping Site Isolation in a production browser is challenging. It is a highly disruptive architecture change affecting significant portions of the browser, so enabling it all at once would pose a high risk of functional regressions. Hence, we deployed incrementally along two axes: isolation targets and users. Before launching full Site Isolation, we shipped two milestones to enable process isolation for selective targets:

1. **Extensions.** As the first use of out-of-process iframes from Section 3.4, we isolated *web* iframes embedded inside *extension* pages, and vice versa [50]. This provided a meaningful security improvement, keeping ma-

icious web content out of higher-privileged extension processes. It also affected only about 1% of all page loads, reducing the risk of widespread functional regressions.

2. **Selective isolation.** We created an enterprise policy allowing administrators to optionally isolate a set of manually selected high-value web sites [6].

Deploying these preliminary isolation modes provided a valuable source of bug reports and performance data (e.g., at least 24 early issues reported from enterprise policy users). These modes also show how some form of isolation may be deployed in environments where full Site Isolation may still be prohibitively expensive, such as on mobile devices.

We also deployed each of these milestones incrementally to users. All feature work was developed behind an opt-in flag, and we recruited early adopters who provided bug reports. For each milestone (including full Site Isolation), we also took advantage of Chrome's A/B testing mechanism [13], initially deploying to only a certain percentage of users to monitor performance and stability data.

## 5 Evaluation

To evaluate the effectiveness and practicality of deploying Site Isolation, we answer the following questions: (1) How well does Site Isolation upgrade existing security practices to mitigate renderer exploit attacks? (2) How effectively does Site Isolation mitigate transient execution attacks, compared to other web browser mitigation strategies? (3) What is the performance impact of Site Isolation in practice? (4) How well does Site Isolation preserve compatibility with existing web content? Our findings have allowed us to successfully deploy Site Isolation to all desktop and laptop users of Google Chrome.

### 5.1 Mitigating Renderer Vulnerabilities

We have added numerous enforcements to Chrome (version 76) to prevent a compromised renderer from accessing cross-site data.<sup>3</sup> This section evaluates these enforcements from the perspective of web developers. Specifically, we ask which existing web security practices have been transparently upgraded to defend against renderer exploit attackers, who have complete control over the renderer process.

**New Protections.** The following web developer practices were vulnerable to renderer exploit attackers before Site Isolation but are now robust.

- **Authentication.** `HttpOnly` cookies are not delivered to renderer processes, and `document.cookie` is restricted based on a process's site. Similarly, the password manager only reveals passwords based on a process's site.
- **Cross-origin messaging.** Both `postMessage` and `BroadcastChannel` messages are only delivered to

processes if their sites match the target origin, ensuring that confidential data in the message does not leak to other compromised renderers. Source origins are also verified so that incoming messages are trustworthy.

- **Anti-clickjacking.** `X-Frame-Options` is enforced in the browser process, and `CSP frame-ancestors` is enforced in the embedded frame's renderer process. In both cases, a compromised renderer process cannot bypass these policies to embed a cross-site document.
- **Keeping data confidential.** Many sites use HTML, XML, and JSON to transfer sensitive data. This data is now protected from cross-site renderer processes if it is filtered by CORB (e.g., has a `nosniff` header or can be sniffed), per Section 3.5.
- **Storage and permissions.** Data stored on the client (e.g., in `localStorage`) and permissions granted to a site (e.g., microphone access) are not available to processes for other sites.

**Potential Protections.** The Site Isolation architecture should be capable of upgrading the following practices to mitigate compromised renderers as well, but our current implementation does not yet fully cover them.

- **Anti-CSRF.** CSRF [3] tokens remain protected from other renderers if they are only present in responses protected by CORB. Origin headers and `SameSite` cookies can also be used for CSRF defenses, but our enforcement implementation is still in progress.
- **Embedding untrusted documents.** The behavioral restrictions of `iframe sandbox` (e.g., creating new windows or dialogs, navigating other frames) and `Feature-Policy` are currently enforced in the renderer process, allowing compromised renderers to bypass them. If sandboxed iframes are given separate processes, many of these restrictions could happen in the browser process.

**Renderer Vulnerability Analysis.** We also analyzed security bugs reported for Chrome for 2014-2018 (extending the analysis by Moroz et al [41]) and found 94 UXSS-like bugs that allow an attacker to bypass the SOP and access contents of cross-origin documents. Site Isolation mitigates such bugs by construction, subject to the limitations discussed in Section 2.2. Similar analyses in prior studies have also shown that isolating web principals in different processes prevents a significant number of cross-origin bypasses [19, 63, 68].

In the six months after Site Isolation was deployed in mid-2018, Chrome has received only 2 SOP bypass bug reports, also mitigated by Site Isolation (compared to 9 reports in the prior six months). The team continues to welcome and fix such reports, since they still have value on mobile devices where Site Isolation is not yet deployed. We also believe that going forward, attention will shift to other classes of bugs seen during this post-launch period, including:

<sup>3</sup>A list of these enforcements is included in Appendix C.

- **Bypassing Site Isolation.** These bugs exploit flaws in the process assignment or other browser process logic to force cross-site documents to share a process, or to bypass the enforcement logic. For example, we fixed a reported bug where incorrect handling of blob URLs created in opaque origins allowed an attacker to share a victim site’s renderer process.
- **Targeting non-isolated data.** For example, 14 bugs allowed an attacker to steal cross-site images or media, which are not isolated in our architecture, e.g., by exploiting memory corruption bugs or via timing attacks.
- **Cross-process attacks.** For example, 5 bugs are side channel attacks that rely on timing events that work even across processes, such as a frame’s onload event, to reveal information about the frame.

In general, we find that Site Isolation significantly improves robustness to renderer exploit attackers, protecting users’ web accounts and lowering the severity of renderer vulnerabilities.

## 5.2 Mitigating Transient Execution Attacks

Transient execution attacks represent *memory disclosure attackers* from Section 2, where lying to the browser process is not possible. Thus, Site Isolation mitigations here depend on process isolation and CORB, but not the enforcements in Section 3.6. This section compares the various web browser mitigation strategies for such attacks, evaluating their effectiveness against known variants.

**Strategy Comparison.** Web browser vendors have pursued three types of strategies to mitigate transient execution attacks on the web, with varying strengths and weaknesses.

First, most browsers attempted to *reduce the availability of precise timers* that could be used for attacks [14, 39, 48, 67]. This focuses on the most commonly understood exploitation approach for Spectre and Meltdown attacks: a Flush+Reload cache timing attack [75]. This strategy assumes the timing attack will be difficult to perform without precise timers. Most major browsers reduced the granularity of APIs like `performance.now` to 20 microseconds or even 1 millisecond, introduced jitter to timer results, and even removed implicit sources of precise time, such as `SharedArrayBuffers` [59]. This strategy applies whether the attack targets data inside the process or outside of it, but it has a number of weaknesses that limit its effectiveness:

- It is likely incomplete: there are a wide variety of ways to build a precise timer [35, 58], making it difficult to enumerate and adjust all sources of time in the platform.
- It is possible to amplify the cache timing result to the point of being effective even with coarse-grained timers [25, 37, 58].
- Coarsening timers hurts web developers who have a legitimate need for precise time to build powerful web

applications. Disabling `SharedArrayBuffers` was a particularly unfortunate consequence of this strategy, since it disrupted web applications that relied on them (e.g., AutoCAD).

- Cache timing attacks are only one of several ways to leak information from transient execution, so this approach may be insufficient for preventing data leaks [8].

As a result, we do not view coarsening timers or disabling `SharedArrayBuffers` as an effective strategy for mitigating transient execution attacks.

Second, browser vendors pursued *modifications to the JavaScript compiler and runtime* to prevent JavaScript code from accessing victim data speculatively [37, 48, 65]. This involved array index masking and pointer poisoning to limit out of bounds access, `lfence` instructions as barriers to speculation, and similar approaches. The motivation for this strategy is to disrupt all “speculation gadgets” to avoid leaking data within and across process boundaries. Unfortunately, there are an increasingly large number of variants of transient execution attacks [8], and it is difficult for a compiler to prevent all the ways an attack might be expressed [37]. This is especially true for variants like Spectre-STL (also known as Variant 4), where store-to-load forwarding can be used to leak data [28], or Meltdown-RW which targets in-process data accessed after a CPU exception [8]. Additionally, some of these mitigations have large performance overheads on certain workloads (up to 15%) [37, 65], which risk slowing down legitimate applications. The difficulty to maintain a complete defense combined with the performance cost led Chrome’s JavaScript team to conclude that this approach was ultimately impractical [37, 49].

Site Isolation offers a third strategy. Rather than targeting the cache timing attack or disrupting speculation, Site Isolation assumes that transient execution attacks may be possible within a given OS process and instead attempts to *move data worth stealing outside of the attacker’s address space*, much like kernel defenses against Meltdown-US [15, 24].

**Variant Mitigation.** Canella et al [8] present a systematic evaluation of transient execution attacks and defenses, which we use to evaluate Site Isolation. Spectre attacks rely on branch mispredictions or data dependencies, while Meltdown attacks rely on transient execution after a CPU exception [8]. Table 1 shows how both types of attacks are able to target data inside or outside the attacker’s process, and thus both Spectre and Meltdown are relevant to consider when mitigating memory disclosure attacks.

Site Isolation mitigates same-address-space attacks by avoiding putting vulnerable data in the same renderer process as a malicious principal. This targets the most practical variants of transient execution attacks, for which an attacker has a large degree of control over the behavior of the process (relative to attacks that target another process). Site Isolation does not depend on the absence of precise timers for

| Attack       | Inside Process |        |          | Outside Process |        |          |
|--------------|----------------|--------|----------|-----------------|--------|----------|
|              | Site Isolation | Timers | Compiler | Site Isolation  | Timers | Compiler |
| Spectre-PHT  | ●              | ◐      | ●        | ○               | ◐      | ●        |
| Spectre-BTB  | ●              | ◐      | ●        | ○               | ◐      | ●        |
| Spectre-RSB  | ●              | ◐      | ◐        | ○               | ◐      | ◐        |
| Spectre-STL  | ●              | ◐      | ○        | -               | -      | -        |
| Meltdown-US  | -              | -      | -        | ○               | ◐      | ○        |
| Meltdown-P   | -              | -      | -        | ○               | ◐      | ○        |
| Meltdown-GP  | -              | -      | -        | ○               | ◐      | ○        |
| Meltdown-NM  | -              | -      | -        | ○               | ◐      | ○        |
| Meltdown-RW* | ●              | ◐      | ○        | -               | -      | -        |
| Meltdown-PK* | ●              | ◐      | ○        | -               | -      | -        |
| Meltdown-BR* | ●              | ◐      | ○        | -               | -      | -        |

Table 1: **Web browser mitigations for Spectre and Meltdown attacks, for targets inside and outside the attacker’s process.** Symbols show if an attack is mitigated (●), partially mitigated (◐), not mitigated (○), or not applicable (-). Site Isolation mitigates all applicable same-process attacks, and it depends on other mitigations for cross-process attacks.

\* Only affects browsers that use these hardware features.

mitigating same-process attacks, and it can mitigate attacks like Spectre-STL that are difficult or costly for compilers to prevent [37]. For Meltdown attacks that target same-process data (e.g., Meltdown-RW, which can transiently overwrite read-only data), Site Isolation applies as well. It is less clear whether Meltdown-PK and Meltdown-BR [8] are relevant in the context of the browser, but Site Isolation would mitigate them if browsers used protection keys [38] or hardware-based array bounds checks, respectively.

Site Isolation does not attempt to mitigate attacks targeting data in other processes or the kernel, such as the “Outside Process” variants in Table 1 and Microarchitectural Data Sampling (MDS) attacks [40, 57, 66]. Site Isolation can and must be combined with hardware and OS mitigations for such attacks to prevent web attackers from leaking data across process boundaries or from the kernel. For example, PTI is a widely used mitigation for Meltdown-US, eliminating kernel memory from the address space of each user process [15, 24]. Similarly, microcode updates and avoiding sibling Hyper-Threads for untrustworthy code may be useful for mitigating MDS attacks [40, 57, 66].

Ultimately, cross-process and user/kernel boundaries must fundamentally be preserved by the OS and hardware and cannot be left to applications to enforce. Within a process, however, the OS and hardware have much less visibility into where isolation is needed. Thus, applications that run code from untrustworthy principals (e.g., browsers) must align their architectures with OS-enforced abstractions to isolate

these principals. As a result, we have chosen Site Isolation as the most effective mitigation strategy for Chrome. When it is enabled, Chrome re-enables `SharedArrayBuffer` and other precise timers and removes JavaScript compiler mitigations, to restore powerful functionality to the web and regain lost performance.

### 5.3 Performance

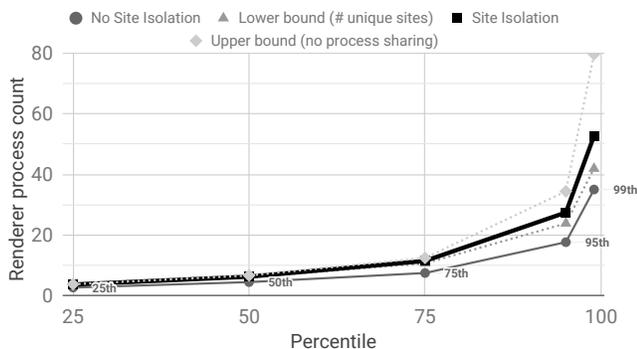

Enabling Site Isolation can affect the browser’s performance, so we evaluate its effect on memory overhead, latency, and CPU usage in the wild and in microbenchmarks. We find that the new architecture has low enough overhead to be practical to deploy.

#### 5.3.1 Observed Workload

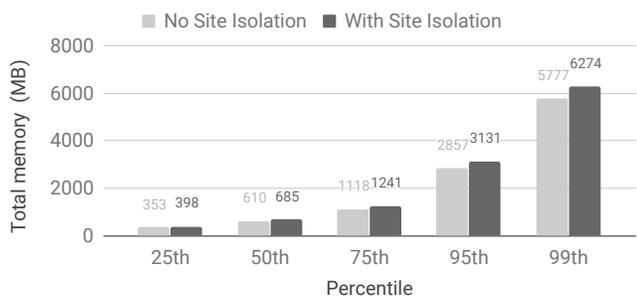

We first focus on measuring performance in the field, because this more accurately reflects real user workloads (e.g., many tabs, long-tail sites) than microbenchmarks do. The data in this section was collected using pseudonymous metric reporting over a two-week period starting October 1, 2018, from desktop and laptop users of Chrome (version 69) on Windows who have this reporting enabled. We compare results from equal-sized test and control groups within the general user population. (These metrics are enabled by default, but users can opt out during installation or later in settings. Our experimental design and data collection were reviewed under Google’s processes.)

**Process Count.** With Site Isolation, the browser process must create more renderer processes to keep sites isolated from each other: at least as many as unique sites open at a time. Using periodic samples, we found that users had 6.0 unique sites open across the entire browser at the 50th percentile of the distribution, and 41.9 unique sites at the 99th percentile. This only provides a lower bound for the number of renderer processes; each instance of a site might live in a separate process. If this were the case, our metrics give an upper bound estimate of 79.7 processes at the 99th percentile. However, thanks to the process sharing heuristics described in Section 4.1.1, far fewer processes were used in practice, as shown in Figure 2. At the 50th percentile, the number of processes increased 43.5% from 4.4 without Site Isolation to 6.2 with Site Isolation. At the 99th percentile, the process count increased 50.6% from 35.0 to 52.7 processes. This indicates that many more processes are needed for Site Isolation, but also that the process consolidation heuristics greatly reduce the count at the upper percentiles.

**Memory Overhead.** On its own, the 50% increase in renderer process count is significant, but this does not necessarily translate to an equivalent increase in memory overhead or performance slowdowns. Site Isolation is effectively dividing an existing workload across more processes, so each renderer process is correspondingly smaller and shorter lived. In reported metrics, we found that private memory use per renderer process decreased 51.5% (87.2 MB to 42.3 MB) at

**Figure 2: Renderer process count.** This graph shows the number of renderer processes before and after Site Isolation, as well as an estimated lower and upper bound on process count, controlled by the amount of process sharing for instances of the same site. Site Isolation finds a middle ground between no process sharing and having at most one process per site.

**Figure 3: Total browser memory usage across all processes.** Overall, Site Isolation has a 9-13% overhead.

the 50th percentile and 28.6% (from 714.2 MB to 509.7 MB) at the 99th percentile. Renderer process lifetime decreased 4.3% at the 50th percentile and 55.5% at the 99th percentile.

This leaves an open question about the overhead of each process relative to the workload of the process, which determines the total memory use. Figure 3 compares the total private memory use across all processes (including browser process, renderer processes, and other types of utility processes) with and without Site Isolation. In practice, we see that total memory use increased only 12.6% at the 25th percentile, and only 8.6% at the 99th percentile. This is significantly lower than the 50% increase in process count might suggest, indicating that the large number of extra processes has a relatively small impact on the total memory use of the browser. We confirmed that this is not due to a change in workload size: there were no statistically significant differences in page load count, and we saw at most a 1.5% decrease in the number of open tabs (at the 99th percentile).

Due to the severity of transient execution attacks and the drawbacks of other mitigation strategies in Section 5.2, the Chrome team was willing to accept 9-13% memory overhead for the security benefits of enabling Site Isolation.

**Latency.** Site Isolation also impacts latency in multiple ways, from the time it takes to load a page to the responsiveness of input events. On one hand, more navigations need to create new processes, which can incur latency due to process startup time. There may also be greater contention for IPC messages and input event routing, leading to some delays. On the other hand, there is a significant amount of new parallelism possible now that the workload for a given page can be split across multiple independent threads of execution. We use observed metrics from the field to study the combined impact of these changes in practice.

Site Isolation significantly increased the percentage of navigations that cross a process boundary, from 5.73% to 56.0%. However, we mask some of the latency of process creation in Chrome by starting the renderer process in parallel with making the network request. Combined with the increased parallelism of loading cross-site iframes in different processes, we see very little change to a key metric for page load time: the time from navigation start to the first paint of page content (e.g., text, images, etc) [22]. Across all navigations, we observe this to increase at most 2.25% at the 25th percentile (457 ms to 467 ms) and 1.58% (14.6 s to 14.8 s) at the 99th percentile. This metric also benefits from the spare process optimization described in Section 4.1.3, which avoids the process startup latency on many navigations. Without the spare process, this “First Contentful Paint” time increases 5.1% at the 25th percentile and 2.4% at the 99th percentile.

If we look closer at various types of navigations, the most significantly affected category is back/forward navigations, which frequently load pages from the cache without waiting for the network. This eliminates most of the benefit of parallelizing process startup with the network request. Here, we see time to First Contentful Paint increase 28.3% (177 ms to 227 ms) at the 25th percentile and 6.8% (4637 ms to 4952 ms) at the 99th percentile. Again, this is better than without using a spare process, in which case we see increases of 40.7% and 12.5% at these percentiles, respectively.

We also looked at the latency impact on input events. The current implementation uses slow path hit testing for mouse and touch events over out-of-process iframes, which results in small increases to input event latency. For key presses, there are no statistically significant differences at the 50th or 99th percentiles, and only a 1.0% latency increase at the 75th percentile (43.6 ms to 44.0 ms). For mouse scroll update events, latency increased 1.3% (21.8 ms to 22.1 ms) at the 50th percentile and 8.6% (228.8 ms to 248.6 ms) at the 99th percentile. For touch scroll update events, latency increased 2.6% (18.4 ms to 18.9 ms) and 10.7% (134.0 ms to 148.3 ms) at these percentiles. We expect to improve these by updating hit testing to avoid the slow path in most cases.

**CPU Usage.** Finally, we study the impact of Site Isolation on CPU usage. Average CPU usage in the browser process increased 8.2% (32.0% to 34.6%) at the 99th percentile,

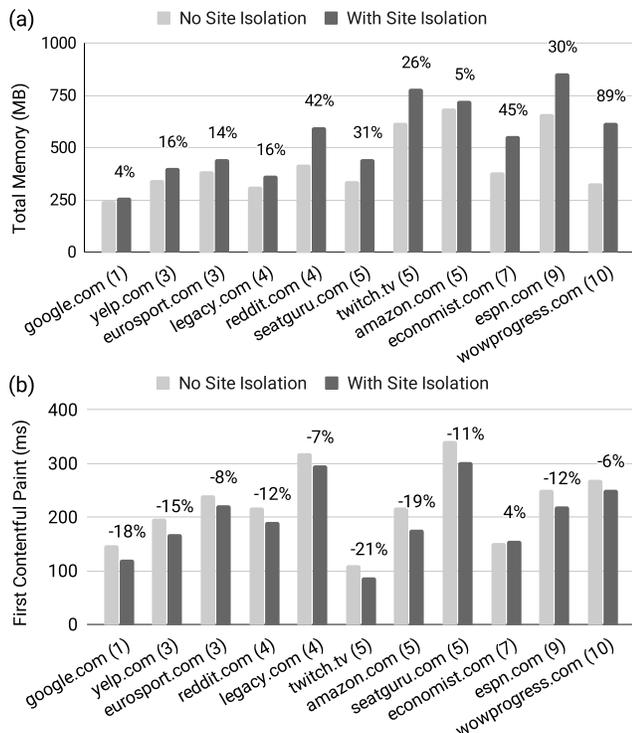

Figure 4: (a) Total browser memory usage and (b) Time to First Contentful Paint for individual sites. Parentheses denote the number of renderer processes required to load each site with Site Isolation. Without Site Isolation, each site requires one renderer process.

due to additional IPC messages and coordination across processes. While there were more renderer processes, each renderer’s average CPU usage dropped 33.5% (47.7% to 31.8%) at the 99th percentile, since the workload was distributed across more processes.

Overall, we found that enabling Site Isolation had a much smaller performance impact than expected due to the properties of the workload. Given the importance of mitigating the attacks in the threat model described in Section 2, the Chrome team has chosen to keep Site Isolation enabled for all users on desktop and laptop devices.

### 5.3.2 Microbenchmarks

We also report microbenchmark results showing the overhead of Site Isolation on individual web pages when loaded in a single tab, with nothing else running in the browser. This setup does not benefit from process consolidation across multiple tabs as discussed in Section 4.1.1, and hence it is not representative of the real-world workloads used in the previous section. However, these measurements establish a baseline and provide a reproducible reference point for future research.

To study a mix of the most popular (likely highly optimized) and slightly less popular sites, we selected the top site as well as the 50th-ranked site in Alexa categories for news,

sports, games, shopping, and home, as well as `google.com` as the top overall URL.<sup>4</sup> This set provides pages with a range of cross-site iframe counts, showing how the browser scales with more processes per page.

Next, we started Chrome version 69.0.3497.100 with a clean profile, and we loaded each site in a single tab, both with and without Site Isolation. We report the median of five trials for each data point to reduce variability, and we re-played recorded network data for all runs using WprGo [69]. Our experiments were performed on a Windows 10 desktop with an Intel Core i7-8700K 3.7 GHz 6-core CPU and 16 GB RAM. Our data collection script is available online [45].

Figure 4 (a) shows the total browser memory use for each site, sorted by the number of renderer processes (shown in parentheses) that each site utilizes when loaded with Site Isolation. As expected, the relative memory overhead generally increases with the number of processes, peaking at 89% for `wowprogress.com` with 10 processes. Sites that use more memory tend to have smaller relative overhead, as their memory usage outweighs the cost of extra processes. For example, a heavier `amazon.com` site has a 5% overhead compared to `seatguru.com`’s 31%, even though both require five processes. `google.com` does not have any cross-site iframes and requires no extra processes, but it shows a 4% increase in memory use due to the spare process that we maintain with Site Isolation, as explained in Section 4.1.3.

The overhead seen in these results is significantly higher than the 9-13% overhead we reported from real-world user workloads in the previous section. This underscores the limitations of microbenchmarks: users tend to have multiple tabs (four at 50th percentile) and a variety of open URLs. In practice, this helps reduce memory overhead via process consolidation, while iframe-heavy sites like `wowprogress.com` may represent only a small part of users’ browsing sessions.

Figure 4 (b) shows time to First Contentful Paint [22] for each site, to gauge impact on page load time. Most paint times improve with Site Isolation because the spare process helps mask process startup costs, which play a larger role than network latency due to the benchmark’s use of recorded network traffic. The speedups are not correlated with process counts; Site Isolation offloads some of the work from the main frame into iframe renderers, which may make the main frame more responsive regardless of process count.

## 5.4 Compatibility

Site Isolation strives to avoid web-visible changes. For example, we found that CORB blocks less than 1% of responses, most of which are not observable; if it only relied on content type and not confirmation sniffing, it would block 20% of responses [17]. Also, since cross-origin frame interactions had been mostly asynchronous prior to our work, making these interactions cross-process is largely transpar-

<sup>4</sup>If a site’s main content required logging in, we picked the next highest-ranked site.

ent to web pages. During deployment, we closely monitored bug reports for several months to judge the impact on actual users and content. We have received around 20 implementation bugs, most of which are now fixed. We did uncover some behavior changes, described below. Overall, however, none of the bug reports warranted turning Site Isolation off, indicating that our design does not result in major compatibility problems when deployed widely.

**Asynchronous Full-page Layout.** With Site Isolation, full-page layout is no longer synchronous, since the frames of a page may be spread across multiple processes. For example, if a page changes the size of a frame and then sends it a `postMessage`, the receiving frame may not yet know its new size when receiving the message. We found that this disrupted behavior for some pages, but since the HTML spec does not guarantee this behavior and relatively few sites were affected, we chose not to preserve the old ordering. Instead, we provided guidance for web developers to fix the few affected pages [7] and are pursuing specification changes to explicitly note that full-page layout is asynchronous [27].

**Partial Failures.** Site Isolation can expose new failure modes to web pages, because out-of-process iframes may crash or become unresponsive independently from their embedder, after having been loaded. Although this may lead to unexpected behavior in the page, it happens rarely enough to avoid being a problem in practice, and for users, losing an iframe is usually preferable to losing the entire page.

**Detecting Site Isolation.** A web page should not know if it is rendered with or without Site Isolation, and we have avoided introducing APIs for doing so: a browser's process model is an implementation detail that developers should not depend on. We did encounter and fix some bugs that allowed detection of Site Isolation, such as differing JavaScript exception behavior for in-process and out-of-process frames. Fundamentally, though, it is possible to detect Site Isolation via timing attacks. For example, a cross-process `postMessage` will take longer than a same-process `postMessage`, due to an extra IPC hop through the browser process; a web page could perform a timing analysis to detect whether a frame is in a different process. However, such timing differences are unlikely to affect compatibility, and we have not received any such reports.

## 6 Future Directions

Site Isolation protects a great deal of site data against renderer exploit attackers and memory disclosure attackers, but there is a strong incentive to address the limitations outlined in Section 2.2.

It is worth noting that web browsers are not alone in facing a new security landscape. Other software systems that isolate untrustworthy code may require architecture changes to avoid leaking data via microarchitectural state. For example, SQL queries in databases might pose similar risks [47].

Applications that download and render untrustworthy content from the web, such as document editors, should likewise leverage OS abstractions to isolate their own principals [42].

### 6.1 Protecting More Data

CORB currently only protects HTML, XML, and JSON responses, and only when the browser can confirm them using sniffing or headers. There are several options for protecting additional content, from using headers to protect particular responses, to expanding CORB to cover more types, to changing how browsers request subresources.

First, web developers can explicitly protect sensitive resources without relying on CORB, using a `Cross-Origin-Resource-Policy` response header [21] or refusing to serve cross-site requests based on the `Sec-Fetch-Site` request header [71].

Second, the Chrome team is working to isolate cross-site PDFs and other types [2, 60]. Developer outreach may also cut down on mislabeled subresources, eliminating the need for CORB confirmation sniffing.

Third, recent proposals call for browsers to make cross-origin subresource requests without credentials by default [73]. This would prevent almost all sensitive cross-site data from entering a renderer process, apart from cases of ambient authority (e.g., intranet URLs which require no credentials).

These options may close the gaps to ensure essentially all sensitive web data is protected by Site Isolation.

### 6.2 Additional Layers of Mitigation

Because Site Isolation uses OS process boundaries as an isolation mechanism, it is straightforward to combine it with additional OS-level mitigations for attacks. This may include other sandboxing mechanisms (e.g., treating different sites as different user accounts) or mitigations for additional types of transient execution attacks. For example, microcode updates and OS mitigations (e.g., PTI or disabling Hyper-Threading) may be needed for cross-process or user/kernel attacks [15, 24, 40, 57, 66]. These are complementary to the mitigations Site Isolation offers for same-process attacks, where the OS and hardware have less visibility.

### 6.3 Practical Next Steps

**Mobile Devices.** This paper has described deploying Site Isolation to users on desktop and laptop devices, but the new web attackers are important to consider for mobile phone browsers as well. Site Isolation faces greater challenges on mobile devices due to fewer device resources (e.g., memory, CPU cores) and a different workload: there are fewer renderer processes in the working set due to proactive discarding by the mobile OS, and thus fewer opportunities for process sharing. We are investigating options for deploying similar mitigations on mobile browsers, such as isolating a subset of sites that need the protection the most.

**Isolation in Other Browsers.** There are opportunities for other browsers to provide a limited form of process isolation without the significant implementation requirements of out-of-process iframes. For example, sites might adopt headers like `Cross-Origin-Opener-Policy` to opt into a mode that can place a top-level document in a new process by disrupting some cross-window scripting [44].

**Origin Isolation.** Within browsers with Site Isolation, further isolation may be practical by selectively moving from a site granularity to a finer origin granularity. Too many web sites rely on modifying `document.domain` to deploy origin isolation by default, but browsers may allow sites to opt out of this feature and thus become eligible for origin isolation [72]. Making this optional may reduce the impact on the process count. Similarly, we plan to evaluate the overhead impact of isolating opaque origins, especially to improve security for sandboxed same-site iframes.

**Performance.** Finally, there are performance opportunities to explore to reduce overhead and take advantage of the new architecture. More aggressive renderer discarding may be possible with less cross-site sharing of renderer processes. Isolating cross-origin iframes from some web applications may also provide performance benefits by parallelizing the workload, moving slower frames to a different process than the primary user interface to keep the latter more responsive.

## 7 Related Work

Prior to this work, all major production browsers, including IE/Edge [76], Chrome [52], Safari [70], and Firefox [43], had multi-process architectures that rendered untrustworthy web content in sandboxed renderer processes, but they did not enforce process isolation between web security principals, and they lacked architectural support for rendering embedded content such as iframes out-of-process. Site Isolation makes Chrome the first widely-adopted browser to add such support. Other research demonstrated a need for an architecture like Site Isolation by showing how existing browsers are vulnerable to cross-site data leaks, local file system access via sync from cloud services, and transient execution attacks [25, 33, 53].

Several research browsers have proposed isolating web principals in different OS processes, including Gazelle [68], OP and its successor OP2 [23, 62], and IBOS [63]. Compared to these proposals, Site Isolation is the first to support the web platform in its entirety, with practical performance and compatibility. First, these proposals all define principals as origins, but this cannot support pages that change `document.domain` [12]. Other research browsers isolate web applications with principals that are similarly incompatible: Tahoma [16] uses custom manifests, while SubOS [31, 32] uses full URLs that include path in addition to origin. To preserve compatibility, we adopt the *site* principal proposed in [52]; this also helps reduce process

count compared to origins. Second, we describe new optimizations that make Site Isolation practical, and we evaluate our architecture on a real workload of Chrome users. This shows that Site Isolation introduces almost no additional page load latency and only 9-13% memory overhead, lower than expected from microbenchmark evaluations. Third, we comprehensively evaluate the implications of new transient execution attacks [8] for browser security. Fourth, we show that protecting cross-origin network responses requires new forms of confirmation sniffing to preserve compatibility; content types and even traditional MIME sniffing are insufficient. Finally, while Gazelle, OP2, and IBOS have out-of-process iframes, our work overcomes many challenges to support these in a production browser, such as supporting the full set of cross-process JavaScript interactions, challenges with painting and input event routing, and updating affected features (e.g., find-in-page, printing).

The OP and OP2 browsers [23, 62] also use OS processes to isolate other browser components, including the network stack, storage, and display. Such additional process separation is orthogonal to Site Isolation and offers complementary benefits, such as making the browser more modular, reducing the size of the browser process, and keeping crashes in one component isolated from the rest of the browser.

Dong et al [19] argued that practical browser designs will require a trade-off between finer-grained isolation and performance. Our experience echoes this finding, and we indeed make trade-offs to reduce memory overhead, such as isolating sites rather than origins. Dong et al's evaluation relied on sequentially browsing top Alexa sites; we additionally collect measurements from browsing workloads in the wild, providing a more realistic performance evaluation. For example, this factors in process sharing across multiple tabs, which significantly reduces overhead in practice.

Other researchers propose disabling risky JavaScript features unless user-defined policies indicate they are safe for a desired site [56, 61]. These approaches aim to disrupt a wide variety of attacks (including microarchitectural), but they impose barriers to adoption of powerful web features, and they rely on users or third parties to know when features are safe to enable. Site Isolation's scope is more limited by compatibility, but it does not require actions from users or disabling powerful features.

## 8 Conclusion

The web browser threat model has changed significantly. Web sites face greater threats of data leaks within the browser due to compromised renderer processes and transient execution attacks. Site Isolation offers the best path to mitigating these attacks in the browser, protecting a significant amount of site data today with future opportunities to expand the coverage. We have shown that Site Isolation is practical to deploy in a production desktop web browser, incurring a 9-13% total memory overhead on real-world work-

loads. We recommend that web developers and browser vendors continue down this path, protecting additional sensitive resources, adding more mitigations, and pursuing similar isolation in environments like mobile browsers.

## 9 Acknowledgements

We would like to thank Łukasz Anforowicz, Jann Horn, Ken Buchanan, Chris Palmer, Adrienne Porter Felt, Franziska Roesner, Tadayoshi Kohno, Antoine Labour, Artur Janc, our shepherd Adam Doupé, and the anonymous reviewers for their input on this paper. We also thank the many Chrome team members who made this work possible.

## A Determining Site Principals

This appendix provides additional details on how we define principals used in Site Isolation. Figure 5 compares principal definitions in monolithic browsers, multi-process browsers that isolate coarser-grained groups of principals, Site Isolation, and Origin Isolation. Origin Isolation, where principals are defined as origins, offers stronger security guarantees at the cost of breaking `document.domain` compatibility and performance challenges due to a larger number of principals.

As noted in Section 3.1, computing site URL for most HTTP(S) URLs is straightforward, but some web platform features require special treatment. For example, frames may be navigated to `about:blank`, a special URL which must inherit the security origin, and hence the site, from the frame initiating the navigation. The web also supports *nested URLs* such as `blob:` URLs. These URLs embed an origin; e.g., `blob:http://example.com/UUID` addresses an in-memory blob of data controlled by the `http://example.com` origin. In these cases, we extract the inner origin from the URL and then convert it to a site.

A document may also embed a frame and specify its HTML content *inline* rather than from the network, either using the `srcdoc` attribute (e.g., `<iframe srcdoc="<html>content</html>">`) or a `data:` URL

(e.g., `data:text/html,<html>content</html>`). `Srcdoc` frames inherit their creator's origin and must stay in the principal of their embedding document. In contrast, `data:` URLs load in an opaque origin [29], which cannot be accessed from any other origin. Browsers may choose to load each `data:` URL in its own separate principal and process, but our current implementation uses the creator's principal (which typically controls the content) to reduce the number of processes required. Similarly, our current implementation keeps same-site iframes with the `sandbox` attribute, which typically load in an opaque origin, in the principal of their URL's site. In practice, sites often use sandboxed iframes for untrustworthy content that they wish to isolate from the rest of the site; we discuss opportunities for finer-grained isolation within a site in Section 6.3.

**Non-web Principals.** Many browsers can load documents that do not originate from the web, including content from local files, extensions, browser UI pages, and error pages. These forms of content utilize the web platform for rendering, so the browser must define principals for them. Each local URL (e.g., `file:///homes/foo/a.html`) is typically treated as its own origin by the browser, so each path could use a separate principal and process. Our current implementation treats all local files as part of the same *file* principal to reduce the process count, since they ultimately belong to a local user. We may revise this to isolate each file in the future, since this group of local files may contain less trustworthy pages saved from the web.

We assign content from extensions to a separate shared principal, and we isolate all browser UI pages, such as settings or download manager, from one another. These pages require vastly different permissions and privileges, and a compromise of one page (e.g., a buggy extension) should not be able to take advantage of permissions granted to a more powerful page (e.g., a download management page that can download and open files). We do allow extensions to share processes with each other to reduce the process count; thus, Figure 5(c) shows extensions in a shared principal. However, extensions never share processes with other types of pages.

## B Features Updated to Support Out-of-process iframes

This appendix lists a subset of Chrome features that needed to be updated to support out-of-process iframes, beyond those discussed in Section 3.4.

- Accessibility (e.g., screen readers).
- Developer tools.
- Drag and drop.
- Extensions (e.g., injecting scripts into frames of a page).
- Find-in-page.

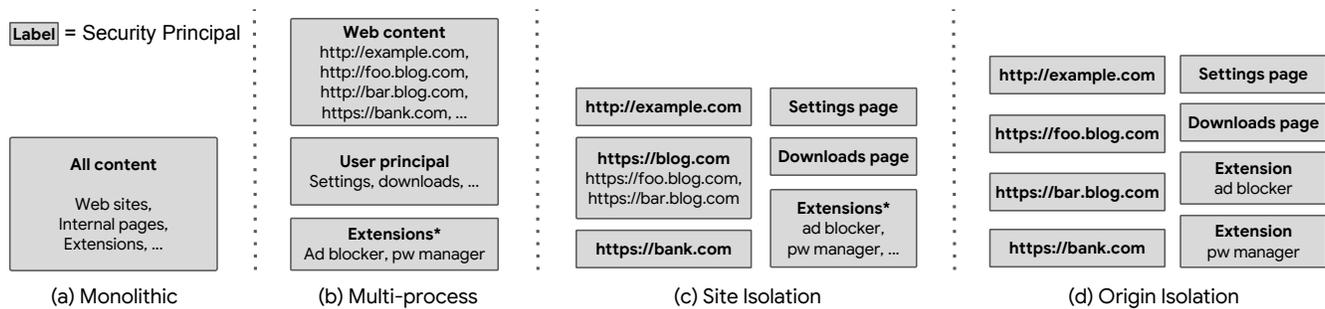

Figure 5: **Evolution of security principals in browser architectures.** Compared to prior browser architectures, Site Isolation defines finer-grained principals that correspond to sites. Origin Isolation (d) further refines sites to origins and is the most desirable principal model in the long term, but backward compatibility and performance challenges currently limit its practicality.

\* In pre-Site-Isolation browsers (b), extensions were isolated in higher-privileged processes, but with a caveat: extensions could embed web URL iframes which would stay in the extension's process. With Site Isolation (c), process sharing across the web/extension boundary is no longer possible, though extensions may still share a process with one another.

- Focus (e.g., tracking focused page and frame, focus traversal when pressing Tab).
- Form autofill.
- Fullscreen.
- IME (Input Method Editor).
- Input gestures.
- JavaScript dialogs.
- Mixed content handling.
- Multiple monitor and device scale factor support.
- Password manager.
- Pointer Lock API.
- Printing.
- Task manager.
- Resource optimizations (e.g., deprioritizing offscreen content).
- Malware and phishing detection.
- Save page to disk.
- Screen Orientation API.
- Scroll bubbling.
- Session restore.
- Spellcheck.
- Tooltips.
- Unresponsive renderer detector and dialog.
- User gesture tracking.
- View source.
- Visibility APIs.
- Webdriver automation.
- Zoom.

## C Compromised Renderer Enforcements

This appendix lists the current places that privileged browser components in Chrome (version 76) limit the behavior of a renderer process based on its associated site, to mitigate compromised renderers.

- Cookie reads and writes (`document.cookie`, `HttpOnly` cookies).
- Cross-Origin Read Blocking implementation [20].
- Cross-Origin-Resource-Policy blocking [21].
- Frame embedding (`X-Frame-Options`).
- JavaScript code cache.
- Messaging (`postMessage`, `BroadcastChannel`).
- Password manager, Credential Management API.
- Storage (`localStorage`, `sessionStorage`, `indexedDB`, blob storage, Cache API, `WebSQL`).
- Preventing web page access to `file://` URLs.
- Web permissions (e.g., geolocation, camera).

We expect the following enforcements to be possible as well, with additional implementation effort.

- Address bar origin.
- Custom HTTP headers requiring CORS.
- Feature Policy.
- `iframe` sandbox behaviors.
- Origin Header and CORS implementation.
- SameSite cookies.
- `Sec-Fetch-Site` [71].
- User gestures.

# Everyone is Different: Client-side Diversification for Defending Against Extension Fingerprinting

## Abstract

Browser fingerprinting refers to the extraction of attributes from a user's browser which can be combined into a near-unique fingerprint. These fingerprints can be used to re-identify users without requiring the use of cookies or other stateful identifiers. Browser extensions enhance the client-side browser experience; however, prior work has shown that their website modifications are fingerprintable and can be used to infer sensitive information about users.

In this paper we present CloakX, the first client-side anti-fingerprinting countermeasure that works without requiring browser modification or requiring extension developers to modify their code. CloakX uses client-side diversification to prevent extension detection using anchorprints (fingerprints comprised of artifacts directly accessible to any webpage) and to reduce the accuracy of extension detection using structureprints (fingerprints built from an extension's behavior). Despite the complexity of browser extensions, CloakX automatically incorporates client-side diversification into the extensions and maintains equivalent functionality through the use of static and dynamic program analysis. We evaluate the efficacy of CloakX on 18,937 extensions using large-scale automated analysis and in-depth manual testing. We conducted experiments to test the functionality equivalence, the detectability, and the performance of CloakX-enabled extensions. Beyond extension detection, we demonstrate that client-side modification of extensions is a viable method for the late-stage customization of browser extensions.

## 1 Introduction

As the web expands and continues being the platform of choice for delivering applications to users, the browser becomes a core component of a user's interactions with the web. Modern browsers advertise a wide range of features, from cloud-syncing and notifications to password management and peer-to-peer video and audio communications. An important feature of modern browsers is their ability to be extended

by users, as they see fit, by installing *browser extensions*. Namely, Google Chrome and Mozilla Firefox, the browsers with the largest market share, offer dedicated browser extension stores that house tens of thousands of extensions. In turn, these extensions advertise a wide range of additional features, such as enabling the browser to store passwords with online password managers, blocking ads, and saving articles for later reading.

From a security perspective, the ability to load third-party code into the browser comes at a cost, even though extensions rely on web technologies such as HTML, JavaScript, and CSS. Browsers afford extensions significantly more privileges than they do to a webpage. For example, the same origin policy restricts webpages from accessing content, such as a cookie, that does not originate from the same domain. For a webpage to bypass this restriction, it must implement cross-origin resource sharing, whereas extensions may not only access resources of any domain but may also alter the content. Historically, malicious extensions abuse these privileges to perform advertising fraud and to steal private and financial user data [22, 28, 44, 47].

Next to security issues, using browser extensions can also lead to the loss of privacy. Given that users choose the extensions to install, it is possible to make inferences about a user's thoughts and beliefs *based solely on the extensions she keeps*. For example, the detection of a coupon-finding extension [1] reveals information about the user's income-level. Additionally, an extension that hides articles about certain political figures [20, 21] reveals the user's political leanings. Lastly, the use of browser extensions may provide a means for websites to persistently identify a user over the course of distinct browser sessions.

Although browser vendors do not offer any programmatic methods for a webpage's JavaScript to detect the extensions currently installed in a user's browser, researchers recently discovered side-channel techniques for fingerprinting many extensions. Sjösten et al. were the first to demonstrate a new method for detecting browser extensions that exploited the public nature of *web-accessible resources* (WARs) [38]. A

WAR is any resource (e.g., JavaScript or image) within an extension that the extension identifies as externally accessible. As a result, a webpage can determine whether a visitor uses an extension by requesting one of the exposed WARs. Sjösten et al. showed that more than 50% of the top 1,000 browser extensions use WARs, which any webpage might use to detect extensions. Later, Starov and Nikiforakis demonstrated another technique for fingerprinting extensions that uses an extension's modifications to the document-object-model (DOM) to detect their presence [42]. The authors developed XHOUND, a system that automatically discovers the DOM side-effects of extensions. Through their experiments, they showed that more than 10% of the top 50K extensions were fingerprintable.

One approach to reducing fingerprintable extensions is through education and developer training. However, historically, developers — and web developers in particular — ignore even well-known security concerns. Even after nearly 20 years, the most common website vulnerabilities are still SQL injection vulnerabilities [43]. Therefore, it is unlikely that asking extension developers to make their extensions less fingerprintable will have the desired effect on the ecosystem.

To empower users to protect their own privacy, in this paper we propose CloakX, a client-side countermeasure against extension detection using fingerprints. Instead of trying to remove the fingerprintable attributes of extensions, our approach is to automatically alter, randomize, and add to these attributes without requiring web browser modifications or any involvement from the extension's developer. Through these modifications, CloakX diversifies the extension's anchorprints, which are fingerprints consisting of items that can be accessed directly from a webpage, and structureprints, which are fingerprints that embody the structural changes an extension makes to a webpage (for more details refer to Section 2.2). On the surface, client-side diversification of the fingerprintable attributes seems straightforward; however, the dynamic nature of JavaScript and the complexity of the browser extension's architecture necessitated a complex approach that relies on both static and dynamic program analysis.

CloakX uses static and dynamic analysis techniques to automatically diversify the extension's fingerprint without modifying the browser, without requiring any changes by the extension's author, and without altering the extension's functionality. To diversify the extension's anchorprint, CloakX automatically renames WARs, IDs, and class names and corrects any references to them in the extension's code, which severs the link between the published extension and the currently installed version. In addition to static changes, the diversification is also performed by our dynamic DOM proxy (Droxy), which intercepts DOM modifications from the extension's code and makes the changes on-the-fly. To diversify the extension's structureprint, Droxy also injects random tags, attributes, and custom attributes into each webpage, which

obfuscates the extension's structureprint. As a result, an extension cloaked by CloakX is undetectable by a webpage using anchorprints and is obfuscated from a webpage using structureprints; however, from the user's point of view, the extension operates the same.

In summary, we make the following contributions:

- We present the design of a novel system that automatically identifies and randomizes browser extension fingerprints to defend against existing extension fingerprinting techniques without requiring any browser changes or any involvement from the extension's developer.
- We describe the implementation of our design into a prototype, CloakX, that uses a combination of: (1) static rewriting of extension JavaScript code and (2) a dynamic DOM proxy, Droxy, that intercepts and rewrites extension requests on-the-fly.
- We use a combination of high-fidelity testing (extensive manual testing) and low-fidelity testing (broad automated testing) on the extensions rewritten by CloakX to quantify the breakage caused by our system, demonstrating that client-side modification of extensions introduces minimal defects.
- We also evaluate the detectability of cloaked extensions and show that some cloaked extensions are undetectable while others are more difficult to detect.

## 2 Background

In this section, we provide insights into the complexity of modern browser extension frameworks that must be taken into account when designing a client-side countermeasure against extension fingerprinting. We start by describing the architecture of browser extensions, focusing on the details that pertain to their fingerprintability. Next, we discuss fingerprinting and detecting extensions using anchorprints (fingerprints that are comprised of items directly accessible from a tracking webpage's JavaScript) and structureprints (fingerprints built from the extension's behavior). Last, we finish this section by presenting the threat model that CloakX can defend against.

### 2.1 Browser Extensions Explained

While modern web browsers provide an ever-increasing range of functionality to users and webpages, an off-the-shelf browser cannot possibly provide a sufficiently large set of features to satisfy every user's browsing needs. To improve the user's browsing experience, browsers enable users to enhance their functionality through extensions. Users add extensions to their browsers to change the browser's look, to add helpful toolbars, to block ads, and to enhance popular webpages [5].

Although extensions utilize web technologies such as HTML, CSS, and JavaScript, they also have access to powerful extension-only APIs that enable them to, among others, access and modify cross-origin content and a browser's

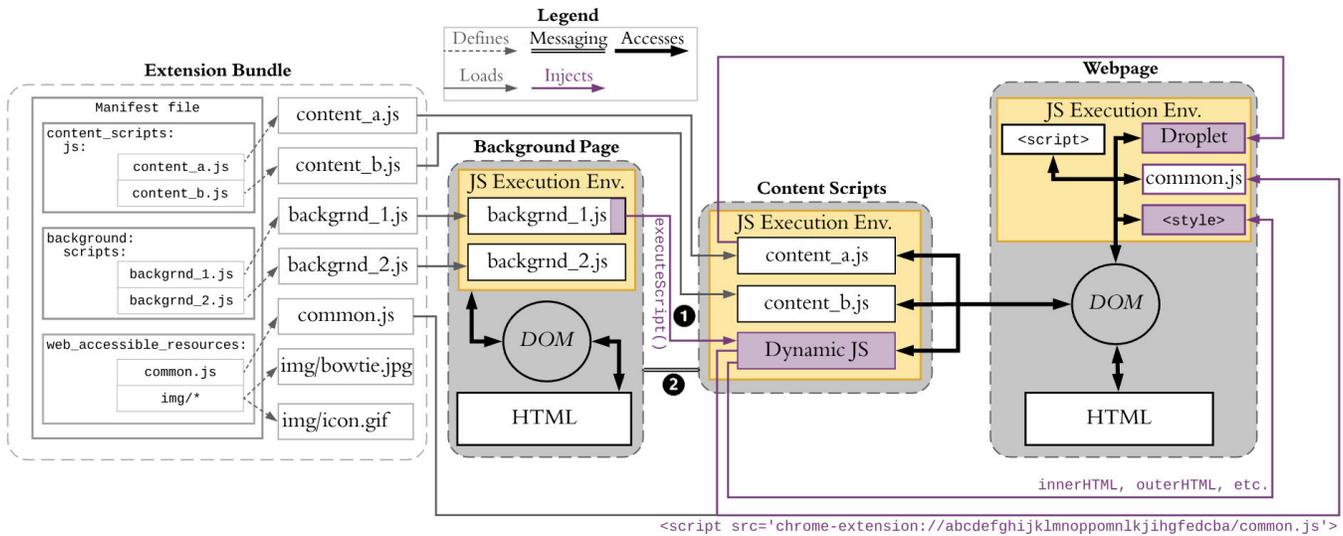

Figure 1: Extension architecture. A high-level overview of Chrome’s extension architecture with the static content of the extension on the left side and the multiple execution environments on the right. Background pages can 1) inject content scripts dynamically using the `executeScript()` method in Chrome’s extension API and 2) send and receive messages from the content scripts.

client-side storage. However, before an extension can access broader privileges or interact with a webpage, it must request this access from the browser. As Figure 1 depicts, the modern extension architecture implements a layered security approach within the browser that creates multiple execution environments with varying levels of persistence and privileges for each extension and webpage.

The left-hand side of Figure 1 depicts the static parts of an extension, including items such as the manifest, JavaScript, HTML, and image files. For the browser to parse and install an extension, it must have a *manifest* file which defines the extension’s properties. Similar to the manifest shown in Figure 1, extensions commonly rely on three properties, which describe background pages, content scripts, and web accessible resources [5].

When the *background* property is included in the extension’s manifest, the browser automatically constructs a hidden background page for the extension. The background page contains HTML, a DOM, and a separate JavaScript execution environment (labeled as “Background Page” in Figure 1). The JavaScript executed in the background page often contains the main logic of the extension, maintains long-term state, and operates independently from the life-cycle of the webpages [28].

Content scripts bridge the gap between the background page and the current webpage. An extension uses content scripts to modify the current webpage and communicate with the background page. These content scripts are either statically declared by an extension in the manifest file or programmatically injected into the current webpage. For example, on the left-hand side of Figure 1, the manifest declares the two content scripts `content_a.js` and `content_b.js`. To program-

matically inject a content script, an extension must call `executeScript()` from a background page (see 1 in Figure 1).

To modify a webpage, a content script uses the webpage’s DOM [10]. DOM APIs provide a systematic way for interacting with a webpage. In this paper, we call the content script’s interaction with the DOM APIs *DOM requests*.

Notice in Figure 1 that the background page, content scripts, and webpage each run their own JavaScript execution environment. The separate execution environments prevent the JavaScript variables and functions from directly interacting. Google Chrome’s documentation states that content scripts “live in an isolated world, allowing a content script to make changes to its JavaScript environment without conflicting with the page or additional *content scripts*” [3] (emphasis added). This statement, however, is misleading because we experimentally discovered that content scripts loaded from the same extension share variables and can call functions from other content scripts. Thus, an extension’s content scripts share a single execution environment; however, they do not share an environment with the background page, webpage, or other extensions (depicted in Figure 1).

Using DOM requests, a content script has significant control over the rendered webpage. Content scripts can inject HTML into the webpage (using DOM element properties such as `innerHTML` or DOM methods such as `appendChild()`). We call this injected HTML *droplets* (the extension drops them onto the webpage). Among other elements, droplets may contain `<script>` tags where the extension includes either inline or remote JavaScript. By injecting JavaScript, the content script purposefully bypasses the isolation between the content scripts and the webpage’s execution environments.

The Chrome Extension API provides privileged functionality available only to extensions. Chrome grants back-

ground scripts broad access to the API's capabilities. However, Chrome grants content scripts limited access to the API while making the API inaccessible to webpages. For example, only an extension's background page can access network resources, view platform information, and communicate with native applications. However, both content scripts and background scripts may use the API to initiate and listen for communications from one another via the appropriate Chrome APIs (as shown by the double lines towards the bottom of Figure 1). Background scripts cannot directly interact with a webpage, however they can *indirectly* send messages to it via the extension API using the method `chrome.runtime.sendMessage()` [2]. Part of the reason for this layered security model, including the separate execution environments, is to isolate the components and prevent webpages from unauthorized access to the extension API's more sensitive functions.

Another important property in the manifest is the *web-accessible-resources* property [7]. Prior to January 2014, Chrome permitted external access to all of an extension's resources, i.e., a webpage could reference resources belonging to installed extensions. In more modern versions of Google Chrome, an extension must explicitly whitelist a resource before a webpage may retrieve it [8]. An extension whitelists its resources by adding them to the *web-accessible-resources* property in the manifest. Once added, a resource becomes accessible to any webpage or any installed extension.

To access a web accessible resource (WAR) from the context of a web page, a webpage developer uses a URL of the format: `chrome-extension://[extId]/[path-to-resource]`. The `extId` in the URL is a unique identifier generated by the Google Web Store upon publication of an extension which does not change when extensions are updated.

## 2.2 Extension Fingerprinting and Detection

In 2017, Sjösten et al. demonstrated that, with WAR fingerprinting, any extension using WARs is trivially detectable by a webpage [38] by creating a database of which WARs are utilized by each extension available in the Google Store. Given that an extension's ID is globally unique and permanent, a tracker can detect an extension by requesting any one of its previously identified WARs. If the request is successful, then the corresponding extension is installed on the user's browser. Next to its simplicity and the 16,479 (28%) of extensions that utilize WARs (and are thus fingerprintable), WAR fingerprinting works in the browser's private mode.

Orthogonally to WAR fingerprinting, Starov et al.'s Extension Hound (XHOUND) [42] creates a DOM fingerprint based on the extension's DOM modifications. XHOUND uses dynamic analysis to exercise extensions and detect changes introduced to the DOM through the extension's operation. By loading a set of webpages with and without a given extension, XHOUND can compare the two resulting DOMs and isolate

the DOM changes that were performed by the given extension. These changes can straightforwardly be converted into fingerprints which trackers can use to detect the presence of any DOM-modifying extension.

When using WAR and DOM fingerprints for detection of extensions, we reclassify all such fingerprints into *anchorprints* and *structureprints* to describe the method and accuracy of the detection techniques. Anchorprints rely on an *anchor* between the webpage's JavaScript and the extension. An anchor is a unique identifier formed to facilitate access and communication between webpages and extensions. An anchor provides a way to directly access elements and resources available to the webpage. Some examples of anchors include WARs, IDs, class names, and custom attributes. For example, the Chrome extension Grammarly adds a unique class to the root `<html>` element on each webpage. Thus, if a webpage uses `document.getElementsByClassName()` and receives the `<html>` element, it is likely the user has Grammarly installed.

An anchorprint is comprised of all the WARs, IDs, class names, and custom attributes made available by an extension. With the items in an anchorprint, a webpage need only to query the DOM or send an XMLHttpRequest to detect an extension. WARs are the most powerful of the anchorprint elements because, due to the unique extension identifier, an anchorprint with even one WAR is always 100% accurate. Although IDs, class names, and custom attributes might be 100% accurate, they often have a much lower per element accuracy than WARs because webpages and extensions alike often use some of the same names. Despite this limitation, the accuracy of the anchorprint improves dramatically with each additional element included in it.

Structureprints are less precise (in terms of fingerprinting) but are formed based on the *structure* of the changes the extension makes to the underlying webpage. Structureprints effectively create a DOM fingerprint that uses the extension's unique and intended behavior to identify the extension. The idea of a structureprint is that it can be used to detect a specific extension because the extension always behaves in a predictable manner and alters a webpage consistently, thus creating a *structure* that is unique among extensions. For instance, consider a popular Google Calendar extension that is the *only* extension with a structureprint that contains the tags `a` and `img` with the following attribute names `href`, `location`, `target`, `blank`, `width`, `height`, `src`, `alt` and `style`. Surprisingly, we found during our experiments that a tracking webpage can reliably detect 28.93% (1,511) of extensions using only the `tagName` of the DOM elements added or deleted from a webpage by an extension. Adding attribute names, attribute values, and the text of the DOM elements to the structureprint increases the number of detectable extensions to 73.65% (3,847).

An important *subset* of structureprints that target an extension's behavior are called *behaviorprints*. For example,

Grammarly creates a green button inside a text area. With manual analysis, it is possible to identify whether the green button has been added to the webpage without relying on the IDs or class names injected by Grammarly. Another example of using behaviorprints are in the detection of ad-blocking extensions, such as Detect AdBlock [4]. However, no recent research has shown how to create a behaviorprint in an automated way at scale. As a result, current behaviorprints are limited to targeted attacks against specific extensions or narrowly constrained categories of extensions (e.g., ad-blocking extensions).

Beyond the obvious implementation differences between anchorprints and structureprints, the fingerprint classes differ in their accuracy and their destructibility. For most anchorprints, matching the WAR, ID, class name, and custom attributes of a published extension often provides a (unique) one-to-one match. However, for structureprints, finding a match is often less certain because many extensions have similar behavior, which results in the same structureprint. Another key difference between anchorprints and structureprints is the permanence of their link between the published extension and the user's installed version. For anchorprints using WARs, IDs, and class names, CloakX completely renames the values. By renaming the values, CloakX completely destroys the link between the published extension and the user's installed version. Without that link, it is impossible for a tracking webpage to use the anchorprint to identify the installed extension because the anchorprint no longer matches the published extension. Whereas with structureprints, the destruction of the link between the published extension and the user's installed version is difficult. This difficulty occurs because of the requirement that a cloaked extension retain the same behavior (i.e., user experience). By maintaining the same behavior, the structureprint of a cloaked extension is only being obfuscated, which means that with enough effort a tracker can eventually deobfuscate the cloaked structureprint and, thus, detect the cloaked extension.

### 2.3 Threat Model

In our threat model, attackers use a database of fingerprints to detect the extensions installed by a visitor to the site. However, we limit the attackers to the information and privileges afforded to the webpage's JavaScript execution environment. In essence, we assume that there are no zero-day vulnerabilities that would allow webpages to bypass the layered-security architecture depicted in Figure 1. Therefore, the attackers cannot access the content of an extension installed on a visitor's device.

In this paper, we explore two different types of attackers. The automated attacker uses automated extension detection techniques. Specifically, we limit the automated attacker to anchorprints and structureprints. To detect an extension, the automated attacker must find either an exact or fuzzy match

to an entry in their fingerprint database. The targeted attacker is permitted to manually generate targeted structureprints using portions of the structureprint (i.e., behaviorprints) for extension detection. While we focus on defending against the automated attacker because automated large-scale detection is a feasible attack, we also include the targeted attacker to explore how CloakX can defend against the targeted attacks.

## 3 CloakX

The core idea behind CloakX is to diversify each extension's fingerprint from the client-side while maintaining equivalent functionality *without making any changes to the browser and without requiring the developers to alter their extensions*. Client-side diversification of the anchorprints (fingerprints comprised of items directly accessible from a tracking webpage's JavaScript) and structureprints (fingerprints built from the extension's behavior) reduces the extension's detectability by breaking a webpage's ability to link together a published extension and the one installed on the user's machine. CloakX defeats detection using an anchorprint by randomizing the names of the WARs, IDs, and classes. However, CloakX does not completely defeat anchorprint detection using custom attributes. CloakX's approaches combat custom attribute-based detection by randomly injecting more unique custom attributes into each webpage. CloakX reduces the efficacy of structureprints by introducing random attributes and tags into the webpage. Although CloakX does not completely prevent detection using custom attributes or structureprints, it is a step beyond current solutions and CloakX achieves these protections without any changes to the browser and without requiring the intervention of extension developers.

Figure 2 shows the overall process of CloakX, a multiphase tool that leverages static- and dynamic-analysis techniques to achieve extension diversification while maintaining functional equivalence. In the first phase, CloakX analyzes the extension for the DOM fingerprints and CloakX identifies the droplets that must be statically analyzed. In the second phase, CloakX renames each WAR within the extension to a unique random value, finds all the references to the original name, and replaces them with their randomized counterpart. In the third phase, CloakX adds a dynamic proxy (Droxy) to the extension's content and background scripts. Droxy dynamically intercepts DOM and WAR requests and substitutes the original ID, class names, and WAR names with their random counterparts. In the last phase, CloakX statically analyzes and rewrites the DOM IDs and class names inside droplets that cannot be dynamically intercepted by Droxy.

### 3.1 XHOUND Analysis

CloakX uses XHOUND (we obtained a copy of the XHOUND prototype by contacting the paper's authors [42]) to generate a DOM fingerprint for the extension and to identify the droplets

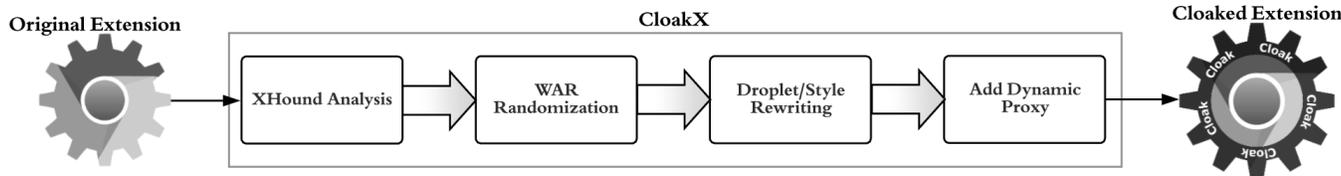

Figure 2: Overview of the CloakX process.

injected into the webpage. Each DOM fingerprint consists of four types of artifacts: (1) adding a new DOM element, (2) deleting a DOM element, (3) setting or altering an element’s attribute, and (4) changing text on the page.

Of the four types, DOM additions are the most common type of detectable artifacts according to XHOUND [42]. This is because DOM additions are generic operations that often rely on loose coupling with a webpage for them to be triggered. Whereas most DOM modifications or deletions require a tighter coupling between the extension and the webpage, which limits their applicability to the problems often solved by developers. For instance, consider a password manager extension that injects a stylized element into every password form field (so that the user can invoke the password manager interface). The extension adds the element to the webpage and gives it a unique ID and a custom class name. It requires the ID to communicate with the element once it’s placed on the webpage. Using the added ID and class name (i.e., the extension’s anchorprint), a webpage can detect the extension by checking for the presence of either the unique ID or class name on the webpage.

Next, CloakX uses XHOUND to identify any droplets the extension injects into the webpage’s execution environment so that CloakX can preprocess the droplets to identify the ID and class names within them. As discussed in Section 2.1, droplets (purple-colored boxes in Figure 1) are JavaScript strings that an extension injects directly into a rendered webpage. Droplets can include any text literal such as HTML, JavaScript, or base64-encoded images; however, the preprocessing is only performed on droplets containing inline JavaScript and those `<script>` elements that reference WARs.

Finally, during this phase, CloakX creates a map from the original ID and class names used to fingerprint the extension to the new randomized values.

### 3.2 Diversification of Web-Accessible Resources (WARs)

The principle behind the diversification of Web-Accessible Resources (WARs) is straightforward: if each installation of an extension has different filenames for the same WARs, then a tracker can no longer create a global database of WARs and, therefore, can no longer detect the presence or absence of any given extension based on its WAR anchorprint.

In the first stage of the WAR diversification process, CloakX identifies all the resources declared as WARs in the manifest file of each extension. Although many extensions explicitly list the resources they wish to make accessible, it is also possible to use a \* wildcard [34]. With wildcards, an entire folder, its contents, and all its subfolders can be designated as web-accessible — this includes using a single \*, which designates every file in the extension as web-accessible. Even though making every file in the extension web-accessible is likely an implementation error, we discovered 419 extensions that made all of their resources web-accessible, out of 59K analyzed extensions. In the second stage, CloakX computes the shortest unique file path to facilitate the search-and-replace in the final stage. Specifically, CloakX reduces the full path of each WAR to the minimum length necessary to uniquely identify the resource (compared to all the other resources in the extension). This operation reduces the number of resource references missed (i.e., false negatives) associated with dynamic string concatenation (often a directory path).

In the final stage of the WAR diversification process, CloakX uses the shortest unique path to find every use of the WAR within the extension’s files and to replace that with the appropriate random value, maintaining the correctness of WAR references for each extension.

In addition to the static alterations described above, CloakX relies on Droxy, discussed in the Section 3.3, to dynamically translate any WAR requests missed by the static replacement method.

### 3.3 Droxy

The next step in the CloakX process adds Droxy to the extension. Droxy is a content script that injects random attributes and tags into the DOM to further obfuscate the extension’s DOM fingerprint while also translating any uncloaked WAR requests and the IDs and class names used in DOM requests into their cloaked versions. CloakX patches Droxy into the extension and configures Droxy to execute before any of the extension’s content scripts.

Droxy adds random attributes and tags to the DOM to reduce the accuracy of detection using structureprints. As each webpage is loaded, Droxy adds a random number of randomly generated tags to the DOM to make extension detection less accurate. To further frustrate detection using structureprint matching, Droxy adds random attributes to the DOM elements added by each extension.

Droxy also uses cross injection of custom attributes to frustrate anchorprint detection. For trackers using custom attributes to detect extensions, cross injection allows the user to impersonate other extensions, which increases a tracker's false positives when using anchorprint detection. This is done by adding custom attributes that are randomly selected from a list of the 244 unique custom attributes used by other extensions with a DOM fingerprint.

Droxy also dynamically catches any WAR requests made using the resource's original filename, which serves as a backup for the static replacement method described in Section 3.2. Droxy achieves this by watching for changes to the DOM using a `MutationObserver()` that checks for un-cloaked WAR requests inside the DOM elements altered by the extension. In addition, Droxy overrides the `XMLHttpRequest.open()` method and adds functionality to translate any WAR requests for the original filename to the new, randomized filename.

Droxy translates the ID and class names used to create a DOM anchorprint. As the first content script to load, Droxy overrides DOM accessor and mutator methods before the extension uses them to interact with the DOM, which effectively wraps all DOM requests in a translation layer (blue area in Figure 3). Each of the overridden methods are augmented to intercept and translate ID and class names used to create the DOM fingerprint. Droxy determines which ID and class names to translate by checking the ID and class names against the cloaking map, created in Section 3.1. The cloaking map contains name-value pairs where each XHOUND-discovered ID and class name is paired with a randomized version. If it finds a match in the cloaking map, it translates the original value on-the-fly into the randomized version. By intercepting and translating the fingerprintable ID and class names to randomized values, Droxy alters the extension's DOM fingerprint from the perspective of a tracker's execution context breaking the link between the user's installed extension and the publicly available version.

To prevent the use of anchorprint detection, Droxy translates IDs and class names into random values according to the map created in Section 3.1. For ID and class name translation, Droxy also tracks DOM queries and DOM mutations. Droxy intercepts and inspects the extension's queries that use IDs, element names, class names, and query selectors, which include the methods `getElementById()`, `getElementsByName()`, `getElementsByTagName()`, `getElementsByClassName()`, `querySelector()`, and `querySelectorAll()`. To handle more complex query selectors, Droxy parses the selectors using the open-source Sizzle engine to accurately identify the ID and class names [9].

For DOM mutations performed via JavaScript, Droxy intercepts all the ways in which an ID or class name can be introduced to the DOM. This dynamic interception of ID and class names is done by overriding `setAttribute()` and `getAttribute()` methods and redefining `id` and `className`

properties to use the overridden `setAttribute()` and `getAttribute()`. In addition, Droxy overrides the `classList` property. Because `classList` is an object, Droxy overrides the `add()`, `contains()`, and `remove()` methods of the `classList`. As a result, Droxy translates the extension's use of IDs and class names whether it is done when a DOM element is created or modified.

For DOM mutations performed via the injection of raw HTML, Droxy uses static and dynamic analysis to make the translation of ID and class names straight-forward and precise. Droxy overrides the methods used to inject raw HTML, such as the `innerHTML` property and `insertAdjacentHTML()` method. Droxy uses the browser to parse the HTML by creating a mock container and adding the HTML to it without attaching the mocked container to the DOM. Droxy queries the mock container to identify and transform the ID and class names into their randomized versions. Droxy then exports the string representation from the mock container's DOM and then calls the original method to apply the modified string to the webpage's DOM.

In addition to DOM queries and mutations, Droxy intercepts styles and translates on-the-fly. An extension can include styles via text content inside `<style>` or `CSSStyleSheet`'s methods such as `addRule()` or `insertRule()`. Once intercepted, Droxy uses CSS parsing to locate the IDs and class names. If found, Droxy replaces the ID or class name with its randomized counterpart.

Droxy replaces an extension's droplets with the statically rewritten version (`content_a.js` and `Dynamic JS` in Figure 3). As a part of the droplet rewriting process described in Section 3.4, Droxy receives a hash value of the original droplet and modified version of the code for each droplet used by the extension. Droxy then matches the current droplet's hash to the ones provided and replaces it with its cloaked counterpart. Droxy performs the matching and replacement by customizing the properties `textContent`, `innerText`, and `HTMLScriptElement`'s and the methods `append()` and `appendChild()`. This process is depicted by the dashed arrow near ❶ in Figure 3. Droxy relies on the preprocessed JavaScript because rewriting the code on-the-fly in the browser efficiently is currently infeasible.

### 3.4 Static Droplet Rewriting

As discussed previously and shown in Figure 1, Droxy cannot intercept a droplet with dynamically inserted JavaScript because when the inserted code is executed in the webpage's JavaScript execution environment. Unfortunately, Droxy is also unable to cloak the droplet before inserting it because the heavy-weight static analysis necessary would significantly degrade the extension's performance. Therefore, CloakX statically analyzes the droplets offline, identifies where the extension adds the fingerprintable ID and class names to the

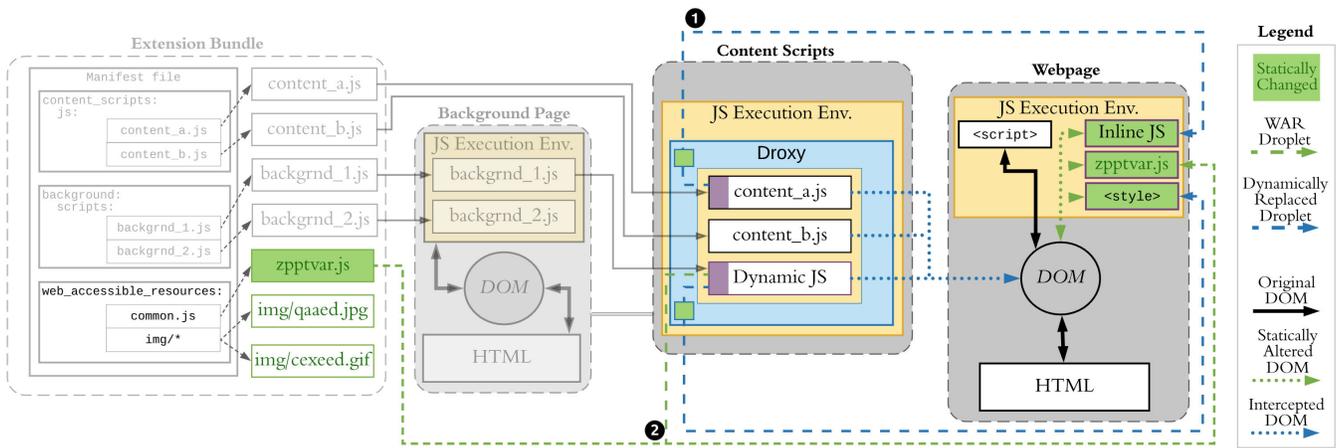

Figure 3: Diversified CloakX rewritten extension. CloakX hides fingerprints by rewriting the droplets, content styles, and renaming of web-accessible resources (WARs) and through Droxy’s on-the-fly substitution. As a result, a tracking webpage cannot access the original identifiers; however, the internal logic of the extension still can because Droxy translates those requests.

DOM, rewrites the JavaScript code, and Droxy dynamically substitutes the original code with its rewritten counterpart.

Extensions commonly use *generic* values for IDs and class names, which often overlap with JavaScript keywords or JavaScript code constructs that refer to the class names and IDs dynamically. In addition, the expressiveness of JavaScript means that the ID and class names usage are context-sensitive. For example, if the fingerprintable class name is `content`, CloakX should only replace the instance of `#content` and ignore `element.content`, `content.maximizer`, and `content-shaper`, as each have a different semantic meaning. Developers often construct ID and class names dynamically in the code, which necessitates a more sophisticated form of static analysis. For example, an extension might attempt to access an element with the ID `content` by using `getElementById("con" + "tent")`, which would be missed by a regular expression searching for the full word.

CloakX statically rewrites droplets offline (i.e., before an extension is installed) using static analysis to identify the appropriate locations in the JavaScript. CloakX limits its rewrites to the ID and class names that occur in the JavaScript and are added to the webpage via the DOM. By identifying and only altering these DOM altering instances, CloakX limits the possibility of breaking the extension with the alterations. In essence, the static rewriting requires a tool that performs taint analysis where it labels DOM interactions as sinks and then analyzes the backward slices of the control flow graph (CFG) until it finds the fingerprintable IDs and class names as sources.

We decided to use TAJs — a state-of-the-art and feature rich JavaScript analyzer — as the program analysis core of the CloakX static rewriting. We chose TAJs because it (1) performs type analysis on JavaScript, (2) supports most of the ECMAScript 5 standard and DOM functionality, (3) is under active development, (4) is open source [6], and (5) is the product of recent research [13, 14, 15, 23, 24, 25, 27].

TAJs performs dataflow analysis by using techniques that examine the flow of data along program execution paths. As TAJs iterates over the CFG, it creates a semilattice of program states that are unique for each basic block in the CFG [26]. For each variable represented in the lattice at a given basic block, TAJs assigns a set of possible values. The dataflow analysis completes when the values inside the lattice reach a fixed point and no longer change with each iteration. Using these values, it is possible to follow data both forwards and backwards through the CFG [26].

### 3.4.1 TAJs for Extensions

We enhanced TAJs to support static rewriting of the droplets by adding support for Chrome extensions, adding DOM taint analysis, and maximizing its exploration of the CFG. In addition, we plan to make our changes to TAJs publicly available because there are currently no other program analysis tools for browser extensions.

We added extension support to TAJs by creating stubs for Chrome’s extension API and implementing support for necessary methods such as `sendMessage()`, `getURL()`, `executeScript()`, `onMessage.addListener()`.

We implemented taint analysis within TAJs that tracks data through an application until it reaches a sink, where a sink is a location of interest within the CFG [16]. For the purposes of this analysis, TAJs tracks string literals matching the fingerprintable IDs and class names through the CFG until they are used to interact with the DOM. As a part of the taint tracking, we added functionality that maintains an *audit trail* of the changes to each variable while traversing the CFG so that upon reaching a sink CloakX can trace the values of interest to their origins.

We increased TAJs’s code coverage by adding edges to the end of the CFG that force a call to every named and anonymous function defined within the code. For the purposes

of extension rewriting, it is necessary that TAJs analyzes all the JavaScript within a droplet because some functions appear unreachable without complete semantic understanding of Chrome’s extension execution environment. However, the dynamic aspects used by TAJs itself to strike a balance between soundness and precision came at the cost of code coverage [15]. For example, TAJs does not analyze functions unless they are called by the JavaScript and the call is also reachable from the beginning of the CFG. Because extension rewriting requires TAJs to analyze all of the JavaScript within a droplet, we added edges to the end of the CFG that simulates a call to every named and anonymous function in the droplet. The potential downside to adding the edges is the decreased precision of our analysis (i.e., we are adding behavior to the application that does not exist at run-time), however for the purposes of identifying DOM fingerprints the trade-off is acceptable.

### 3.4.2 Static Analysis Results

Automated analysis of real-world JavaScript code is a difficult problem and despite all the advances made by TAJs, it, as well as similar tools, cannot analyze some JavaScript programs. As a JavaScript program increases in complexity and size, it becomes increasingly less likely TAJs will complete the analysis due to the explosion of dataflows (i.e., the classic state space explosion problem). As acknowledged by the authors, TAJs initially targeted hand-written JavaScript applications of a “few thousand lines of code” [26]. Plus, the addition of the fake edges dramatically increased the complexity of the CFG and the number of states, which decreased the code TAJs could successfully analyze to about 1,000 lines of code.

Fortunately, CloakX only needs TAJs analysis for the 197 extensions using droplets, which is only 3.2% of the extensions identifiable by XHOUND, because Droxy handles the rest of the extensions. Out of those 197 extensions, TAJs analyzed 212 total scripts of which 94 were JavaScript files that were designated as a WAR (and thus accessed via a `src` attribute, see Figure 3) and 118 were inline JavaScript. TAJs successfully completed analysis of 134 scripts (63.2%) finding 19,380 basic blocks and analyzing 18,497 (95.44%). However, TAJs was unable to analyze 78 (36.8%) of the inline JavaScript and WARs because the analysis for 34 scripts timed out, 6 scripts failed with an analysis exception, 6 scripts failed due to syntax errors in the JavaScript, and 32 scripts failed when TAJs crashed.

After manually analyzing the results we found the following reasons for why TAJs failed.

**Exceeded timeout threshold.** Most of the JavaScript code that caused TAJs to timeout were large JavaScript files that varied in size from 75 kilobytes to over a megabyte. In other cases, TAJs failed to finish analyzing smaller JavaScript code because of a bug in the forced path exploration code.

**Analysis exceptions.** TAJs failed to complete the analysis because it was missing support for the ECMAScript standard.

**Syntax errors.** TAJs was unable to analyze scripts with error in the JavaScript syntax.

**Crashed.** Some of the scripts triggered a bug in TAJs, causing it to crash with null pointer, stack overflow, or other miscellaneous exceptions.

## 3.5 Cloaked Extension

Once CloakX completes its modifications to the extension, the extension is cloaked and it appears to a webpage using anchorprint or structureprint detection techniques as though the user no longer has that particular extension installed. Architecturally, the resulting extension is similar to Figure 3 with Droxy surrounding the content scripts and translating the extension’s DOM requests and droplet injections. To a webpage, the results look similar to the HTML source shown in Figure 4.

The permanence of the cloaked anchorprint and structureprint depends on whether the extension is subject to static rewriting. For cloaked extensions that rely on purely dynamic mutations, the structureprint changes each time the cloaked extension is loaded. Droxy alters the structureprint by injecting new randomly generated noise into the DOM and re-randomizing the cloaked ID and class names. However, CloakX must statically alter extensions with WARs or droplets. As a result, the cloaked fingerprint of extensions requiring static rewriting remains the same until a new version of the extension is reprocessed by CloakX. Although guessing the name of a cloaked WAR is unlikely because CloakX generates a random alphanumeric value that is at least ten characters in length for each WAR; even if an adversary guesses the name of a WAR, the detectability would cease when a new version of the extension was released.

## 3.6 Deployment

Although we describe CloakX as a client-side mechanism (as this is where the fingerprint rewriting is done), to reduce end-user friction, we envision CloakX as the final step in an extension’s release and update process, all of which can be performed by the extension store and would require no intervention by the users. Prior to releasing the extension to users, the store sends the extension to CloakX for preprocessing. During CloakX’s preprocessing, CloakX installs Droxy and generates a cloaking-template for the extension. The cloaking-template contains a configuration file that identifies the static variable replacements necessary for WARs, IDs, and class names. When a user requests a preprocessed extension, CloakX uses the cloaking-template to quickly generate and implement random WAR, IDs, and class names for the current user.

## 4 Evaluation

Altering extensions without modifying the browser or relying on extension developers to make changes is a complex process, and while CloakX is a prototype and does not cover every possible scenario, we wanted to evaluate its current effectiveness. Thus, in this section we evaluate the efficacy of CloakX by (1) testing the breakage introduced by its use (2) the detectability of the cloaked extensions and (3) the performance of the cloaked extensions.

In November 2017, we extracted 59,255 extensions from the Chrome Store. Of those, we identified 13,693 extensions with only WAR fingerprints; however, 67 of the extensions had errors that prevented them from loading. Next, we identified 2,537 extensions having only DOM fingerprints, but Chrome could not load nine of the extensions. The last set of 2,786 extensions had both WAR and DOM fingerprints, one of which would not load in Chrome.

### 4.1 Functionality Experiments

Testing the functionality of a large set of applications is subject to two problems. First, the tests must explore all the relevant execution paths in the application. Second, the tests should test the entire set of applications. Furthermore, any testing approach will leave code unexplored and applications uncovered, and thus the results form an estimation of functionality breakage. In this work, we perform two different experiments to address both of these challenges: a low-fidelity and a high-fidelity experiment.

The low-fidelity experiment tested the entire population and the high-fidelity experiment randomly sampled from the population. The low-fidelity experiment automatically exercised the original and cloaked extensions and compared the error messages generated by each. The low-fidelity experiment provides a lower bound on the breakage across the entire population. The high-fidelity experiment involved manually—and extensively—exercising the extension, which provided deeper coverage of the extension’s functionality. Due to the time-consuming nature of each high-fidelity run, we used a random sample of the extensions from each population.

#### 4.1.1 Low-fidelity Functionality Experiments

To measure functionality breakage introduced by CloakX broadly across all extensions, we performed automated experiments that measured the change in errors from the original extension to the cloaked extension. To execute the experiment, we created a headless browser session using Selenium’s ChromeDriver with full logging enabled, which includes errors from the extension’s content scripts. Next, we visited a triggering web page, which is similar to the webpage used by XHOUND to activate the extension’s functionality. In addition, for those extensions with DOM fingerprints identified by XHOUND, the triggering webpage also included dynamically generated triggers. After the page loaded, the browser waited 30 seconds for any delayed actions to execute. Other than the static and dynamic triggers, the automated experiments do not simulate additional user actions, which might be necessary to execute all the extension’s functionality. These steps comprise a *run*, which is completed once for the original extension and once for the cloaked extension.

After both runs finish, we compared the severe JavaScript error messages between the two runs. If the cloaked extension generated the same errors, then the extension passed. Otherwise, if the cloaked extension generated any new or different errors, then the extension failed. Because the automated tests exercise limited functionality and only compare errors, this experiment represents the best case scenario (i.e., the lower bound) on the errors introduced by CloakX. However, the automation allowed us to run the experiment across the entire population.

Table 1 shows the results for WAR and DOM cloaking separately. Note that at the time we ran the experiments, which took place several months after collecting the extensions, some of the original versions stopped working because of Chrome browser updates, obsolete back-end servers, etc. As a result, we only tested working extensions and, therefore, the results only contain errors introduced by CloakX.

In the low-fidelity experiments, CloakX retained equivalent functionality for 99.02% (13,493) of the WAR fingerprintable extensions, 98.69% (2,493) of DOM fingerprintable extensions, and 97.92% (2,727) of WAR and DOM fingerprintable

Table 1: Automated Test Results

| Extension set             | Total         | Tested        | Passed        | Results       |              |
|---------------------------|---------------|---------------|---------------|---------------|--------------|
|                           |               |               |               | Pass          | Fail         |
| WAR Fingerprintable       | 13,693        | 13,626        | 13,493        | 99.02%        | .98%         |
| DOM Fingerprintable       | 2,537         | 2,526         | 2,493         | 98.69%        | 1.31%        |
| WAR & DOM Fingerprintable | 2,786         | 2,785         | 2,727         | 97.92%        | 2.08%        |
| <b>Totals</b>             | <b>19,016</b> | <b>18,937</b> | <b>18,713</b> | <b>98.82%</b> | <b>1.18%</b> |

extensions. For the WAR fingerprintable extensions, we found that the most frequent cause of the failures was the loading of WARs from remote websites. For the DOM fingerprintable extensions, most of the new error messages generated by the cloaked extensions were severe JavaScript errors caused by (1) extensions loading remote content or (2) missing functionality in Droxy. For the WAR and DOM fingerprintable extensions, we found the same errors as seen in the WAR and DOM only tests. To verify the WAR and DOM cloaking did not interfere with one another, we also ran this group using only one of the modifications at a time. The total number of errors was the same for the joint run as it was for the two additional runs with the single modifications, which indicates the modifications did not interfere with one another.

#### 4.1.2 High-fidelity Functionality Experiments

The high-fidelity experiments consisted of manually exercising and evaluating the operation of the cloaked extensions. The high-fidelity evaluation was inspired by the methodology used by Snyder et al. [39]. This methodology focuses on the extension’s operation from the perspective of the user. If the cloaking process introduces an error, but the user does not perceive a difference in the extension’s operations, then we deem the extension passes. This method of evaluation exercises much more of the extension’s code than the automated tests and it provides an additional metric that evaluates the actual operation of each extension. The high-fidelity experiments were performed by the authors using the testing framework detailed next.

We built a custom framework to methodically follow a four-phase evaluation of each extension and advise the tester on the current step in the process. In phase one, the framework loads the original extension and gives the user five minutes to understand its basic operation (including the time necessary to read the extension’s description in the Chrome Store). In phase two, the framework reloads the original extension and the user exercises its functionality for five minutes. In phase three, the framework loads the modified extension and the user spends five minutes completing operations similar to the ones completed in phase two to verify it is still operational. In the last phase, the user records any notes on the evaluation and chooses whether the extension passed or failed.

Similar to the automated tests, we divided the extensions into three groups based on the type of fingerprints they emitted. As a result, the populations for each of the high-fidelity tests were as follows: 13,626 WAR fingerprintable extensions,

Table 2: Manual Test Results

| Extension set             | Random    | Top 25    | Overall   |
|---------------------------|-----------|-----------|-----------|
|                           | Pass/Fail | Pass/Fail | Pass/Fail |
| WAR Fingerprintable       | 25 / 0    | 25 / 0    | 50 / 0    |
| DOM Fingerprintable       | 24 / 1    | 24 / 1    | 48 / 2    |
| WAR & DOM Fingerprintable | 24 / 1    | 24 / 2    | 47 / 3    |

2,526 DOM fingerprintable extensions, and 2,727 WAR and DOM fingerprintable extensions.

To create samples for these groups, we created both random and systematic samples containing 25 extensions each. We created the first sample by randomly selecting 25 extensions from the population. We formed the systematic sample by selecting the top 25 most popular extensions based on the number of downloads listed on the Chrome Web Store. Throughout the manual tests, if we could not test an extension because the original version was broken or it was only available in a foreign language, then it was discarded and another one was selected according to the associated sampling method. The resulting samples contained quite a bit of diversity between the extensions. Although we found a few instances of overlapping functionality, we kept these extensions in the samples. However, when we found a duplicate extension, we discarded the duplicate and tested a different extension. Some example extensions included in the test samples included a utility for those who are color blind, a search bar tool, a product search by image, a data extraction tool, and a gesture utility for navigation.

Out of all 150 experiments, 145 of the cloaked extensions retained equivalent functionality (see Table 2). All of the WAR fingerprintable extensions retained their functionality. 96% (48 out of 50 extensions) of the DOM fingerprintable extensions and 94% (47 out of 50 extensions) of the WAR and DOM fingerprintable extensions retained their functionality.

After analyzing the broken extensions, we found three different causes for the broken extensions.

**Remote source code using original resource name.** The extension loads remote Facebook SDK, which looks for obfuscated ID and class values.

**Extension relies on hardcoded values that Droxy alters.** An extension relies on hardcoded logic that expects its content scripts to appear in a specific order. However, Droxy must be the first content script, which changes the position of all of the extension’s original content scripts, and in one case, it broke the extension.

**Droxy implementation limitation.** Droxy does not currently support recursive iframe sourcing, *cloneNode*, and some advanced CSS rules that the *cssutils* Python library fails to properly parse.

With engineering improvements to Droxy, we can remediate each of the errors listed above and increase the success rate. For the remote source code, Droxy could intercept the remote source code request and parse it before it is executed. This, of course, would add additional performance overhead. The

hardcoded logic could be rectified by overriding the methods that accesses the content scripts. The implementation limitations can be addressed by adding logic to support them into Droxy.

## 4.2 Detectability Experiments

The detectability experiments evaluated the efficacy of the cloaking against an extension tracking webpage. In the first experiment, the tracker used anchorprints to detect extensions with either WAR or DOM fingerprints. In the second experiment, the tracker used structureprints to detect the extensions with DOM fingerprints. In the third experiment, we investigated the use of behaviorprints to detect cloaked extensions. Last, we explored different methods for detecting the use of CloakX on an extension.

For the first three experiments, we set the fingerprint matching threshold to three. To meet the matching threshold, the tracker must be able to match the extension's fingerprint to three or fewer extensions in its repository. When the tracker meets the matching threshold, it has successfully detected the extension.

We chose a threshold of three because thresholds higher than three showed a sharp decrease in the tracking benefit gained from an extension detection. The matching threshold represents the number of extensions that match a structureprint. The best threshold depends on the requirements of the web tracker and the resources available. The main purpose of the threshold for our experiments was to balance the search time complexity of the fuzzy searches with the increase in the matching of cloaked extensions. For example, by raising the threshold to 20, the web tracker matches three additional cloaked structureprints (one of which matches 18 extensions).

### 4.2.1 Detectability Experiment Using Anchorprints

The anchorprint detectability experiments focused on detection using WARs, IDs, and class names. In the first phase of the experiment, we harvested the anchorprints of the extensions. Next, we loaded each of the original extensions and used a tracking webpage to verify that the extensions were detectable using the anchorprint. Finally, we loaded each of the cloaked extensions and used a tracking webpage to evaluate the detectability of the cloaked extensions using its anchorprint. For a successful detection, the tracker must meet the matching threshold.

In our experiment, we found that none of the cloaked extensions were detectable using their WARs, IDs, and class names after cloaking. In the first phase, we harvested 17,833 anchorprints, which includes 16,411 extensions with WAR fingerprints and 1,422 that have DOM fingerprints with IDs and classes. However, we chose to limit the testing to the 17,678 extensions that could be executed after being cloaked

and assumed that the 155 broken extensions were detectable (thus providing a lower bound on detectability).

In the second phase, we matched 17,534 of the 17,678 original extensions. The ID and class name functionality of the tracker failed to match 144 extensions because it either failed to trigger the extension's anchorprint or it found too many matching extensions. The ID and class name tracker did not find matches for 26 extensions because those extensions required dynamic triggering and the tracker could not use dynamic triggering and still extract the anchorprint; thus, the extensions did not inject their anchorprint into the webpage. The remaining 118 extensions did not count as a detection because the IDs and class names matched more than three other extensions, which exceeded our threshold for a detection.

Initially, the WAR functionality of the tracker failed to find 956 of the WAR fingerprinted extensions using XMLHttpRequest because none of the WAR declarations in the manifest file existed in the extension. However, we discovered we could reliably match these extensions by timing how long it took for three WAR requests to return. The first request is for the declared but missing resources of the extension. The second request was for the extension's manifest.json, which was not declared as a WAR. The third request was for a randomly generated resource that does not exist in the extension and is not a WAR. If the missing request (i.e., the first) takes the longest to return, then the extension has the resource defined as a WAR but the resource does not exist in the extension. Thus, we improved the tracker such that if the tracker failed to match an extension using any of the WARs, then it performs these three requests for each of the WARs in the 956 extensions and if the first request takes the longest it has detected the extension.

In the third phase, we were able to detect 96 of the cloaked extensions using their anchorprints. After investigating several extensions that were detected, we found that matches occurred because CloakX was not translating the ID and classes for the extensions due to errors introduced through the cloaking process. In other words, the experiment found 96 additional cloaked extensions that did not maintain functionality equivalent to their original versions. Thus, with the additional errors but no actual matches, we found that 98.55% (17,582) of the extensions were undetectable using anchorprints.

### 4.2.2 Detectability Experiment Using Structureprints

The structureprint experiment tested the detectability of cloaked extensions using exact and fuzzy matching to detect the extensions. In the first phase, we ran each of the 5,311 DOM fingerprintable and WAR and DOM fingerprintable extensions through XHOUND to gather the structureprints. In the next phase, we ran each of the 5,223 cloaked extensions through XHOUND to gather cloaked fingerprints. We considered the extensions that failed the automated tests as detectable. Similar to the WAR detection experiments, we

Table 3: Structureprint Detection Test Results

| Structureprint Key Type   | Exact Matching |            | Fuzzy Matching |
|---------------------------|----------------|------------|----------------|
|                           | Original       | Cloaked    | Cloaked        |
| Tags, Attributes, Text    | 3,756 (71.91%) | 91 (1.74%) | 217 (4.15%)    |
| Tags and Attribute Values | 2,092 (40.05%) | 91 (1.74%) | 95 (1.82%)     |
| Tags                      | 1,420 (27.19%) | 91 (1.74%) | 91 (1.74%)     |

did not test the broken extensions, but we assume that they were detectable. In the last phase, we used the structureprints generated in phase one to match the cloaked fingerprints.

The accuracy and precision of detecting structureprints varies depending on both (1) the DOM elements used to build the structureprint and (2) the matching technique used to identify the extension. Therefore, to explore how CloakX can prevent the detection of various types of structureprints, we ran the last phase several times using three different structureprints (each one representing less information used in the structureprint) and two different matching techniques (one on exact matching and one on fuzzy matching) to ensure CloakX reduced detection for each of them.

The structureprints varied based on the contents used to build the fingerprint. The first type used all the XHOUND data, in other words, each fingerprint included added and changed tags, attribute names, attribute values, and text data. While these are the most accurate, they are also the most brittle; as a result, it is likely that the accuracy will degrade considerably in a real-world environment with dynamic HTML content and visitors that have several extensions installed. The second type of structureprint used only the tags and attribute names, which means the fingerprint did not use the attributes values or text. The third type of structureprint used only the tags.

For detection, the experiment extracted an extension's structureprint and then used exact and fuzzy matching against the structureprint database to identify the extension. Exact matching worked well for detecting uncloaked extensions; however, due to the preciseness required for an exact match, cloaked extensions evaded exact matching. Thus, we also tested using fuzzy matching with a 90% level of confidence. Fuzzy matching was successful when the match was made with a 90% level of confidence. Using either matching technique, if the tracker met the matching threshold (three or fewer matches) using the extension's structureprint then we counted the extension as detected.

Overall, we found that cloaking significantly limited the number of extensions detectable using structureprints. With the full structureprints (tags, attribute names, attribute values, and text) and exact matching, we were able to detect 3,756 of the 5,311 original extensions. The reason that 1,555 extensions were undetectable is because the number of matches made using the extension's structureprint exceeded the matching threshold for a detection (a structureprint must match three or fewer extensions for a successful detection). Using the full structureprints on cloaked extensions, none of the cloaked extensions were detected using exact matching

and only 126 extensions were detected using fuzzy matching. Using partial structureprints (attributes and tags), we were able to detect 2,092 of the original extensions; however, the cloaked extensions were undetectable using exact matching and only four were detectable using fuzzy matching. Using the tag only structureprints, we detected 1,420 of the original extensions; however, we were unable to detect any of the cloaked extensions using either matching technique.

### 4.2.3 Detectability Experiment Using Behaviorprints

To understand the limitations of CloakX, we performed an experiment to test the detectability of cloaked extensions using behaviorprints. We chose ten of the most popular extensions with structureprints and to avoid duplication we excluded all ad-blocking extensions except AdBlock. In addition, we examined ten extensions that we randomly selected from those with structureprints. By analyzing their structureprints, we manually created their behaviorprints from portions of the structureprint that remain constant after cloaking.

For the popular extension sample, six of the extensions added elements to the DOM that made them uniquely identifiable. The extensions LastPass, Pinterest Save Button, and Grammarly all add a base64 encoded image to the DOM that makes them uniquely identifiable. The extensions Ghostery, Evernote, and Skype add a style tag to the head element with features that made them uniquely identifiable. The extension Turn Off the Lights adds a data-video attribute. Although the data-video attribute is detectable when the extension is cloaked, CloakX randomly includes this attribute even when the extension is not installed, which increases the attacker's false positive rate and makes it more difficult to correctly detect when the extension is truly installed. Even though the cloaked version of AdBlock was detectable, its behaviorprint was not distinguishable from other popular ad-blocking extensions (e.g., AdBlock Plus, uBlock Origin, and AdGuard AdBlocker) because they all perform the same behavior by deleting ads from the DOM and not injecting any other elements into the DOM. Thus, the detection of ad-blocking extensions exceeds the matching threshold for the identification of a user. Ace Script and Honey added div tags with an ID, which means CloakX obfuscated the behaviorprint, and the extensions were not detectable.

For the random sample of ten extensions, five extensions were detectable using behaviorprints and five were undetectable. Similar to popular extensions, five of the ten extensions added elements to the DOM that made them uniquely identifiable. For example, two of them added custom text to the web page. Two of the undetectable extensions performed actions on the DOM, which were duplicated by a number of other extensions. Thus, those extensions exceeded the matching threshold and were undetectable. Finally, the three remaining undetectable extensions only added class names, IDs, and common tags to the DOM, which are obfuscated by CloakX.

### 4.3 Detectability of CloakX

For our last set of experiments, we evaluated three different techniques meant to determine whether an extension was cloaked by CloakX, thus detecting CloakX. These detection experiments were limited to the 2,447 extensions with structureprints that contained at least one ID or class name.

In the first experiment, we created a method for detecting CloakX after analyzing the lengths of the IDs and class names in cloaked and uncloaked extensions. The IDs and class names generated by CloakX were initially six characters in length and comprised of random alphanumeric characters. However, the IDs and class names in uncloaked extensions averaged 15.1 characters for IDs and 15.9 characters for class names. In addition, we discovered that only 62 uncloaked extensions met the criteria of having all their IDs and class names with a length of six (most of which had only one ID or class name). As a result, we created a method for detecting CloakX that marked an extension as CloakX-enabled if all the IDs and class names injected by the extension were six characters in length. Next, we ran the CloakX detector on 2,447 uncloaked extensions and cloaked extensions, thus evaluating 4,894 extensions. The CloakX detector reported 2,509 cloaked extensions, which means we had 62 false positives, 2,447 true positives, and 2,385 true negatives with an accuracy of 98.7%. As a result, we modified CloakX to randomize the length of the IDs and class names it renames. After making this change, we were no longer able to accurately detect the existence of CloakX based on the length of IDs and class names.

As a follow up, the second experiment attempted to identify cloaked extensions by measuring the entropy of the injected ID and class names. Our hypothesis was that the entropy of randomly generated IDs and class names would be measurably different from those chosen by extension developers. We found that the uncloaked ID and class names exhibited nearly the same amount of entropy as their randomized counterparts. As a result, we could not accurately identify the existence of CloakX using the entropy of ID and class names even though the cloaked values contained randomly generated characters.

In the last CloakX detection experiment, we identified the use of CloakX by exploiting popular extensions that both exhibited a behaviorprint and injected an ID or class name into the webpage. In particular, we found Evernote and Grammarly offered a strong behaviorprint and a related ID. Once we identified the existence of the extension's behaviorprint we looked for the ID or class name, if it did not exist then we determined CloakX was likely installed. For instance, Evernote injects a style tag with unique elements and it uses an ID for the same style tag. When a style tag is found that contains Evernote's elements and the style's ID is not style-1-cropbar-clipper, then the tracker records that it found a cloaked version of Evernote. Similarly, when Grammarly's green icon is detected and the top level html tag does not

contain a class starting with gr, the tracker records that it found a cloaked version of Grammarly. We tested this by running the tracker against all 2,447 uncloaked extensions and the two cloaked versions of Evernote and Grammarly. The tracker accurately identified the cloaked versions of both extensions with zero false positives.

### 4.4 Performance Experiments

CloakX minimally impacts the performance of Chrome in our automated tests. We tested CloakX's performance by randomly selecting 500 extensions that contain structureprints because their cloaking requires more resources. Each individual test loaded Chrome, loaded the extension, and ran a triggering webpage from the local machine, which either triggered a page load event or timed out. We executed the tests ten times on both the original and modified extensions. The tests were performed across 16 cores with each core running at 2.2 Ghz. On average, the original extensions took 12.3128 seconds and used 66,790 KB of memory whereas the modified extensions took 12.3221 seconds and used 67,123 KB of memory. Thus, the average increase in overhead for the cloaked extensions was a .07% increase in execution time (0.0093 seconds per extension) and a .49% increase in memory use (333 KB per extension).

## 5 Discussion

Using the highest failure rate for each of the fingerprint types and using fuzzy matching, CloakX retained the functionality and hid from detection 96.23% (18,222) of the tested extensions. For anchorprint detectable extensions, CloakX rendered 98.55% (17,574) of the extensions undetectable and with equivalent functionality. For structureprint detectable extensions, the tracker was unable to detect 95.91% (5,094) of the cloaked extensions.

CloakX rendered the detection of extensions using anchorprints significantly less accurate. CloakX increases user's anonymity by diversifying WARs, IDs, class names, and custom attributes used for anchorprints. In our experiments, cloaking the WARs, IDs, and class names destroyed the link between the published extension and the currently installed version. As a result, none of the successfully cloaked extensions could be detected based solely on their WAR, ID, or class name. Although it is possible to cloak custom attributes in a similar fashion, CloakX uses cross extension injection of custom attributes to cloak extensions. For trackers using custom attributes to perform anchorprint detection, CloakX increases the number of matches the tracker makes when evaluating an extension's anchorprint, which causes it to exceed the matching threshold and, thus, not detect the extension.

For detection using structureprints, CloakX obfuscated 95.91% (5,094) of the previously detectable extensions even when fuzzy matching with 90% level of confidence was used.

To prevent structureprint matching, CloakX diversifies the tags and attributes added to the DOM by the extension. While these changes were effective against exact and fuzzy matching, the changes only obfuscate the structureprint. Therefore, it is possible that a tracker could create a more sophisticated matching process (as has been the case in fingerprinting attacks and countermeasures) that limits the search to those DOM modifications that are constant.

For example, cloaked extensions are still sometimes identifiable with behaviorprints. In our experiments with twenty extensions, we were able to manually create unique behaviorprints for eleven of the twenty cloaked extensions.

However, behaviorprinting does not currently scale. First, the creation of behaviorprints requires human intelligence and no recent research has shown how to automatically generate a behaviorprint. Second, consistent human intervention is required to prevent the behaviorprints from going stale and no longer being able to identify the extension. For example, LastPass could update their icon, which would no longer match the saved behaviorprint. Third, due to the dynamic nature of the web ecosystem many of the behaviorprints will likely be difficult to use in practice. Lastly, the more popular an extension is the less value the detection of that extension offers towards the goal of identifying users. As a result, for a tracking website to effectively utilize behaviorprints they need to obtain a large number of behaviorprints from both popular and less popular extensions, which exacerbates the scaling problems.

Protection from behaviorprints is a fundamentally difficult problem because the extensions and the browser share the same view of the DOM. CloakX provides some protection from behaviorprints through its injection of noise into the DOM and with additional features could provide even more protection against behaviorprinting. For example, CloakX can make user identification via behaviorprints even more difficult by adding a feature that randomly injects the behaviorprints of the popular extensions, which increases the false positive detections and further dilutes the user's fingerprint. In addition, it is important to point out that only 3,756 extensions (of the 59,255 extensions we used in our study) have unique enough changes to the DOM to form behaviorprints and many of those are not unique enough to provide a robust means of detecting extensions. Nevertheless, the more complete privacy solution for extension fingerprinting is to modify the browser so that the extension and the website JavaScript see their own views of the DOM.

Although we were able to detect the use of CloakX, detecting the presence of a defense mechanism, like CloakX, is different than defending what the mechanism is explicitly trying to protect against (i.e., the presence of specific browser extensions). The fingerprinting value realized by detecting an extension cloaked with CloakX diminishes with each user that uses cloaked extensions. However, it is unlikely any attackers will try to detect cloaked extensions until CloakX

becomes popular enough to warrant the attention. As a result, the fingerprint value of detecting CloakX is limited. However, as CloakX becomes more popular it is possible that malicious or shady websites could deny service to users with CloakX-enabled extensions, but this issue exists with any defensive mechanism (similar to what users experience with ad-blocking extension detection).

Thus, despite the limitations described above, CloakX takes a large step forward towards protecting users from wide-spread automated fingerprinting using anchorprints and structureprints.

## 5.1 Case Study of Failures

Despite their large size and complexity, CloakX cloaks and retains equivalent functionality of 97.88% of the extensions detectable through their anchorprints and structureprints.

Functional breakage caused by the remote loading of scripts was common in broken extensions. One approach to address this issue is to find droplets that load remote scripts which CloakX could download, cloak, and save inside the extension. While an improvement over our current CloakX prototype, the downside of this approach is that the remote scripts might be dynamically generated and copying them inside the extension would not solve the problem. At a high level, we consider the loading of remote code in browser extensions an open problem because remote code can drastically alter the extension's logic *after* that extension has been vetted by the extension store.

Droxy relies on hash values calculated from a static version of the JavaScript code; however, some extensions dynamically change their inline JavaScript code each time it is produced. As a result, Droxy was unable to find the inline code because the current script would not match the one stored in CloakX's metadata. In most cases, we observed that the differences between the original and live scripts were minor which suggests that alternative search routines that allow for fuzzy-matching would be able to handle most of the observed code-matching issues, such as the one used by Soni et al. [40].

## 5.2 A New Avenue of Security Exploration

Due to the often-misaligned incentives between extension developers and end users, it is desirable to be able to perform late-stage customizations of browser extensions not only to make extensions less fingerprintable, but to also improve their overall security and privacy. In this work, we showed that despite the complexity of the rewriting process, we were able to automatically modify extensions, without requiring browser changes or changes to the development process of browser extensions. Therefore, our approach could be used in additional contexts, such as removing unnecessary third-party trackers and PII leaks [41, 46] or automatically patching vulnerabilities discovered in browser extensions [17].

## 6 Related Work

To the best of our knowledge this paper proposes the first client-side countermeasure against the fingerprinting of browser extensions. In this section, we briefly describe prior work on generic browser fingerprinting and the related countermeasures.

Eckersley conducted the first large-scale study that showed browser fingerprinting was sufficient to uniquely identify users without cookies or other stateful identifiers [18]. Since then, researchers studied several related topics including tracking the adoption of fingerprinting in the wild [11, 12, 19, 31, 36], proposing new vectors for browser fingerprinting [32, 33, 37, 38, 42, 45], and describing potential defenses against it [29, 30, 35].

Of all the new vectors proposed for browser fingerprinting, in 2017, researchers discovered three different types of side-channels for detecting the presence of specific browser extensions. Sjösten et al. used WARs to determine whether a browser extension is installed [38]. Using this method, they found unique fingerprints for 12,154 extensions and more than 50% of the 1,000 most popular extensions. With the fingerprint, extension detection is straightforward for an attacker to execute (one check per extension) and works even if the user utilizes incognito mode. To defend against this attack, CloakX dynamically renames all of an extension's WARs and rewrites all references to these WARs from the extension's code. As such, every different installation of the same cloaked extension will now have different WARs.

Starov and Nikiforakis utilized the changes in a webpage's DOM to detect extensions. Similar to the WAR detection technique, the attacker pre-processes all the extensions of interest to extract the DOM fingerprints that can be later used to detect the extension's presence [42]. As with WARs, CloakX dynamically rewrites the IDs and class names of all injected DOM elements, which changes the extension's fingerprint and makes it undetectable.

The last browser extension fingerprinting technique, proposed by Iskander-Rola et al. [37] relies on timing channels to detect the presence of files associated with a browser extension. Their method works regardless of whether the extensions declares the files as web accessible. Similarly, Van Goethem and Joosen propose a variation of the same technique using different timing side channels [45]. Because these attacks abuse the access-control mechanisms of a browser, no amount of extension rewriting can counter them. As such, we consider these attacks as out-of-scope for CloakX because our goal is to counteract the detection techniques without modifying the browser.

## 7 Conclusion

In this paper, we presented the first client-side countermeasure for defending against the detection of browser extensions.

Our system, CloakX, uses the principle of diversification so that two installations of the same extension expose different fingerprintable attributes. CloakX operates in an extension-agnostic fashion by rewriting extensions on the client-side, without requiring any modifications to the web browser. Overall, through a combination of large-scale experiments and manual testing, we showed that our CloakX prototype can successfully handle the majority of browser extensions while causing minimal breakage.

## Abstract

As software becomes increasingly complex, its attack surface expands enabling the exploitation of a wide range of vulnerabilities. Web applications are no exception since modern HTML5 standards and the ever-increasing capabilities of JavaScript are utilized to build rich web applications, often subsuming the need for traditional desktop applications. One possible way of handling this increased complexity is through the process of software debloating, i.e., the removal not only of dead code but also of code corresponding to features that a specific set of users do not require. Even though debloating has been successfully applied on operating systems, libraries, and compiled programs, its applicability on web applications has not yet been investigated.

In this paper, we present the first analysis of the security benefits of debloating web applications. We focus on four popular PHP applications and we dynamically exercise them to obtain information about the server-side code that executes as a result of client-side requests. We evaluate two different debloating strategies (file-level debloating and function-level debloating) and we show that we can produce functional web applications that are 46% smaller than their original versions and exhibit half their original cyclomatic complexity. Moreover, our results show that the process of debloating removes code associated with tens of historical vulnerabilities and further shrinks a web application's attack surface by removing unnecessary external packages and abusable PHP gadgets.

## 1 Introduction

Despite its humble beginnings, the web has evolved into a full-fledged software delivery platform where users increasingly rely on web applications to replace software that traditionally used to be downloaded and installed on their devices. Modern HTML5 standards and the constant evolution of JavaScript enable the development and delivery of office suites, photo-editing software, collaboration tools, and a wide range of other complex applications, all using HTML, CSS, and JavaScript and all delivered and rendered through the user's browser.

This increase in capabilities requires more and more complex server-side and client-side code to be able to deliver the features that users have come to expect. However, as the code and code complexity of an application expands, so does its attack surface. Web applications are vulnerable to a wide range of client-side and server-side attacks including Cross-Site Scripting [4, 47, 72], Cross-Site Request Forgery [3, 33, 46], Remote Code Execution [18], SQL injection [19, 41], and timing attacks [35, 40]. All of these attacks have been abused numerous times to compromise web servers, steal user data, move laterally behind a company's firewall, and infect users with malware and cryptojacking scripts [43, 49, 74].

One possible strategy of dealing with ever-increasing software complexity is to customize software according to the environment where it is used. This idea, known as *attack-surface reduction* and *software debloating*, is based on the assumption that not all users require the same features from the same piece of software. By removing the features of different deployments of the same software according to what the users of each deployment require, one can reduce the attack surface of the program by maintaining only the features that users utilize and deem necessary. The principle of software debloating has been successfully tried on operating systems (both to build unikernel OSs [53] and to remove unnecessary code from the Linux kernel [51, 52]) and more recently on shared libraries [56, 61] and compiled binary applications [42].

In this paper, we present the first evaluation of the applicability of software debloating for web applications. We focus on four popular open-source PHP applications (phpMyAdmin, MediaWiki, Magento, and WordPress) and we map the CVEs of 69 reported vulnerabilities to the source code of each web application. We utilize a combination of tutorials (encoded as Selenium scripts), monkey testing, web crawling, and vulnerability scanning to get an *objective* and *unbiased* usage profile for each application. By using these methods to stimulate the evaluated web applications in combination with dynamically profiling the execution of server-side code, we can precisely identify the code that was executed during this stimulation and therefore the code that should be retained during the process of debloating.

Equipped with these server-side execution traces, we evaluate two different debloating strategies (file-level debloating and function-level debloating) which we use to remove unnecessary code from the web applications and quantify the security benefits of this procedure. Among others, we discover an average reduction of the codebase of the evaluated web application of 33.1% for file-level debloating and 46.8% for function-level debloating, with comparable levels of reduction in the applications' cyclomatic complexity. In terms of known vulnerabilities, we remove up to 60% of known CVEs and the vast majority of PHP gadgets that could be used in Property Oriented Programming attacks (the equivalent of Return-Oriented Programming attacks for PHP applications).

Overall, our contributions are the following:

- We encode a large number of application tutorials as Selenium scripts which, in combination with monkey testing, crawling, and vulnerability scanning, can be used to objectively exercise a web application. Similarly, we map 69 CVEs to their precise location in the applications' source code to be able to quantify whether the vulnerable code could be removed during the process of debloating.
- We design and develop an end-to-end analysis pipeline using Docker containers which can execute client-side, application stimulation, while dynamically profiling the executing server-side code.
- We use this pipeline to precisely quantify the security benefits of debloating web applications, finding that debloating pays large dividends in terms of security, by reducing a web application's source code, cyclomatic complexity, and vulnerability to known attacks.

To motivate further research into debloating web applications and to ensure the reproducibility of our findings, we are releasing *all* data and software artifacts.

## 2 Background

In this section, we briefly describe the effect of package managers on software bloat and provide a motivating example for debloating web applications.

### 2.1 Package managers and software bloat

To ease the development of software, developers reuse third-party libraries, external packages, and frameworks for their applications. This approach enables developers to focus on their applications while relying on proven and tested components. Statistics from popular package managers show that reliance on external packages is a widely adopted practice across many different languages. NPM, the registry hosting NodeJS packages, reports more than 10 billion package downloads a month [73]. Similarly, PyPI, the package manager for Python, reports more

than a billion a month [30], while Packagist, the main repository for Composer package manager for PHP, reports the download of 500 million packages each month [29].

At the same time, it is doubtful that *all* the code and features obtained through these packages and frameworks are actually used by the applications that rely on them. For the most part, when developers rely on external dependencies, they include entire packages with no effective way of disabling and/or removing the parts of these packages and frameworks that their applications do not require.

### 2.2 Motivating web-application debloating

In this study, we look at the bloat of web applications and quantify how debloating can provide concrete security benefits. Even though debloating has been successfully applied in other contexts, we argue that the idiosyncrasies of the web platform (e.g. the ambient authority of cookies and the client/server model which is standard for the web but atypical for operating systems and compiled software) require a dedicated analysis of the applicability of debloating for web applications.

To understand how the bloat of a web application can lead to a critical vulnerability, we use a recent vulnerability of the Symfony web framework (CVE-2018-14773 [28]) as a motivating example. Specifically, the Symfony web framework supported a legacy IIS header that could be abused to have Symfony return a different URL than the one in the request header, allowing the bypassing of web application firewalls and server-side access-control mechanisms. If this type of header was never used by the server, debloating the application would have removed support for it, which ultimately would have prevented anyone from exploiting the vulnerability. Drupal, a popular PHP Content Management System (CMS), was also affected by the same vulnerability since it uses libraries from the Symfony framework to handle parts of its internal logic [26]. Even if Drupal developers were not responsible for the code that leads to the vulnerability, their application could still be exploited since Symfony was an external dependency. Even more interestingly, an analysis of the official Symfony patch on GitHub [27] reveals that the vulnerable lines were derived from yet another framework called Zend [31]. This shows that the structure of web applications can be very complex with code reuse originating from many different sources. Even if developers take all possible precautions to minimize vulnerabilities in their own code, flaws from external dependencies can cascade and lead to a critical entry point for an attacker.

Overall, there are clear benefits that debloating could have on web applications. Assuming that we are able to pinpoint all the code that is required by the users of a given software deployment, all other code (including the code containing vulnerabilities) can be removed from that deployment.

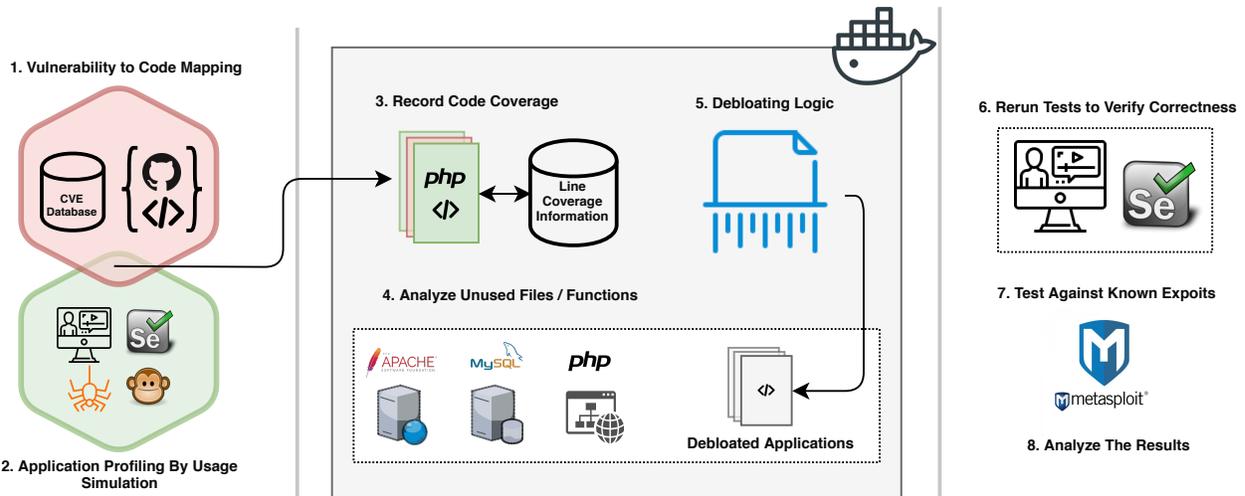

Figure 1: Overview of the architecture of our pipeline for debloating web applications and assessing the effects of different debloating strategies.

### 3 Setup

In this section, we describe the process of gathering information regarding known vulnerabilities (in the form of CVEs) for web applications, designing and executing tests against web applications of interest, and identifying the server-side code that was executed as a result of client-side actions.

#### 3.1 Overview

The setup for our framework is depicted in Figure 1. To debloat target applications, we first collect information about the vulnerabilities of the applications that we analyze in our study. This information includes the files, functions, and line numbers where each vulnerability resides (Step 1, Section 3.3). Then, we simulate usage of the application through a combination of different techniques (Step 2, Section 3.4). Using a PHP profiler tool (XDebug), we record the lines, functions, and files, that are triggered during the simulation (Step 3, Section 3.5).

In the middle part of our pipeline, the debloating engine takes both the target applications and coverage information to perform debloating at different levels of granularity, and rewrite parts of the application to remove unused pieces of code based on the debloating strategy being evaluated (Steps 4 and 5, Section 4). Our framework also provides a complete reporting panel to assist human analysts in understanding which vulnerabilities can be removed by the present debloating strategies.

Last, we verify the correctness of our debloating process by running a set of tests against the debloated web applications, and verifying that no removed piece of code is triggered (Step 5). To this end, we utilize assertions in place of the removed code blocks. An absence of error messages from these assertions means that all tests were successfully completed without triggering any missing server-side code. As an final step of verification, we also test the debloated applications against a series of exploits and verify that exploits which abuse any of

the vulnerabilities that were removed as part of the debloating process, do not succeed (Step 6, Section 5.6).

To ease integration and facilitate the analysis of new web applications, we adopted a modular architecture that relies on three Docker containers. The *Application* container hosts our web applications. The profiler enabled on its web server is responsible for collecting code coverage information. The *Database* container runs a MySQL server that stores the code coverage information along with the databases of the tested applications. Lastly, the *Debloating* container which includes our debloating logic, analyzes the coverage information and generates debloated versions of applications. It also provides a reporting panel that indicates which vulnerabilities are removed in each application after debloating. To add a new vulnerability, a user simply has to provide the details of the vulnerable file(s) and line(s).

#### 3.2 Analyzed web applications

To understand how the process of debloating increases the security of web applications, we decided against using toy-like web applications. Instead, we focused on established open-source applications with millions of users, and the presence of a sufficient number of known historical vulnerabilities (in the form of CVEs) to allow us to generalize from them. To this end, we selected phpMyAdmin [60], MediaWiki [59], Magento [58], and WordPress [75], which are representative samples of four different types of web applications namely web-administration tools, wikis, online shops, and blogging software. Table 1 shows the versions of these web applications that we utilized, in order to map CVEs to the location of the vulnerability in the source code of each application.

#### 3.3 Vulnerability to source-code mapping

To determine whether debloating web applications can actually remove vulnerabilities, we performed a mapping of known CVEs

*Table 1: Analyzed open-source web applications.*

| Web Application | Version                            | Known CVEs<br>( $\geq 2013$ ) |
|-----------------|------------------------------------|-------------------------------|
| Magento         | 1.9.0, 2.0.5                       | 10                            |
| MediaWiki       | 1.19.1, 1.21.1, 1.24.0, 1.28.0     | 111                           |
| phpMyAdmin      | 4.0.0, 4.4.0, 4.6.0, 4.7.0         | 130                           |
| WordPress       | 3.9.0, 4.0, 4.2.3, 4.6, 4.7, 4.7.1 | 131                           |

to the vulnerable lines, functions, and files, that they exploit in each application. This way, by looking at an application after debloating, we can determine if the files, functions, or lines responsible for the vulnerability, are still present or were removed during the debloating process.

Even though there exist multiple databases listing the current and historical CVEs of popular software (including the web applications in question) [36, 37], locating the actual source code containing the vulnerability described in a CVE, is a non-trivial process which requires careful investigation. In some cases, the right patch can be discovered because of a direct reference to a CVE in a commit message, or in a bug report on official public repositories of web applications. For others, the fix is included within numerous commits that have to be carefully analyzed to locate the appropriate lines of code. Since a vulnerability can span over multiple lines, functions, and even multiple files, we record all affected locations in a database so that this information can be later correlated with each evaluated application.

Given the time-consuming nature of mapping CVEs to existing code, for this study, we limited ourselves to, at most, 20 CVEs per application of interest. The complete list of CVEs we mapped for this study can be found in Table 9 in the Appendix. To select these CVEs, we ordered existing vulnerabilities by their CVSS score (thereby selecting the ones that are the most critical) and we did not consider vulnerabilities that were reported before 2013. This focus on fairly recent vulnerabilities (i.e. in the last five years) makes our results more generalizable to the current state of web applications, as opposed to quantifying vulnerabilities in source-code which has since dramatically evolved. Note that, because not all versions of a web application are vulnerable to all evaluated CVEs, we had to map vulnerabilities across a number of different versions, as shown in Table 1.

### 3.4 Application usage profiling

Modern web applications provide an incredibly wide range of features and options to their users. Even though, from a functional perspective, more features are desirable, from a security perspective, the code that implements new features may contain new vulnerabilities thereby further expanding a program’s attack surface. In order for a system to be able to remove code related to unnecessary features, one must first identify which features are necessary for a target set of users.

Given a usage profile, the goal of our framework is to produce debloated versions of web applications which maintain the code

and features that are part of that profile but remove the rest. To be as objective as possible with what features are considered “necessary,” we utilize four independent sources of web application usage: i) online tutorials describing how to use the applications of interest, ii) web crawlers that autonomously navigate the application, iii) vulnerability scanners that feed malicious content to the application, and iv) monkey testing tools that click on random parts of webpages and type random keystrokes. The combination of all four gives our profiles both breadth (through the crawler and monkey testing) as well as depth (through the user following complicated paths while providing expected inputs and the vulnerability scanner which provides large amounts of malicious inputs trying to exploit the web application).

#### 3.4.1 Tutorials

To simulate common interactions with an application, we use a popular search engine to search for the application’s name followed by the word “tutorials” (e.g. “phpMyAdmin tutorials”) and follow the tutorials from the first two pages of search results.

Specifically, we map each tutorial to a Selenium script that allows us to both execute the same tutorial multiple times and also assess the correctness of the results (e.g. encode that when we delete a database using phpMyAdmin, the deleted database is no-longer shown in the list of databases). Note that this mapping of tutorials to Selenium scripts is yet another time-consuming process which, occasionally, has to be repeated for different versions of the same web application. One change in a form field or in a selector can break the complete flow of a test suite and we observed a significant number of cases with slight interface changes between two consecutive versions of the same application.

Overall, after fine-tuning the scripts for all our tested versions, we obtained 46 tutorials which translated into 302 use cases scripted as Selenium tests requiring 16,025 lines of code. Given our desire for complete reproducibility of our results, we include the complete list of tutorials in the Appendix (Table 8) along with WebArchive links that will remain available despite potential future domain expirations and linkrot of the original URLs [48].

Below, we provide a non-exhaustive list of actions that were part of the followed tutorials of each web application. Full details are available in the actual tutorials and in the Selenium scripts which we will release together with this paper.

**Actions covered by phpMyAdmin tutorials:** As a web administration tool, all phpMyAdmin functionality is protected by an authentication mechanism. We followed the actions described by tutorials when logged in as a root user account with full application access. The Selenium-encoded tutorials cover database operations including creating and dropping databases, filling tables with data, querying, table indexes, and importing/exporting data. They also include administration tasks such as adding new user accounts, optimizing databases, checking database server status, obtaining performance metrics, and accessing server settings such as variables, charsets, and engines.

**Actions covered by MediaWiki tutorials:** MediaWiki provides different features depending on the privileges of the user. Unauthenticated users can only visit and search pages. Registered ones can post and edit content while administrators can perform moderation and management operations. The tutorials that we followed cover all these different use cases. More specifically, actions coded in our tutorials include authentication, creating and renaming pages, importing and exporting content from the wiki, as well as changing settings such as skins, styles, and formatting options.

**Actions covered by WordPress tutorials:** As a blogging software, WordPress has two distinct entry points, one for normal unauthenticated users to read blogs and post comments, and a separate administration panel accessible to privileged and authenticated users. WordPress tutorials mostly focus on administrative tasks since normal users have limited abilities. The Selenium-encoded tutorials include actions such as creating a new post using HTML for the content, modifying most post options (ranging from visibility and tags to setting featured images), as well as downloading and changing WordPress themes. For the administration panel, the tutorials include exporting content, setting up user accounts, and uploading media. Finally, the tutorials include the visiting of posts and the posting of comments as well as the management of comments, such as approving them, marking them as spam, and deleting them.

**Actions covered by Magento tutorials:** Magento is the largest evaluated web application in terms of source code and has the most features compared to the other applications. Similar to WordPress, the tutorials mostly target administration tasks which include store settings, advanced product search options, order notification via RSS, product pricing, currencies and tax rules, delivery and payment methods, emails and notifications, reviews and ratings and cache control. Some tutorials go in even more details by covering product and stock management, managing customers and groups configurations, modifying the UI, creating pages, and using widgets. On the customer side, we followed tutorials that included registration of a new account, authentication actions, and purchasing products until checkout.

### 3.4.2 Monkey testing

Monkey testing is a method for testing software where the simulated user sends random clicks and keystrokes to the target application. This unpredictable behavior can uncover bugs in an application as it can trigger paths and actions that were not anticipated by developers. In our case, we use such a technique to trigger additional code, not covered by tutorials. We observe that this approach adds breadth to the code coverage by reaching easy to access features. In addition, by feeding random key strokes into forms, monkey testing can bring the application in an error state thus exercising error-handling pieces of code.

We rely on the stress-testing library called `gremlins.js` [7] in conjunction with the GreaseMonkey browser extension [6] to inject the library into web application pages. Since this kind of testing can occasionally trigger unwanted actions, we have

to take necessary steps to stop them, e.g., prevent the test from leaving the web application and visiting external websites. We also want to prevent `gremlins.js` from getting trapped on a single page as an unexpected JavaScript dialogue box or a dead end page can pause our test execution. An additional issue is that of accidentally logging out a web application by clicking on a logout link. Given that we run monkey-testing under three different usage profiles (public user, logged-in user, and administrator) we took steps to avoid accidental logouts. Overall, we perform the following modifications: i) we remove all links that lead to external pages, ii) we remove logout buttons for applications that require authentication, iii) we override the aforementioned JavaScript functions and iv) we set a timeout to detect when the monkey is stuck and reset it to a known good state. All these actions are done using injected JavaScript on target pages prior to starting the `gremlins.js` library.

To cover a large set of pages from a web application, we run `gremlins.js` for 12 hours for each of the test profiles. To guarantee the reproducibility of our experiment, we choose a fixed seed for each run that will generate the same sequence of pseudo-random actions.

### 3.4.3 Crawling

Web spiders (also known as crawlers) are a type of bot that follows the links of a web application and optionally submits forms with predefined content. Each newly crawled page is added to a database of the application that the crawler uses to prevent repeated visits to the same pages. For our study, we use BurpSuite Spider v2.0.14beta [2] to crawl our web applications. As a result, we augment the application coverage with code paths that were not triggered, either through the followed tutorials or through monkey testing.

### 3.4.4 Running vulnerability scanners

Vulnerability scanners are tools that try to detect security flaws in web applications. We use BurpSuite Scanner v2.0.14beta [2] based on the URLs extracted by the spider to look for vulnerabilities in headers, URLs and forms. Notably, the scanner tries different injection mechanisms like SQL injection, XSS, PHP file injection, and path traversal, to trigger errors and reach unwanted states in the application. The vulnerability scanner goes beyond what the crawler and the monkey cover by modifying headers and URL parameters. By inspecting the resulting coverage, we observe that each of these four methods result in exercising server-side code that would not have been exercised through the other methods. We quantify this relationship in Section 5.

## 3.5 Recording server-side code coverage

Regardless of the method that is used to interact with a web application, in order to be able to successfully remove unused code (i.e. debloat the web application), we must be able to

associate client-side requests with server-side code. To record the files and lines of code that are triggered by user requests, we make use of PHP profilers.

PHP profilers are available as PHP extensions that modify the PHP engine to collect code-coverage information. There exist a number of different profilers, such as, XDebug [23], phpdbg [16], and xhprof [24] all of which require a similar setup to record code coverage. For our framework, we decided to use XDebug as it is the most mature profiler and is actively maintained.

### 3.5.1 Adding coverage support in a web application

**Connecting a web application to XDebug.** To be able to perform dynamic analysis and record lines of code that are triggered by user requests, our framework must add calls to specific XDebug functions in every PHP file of a web application. Specifically, both `xdebug_start_code_coverage()` and `xdebug_get_code_coverage()` functions are called to, respectively, start and receive coverage information. If the “get” function is never called, the coverage information is lost. In the following paragraphs, we describe challenges related to obtaining the code coverage from XDebug and how we overcame them.

**The case of unrecorded lines.** Boomsma and Gross reported on the possibility of removing unused code in a custom PHP application [34]. By performing dynamic analysis, they observed which files were not used and removed them from their application. The authors utilized their own profiler and took advantage of the `auto_append` built-in function of PHP to add the necessary log functions at the very end of all PHP files [1].

For our study, we initially attempted to use the same approach and ran preliminary tests by appending XDebug function calls at the end of our tested files. However, we discovered that the coverage was incomplete and that some lines were not properly recorded. Given that any PHP file can call the `exit()` or `die()` function at any time to terminate the current script, our XDebug calls which were located at the end of each file, were not always executed thus leading to under-reported code coverage.

### 3.5.2 Main challenges for getting full coverage

**Avoiding early exits.** To overcome the coverage problems due to calls to exit functions, we utilized a specific type of PHP callback functions, called *shutdown* functions. When registered, these functions are triggered after all the code on the page has finished running or after either `exit()` or `die()` functions are called. This way, we are able to obtain the desired coverage information even if a PHP script used one of the aforementioned functions. Interestingly, we also discovered that calls to `exit()` inside a shutdown function prevent the execution of other shutdown functions including the call to collect our own code-coverage information. To correct this issue, we statically analyzed the

evaluated applications and automatically added calls to collect code coverage before these exit calls (e.g. Line 7 in Listing 1).

#### **Getting correct coverage information of shutdown functions.**

Another challenge, in terms of recording correct code-coverage information, is to properly record the executed lines of code inside shutdown functions. As mentioned by the PHP manual [12], shutdown functions are called in the order they were registered. This means that if our own shutdown function is registered first, it will also be triggered first, thereby missing any calls to subsequent shutdown functions present in the same PHP file. To get full coverage, we use the following approach: our own shutdown function will perform a late registration of a final shutdown function that will be added at the very end of the execution queue. This way, we can be certain that the very last shutdown function that will be executed in a script will be our own, providing us with the desired coverage information.

#### **Getting correct coverage information of destructors.**

The final challenge that we faced was to properly record covered lines for all class destructors. PHP uses garbage collection and reference counting to remove objects from memory, whenever they are no longer necessary. However, there is no real way to anticipate when the garbage collector will effectively remove objects during program execution. If objects are destroyed *before* the shutdown functions are executed, our framework has no issue recording them. However, if they are destroyed after, our shutdown functions are incapable of registering the execution of these destructors.

To handle this special case, we rewrote class destructors so that they register themselves while they are executing. Every time a destructor is called, we query the XDebug engine to check whether code-coverage recording is currently in progress. This way, we can determine whether the destructor is called before or after shutdown functions. If the destructor is called after shutdown functions, we dynamically decide to start recording all executed lines within the destructor and save the coverage information when it finishes executing.

**Summary.** As witnessed through the above use cases, collecting the correct code coverage information for a web application is significantly more complicated than one would initially expect. Through the preprocessing of code, and the use of destructors and shutdown functions, we solve the issues that were not even mentioned in prior work and get a precise view of the code that executes at the server side, as a result of user requests. Listing 1 provides an example of concrete modifications in a PHP file. On line 7, we added a code-coverage call before an `exit` which happens inside a shutdown functions to prevent information loss due to early exits. On lines 14 and 17, we wrapped the destructor with code-coverage calls.

```

1 <?php
2 register_shutdown_function("PMA_Response::resp");
3 class PMA_Response {
4     public static function resp() {
5         $buffer->flush();
6         // Prepend original call to exit:
7         collect_code_coverage();
8         exit;
9     }
10 }
11
12 class TCPDF {
13     public function __destruct() {
14         // If called after shutdown_functions
15         // start recording code coverage
16         ...
17         // If called after shutdown_functions
18         // stop coverage
19     }
20 }
21 ?>

```

*Listing 1: Code rewritten by the debloating framework to ensure correct code coverage of corner cases.*

## 4 Debloating web applications

In this section, we briefly describe the evaluated debloating strategies and the steps we took to ensure that the debloated applications remain functional.

### 4.1 Debloating strategies

By combining the simulated usage of a web application (achieved through tutorials encoded in Selenium scripts, web crawlers, monkey testing, and vulnerability scanning) with server-side code profiling, we can identify the code that was executed as part of handling web requests. Consequently, code whose execution was not triggered by any client-side request can presumably be removed since it is not necessary for any of the functionality that is desired by users (as quantified by the utilized usage profiles). In this work, we evaluate the following debloating strategies:

- **File-level debloating:** Given that the source code of web applications spans tens or hundreds of different files, we can completely remove a file, when none of the lines of code in that file were executed during the stimulation of the web application.
- **Function-level debloating:** In function-level debloating, not only can we remove entire files but we can also selectively remove some of the functions contained in other files. This is a more fine-grained approach which allows us to remove more code, than the more conservative, file-level debloating strategy.

More fine-grained approaches are possible, such as, the removal of specific code statements from retained functions which were not exercised during stimulation. However, such changes essentially modify the logic of a function (e.g. removing conditional code blocks) thereby increasing the probability of breaking the resulting program when a minute change of a client-side request would lead the execution into these blocks of code.

### 4.2 Detecting the execution of removed code

We replace all removed functions and files with placeholders which, if executed, have the following tasks:

- **Exit the application:** If a placeholder happens to be triggered, the PHP application will start its shutdown procedures. This way, the application does not enter an unexpected state that was not planned by the debloating process.

- **Record information about the missing function:** In order to better understand which missing placeholders were triggered and how, our framework logs several pieces of information, such as, the URL that triggered the execution of the removed code, the name of the class and function of the removed code, and the corresponding line numbers.

To ensure that the debloating process has preserved the functionality of the debloated web application, we rerun all the Selenium-mapped tutorials and monkey scripts after the debloating stage. If our placeholder code for removed files and functions executes during this stage, this means that this code should not have been removed.

This feedback mechanism proved invaluable during the development of our framework since it helped us identify problems with our coverage logic which in turn revealed the challenges that we described in Section 3.5.2.

## 5 Results

To assess the impact of debloating web applications, we analyze our results from a number of different perspectives. First, we show the contributions of different application-profiling methods and then compute different metrics to understand the effectiveness of debloating in terms of reducing the attack surface of our tested applications. Next, we focus on CVEs to determine whether debloating can actually remove critical vulnerabilities. Then, we take a closer look at the bloat introduced by external packages along with the security implications that come with using this specific development practice. Finally, we look at what has effectively been removed in debloated applications and test a number of exploits against the original and debloated versions of the evaluated web applications.

### 5.1 Tutorials vs. Monkey Testing vs. Crawling vs. Vulnerability Scanning

As described in Section 3.4, to ensure that we exercise web applications in an objective and repeatable way, we utilized tutorials, monkey testing, crawlers, and vulnerability scanners. Figure 2 shows the coverage, in terms of server-side files, that each method obtained on the latest version of each web application in our testbed. We can clearly see that all four methods are required, with each method contributing differently for different web applications. For example, tutorials trigger

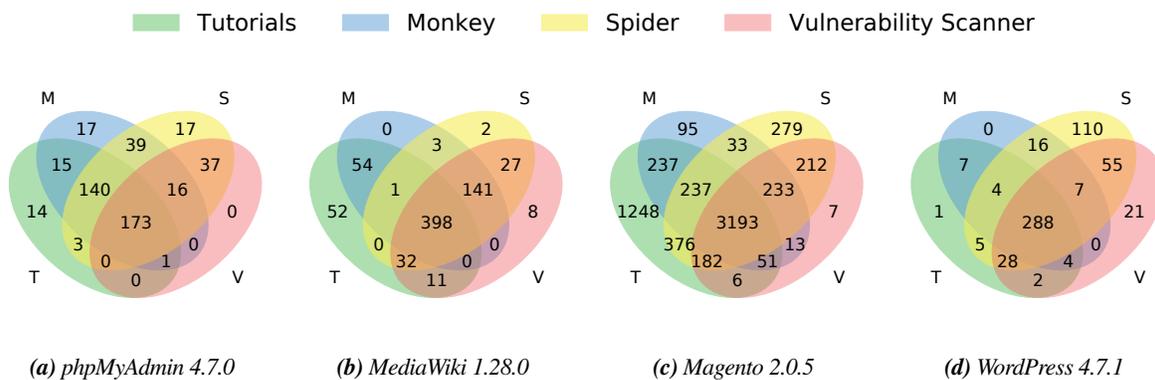

Figure 2: Venn Diagrams showing covered files during the execution of Tutorials, Crawler, Monkey testing and Vulnerability scanner

more files in Magento compared to other applications, while Spider covers most unique files in WordPress.

## 5.2 Debloating by the numbers

To evaluate the effectiveness of our two debloating strategies, we computed different metrics that provide insights into what has actually been removed during the debloating process.

### 5.2.1 Logical lines of code

The size of a program positively correlates with the number of programming errors (i.e. bugs). According to McConnell [55], the industry average, at least in 2004, was to have between 1 and 25 bugs for every one thousands lines of code. Given the importance of the size of an application to its overall security, we start by estimating the reduction of the attack surface by looking at the Logical Lines Of Code (LLOC, sometimes also called Effective Lines Of Code). LLOC is intended to measure lines of code without comments, empty lines and syntactic structure required by the programming language. LLOC reduction is a robust and precise indicator of how much the volume of the code was reduced. Figure 3 reports on the LLOC for all versions of the applications we debloated.

**Number of logical lines over time.** Looking at the number of LLOC of the original applications, we can observe two different evolution behaviors. For WordPress, the amount of code is stable and there is even a small decrease of 2% of LLOC between versions 4.7 and 4.7.1. For the other applications, we observe the opposite where the source code in the latest versions spikes, compared to the ones released just before them: 82% LLOC increase for phpMyAdmin, 99% for MediaWiki, and 171% for Magento. By analyzing the code of these newer versions in an attempt to understand their sudden expansion in size, we discovered that these spikes can be attributed to a change in development practices, namely the reliance on external packages. As WordPress does not rely on external packages, it does not

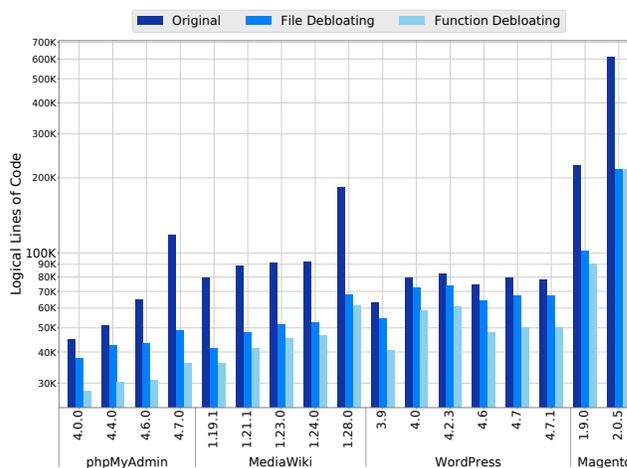

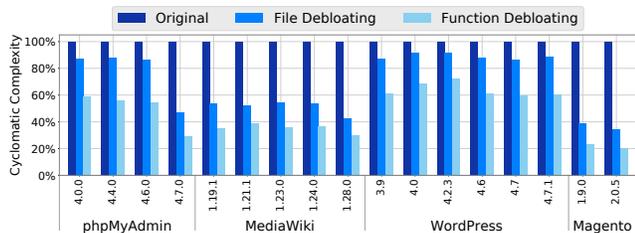

Figure 3: Logical Lines of Code before and after debloating

exhibit this kind of behavior. We discuss the issue of relying on external packages in more detail in Section 5.4.

**File-level debloating.** Overall, file-level debloating, the most conservative of the two evaluated debloating strategies, is already effective in reducing the number of LLOC with an average of 33.1% reduction. The minimum observed in our experiment is 9.2% for WordPress v.4.0 and a maximum of 64.5% for Magento v.2.0.5. For Magento, this reduction represents a removal of 393K lines of code. This number is a clear sign that large web applications encompass many different features that may not be used by all users and therefore result in bloated applications with an unnecessarily large attack surface. At the same time, it is worthwhile repeating that all debloating results presented in this section are conditional to how web applications are used. Therefore, these large levels of debloating cannot be guaranteed for all possible deployments of web applications. We discuss this issue in Section 7.

**Figure 4:** Evolution of cyclomatic complexity before and after debloating

**Function-level debloating.** On average, function-level debloating is able to remove 46.8% of lines of code. For both Magento and MediaWiki, it can remove up to 7% more code over file-level debloating. For phpMyAdmin and WordPress, we observe an increase of debloating capability of up to 24%. This larger reduction (compared to MediaWiki and Magento) is mainly due to the differences in software development practices.

Compared to the other tested applications, phpMyAdmin and WordPress are more monolithic with a smaller number of large source-code files. Since file-level debloating only removes files when none of their functions were executed, the monolithic nature of these two applications resists this kind of coarse-level debloating. Contrastingly, Magento and MediaWiki are developed in a much more modular fashion (many small files each responsible for a small number of well-defined tasks) and therefore lend themselves better to file-level debloating. The more fine-grained, function-level debloating bypasses this issue and can therefore reduce the attack surface of a web application, even for more monolithic web applications.

### 5.2.2 Cyclomatic complexity

Next, we look at the evolution of cyclomatic complexity (CC). CC is defined as the number of linearly independent paths through the code of an application [54]. A high CC for a single class implies complicated code that is difficult to debug and maintain [39] and therefore more prone to contain vulnerabilities when compared to code with low CC [52, 69].

Figure 4 reports on the evolution of the overall CC for each tested version in our experiment. File-level debloating decreases CC between 5.9% to 74.3% with an average of 32.5%. Function-level debloating decreases the program complexity between 23.8% and 80.2% with an average of 50.3%. These statistics demonstrate that debloating can remove complex instructions and execution paths in addition to simple ones. Moreover, the difference between file-level and function-level debloating shows that code removal through function-level debloating is much more suited to all kinds of web applications as shown earlier through LLOC reduction achieved via function-level debloating.

**Table 2:** Number of CVEs removed after application debloating

| Application | Strategy            | Total Removed CVEs | Removed Exploitable CVEs |
|-------------|---------------------|--------------------|--------------------------|
| phpMyAdmin  | File Debloating     | 4/20 20 %          | 3/19 15.7 %              |
|             | Function Debloating | 12/20 60 %         | 11/19 57.8 %             |
| MediaWiki   | File Debloating     | 8/21 38 %          | 3/16 18.7 %              |
|             | Function Debloating | 10/21 47.6 %       | 5/16 31.2 %              |
| WordPress   | File Debloating     | 0/20 0 %           | 0/20 0 %                 |
|             | Function Debloating | 2/20 10 %          | 2/20 10 %                |
| Magento     | File Debloating     | 1/8 12.5 %         | 1/8 12.5 %               |
|             | Function Debloating | 3/8 37.5 %         | 3/8 37.5 %               |

## 5.3 Analysis of CVEs

In this section, we investigate the number of removed CVEs after debloating along with the effects of debloating on different vulnerability categories.

### 5.3.1 CVE reduction after debloating

One practical way to measure the security benefits of debloating web applications is to study the effects of debloating on known historical vulnerabilities. If vulnerabilities were part of the core functionality of the program, the evaluated debloating strategies will not be able to remove the code associated with them. However, if some vulnerabilities reside in parts of a web application that are not commonly used, the process of debloating can effectively remove them.

Table 2 compares the effectiveness of debloating strategies by listing the fractions of removed CVEs. We consider a vulnerability to have been successfully removed if all the lines of code and functions associated with that vulnerability were removed during the stage of debloating. This is a conservative approach as one modification performed on a single line could thwart a complete attack. As such, the numbers we report in this section can be interpreted as lower bounds of the actual number of removed CVEs.

In terms of configuration, we selected the default one for each application. However, certain vulnerabilities may not be exploitable under this configuration. For example, there exists 5 CVEs in our dataset for MediaWiki which require file upload functionality to be enabled. Since this option is disabled by default, we make an explicit distinction in the table. “Total Removed CVEs” is the total number of CVEs removed by debloating regardless of whether the vulnerable code is enabled or disabled through a configuration option. “Removed Exploitable CVEs” reports on the CVEs that are reachable under default configurations of target web applications.

On average, we discovered that up to 38 % of vulnerabilities are removed by file debloating whereas 10-60 % are removed by function debloating. As shown in Table 2, function-level debloating can triple (in the case of phpMyAdmin and Magento) the number of removed CVEs, compared to file-level debloating. This behavior can be generalized to web applications that do not have CVE information and demonstrates that the reduction of a web application’s LLOC (Section 5.2.1) and its cyclomatic complexity (Section 5.2.2) translates to a reduction of concrete

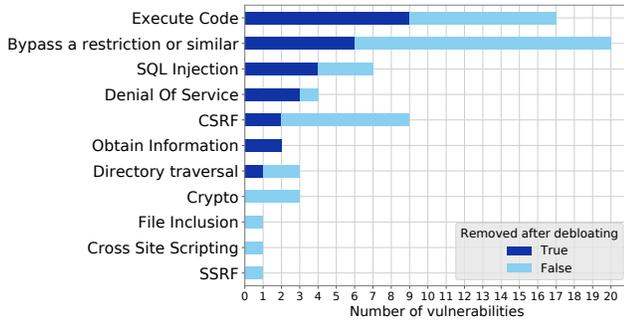

Figure 5: Vulnerability Categories

vulnerabilities. Wordpress is a clear negative outlier with only 10% CVE reduction, even through the more flexible function-debloating strategy. As mentioned earlier, WordPress is a relatively monolithic application and most of our mapped CVEs are located in core WordPress code (e.g., Authentication, CSRF tokens, and post/comment-related actions) which cannot be removed by our debloating framework.

### 5.3.2 Types of CVEs in analyzed web applications

Even though our results demonstrate the ability to remove vulnerabilities from web applications through the use of debloating, one may wonder whether debloating is better suited for some types of vulnerabilities over others. Figure 5 provides details on the categories of the CVEs we removed through debloating.

One can observe that for certain classes of vulnerabilities, such as, Denial-of-Service attacks and Information-Revealing vulnerabilities, debloating can almost completely remove them. For others, such as, restriction bypassing, command execution, and SQL injection, debloating can substantially reduce them. Our interpretation of these findings has to do with the maturity of the evaluated web applications. Specifically, all four web applications have been available for a long period of time, allowing many shallow vulnerabilities to have already been discovered and corrected. The remaining vulnerabilities are likely to be situated in parts of a web application that are less commonly exercised. For example, the code-execution vulnerabilities that can be removed for phpMyAdmin are inside very specific features, such as, the ability to export PHP arrays (CVE-2016-6609), the support of the ZIP extension while importing data (CVE-2016-6633), and the abilities to copy table definitions (CVE-2013-3238) and perform Regex search and replace over table columns (CVE-2016-5734).

Contrastingly, the three cryptography-related vulnerabilities we analyzed are still present in the debloated versions of web applications. One of the CVEs related to this category is about a flaw in the cookie encryption algorithm in phpMyAdmin (CVE-2016-6606). Since every page interacts with user cookies to, at the very least, verify them, vulnerable code cannot be removed. Another vulnerability in this category relates to an insecure random number generator used in cryptographic

operations by Magento (CVE-2016-6485). This vulnerability exists in a constructor of the main encryption classes which is widely used throughout the application. When considered together, these findings suggest that cryptography-related vulnerabilities are a core part of web applications and thus unlikely to be removed through the process of debloating.

## 5.4 External packages

### 5.4.1 Quantifying the bloat from external packages

In our testbed, phpMyAdmin v.4.7.0, MediaWiki v.1.28.0 and Magento v.2.0.5 rely on external dependencies that can be downloaded via Composer (WordPress does not rely on external packages). As described in Section 2, Composer is a package manager for PHP (similar to the NPM manager for NodeJS applications) which allows web applications to specify which external packages they rely on and have these packages be tracked and updated.

As we briefly discussed in Section 5.2.1, the number of LLOC of these three specific versions dramatically increases (compared to prior versions) because of this dependency on external packages. Table 3 provides statistics on the number of packages pulled by these applications and how much bloat they provide against our usage profiles.

First, one can observe that external packages introduce a large amount of unused code. For all three debloated applications, more than 84% of their code was removed from them. This means that the attack surface is unnecessarily large through the dependency on external packages. The number of removed lines from external packages for Magento is particularly noteworthy with more than 178,000 lines of code removed. Moreover, the number of packages that can be completely removed is also quite large: 84% for phpMyAdmin, 60% for MediaWiki and 81% for Magento. This confirms that most packages are unnecessary for the usage profiles that we recorded. Finally, focusing exclusively on the lines of code, phpMyAdmin is the only application where external packages have more lines than the main application. However, after debloating, this relationship is reversed with the codebase of phpMyAdmin being three times the size of the introduced external packages.

Despite the advantages of using package managers (e.g. the ability to track dependencies and update vulnerable libraries without the need to update the main application), our findings show that these advantages come at a considerable cost in terms of unnecessarily expanding the attack surface of a web application with code that is seldomly executed. As such, developers must take special care to include the bare minimum of external packages, knowing the unwanted side-effects that each external package brings.

### 5.4.2 Removing POI gadgets

**What are POI gadgets?** Property Oriented Programming (POP) is an exploitation technique in PHP which works similarly to Return Oriented Programming (ROP) [67] and is used to exploit

**Table 3:** Statistics on the external packages included in web applications and the effects of debloating in terms of reducing their LLOC.

| Application      | Before debloating           |                     |            | After function-level debloating |                     |                               |                                               |               |      |
|------------------|-----------------------------|---------------------|------------|---------------------------------|---------------------|-------------------------------|-----------------------------------------------|---------------|------|
|                  | # lines in main application | # lines in packages | # packages | # lines in main application     | # lines in packages | # packages completely removed | # packages where a given % lines were removed |               |      |
|                  |                             |                     |            |                                 |                     |                               | >70%                                          | <70% and >30% | <30% |
| phpMyAdmin 4.7.0 | 35,739                      | 82,604              | 45         | 26,377 (-26.2%)                 | 9,653 (-88.3%)      | 38 (84.4%)                    | 2                                             | 1             | 4    |
| MediaWiki 1.28.0 | 133,019                     | 50,898              | 40         | 54,827 (-58.8%)                 | 6,285 (-87.7%)      | 24 (60.0%)                    | 2                                             | 2             | 12   |
| Magento 2.0.5    | 396,448                     | 212,906             | 71         | 181,696 (-54.2%)                | 34,038 (-84.0%)     | 58 (81.7%)                    | 6                                             | 5             | 2    |

PHP Object Injection (POI) vulnerabilities [11]. In this technique, the attacker creates exploit gadgets from available code in the applications. By chaining multiple gadgets within the application, an attacker can usually run arbitrary code, write to arbitrary files, or interact with a database. Dahse et al. have studied the automatic generation of such gadget chains for PHP applications [38].

**PHP unsafe deserialization.** The PHP language gives developers the ability to serialize arbitrary objects in order to store them as text, or transfer them over the network. Deserialization reverses this process, generating PHP objects from serialized data. This mechanism can be abused by an attacker to load specific classes in the application and build a gadget chain. Practical examples of this vulnerability are when `unserialize` is called on a database field or value of a field within a cookie that can be manipulated by the users.

Historically, this attack was very difficult to successfully execute. Attackers could only build gadgets with the classes that were present in the context of the vulnerable file. They needed insights into how the application was built in order to know which classes could be abused for gadgets. However, starting from PHP 5, the `__autoload()` magic function [10] was introduced and unintentionally made exploitation of deserialization vulnerabilities easier. This new loading feature was beneficial for PHP developers who did not have to manually include all the files they wanted to use at the very top of each of their PHP files. It also helped the adoption of package managers like Composer, as any external dependency could be easily called from anywhere in the application. The downside of this new function was that it also allowed attackers to instantiate any PHP class across the entire application thereby enabling the easier construction of gadget chains.

In order to build a chain, attackers use these so-called “magic” functions [13] that form the basis of their gadget chain. One of the functions that is widely used in POI exploits is the `destruct` function. In Section 3.5, we detailed the challenges in getting complete coverage of destructors in our tested applications. Accurate coverage of destructors also allows us to precisely analyze the impact of debloating on gadget creation.

### Can debloating remove gadgets from external packages?

Given the increased footprint of web applications due to their reliance on package managers and external dependencies, one may wonder about the possibility of abuse of these packages for

**Table 4:** List of packages with known POP gadget chains

| Application      | Package       | Removed by Debloating |          |
|------------------|---------------|-----------------------|----------|
|                  |               | File                  | Function |
| phpMyAdmin 4.7.0 | Doctrine      | ✓                     | ✓        |
|                  | Guzzle        | ✓                     | ✓        |
| MediaWiki 1.28.0 | Monolog       | ✓                     | ✓        |
| Magento 2.0.5    | Doctrine      | ✓                     | ✓        |
|                  | Monolog       | ✗                     | ✓        |
|                  | Zendframework | ✗                     | ✓        |

the creation of gadgets. To measure the effect of debloating on Property-Oriented-Programming (POP) gadgets, we utilized the PHPGGC [17] library. PHPGGC (which stands for PHP Generic Gadget Chains) contains a list of known gadgets in popular PHP packages such as Doctrine, Symfony, Laravel, Yii and Zend-Framework. When a vulnerable PHP application includes any of the packages listed in PHPGGC, the attackers can generate gadget chains to achieve RCE, arbitrary file writes, and SQL injections.

We analyzed the available gadget chains in PHPGGC and checked whether any of our tested PHP applications included these chains. Table 4 summarizes the presence of each gadget and whether debloating removes them or not. WordPress is not included in this table because it does not rely on external packages. This does not make WordPress immune to POI attacks, but universally known gadget chains in popular external packages can not be used to exploit WordPress. For the affected applications, file-level debloating removes 4/6 gadgets while function debloating removes 6/6 available gadget chains. This again demonstrates the power of debloating which can not only remove some fraction of vulnerabilities but also make the exploitation of the remaining ones harder by removing the gadgets that attackers could abuse during a POI attack.

### 5.4.3 Utilizing development packages in production

During our analysis of external packages, we identified yet another source of bloat in new versions of web applications. When declaring external dependencies through Composer, two options are available: “require” and “require-dev”. The first option indicates packages that are mandatory for the application to run properly. The second lists packages that should only be used in development environments, such as, packages providing

support for unit testing, performance analysis, and profiling. We discovered that applications downloaded from official websites often include these development packages. As such, when these packages are used to deploy web applications in production mode, they will contain unnecessary development libraries. This does not only increase the attack surface by having unnecessary code bloating the application, but can also lead to exploitation for misconfigured applications.

CVE-2017-9841 presents one example of such a vulnerability [25]. Specifically, this CVE refers to an RCE attack in specific versions of the PHPUnit library, which is a popular unit testing library for PHP. By default, Composer places all external packages under “vendor” directory. If this specific directory happens to be accessible through a misconfiguration of the server, PHPUnit files are then accessible and can be exploited to conduct an RCE attack.

The four web applications that we evaluated for this study, present different behaviors with respect to development packages. WordPress does not rely on external packages downloaded through Composer. MediaWiki never included development packages in its releases. phpMyAdmin had them in version 4.7.0 but stopped including them in version 4.8.3 (the latest at the time of writing). Magento started including them from version 2.0 and still includes them today. We have reached out to Magento and informed them about this issue.

## 5.5 Qualitative analysis of the removed code

In the previous sections, we analyzed the effects of debloating on the source code of applications from a software-engineering perspective (i.e. LLOC and Cyclomatic Complexity reduction) as well as from a security standpoint (i.e. number of CVEs and gadgets removed). At the same time, one may wonder what exactly was removed from each application during the process of debloating.

Given that thousands of files were removed, manually analyzing each file does not scale. As such, we turn to NLP techniques that allow us to cluster the removed files together and provide us with hints about the nature of each cluster. Specifically, we use the k-means clustering algorithm based on text vectors extracted from removed file names and file paths. Each file path includes directories that indicate which library or package, the file belongs to. For most modern web applications, this allows for a reasonable separation of files across different application plugins and modules. To end up with meaningful clusters, we tuned TFIDF vectorizer parameters along with the number of k-means clusters. We used the TFIDF maximum frequency limit to ignore common terms appearing in more than 50% of the files. Depending on the size and modularity of the application, 10 to 20 clusters yielded the most instructive grouping of files.

Table 5 shows the categories of the three largest removed clusters from each web application. Across all four applications, we observe the removal of source code related to external packages (e.g. Symfony for phpMyAdmin, Elastica for MediaWiki, and

**Table 5:** Features and external packages with the most removed files after file debloating (removed features are marked in *italic*). Entries marked with \* are packages that are indirectly pulled by other “require-dev” packages (not used by core application) for the purpose of test coverage reporting and coding standard enforcement.

| Applications            | Features/Packages with most files removed                                                                                                                               |
|-------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>phpMyAdmin 4.7.0</i> | 1) Guzzle [8]: “Generating API HTTP response” *<br>2) Symfony [20]: “Parsing configuration files” *<br>3) PHP_CodeSniffer [15]: “Enforcing coding standards” *          |
| <i>MediaWiki 1.28.0</i> | 1) <i>Messages &amp; Languages</i><br>2) Less.php [9]: “Generating CSS code”<br>3) Elastica [5]: “Elastic search interface used by extensions”                          |
| <i>WordPress 4.7.1</i>  | 1) Twentyfourteen theme [21]<br>2) Twentytwo theme [22]<br>3-4) Also theme related<br>5) <i>Multi-site administration</i>                                               |
| <i>Magento 2.0.5</i>    | 1) Zendframework1 [14]: “Generating web pages and database operations”<br>2) <i>Sales, Orders &amp; Credit Memo</i><br>3) <i>Internal framework filters &amp; Views</i> |

Zendframework1 for Magento), followed by localization/theme files (e.g. twentyfourteen theme for WordPress), and unused database drivers. We provide more application-specific details of removed features in the next paragraphs.

**phpMyAdmin’s** removed features include the uploading of plugins, GIS visualizations, and unused file formats used in import/export (such as, Dia, EPS, PDF, SVG, and ZIP). In addition, debloating removed unused plugins and external packages which make up the top 3 features removed from this web application as shown in Table 5. phpMyAdmin version 4.6.0 and 4.7.0 include unit tests which are also removed by our system. The LLOC for the removed test files is less than 2% of the whole code base of the application.

**MediaWiki** provides an API to interact with the wiki which is separate from the regular web interface that users interact with. Most actions within this API, including queries, file upload, and non-default output formats for this API were removed. Top categories of removed files consist of localization of messages and language files in addition to external dependencies (Lines 2 and 3) as listed in Table 5. The debloating process also removes file-upload modules which are disabled, by default, in MediaWiki. It is important to note that even if a module is “disabled,” the code still resides on the server and could be abused by specific types of attacks. For example, in a recent attack against a WordPress plugin, the vulnerability could be exploited even if that plugin was disabled [32]. Debloating *removes* the source code of disabled and unused features and therefore does not suffer from this type of attack. Finally, the process of debloating, removed unused extensions of Mediawiki (e.g. citation, input box, pdf handler, poem and syntax highlighting). Mediawiki 1.19.1 and 1.28.0 include unit tests, and they measure less than 1.5% of LLOC in the whole code base of their respective versions.

**WordPress** takes a slightly different approach where the core functionality is concentrated in a relatively small number

**Table 6:** Verifying exploitability of vulnerabilities by testing exploits against original & debloated web applications

| CVE            | Target Software  | Exploit Successful? |           |
|----------------|------------------|---------------------|-----------|
|                |                  | Original            | Debloated |
| CVE-2013-3238  | phpMyAdmin 4.0.0 | ✓                   | ✓         |
| CVE-2016-5734  | phpMyAdmin 4.4.0 | ✓                   | ✗         |
| CVE-2014-1610  | MediaWiki 1.21.1 | ✓                   | ✓         |
| CVE-2017-0362  | MediaWiki 1.28.0 | ✓                   | ✗         |
| CVE-2018-20714 | WordPress 3.9    | ✓                   | ✓         |
| CVE-2015-5731  | WordPress 4.2.3  | ✓                   | ✓         |
| CVE-2016-4010  | Magento 2.0.5    | ✓                   | ✗         |
| CVE-2018-5301  | Magento 2.0.5    | ✓                   | ✗         |

of large PHP files. The removed features of WordPress include installation files, unused modules (FTP, multi-site, user registration), disabled themes and update files (note that we could not exercise update files during our tests because this would change the version of the evaluated web application and create inconsistencies in our analysis of removed CVEs). In terms of testing, the installation files that we obtained from the WordPress website do not contain any unit tests.

**Magento** consists of both external packages and internal modules. We observed that various internal modules were removed, including an XML API for mobile, wishlists, ratings, and specific payment modules (such as, Paypal). Since many packages and internal modules include the terms “sales,” “orders,” and “tax,” these individual files across multiple modules were clustered into the same category by k-means. Finally, Magento 1.9.0 does not include unit tests while the test files included in Magento 2.0.5 and its external packages measure up to 15% of its code base. For Magento 2.0.5, Zendframework1 which is an external dependency has most of its files removed by debloating.

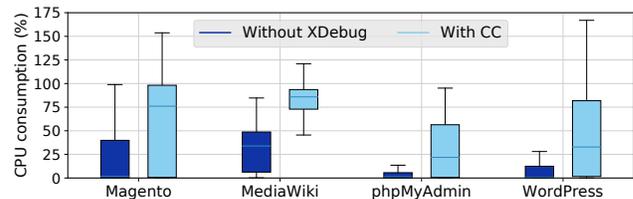

## 5.6 Testing debloated web applications against real exploits

To ensure the correct mapping of CVEs to source code and the ability of debloating to stop real attacks, we collected 4 exploits available in the Metasploit framework and augmented them with 4 POCs that we developed based on public bug-tracker records and vulnerability details. After verifying that we can successfully exploit the original versions of the evaluated web applications, we tested the same exploits on the debloated versions. Half of the previously successful exploits failed because the vulnerable code was removed during the process of debloating. Table 6 lists the tested exploits against original and debloated applications.

As before, this demonstrates that while debloating is not a panacea against all possible issues, it can substantially improve the security of web applications. Finally, we present a demonstration of CVE-2016-4010 on Magento 2.0.5 in the following video: <https://vimeo.com/328225679>.

**Table 7:** Measurements of the execution time, the CPU and memory consumption for the tested web applications with XDebug and Code Coverage (CC) and without XDebug. The reported values for the CPU and memory correspond to the average for each application.

| Application      |                | Execution (s) | CPU (%)      | Memory (%)    |
|------------------|----------------|---------------|--------------|---------------|
| Magento 2.0.5    | Without XDebug | 317           | 21.7         | 10.7          |
|                  | With CC        | 584 (x1.85)   | 56.9 (x2.62) | 11.82 (x1.10) |
| MediaWiki 1.2.8  | Without XDebug | 36            | 30.7         | 5.2           |
|                  | With CC        | 121 (x3.38)   | 79.3 (x2.58) | 6.9 (x1.31)   |
| phpMyAdmin 4.7.0 | Without XDebug | 102           | 3.7          | 5.7           |
|                  | With CC        | 116 (x1.14)   | 31.5 (x8.47) | 5.6 (x0.97)   |
| WordPress 4.7.1  | Without XDebug | 68            | 8.2          | 8.2           |
|                  | With CC        | 170 (x2.50)   | 42.6 (x5.22) | 12.5 (x1.53)  |

**Figure 6:** Measurement of the CPU consumption for the tested web applications. 100% corresponds to the use of a single CPU core.

## 6 Performance analysis

It is known that code-coverage tools impose a non-negligible overhead on web applications [65]. In this section, we report on the results of conducting all the Selenium tests with and without XDebug (our chosen PHP profiler) while measuring execution time, and recording server-side CPU usage and memory consumption. Table 7 presents the overall results and Figure 6 focuses on CPU consumption.

First, looking at the execution time, we can see that code coverage has a varying impact on the tested web applications. On one hand, phpMyAdmin is lightly affected with a 14% increase. On the other hand, the time it takes to run all tests for MediaWiki has tripled. For CPU consumption, the overhead is noticeable and all applications at least double their use of resources when code coverage is active. phpMyAdmin is exhibiting the biggest performance hit with a reported average almost 9 times higher than the one from the base application. Figure 6 shows that all median values are higher for applications with XDebug and most applications, at some point, require a second core with values above 100%. Finally, in terms of memory consumption, the server-side code profiler incurs a relatively modest increase for most applications. The worst overhead is observed when evaluating WordPress with an increase of 4.3% of the total device memory (16GB), i.e., an additional 700MB of RAM.

Even though our results show that the overall overhead is substantial, it is important to note that this overhead is not the overhead of the debloated web applications. Debloated web applications do not require code-coverage statistics and will therefore execute in the exact same environment as the original application (i.e. without XDebug). Depending on how code-coverage infor-

mation is obtained, this overhead may or may not be an issue. For example, if the coverage is calculated in an offline fashion where traces of application usage are replayed against a testing system, this overhead will have no impact on the real production systems. To allow for the online computation of code coverage (using real-time user traffic), we need more optimized code profilers. For example, XDebug currently overloads 43 opcodes to obtain line-level code-coverage information that is more fine-grained than required by our debloating techniques and incurs an unnecessary performance overhead [64]. We leave the development and evaluation of faster code profilers for future work.

## 7 Limitations and future work

In this study, we set out to precisely quantify the security benefits of debloating, when applied to web applications. Through a series of experiments, we demonstrated that debloating web applications has a number of very concrete advantages. We showed that debloating can, on average, decrease an application's code base by removing hundreds of thousands of lines of code, reduce its cyclomatic complexity by 30-50% and remove code associated with up to half of historical CVEs. Moreover, even for vulnerabilities that could not be removed, debloating can remove gadgets that makes their exploitation significantly harder. Next, we discuss some of the inherent and technical limitations of our approach and future direction.

**Lack of available exploits:** The number of exploits publicly available compared to the total number of registered CVEs is low. At the same time, the effort to study vulnerability reports, find the relevant patch or bug report, and track the actual vulnerability down to source code level takes a non-negligible amount of manual labor. This lack of available exploits limits our ability to test the exploitability of vulnerabilities before debloating since certain vulnerabilities might only be exploitable under specific configurations. For example the set of five file-upload-related vulnerabilities in our MediaWiki dataset (marked as gray in Table 9) require access to file upload functionality which is disabled by default. A maintained set of automated, replayable exploits against popular web applications similar to "BugBox" introduced by Nilson et al. in 2013, could substantially help researchers at this step [57].

To address this issue, we mapped the CVEs to features within those applications. This is done by studying the architecture of target applications based on documentation within the code and available on their websites. We marked a CVE as unexploitable if the underlying feature is disabled by default, and online tutorials in our dataset do not require users to enable that functionality. This limitation only applies to reported numbers on removed CVEs and does not affect our results on POI gadgets since their mere existence is enough for them to be used in gadget chains.

Our approach results in lower bounds for CVE removal since disabling modules through application configuration does not guarantee removal of all code paths that trigger those modules. Taking CVE-2019-6703 as an example, a vulnerability was

discovered in the WordPress "Total Donations" plugin [32] and disabling this plugin did not prevent attackers from invoking the vulnerable end point and running their exploits.

**Dynamic code coverage:** Given our reliance on dynamic code-coverage techniques, it is clear that the success of debloating a web application is tightly related to its usage profile. Even though we constructed profiles in a way that is reproducible and unbiased (i.e. by relying on external popular tutorials, monkey testing, crawlers, and vulnerability scanners), we cannot claim that real web users would not trigger code that was removed during the stage of debloating, while they are interacting with a debloated web application.

More specifically, our modeled usage profiles do not cover all possible benign states of target web applications as we assume that users do not use all available features. Our intuition behind debloating proves to be successful to a large degree since removing unnecessary features brings clear security improvements. At the same time, our current usage model may not cover deep error states (e.g. logical errors in multi-stage form submissions, or the invalid structure of uploaded files). As such, we intend to follow-up this work with crowd sourcing and user studies to understand how administrators, developers, and regular users utilize the evaluated web applications and whether their usage profiles would allow for similar levels of debloating.

Due to nature of our approach, we can not take advantage of standard static-analysis techniques, since we aim to remove the features that are not useful for a given set of users, not those that are not reachable by other code. Using static analysis would greatly overestimate the code that needs to be maintained through the process of debloating and the resulting web application would contain code (and therefore vulnerabilities) that is not useful to all users. Going forward, we envision a hybrid approach where dynamic analysis is used as a first step to identify the core features that are useful for a specific set of users. These features can then be used as a starting point for a follow-up static analysis phase to ensure that all code related to these features is maintained when debloating a web application.

**Handling requests to removed code:** A separate issue is that of handling requests to removed code. Our current prototype utilizes assertions to log these requests so that we can investigate why the corresponding server-side code was not captured by our coverage profiler. When real users utilize debloated web applications, one must decide how these failures (i.e. client-side requests requiring server-side code that was removed) will be handled. Assuming that cleanly exiting the application and showing an error to the user is not sufficient, we need methods to authenticate the user's request, determine whether the request is a benign one (and not a malicious request that aims to exploit the debloated web application) and potentially re-introduce the removed code. The client/server architecture of web applications lends itself well to this model since the web server can decide to re-introduce debloated code and handle the user's request, without any knowledge of this happening from the side of

the user. All of this, however, requires server-side systems to introduce the code at the right time and for the appropriate users. We leave the design of such systems for future work.

**Metrics to measure debloating effectiveness:** In this paper, we use Cyclomatic Complexity (CC), Logical Lines of Code (LLOC), reduction in historical CVEs, and POP gadget reduction as four metrics to measure the effects of debloating on different web applications. However, not every line of code contributes equally to a program's attack surface. For example, 15% of removed files from Magento 2.0.5 are test files for external packages and the core of the application. Such code may not be directly exploitable or used in a POP chain unless there is a misconfiguration (e.g., autoloading including these files, or the directories being publicly accessible). As such, the resulted reduction in source code metrics (CC and LLOC) may also reflect the code that does not contribute to the attack surface. Contrastingly, the reduction of exploitable CVEs draws a more realistic picture of real world attacks. The drawback of this metric is its unavailability for proprietary software and the manual effort required to map CVEs to source code and verify their exploitability.

**Debloating effectiveness:** Through our debloating experiments we discovered that, in terms of debloating, not all applications are "equal." Modular web applications debloat significantly better than monolithic ones (such as Wordpress). We hope that our findings will inspire different debloating strategies that lend themselves better to monolithic web applications which resist our current function-level and file-level debloating strategies.

## 8 Related work

Over the years, different approaches that target very different parts of the software stack have been studied in the context of software debloating.

### 8.1 Debloating for the web

Despite the importance of the web platform, there has been very little work that attempts to apply debloating to it. Snyder et al. investigated the costs and benefits of giving websites access to all available browser features through JavaScript [70]. The authors evaluated the use of different JavaScript APIs in the wild and proposed the use of a client-side extension which controls which APIs any given website would get access to, depending on that website's level of trust. Schwarz et al. similarly utilize a browser extension to limit the attack surface of Chrome and show that they are able to protect users against microarchitectural and side-channel attacks [66]. These studies are orthogonal to our work since they both focus on the client-side of the web platform, whereas we focus on the server-side web applications.

Boomsma et al. performed dynamic profiling of a custom web application (a PHP application from an industry partner) [34]. The authors measured the time it takes for their dynamic profile system to get complete coverage and the percentage of files that

they could remove. Since the application was a custom one, the authors were not able to report specifics in terms of the reduction of the programs attack surface, as that relates to CVEs. Contrastingly, by focusing on popular web applications, and utilizing function-level as well as file-level debloating, we were able to precisely quantify the reduction of vulnerabilities, both in terms of known CVEs as well as gadgets for PHP object-injection attacks.

### 8.2 Debloating in other platforms

Regehr et al. developed *C-Reduce* which is a tool that works at the source code level [63]. It performs reduction of C/C++ files by applying very specific program transformation rules. Sun et al. designed a framework called *Perses* that utilizes the grammar of any programming language to guide reduction [71]. Its advantage is that it does not generate syntactically invalid variants during reduction so that the whole process is made faster.

Heo et al. worked on *Chisel* whose distinguishing feature is that it performs fine-grained debloating by removing code even on the functions that are executed, using reinforcement learning to identify the best reduced program [42].

All three aforementioned approaches are founded on Delta debugging [76]. They reduce the size of an application progressively and verify at each step if the created variant still satisfies the desired properties.

Sharif et al. proposed *Trimmer*, a system that goes further than simple static analysis [68]. It propagates the constants that are defined in program arguments and configuration files so that it can remove code that is not used in that particular execution context. However, their system is not particularly well suited for web applications where we remove complete features. Our framework goes beyond this contextual analysis by mapping what is actually executed by the application.

Other works include research that revolves mainly around static analysis to remove dead code. Jiang et al. looked at reducing the bloat of Java applications with a tool called *JRed* [45]. Jiang et al. also designed *RedDroid* to reduce the size of Android applications with program transformations [44]. Quach et al. adopted a different approach by bringing dead-code elimination benefits of static linking to dynamic linking [61].

Rastogi et al. looked at debloating a container by partitioning it into smaller and more secure ones [62]. They perform dynamic analysis on system-call logs to determine which components and executables are used in a container, in order to keep them. Koo et al. proposed configuration-driven debloating [50]. Their system removes unused libraries loaded by applications under a specific configuration. They test their system on Nginx, VSFTPD, and OpenSSH and show a reduction of 78% of code from Nginx libraries is possible based on specific configurations.

## 9 Conclusion

In this paper, we analyzed the impact of removing unnecessary code in modern web applications through a process called

*software debloating*. We presented the pipeline details of the end-to-end, modular debloating framework that we designed and implemented, allowing us to record how a PHP application is used and what server-side code is triggered as a result of client-side requests. After retrieving code-coverage information, our debloating framework removes unused parts of an application using file-level and function-level debloating.

By evaluating our framework on four popular PHP applications (phpMyAdmin, MediaWiki, Magento, and WordPress) we witnessed the clear security benefits of debloating web applications. We observed a significant LLOC decrease ranging between 9% to 64% for file-level debloating and up to an additional 24% with function-level debloating. Next, we showed that external packages are one of the primary source of bloat as our debloating framework was able to remove more than 84% of unused code in versions that used Composer, PHP's most popular package manager. By quantifying the removal of code associated with critical CVEs, we observed a reduction of up to 60% of high-impact, historical vulnerabilities. Finally, we showed that the process of debloating also removes instructions and classes that are the primary sources for attackers to build gadgets and perform POI attacks.

Our results demonstrate that debloating web applications provides tangible security benefits and therefore should be seriously considered as a practical way of reducing the attack surface of web-applications deployments.

**Acknowledgements:** We thank our shepherd Giancarlo Pellegrino and the anonymous reviewers for their helpful feedback. This work was supported by the Office of Naval Research (ONR) under grants N00014-16-1-2264 and N00014-17-1-2541, as well as by the National Science Foundation (NSF) under grants CNS-1813974 and CMMI-1842020.

## 10 Availability

The main purpose of our work is to quantify the security benefits of debloating web applications, allowing the community to have informed discussions about the advantages of debloating, without the need of vague references to attack-surface reduction. To ensure the repeatability of our findings and to motivate more research in this area, *all* developed code and data artifacts are publicly available at: <https://debloating.com>.

# The Web’s Identity Crisis: Understanding the Effectiveness of Website Identity Indicators

Christopher Thompson, Martin Shelton, Emily Stark,  
Maximilian Walker, Emily Schechter, Adrienne Porter Felt  
*Google*

## Abstract

Users must understand the identity of the website that they are visiting in order to make trust decisions. Web browsers indicate website identity via URLs and HTTPS certificates, but users must understand and act on these indicators for them to be effective. In this paper, we explore how browser identity indicators affect user behavior and understanding. First, we present a large-scale field experiment measuring the effects of the HTTPS Extended Validation (EV) certificate UI on user behavior. Our experiment is many orders of magnitude larger than any prior study of EV indicators, and it is the first to examine the EV indicator in a naturalistic scenario. We find that most metrics of user behavior are unaffected by its removal, providing evidence that the EV indicator adds little value in its current form. Second, we conduct three experimental design surveys to understand how users perceive UI variations in identity indicators for login pages, looking at EV UI in Chrome and Safari and URL formatting designs in Chrome. In 14 iterations on browsers’ EV and URL formats, no intervention significantly impacted users’ understanding of the security or identity of login pages. Informed by our experimental results, we provide recommendations to build more effective website identity mechanisms.

## 1 Introduction

To use the web safely, users must be able to understand the identity of the website that they are visiting. Without understanding a website’s identity, users cannot make an informed decision about whether to provide it with their personal information or trust its content. Such misunderstandings result in common attacks like phishing and social engineering [36].

Web browsers use two mechanisms to communicate website identity to users. The first is the URL displayed in the browser address bar, along with a padlock icon to indicate an authenticated connection. For example, before a user types their Google password into a webpage, the user should verify that the domain in the browser address bar is “google.com” and that the padlock icon is present. Second, some HTTPS connections are authenticated with an Extended Validation

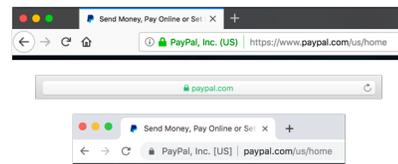

Figure 1: Examples of EV certificate UI in different web browsers (from top to bottom: Firefox, Safari, and Chrome).

(EV) certificate. An EV certificate associates a website with a legal entity, whose name and jurisdiction is typically displayed alongside the URL in the address bar (Figure 1). Users can check the EV indicator to verify that a website is associated with an established legal entity that they trust.

Prior work suggests that neither URLs nor EV indicators work very well as indicators of website identity. Many users do not look at the URL even when primed to try to identify fraudulent sites [12]. EV indicators also do not help users identify fraudulent sites [24]. Even if users did notice the EV indicator, EV certificates can contain misleading information that limits their usefulness [10, 11].

However, much of the work that studies the effectiveness of website identity indicators is dated, testing browser UIs that are no longer in common use. For example, most EV indicator research is ten years old and studied the first browser EV UI from Internet Explorer 7. Browser security indicators and the web security landscape have changed dramatically since these studies were conducted, with widespread adoption of HTTPS [15] and constant evolution of browser UI [16]. Further, prior work does not examine how users react to website identity indicators in the wild.

In this paper, we examine the effectiveness of browser identity indicators – URLs and EV UI – from several angles. We focus primarily on how users react to the EV indicator, since it is designed to provide human-meaningful identity information, and we also investigate whether browser UIs can be tweaked to make the URL more human-meaningful. Our

goal is to study the effectiveness of modern browser identity indicators at a much larger scale than previous work.

First, we analyzed a large-scale field experiment (Section 3) from the Google Chrome web browser. We examined a suite of user behavior measurements with and without the EV indicator present on websites that serve EV certificates. This experiment simulates a situation in which a user visits an attack website that mimics a victim website exactly but does not possess an EV certificate for the victim site. We find little evidence that the absence of the EV indicator affects how users interact with the site. We do find, however, that the EV indicator itself draws clicks.

Second, we conducted a series of survey experiments (Section 4) to investigate follow-up questions about EV UI that we could not answer with field data. Our surveys, with over 1,800 total participants from the U.S. and U.K., sought to answer two questions: (1) Would a recent proof-of-concept attack on EV certificates [11] be effective on real users? (2) How do users react to other browsers' EV UIs? In these surveys, we find no evidence that the EV UI in either Chrome or Safari impact how comfortable users feel when logging into a webpage.

Finally, having found little evidence that EV indicators influence user behavior, we consider whether URLs can be more effective identity indicators (Section 5). We surveyed over 1,000 users to assess reactions to different variations on Chrome's URL display. Each variation was designed to draw users' attention to the domain name, in hopes that they would notice that the webpage was a phishing site. We found no significant differences among any of the variations, leading us to believe that a more radical redesign is necessary for URLs to effectively communicate website identity to users.

Our results, along with the body of existing work, suggest that modern browser identity indicators are not effective. We use these results to provide recommendations for building better website identity mechanisms. Based on promising results from prior research [7, 14], we argue that negative, active indicators (such as full-page warnings) are a more promising avenue than passive, positive indicators (such as the padlock icon or EV indicator in the address bar). We further recommend that user research should be incorporated into the design phase for future browser identity indicators.

## 2 Background

### 2.1 URLs and website identity

The fundamental identity indicator of the web is the URL. All major web browsers display the URL of the page in order to convey the website's identity. Figure 2 shows how different web browsers display URLs to users.

#### 2.1.1 HTTPS and certificates

In the URL bar, the presence of the "https://" scheme and/or a padlock icon indicate that the identity of the site has been verified through a cryptographic certificate. Most websites

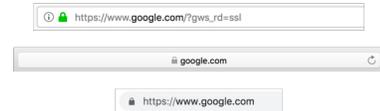

Figure 2: Examples of different browser URL displays (from top to bottom: Firefox 64, Safari 12.0.3, and Chrome 72).

use *domain-validated (DV) certificates*. A website owner can obtain a DV certificate by proving control over a domain to a certificate authority (CA) [1]. DV certificates can be obtained easily and inexpensively from a number of CAs.

#### 2.1.2 Registrable domain

In most situations, a user who is making a security decision should pay attention to the *registrable domain* [6] rather than the full URL. The registrable domain is composed of the high-level domain name suffix under which internet users can register names [5], plus the DNS label immediately preceding it. For example, "google.com" is the registrable domain in the URL "https://accounts.google.com/", and "google.co.uk" in "https://accounts.google.co.uk/".

The registrable domain is typically the identity indicator of interest because when an organization controls a registrable domain, the same organization can typically control all the subdomains and paths within that domain.

### 2.2 Extended Validation (EV) certificates

EV certificates are a type of HTTPS certificate in which a domain owner undergoes additional validation with a CA to tie their domain to a legal entity. Most major web browsers display the legal entity name and jurisdiction in the URL bar alongside the URL, as shown in Figure 1. Notably, Safari recently stopped displaying the legal entity name and simply colors the domain green when an EV certificate is present.<sup>1</sup>

Section 2 of the CA/Browser Forum guidelines for EV certificates [3] specifically states that one primary purpose of EV certificates is to enable a browser to inform the user about the specific legal identity of the business with which they are interacting when using a website. A secondary purpose given by the guidelines is that EV certificates can be considered to combat phishing and other malicious web activity.<sup>2</sup> If an attack website is impersonating a victim business, the attack site is not supposed to be able to obtain an EV certificate for the victim business. A user visiting the attack website might notice that there is no EV indicator for the victim business and thereby conclude that the website is not the legitimate website for the victim business.

EV certificates are typically more cumbersome to obtain than DV certificates. Domain owners pay a premium for

<sup>1</sup> Apple did not mention this change in their release notes, however it was discussed on Twitter [13, 30] and technical blogs [23].

<sup>2</sup>Microsoft [18] and Mozilla [21] gave similar motivations for their introduction of browser EV UI.

EV certificates and undergo a days- or weeks-long validation process.

### 2.2.1 Weaknesses of EV certificates

EV certificates suffer from a number of security and usability weaknesses. These weaknesses have led to a vigorous debate in the security community about whether browsers should continue to display EV certificate UI [22, 23, 32]. Our work seeks to inform this debate with up-to-date, large-scale, in situ data about how users react to EV indicators.

**Malicious EV certificates.** EV is not intended to verify that the holder of the certificate is law-abiding, trustworthy, or safe [3]. Researchers have shown that EV certificates can be obtained for misleading names that could be useful in an attack. We describe these attacks in Section 7.1.2.

**Usability issues.** A body of work from the mid-2000s indicates that EV certificates are not an effective phishing defense because users do not pay attention to the EV UI in web browsers. We survey this work in Section 7.1.1.

Further, the legal entity names in EV certificates are not always intuitive or understandable, because the legal entity does not always match the company’s user-visible brand. For example, the personal finance management site `mint.com` has a legal entity name of “Intuit Inc.”

## 3 EV field experiment

To understand whether browser EV UI has an effect on user behavior in the wild, we analyze data from a large-scale field experiment. In this experiment, the EV UI was disabled for a subset of Google Chrome users. We compare a variety of metrics representing users’ interactions with EV websites in the experimental and control groups. We do not find evidence that the EV UI impacts user behavior significantly for most metrics. The exception is that users who see the EV UI are more likely to open and interact with the Page Info bubble, which is anchored to the connection security indicator chip (Figure 3). Additionally, we examined the effects of removing the EV UI on a set of 20 top EV sites. We found a small negative impact on navigations to one of these sites.

### 3.1 Methodology

#### 3.1.1 Dataset

We analyze data from Chrome’s user metrics program. Chrome collects metrics in the form of enums, booleans, counts, and times. Our dataset comes from the Stable channel, which has the largest set of users and is the default installation release channel. Stable channel is considered the most representative for measurement and experimentation purposes.

Chrome metrics reports are pseudonymous, containing client information such as the operating system and country, but no personal information (e.g., age or gender). The user

metrics program is enabled by default for consumer installs. Users may opt out during installation or in browser settings.

A subset of metrics are keyed by the URL on which the metric is recorded. URLs are only provided for users who have also opted to sync their browsing data with Google servers [20]. We use these URL-keyed metrics to check for changes in user behavior on specific well-known sites with EV certificates. We analyze a subset of our metrics on each of the top 20 EV sites, as visited by Chrome users during our experimental period. We report these results with the domains blinded.

Our dataset includes metrics collected from January 15, 2019 to January 28, 2019. Chrome 71 was fully rolled out to the Stable channel during this time period.<sup>3</sup>

#### 3.1.2 Experimentation framework

Chrome contains an experiment framework in which users can be randomly assigned to experiment groups. Metrics reports are then tagged with the user’s group. In our dataset, 1% of Stable channel users were assigned to an experimental group in which the EV certificate UI was disabled, and 1% to a control group. In the experimental group, users who visited EV sites saw a padlock but no additional HTTPS UI.

#### 3.1.3 Metrics

In our study, we analyzed a set of user behaviors that we hypothesized might be affected by a user’s perception of the security and identity of a site.

Our selection of metrics is informed by a review of related work (Section 7). We sought to measure behaviors in situ that previous work measured via lab studies or surveys. Below we describe each metric and why we included it.

- **Navigations.** Do users navigate to different sites, or navigate away from EV sites more in the experimental group? We measure:
  - The number of navigations to EV pages, normalized by the total number of navigations.
  - The median time spent on each page visit (not including time spent in the background).<sup>4</sup>
  - The number of times that users left EV pages, by closing the tab, using Back/Forward functionality, or reloading. We normalize by the total number of navigations to EV pages.

We are interested in navigations because prior work on browser security indicators surveyed users on whether they would leave the page if a particular security indicator appeared in their browser [16].

- **Form submissions.** A metric is recorded when a user submits an HTML form. We consider the number of

<sup>3</sup>During this period, our dataset included millions of clients in each group for our main analysis. For our per-origin analysis, we had tens of thousands of clients on average in each group for each origin.

<sup>4</sup>Due to a bug in our initial data collection for this metric, we instead use data from May 15–28 (after a fixed version reached Chrome’s Stable channel) for this metric.

form submissions that occur on pages with EV certificates, normalized by the total number of navigations to EV pages. Previous studies have surveyed users on their willingness to enter login [31] or credit card [16] details, both of which typically involve submitting a form.

- Autofill interactions.** Chrome’s autofill feature saves credit card details that the user enters and provides suggestions when users fill out payment forms. We analyze the number of times a suggestion was selected normalized by the number of times a suggestion was shown. As with form submissions, these metrics provide insight into whether users in the experimental group are less comfortable providing credit card details to the page.
- Page Info interactions.** Chrome’s Page Info bubble is the dialog that appears when a user clicks on the main connection security indicator in the address bar (Figure 3). A metric is recorded every time a user opens the Page Info bubble and every time they use its functionality (e.g., opening the certificate details dialog or inspecting cookies). We analyze Page Info behavior because previous lab studies have examined users’ interactions with the equivalent dialog in other browsers [33]. We normalize the number of times the Page Info bubble was opened by the total number of navigations to EV pages. We normalize the number of different actions within the Page Info bubble by the total number of times the Page Info bubble was opened.
- Downloads.** Downloading a file, particularly an executable, may represent a trust decision for users. We record the number of downloads initiated from EV pages, normalized by the total number of EV navigations.
- Site Engagement.** Chrome records an aggregate metric called Site Engagement (SE) that approximately measures how much active time a user spends on a site.<sup>5</sup> Each web origin receives a SE score between 0 and 100. It goes up as a user clicks, scrolls, performs keypresses, or plays media on a site, and decays over time as a user does not interact with the site. We compare SE scores with and without the EV UI to see if there might be effects related to user engagement that are not captured by our other metrics. We analyze this metric on a per-site basis. For each user on each origin, we compute the average SE score per visit as well as the average change in SE score over each visit.

### 3.1.4 Analysis

To see if there are statistically significant effects on any of our metrics of user behavior between our control group and our experimental group, we perform a Welch’s *t*-test for unequal sample variances (as our sample sizes and variances

<sup>5</sup><https://www.chromium.org/developers/design-documents/site-engagement>

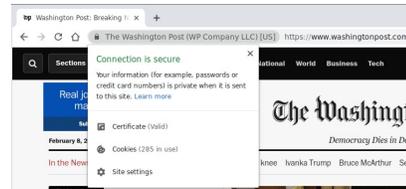

Figure 3: The Page Info bubble in Chrome.

are not guaranteed to be equal between our treatment and control groups) for each metric of interest.

For each metric, we report the difference between the experimental group and the control group, the 95% confidence interval for the difference, and the *p*-value of the *t*-test.

### 3.1.5 Limitations

**Incompletely capturing user reactions.** It is possible that users in the experimental group reacted differently than the control group in ways that we did not measure. For example, perhaps when the EV UI is disabled, users use a throwaway password or deny all permission prompts. Though we cannot feasibly measure all such user reactions, we feel that our study still provides value by (a) measuring a wide variety of user behaviors that one could reasonably expect to be influenced by a security or identity indicator, and (b) studying user behaviors in a naturalistic scenario that have previously been studied only in labs or surveys.

**Limited insight into per-site effects.** Some, but not all, of our metrics are keyed by URL (Section 3.1.1). For metrics which are not URL-keyed, we can draw conclusions only about user behavior in aggregate over all sites. It is possible that the absence of the EV indicator influenced these metrics on particular sites but did not have a significant effect when aggregated over all EV sites.

**Incomplete simulation of attack scenarios.** Our study analyzes whether users react to a missing EV indicator on a website that does not otherwise look suspicious. This simulates an attack scenario in which an attack website mimics a victim website exactly except for the EV certificate. This attack scenario could arise if an attacker obtains a homograph domain (one that looks nearly or exactly identical to a victim domain)<sup>6</sup> or an ordinary domain-validated certificate for the victim site. However, EV certificates might significantly influence user behavior in other attack scenarios that we did not study. For example, consider a website that spoofs paypal.com but is hosted at an obviously incorrect URL. In this scenario, a missing EV indicator might prompt a user to inspect the URL and thereby detect the attack. While our experiment does not cover such attack scenarios, we feel that our experiment’s attack scenario is of particular interest: the purpose of EV indicators are to provide human-meaningful identity information on the premise that other signals, such

<sup>6</sup>[https://en.wikipedia.org/wiki/IDN\\_homograph\\_attack](https://en.wikipedia.org/wiki/IDN_homograph_attack)

as the URL, are not sufficient tools for identifying websites. We explore an additional attack scenario of practical interest via a survey experiment, as described in Section 4.

**Dataset selection.** Our dataset does not come from a truly random sample of Chrome’s user population: users can opt out of the user metrics program, and users must specifically opt in to browsing data syncing to report URLs (Section 3.1.1). However, we still believe this data is valuable in light of its scale and naturalistic observation.

### 3.1.6 Ethical considerations

Although our institution is not subject to IRB approval, the EV experiment went through an internal review process before launching, including security and privacy reviews. As discussed in Section 3.1.1, Chrome metrics reports are pseudonymous [20].

The experiment rolled out in several release channels before Stable, per Chrome’s usual release process. The experiment was monitored as it rolled out, and had any problems been detected, it could have been disabled at any time.

For users in the experimental group, the Chrome developer console contained a message explaining the experiment. This message was intended to inform site owners why their EV certificate UI might not be showing.<sup>7</sup>

Changes to browser security and identity indicators come with the risk that users feel safer on malicious sites and take actions that they wouldn’t otherwise take (for example, a user might enter credit card details on a scam site because the UI change made them believe it was safe). Our approach is similar to other field studies on browser security UI, such as exploring new security indicator icons [16], and more conservative than default feature rollouts in Chrome, as the experiment targeted only a small percentage of users and could have been disabled at any time had there been unexpected effects indicating that the experiment put users at risk. In this case, we expected the experiment to, at most, make users act more cautiously on legitimate sites, since we were only modifying positive security UI (compared to, for example, prior work experimenting with full page connection security warnings [14]).

We note that Brave Browser, which is based on the Chromium project, has opted in to not showing the EV UI using our experimental feature [2]. Brave’s previous implementation (based on Muon) also intentionally did not show any EV UI [4]. Our dataset only includes data from official Chrome clients.

<sup>7</sup>The developer console is a default-hidden UI intended for web developers, where many technical warnings about the page are printed (e.g., identifying specific mixed content subresources, or the use of deprecated APIs). In the Stable channel, the console was opened by 2% of clients over the 14-day period of our study. We believe that this indicates that the console warning would not be a potential source of priming for a vast majority of participants. We did not see a significant difference in how often the console was opened (normalized by page loads) between our experimental and control groups ( $p=0.57$ , 95% CI: [-0.000052,+0.000028]).

## 3.2 Results

### 3.2.1 Summary

We did not see any significant differences in user behavior in our navigation or on-page metrics between our experimental group and our control group. Table 1 summarizes the results of our statistical analysis for each of our metrics.

### 3.2.2 Page Info interactions

Users in the control group, who saw EV UI, were significantly more likely to open the Page Info bubble. However, users in the experimental group, who did not see EV UI, were more likely to take an action in the Page Info bubble after opening it.

The experimental group opened the Page Info bubble on 0.02% of EV page loads, compared to 0.25% in the control group. Additionally, participants in our experimental group were much more likely to take an action in the Page Info bubble after opening it, across all Page Info action types.

To investigate further, we performed an additional analysis where we normalized the number of Page Info actions by the total number of EV page loads, to see if the overall number of Page Info actions taken went down in the experimental group. Table 2 shows the results of this analysis. While some Page Info actions were more common per page load in the control group, the effect sizes were very small. That is, hiding the EV UI did not make users substantially less likely to perform actions in the Page Info bubble.

Applying a Bonferroni correction for multiple testing with  $m = 19$  (for each of the tests in Tables 1 and 2), the corrected significance level would instead be  $\alpha = 0.05/m = 0.002$ . This implies that the significant results in Table 2 may be due to chance only.<sup>8</sup>

One possible explanation for this finding is that the large size of the EV indicator draws accidental clicks, leading users to open the Page Info bubble but not actually use it. Another hypothesis is that users notice and are curious about the EV indicator, even if it does not influence their security decisions (consistent with prior work that found that users noticed identity indicators but did not use them in their decision-making processes [28, 33, 40]). We cannot conclusively differentiate between these two hypotheses.

### 3.2.3 Per-site metrics

We analyzed three URL-keyed metrics (navigations, Site Engagement score, and change in Site Engagement score) on each of the top 20 EV sites. For 14 of the 20 most-visited EV origins, there were no differences with  $p < 0.05$ . The remaining 6 origins are shown in Table 3, each with one metric with  $p < 0.05$ . Five of these are very small to small negative effects on the number of navigations to the site, while one

<sup>8</sup>Using a Bonferroni correction allows us to control for Type I errors. We show results significant at both the  $p < 0.05$  level and the multiple testing-corrected level, as the Bonferroni correction can be too conservative in cases of correlated tests.

|                              | Control ( $\sigma$ ) | Experiment ( $\sigma$ ) | $\Delta$ | 95% CI             | $p$ -value | Cohen's $d$ |

| Connection help opened       | 0.21% (0.04%)        | 1.51% (0.11%)           | +1.29    | (+0.89, +1.69)     | 0.00       | 0.26        |
| Site settings opened         | 0.83% (0.08%)        | 5.80% (0.22%)           | +4.97    | (+4.17, +5.76)     | 0.00       | 0.49        |

Table 1: Summary of statistical tests for our EV field experiment metrics. The only differences that were significant at the  $p < 0.05$  level were for Page Info behavior (highlighted).

|                           | Control ( $\sigma$ ) | Experiment ( $\sigma$ ) | $\Delta$ | 95% CI              | $p$ -value | Cohen's $d$ |
|---------------------------|----------------------|-------------------------|----------|---------------------|------------|-------------|
| Cookies dialog opened     | 0.0019% (0.0026%)    | 0.0010% (0.0017%)       | -0.001   | (-0.0017, -0.00002) | 0.01       | 0.004       |
| Changed permissions       | 0.0031% (0.0028%)    | 0.0025% (0.0024%)       | -0.0006  | (-0.0015, +0.0003)  | 0.18       | 0.002       |
| Certificate dialog opened | 0.0022% (0.0026%)    | 0.0017% (0.0026%)       | -0.0005  | (-0.0014, +0.0004)  | 0.28       | 0.002       |
| Connection help opened    | 0.0009% (0.0017%)    | 0.0005% (0.0014%)       | -0.0004  | (-0.0009, +0.0002)  | 0.17       | 0.002       |
| Site settings opened      | 0.0028% (0.0028%)    | 0.0014% (0.0014%)       | -0.0014  | (-0.0023, -0.0006)  | 0.007      | 0.006       |

Table 2: Summary of our followup analysis of Page Info behavior, with counts of actions normalized by the number of EV page navigations instead. The highlighted rows were significant at the  $p < 0.05$  level, but the effect sizes are negligible.

is a very small *positive* effect on the per-visit change in the Site Engagement score. However, if we apply a Bonferroni correction with  $m = 60$  (three metrics checked across 20 origins), then we should instead consider a significance level of  $\alpha = 0.05/m = 0.0008$ . With the correction, only one origin had a significant difference in user behavior: Origin 15 had 4.26 (95% CI: 2.20 to 6.32,  $d = 0.24$ ) fewer navigations on average per user in the experimental condition.

We note that our navigation metric used here is not normalized due to limitations of the URL-keyed metrics dataset, so these results may be affected by natural variations in browsing volume between users.

## 4 EV survey experiments

In our EV field study, we failed to find evidence that the absence of the EV indicator influences most user behaviors. In this section, we examine two follow-up questions that were infeasible to answer via field experiment:

1. **Does the EV UI help users detect cross-jurisdiction collision attacks?** We were particularly interested in cross-jurisdiction collisions due to a recent high-profile proof of concept [11]. In this attack, two EV certificates are registered with the same legal entity name in different jurisdictions. We studied this question via survey because a field experiment would have required the browser to display incorrect information.

2. **How do users react to EV UI in modern browsers other than Chrome?** We focused on the Apple Safari browser because it recently made a significant change to its EV UI, removing the legal entity name and simply showing the domain in green (Figure 5). Because we did not have access to Safari field data, we instead conducted a survey experiment.

### 4.1 Methodology

We ran two online survey experiments, corresponding to the two research questions described above.

#### 4.1.1 Questions

The surveys showed participants a login screen for a well-known financial webpage in their respective countries: PayPal in the U.S. and HSBC in the U.K. We asked participants three questions, displayed underneath the screenshot.

First, in a five-point Likert scale, we asked participants to rate their comfort level logging into the webpage: *Would you feel comfortable logging in on this website? Very comfortable / Somewhat comfortable / Neither comfortable nor uncomfortable / Somewhat uncomfortable / Very uncomfortable*

To avoid leading participants' responses, we intentionally left this question up to their interpretation and allowed them to elaborate. We next asked participants for open-ended de-

| Origin | Metric                   | Control | Experiment | $\Delta$ | 95% CI         | $p$ -value | Cohen's $d$ |
|--------|--------------------------|---------|------------|----------|----------------|------------|-------------|
| 3      | Navigations              | 18.55   | 14.78      | -3.77    | (-6.78, -0.76) | 0.014      | 0.17        |
| 4      | Navigations              | 25.80   | 23.08      | -2.72    | (-4.73, -0.72) | 0.0078     | 0.10        |
| 10     | Navigations              | 13.37   | 11.10      | -2.27    | (-4.33, -0.21) | 0.031      | 0.14        |
| 14     | Navigations              | 20.40   | 15.65      | -4.74    | (-8.48, -1.01) | 0.013      | 0.21        |
| 15     | Navigations              | 18.57   | 14.31      | -4.26    | (-6.32, -2.20) | 0.00005    | 0.24        |
| 18     | $\Delta$ Site Engagement | 0.88    | 1.40       | +0.52    | (+0.09, +0.95) | 0.017      | 0.13        |

Table 3: Summary of our (blinded) per-origin analysis from our UKM dataset. The included rows are the origin/metric pairs that were significant at the  $\alpha = 0.05$  level. The highlighted row is the only significant result after applying a Bonferroni correction ( $\alpha = 0.0008$ ). All the differences have at most a small effect size (Cohen's  $d$ ).

tails about their reasoning: *Can you tell us why you feel that way? (If there's nothing to add, leave blank.)*

The final question appeared with the same login page screenshot, allowing users to click on it up to three times to mark the relevant sections: *Click the item(s) on the screen that make you feel that way.*

#### 4.1.2 Participants

We recruited U.S. participants through Mechanical Turk and U.K. participants through Clickworker. We selected the U.S. and U.K. because EV usage was common in these countries (based on our dataset from Section 3), and we were unable to recruit enough participants in other countries where EV usage is common. Participants received a \$.40 or € .35 incentive for participation. Our cross-jurisdiction collision survey ran from January 29 to February 3, 2019, with 592 U.S. participants and 650 U.K. participants. Our Safari EV survey ran from January 29 to February 1, 2019, with 290 U.S. participants and 305 U.K. participants.

**Demographics.** In both surveys, U.S. participants skewed slightly older than U.K. participants, who were overrepresented in the 18-24 age range. In the cross-jurisdiction attack survey, U.S. participants skewed slightly male (55%) and U.K. participants skewed slightly female (55%). Full demographic details can be found in the Appendix.

#### 4.1.3 Experimental conditions

**Cross-jurisdiction collision survey.** In this survey, we randomly assigned participants to see one of five conditions with a screenshot of the login page, each manipulating the country code displayed in the EV indicator, as shown in Figure 4. One condition omitted the country code entirely, one showed the correct country code (US or GB), and three showed incorrect country codes (MX, RU, and BR).

**Safari EV UI survey.** Safari changed its EV display in macOS 10.14 to no longer display the legal entity name. In this survey, we randomly assigned participants to one of two conditions. In the first, users saw the login webpage with the EV display used in macOS 10.13, and in the second condition, users saw the EV display from macOS 10.14 (Figure 5).

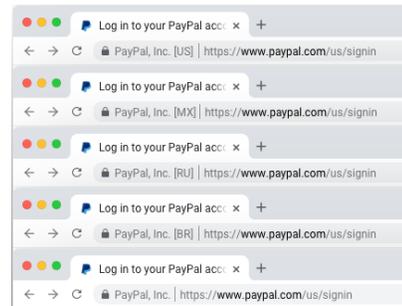

Figure 4: Five conditions shown to U.S. participants, manipulating only country code.

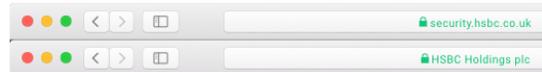

Figure 5: Two conditions shown to U.K. participants, manipulating display of EV to include the site's registrable domain (macOS 10.14) or EV legal entity name (as in macOS 10.13).

#### 4.1.4 Data coding

Two researchers coded the qualitative responses on users' comfort level, with one team member (the *codemaster*) open coding the initial coding rounds, and the other iteratively providing feedback to the codemaster. In the final round of iteration, both researchers coded all responses for both surveys. Cohen's  $\kappa$ , a measure of inter-rater reliability, was 0.974 in the cross-jurisdiction survey (with 95.3% agreement), and 0.949 (with 97.6% agreement) in the Safari EV formatting survey, both indicating strong consistency between coders. The codemaster resolved the remaining conflicts.

#### 4.1.5 Limitations

**Artificial scenario.** As with previous lab and survey studies about browser identity indicators, our surveys are an artificial scenario. This approach has limited ecological validity, as participants are not tasked with signing into a real website, nor with their real credentials, and thus they may feel less concerned than usual. However, in a more naturalistic scenario, we would expect that users would also pay less

|                                          | Cnd 1 | Cnd 2 | Cnd 3 | Cnd 4 | Cnd 5 |
|------------------------------------------|-------|-------|-------|-------|-------|
| <i>U.S.</i>                              |       |       |       |       |       |

| <i>n</i>                                 | 125   | 132   | 128   | 132   | 133   |

Table 4: Users’ comfort levels logging into a webpage with different EV country codes. Cnd 1 is the topmost variation shown in Figure 4 and Cnd 5 is the bottommost.

overall attention to security concerns because no one would ask them about their comfort level before they logged in. We therefore consider our results to describe upper bounds on how EV indicators influence user behavior.

**Demographics.** Since we only surveyed U.S. and U.K. participants, our results may not generalize to other contexts and cultures.

## 4.2 Results

Across surveys and conditions, we found that most users felt comfortable logging into each webpage, regardless of the EV UI. In nearly all cases, we found no differences among users’ self-reported comfort levels with each login page.

### 4.2.1 Cross-jurisdiction collision survey

We found no evidence that the country code displayed in the EV indicator helps users detect a cross-jurisdiction attack.

**Quantitative results.** In both the U.S. and U.K., participants were most likely to say they felt “Very comfortable” logging into the webpage, regardless of the country code presented. We conducted a Kruskal-Wallis test, and in both the U.S. ( $\chi^2 = 1.1783, df = 4, p = 0.8817$ ) and U.K. ( $\chi^2 = 2.4994, df = 4, p = 0.6447$ ), we found no significant differences among users’ comfort levels in each condition. Table 4 shows the full results.

**Reasons for comfort or discomfort.** When asked to identify why they felt “somewhat” or “very comfortable”, participants were more likely to refer to cues in the content area, rather than Chrome UI.

Responses varied somewhat in each region. U.S. participants were most likely to describe feeling familiar with the webpage (e.g., “PayPal is well known so it makes me feel somewhat comfortable.”), while U.K. participants most com-

monly pointed to an HTTPS indicator (e.g., “the https along with the padlock in the address bar”) but not EV-specific UI.

Participants referred to cues in the content area such as:

- familiarity with the webpage
- the page’s simplicity or ease of use (e.g., “I feel very comfortable because it is easy to understand...”)
- the page’s general design (e.g., “A comfortable amount of white space without the page feeling empty”)
- the page looking normal or expected (e.g., “The sign in system here has followed a standard sign in page and gives all necessary help”)

When referring to cues in the browser itself, participants most commonly referred to the HTTPS indicator, specifically identifying the padlock icon (e.g., “Mainly because of the padlock on the top search bar makes me think it’s secure enough to use safely”). Participants also noted that the URL looked normal or expected (e.g., “... the link web address doesn’t look abnormal”). They were far less likely to refer to EV UI specifically (e.g., “The site displays that it is secure with a registered identity, PayPal Inc...”).

As many as 3% of U.S. participants and 14% of U.K. participants in each condition referred to the site as safe or secure, without describing their reasoning (e.g., “It’s a secure bank login page”).

Few noticed oddities in the page’s country code (no more than 8% in any U.S. condition and 5% in the U.K.). Even when participants did notice, it did not necessarily make them uncomfortable (e.g., “I never noticed the MX on a PayPal page, but it seems legit.”).

Table 5 shows a subset of results of our open-ended question about why users felt comfortable or uncomfortable.

**Items on the page.** When asked to “click item(s) on the page that make you feel that way”, participants were most likely to click the HTTPS indicator (but not EV UI specifically), parts of the URL, or page logos. Figure 6 displays an example heatmap for these clicks. The other heatmaps can be found in the Appendix.

These results suggest that many users do use HTTPS security indicators and site URLs to determine the legitimacy of a website. However, in both qualitative and quantitative responses, almost no participants appear to notice EV UI. Additionally, these results suggest a cross-jurisdiction attack could be viable in part because users infer the legitimacy of a website from the presence of HTTPS indicators.

### 4.2.2 Safari EV UI survey

We found no evidence that the change in Safari’s EV format affected users’ comfort logging in to a webpage.

**Quantitative results.** In both the U.S. and U.K., in both conditions, participants were most likely to say they felt “Somewhat comfortable” or “Very comfortable” logging into the webpage. We conducted a Kruskal-Wallis test, and in both the U.S. ( $\chi^2 = 0.0808, df = 1, p = 0.7762$ ) and U.K.

|                                 | U.S.  |       |       |       |       | U.K.  |       |       |       |       |

| Page looks bland                | 1%    | 1%    | 4%    | 1%    | 3%    | 10%   | 2%    | 1%    | 5%    | 1%    |
| URL looks odd                   | 0%    | 1%    | 0%    | 1%    | 1%    | 1%    | 2%    | 2%    | 2%    | 3%    |
| Page looks poorly-designed      | 0%    | 0%    | 0%    | 0%    | 0%    | 6%    | 7%    | 9%    | 7%    | 4%    |

Table 5: Sample results of the open-ended question “Can you tell us why you feel that way?” when participants were asked how comfortable they were logging in to a site. Cnd 1 is the topmost condition shown in Figure 4 and Cnd 5 is the bottommost. Full results are shown in the Appendix.

Figure 6: Example click heatmap, displaying what U.K. participants say made them feel comfortable or uncomfortable on a webpage with an RU country code in the EV indicator.

( $\chi^2 = 0.50313, df = 1, p = 0.4781$ ), we found no significant differences in users’ comfort levels across conditions. Table 6 shows the full results.

**Reasons for comfort or discomfort.** Similar to the results from our cross-jurisdiction attack survey, U.S. participants were most likely to say they felt comfortable logging in because they are familiar with the webpage, while U.K. respondents were more likely to say they felt comfortable because they saw an HTTPS indicator. However, most participants in both conditions also referred to content area cues, such as the page looking as expected, or the page being simple or well-designed. Table 7 shows the full results.

Once again, as much as 6% in the U.S. and 9% in the U.K. said the website they saw is “safe” or “secure” without mentioning whether the browser or content area made them feel that way.

|                                       | Cnd 1 | Cnd 2 |

| Very uncomfortable                    | 4%    | 1%    |
| <i>n</i>                              | 152   | 153   |

Table 6: Users’ comfort levels logging into a webpage with different Safari EV UIs. Cnd 1 is the variation with the site’s registrable domain and Cnd 2 is the EV legal entity name.

Participants said they felt uncomfortable logging in for several reasons, varying by region. In the U.S., participants were most likely to say they felt uncomfortable logging in because they could not see the URL (e.g., “There’s no web address present, so it could be a spoofed page”). In the U.K. participants were most likely to say they felt uncomfortable because something in the content area was poorly-designed (e.g., “The page looks very cold and sterile”). Overall, however, participants were uncomfortable for very similar reasons in each region. When referring to the browser UI, they cited issues with the appearance or (in)visibility of the URL. When referring to issues with the content area, participants said the page looks bland or poorly designed.

Participants were split as to whether the EV indicator made them feel comfortable or uncomfortable, with many stating they wanted to be able to see the full URL (e.g.,

|                                              | U.S.  |       | U.K.  |       |

Table 7: Results of the open-ended question “Can you tell us why you feel that way?” when participants were asked how comfortable they were logging in to a site. Cdn 1 is the top condition shown in Figure 5 and Cdn 2 appears below.

“Looks like the genuine page but I’d like more reassurance of this, like being able to see the URL”).

As many as 7% of U.S. participants and 5% of U.K. participants said they weren’t sure if the site was safe or secure, but were unclear how (e.g., “It doesn’t look secure”).

**Items on the page.** When asked to “click item(s) on the page that make you feel that way”, participants were most likely to click the HTTPS indicator, as well as the page logo. Figure 7 displays a heatmap for these clicks in one condition. The other heatmaps can be found in the Appendix.

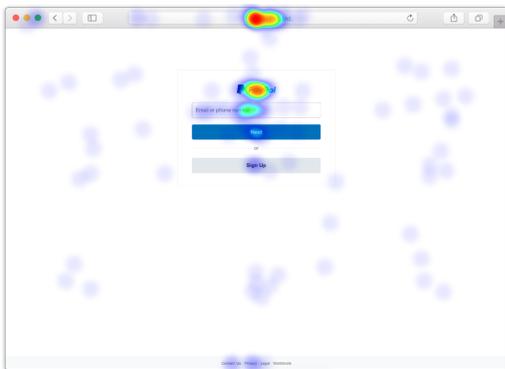

Figure 7: An example of a click heatmap from U.K. participants. This condition displayed the EV legal entity rather than a registrable domain.

## 5 URL highlighting survey experiment

As with the EV indicator, prior research has found that users often do not notice URLs or do not use them to make security decisions [12, 28, 40]. We conducted a survey experiment to learn whether more pronounced URL formatting changes in the browser address bar would draw attention to the URL and help users understand its security properties, but we found that these URL formatting changes were not effective.

### 5.1 Methodology

In this survey, we showed users a screenshot of a Google login page with a suspicious URL in the browser address bar (`accounts.google.com.amp.tinyurl.com` instead of `accounts.google.com`). We asked users to identify the website and then asked them if they would be comfortable entering their login credentials on the site.

#### 5.1.1 Questions

The first question in the survey asked participants to identify the website in an open-ended response: *Before we move ahead, please identify the above website.* The subsequent questions asked users how comfortable they were logging in to the website and why. These questions were identical to Section 4.1.1 except that we did not ask participants to “click the item(s) on the page that make you feel that way.”

#### 5.1.2 Participants

Our survey ran from November 20 to November 21, 2018. We recruited 1,180 U.S. participants from Mechanical Turk who were paid a \$.40 incentive.

**Demographics.** Similar to our previous U.S. surveys, the sample skewed slightly male (53%), with adults 55 and older underrepresented. Full demographic details can be found in the Appendix.

#### 5.1.3 Experimental conditions

This survey showed participants a Google sign-in page with an incorrect URL (`accounts.google.com.amp.tinyurl.com`), simulating a phishing attack. We randomly assigned participants to one of seven conditions (Figure 8). Condition 1 (the control) used the Chrome 69 address bar UI, while other conditions attempted to draw attention to the registrable domain (`tinyurl.com`) in various ways.<sup>9</sup>

#### 5.1.4 Data coding

Because there was almost no ambiguity in participant responses to our first question about the website’s identity, only one researcher coded these responses. For all other questions, we coded the data as in Section 4.1.4. Based on a subsample of 100 responses coded by two security researchers,

<sup>9</sup>We chose these particular URL highlighting formats as we wanted to examine variants that we believed would (1) give emphasis to the registrable domain by manipulating color and spatial layout, (2) be noticeably distinguishable from the existing format but (3) not overtly distracting from browsing, so each variant could viably be deployed in the real world.

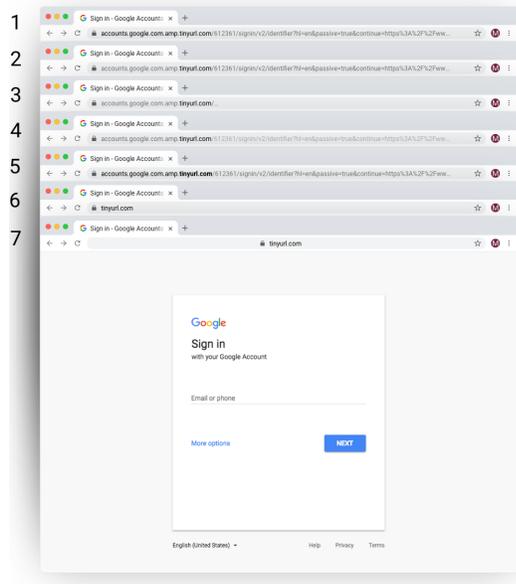

Figure 8: Conditions shown to U.S. participants, manipulating the URL display to emphasize the registrable domain.

Cohen’s  $\kappa$  was 0.946, indicating strong agreement, with the two coders in agreement 95.4% of the time. The codemaster resolved the remaining conflicts.

### 5.1.5 Limitations

This survey suffers the same limitations as in Section 3.1.5: namely, an artificial scenario and limited generalizability beyond the U.S. Additionally, in this survey, participants may have responded to the novelty of the URL format, and not just the URL content, making it difficult for us to isolate the impact of the URL format alone. However, this did not appear to significantly impact our results because we did not detect any significant differences across variations.

## 5.2 Results

### 5.2.1 Website identification

Few participants noticed anything strange about the website when asked to identify it. 85% of all participants said the website was Google, when in fact, the address said `tinyurl.com`. 13% of participants correctly identified the website by its URL. 1% described both Google and TinyURL, and 1% provided a different response.

### 5.2.2 Comfort logging in

In all conditions, participants were most likely to say they felt comfortable logging into the webpage, despite the suspicious URL. Across the seven conditions, we found no significant differences ( $\chi^2 = 2.847, df = 6, p = 0.8278$ ). Table 8 shows the coded results of our question about why users felt comfortable or uncomfortable logging in.

When asked why users reported feeling “somewhat” or “very comfortable”, the majority of responses described looking at cues in the content area, citing that the website looked familiar (e.g., “*Because it’s familiar. I’ve seen it plenty of times.*”), or that they trust the website that appeared in the content area (e.g., “*Google is a secure company*”).

When describing discomfort, participants most commonly cited oddities with the URL (e.g., “*It seems to be an attempt to spoof Google on tinyurl*”). Relatively few participants mentioned concerns with feeling unsure how they would have navigated to this site (e.g., “*Because I have no idea how or why I’m here*”), while some described feeling unsure about the general security or safety of the site, but did not specify why (e.g., “*It’s an imposter*”).

Notably, even in open-ended responses where participants appear to have been looking at the URL, they did not necessarily notice any oddities. For example, one participant reported feeling “Very comfortable” with the `tinyurl.com` URL: “*Because the URL looks like a Google page should.*”

Condition 6, which showed only the registrable domain on the left of the address bar, stood out as the most distinct, with users citing oddities in the URL and generalized safety concerns at a disproportionate rate. However, the differences in comfort level between the control and this condition were not statistically significant ( $\chi^2 = 0.4541, df = 1, p = 0.5004$ ).

## 6 Discussion

### 6.1 Summary of results

In this paper, we used large-scale field data and surveys to corroborate past results on browser identity indicators and to contribute new findings.

Our EV field experiment (Section 3) found that removing the EV UI has no effect on most user behavior metrics. However, removing EV UI did cause users to open the Page Info bubble (Figure 3) less often, and it caused a small decrease in navigations for one of the top 20 EV sites. Our experiment corroborates prior work suggesting that EV UI does not help users detect attacks [24], but at a much larger scale, with naturalistic data, and with up-to-date browser UIs. The effect on Page Info is also consistent with prior findings that users may notice EV UI but not use it in their security decisions [33].

Our EV surveys (Section 4) are the first to study cross-jurisdiction collisions and Safari’s recent EV UI change. In all conditions across both surveys, EV UI did not appear to affect users’ comfort levels when logging into a webpage. Our qualitative data corroborates past results that users use the content area rather than browser UI to make trust decisions [12] and that connection security indicators can be mistaken to mean that the site is safe [16]. We contribute new findings that EV indicators are likely ineffective against cross-jurisdiction collision attacks and that Safari’s old and new EV UIs have similar impacts on users’ comfort levels.

Table 8: Coding results of the open-ended question “Can you tell us why you feel that way?” when participants were asked how comfortable they were logging in to a site. Cdn 1 is the topmost condition shown in Figure 8 and Cdn 7 is the bottommost.

Finally, we surveyed users to determine if variations on Chrome’s URL display can make it a more effective identity indicator (Section 5). None of our variations appeared to make users uncomfortable to log in to a phishing webpage. This survey corroborated prior studies showing that URLs are ineffective identity indicators [12, 28, 40], and extended them to show that several variations on browser URL display are ineffective as well. There were small but statistically insignificant differences among our variations; while a larger sample size might yield statistically significant differences, we think they are unlikely to be large effects.

## 6.2 Ineffectiveness of identity indicators

Removing the EV indicator did not affect most user behaviors, suggesting that an EV certificate does not provide a good defense against phishing or social engineering. While the EV UI did cause users to open Page Info more often, users did not use its functionality substantially more often. We therefore believe that users may notice the EV indicator, but do not appear to use it in making security decisions. Moreover, our survey results suggest that recent proof-of-concept attacks against EV [11] would likely be effective, and that simple UI tweaks do not make URLs an effective identity indicator either. We conclude that browser vendors should pursue more radical redesigns of their current website identity indicators if they want them to be more effective.

## 6.3 Guidance for designing identity indicators

Based on our experimental results and our review of prior work (Section 7), we provide the following recommendations for the design of identity indicators:

- **Prefer active, negative indicators to passive indicators.** Our UI changes failed to make the URL an effective identity indicator. Prior work has seen some success in redesigning EV indicators to make them more noticeable [33] or more understandable [8], but not better able to help users detect attacks. In contrast, ac-

tive warnings like SSL errors have been successfully redesigned to reduce clickthrough rates [14]. We therefore recommend that the security community focus on triggering active warnings when a website’s identity is suspicious (for example, when a domain is suspiciously similar to a popular domain), rather than relying on users to notice and act on passive identity indicators.

- **Prominent UI is an opportunity for user education.** Removing the EV indicator caused users to open the Page Info bubble less (Section 3.2.2). This effect suggests that prominent browser UI can be an opportunity to draw users’ attention and educate them about the browser’s identity indicators. For example, the Page Info bubble could explain the site’s identity and how users should take action on it. However, we saw that in both our control and experimental groups the typical user never opened the Page Info bubble (4.65% of users in the control group opened Page Info, while 0.45% of users in the experimental group did). It is unclear if this is due to a lack of user understanding or a mismatch between users’ goals and the controls provided by Page Info. Additionally, prior attempts at user education about identity indicators have been only marginally effective (e.g., [24, 28, 40]). Combined, we believe this indicates that more work is needed to understand if this approach is viable.
- **Incorporate user research in identity indicator design.** We recommend that browser vendors undergo extensive user research before launching new identity indicators, via both browser telemetry and user studies. As our work shows, both types of user research provide value: telemetry from field experiments can measure aggregate or per-site effects over large numbers of users in naturalistic settings, whereas user studies can provide insight into users’ thought processes.

## 7 Related work

In this section, we survey related work on browser identity indicators and EV certificates.

### 7.1 EV effectiveness

#### 7.1.1 User studies

**Detecting fraudulent sites.** In the 2000s, a number of studies analyzed how users react to EV indicators, finding that they were not effective in helping users detect phishing.

Jackson et al. [24] surveyed 27 participants about Internet Explorer 7's new EV UI. They concluded that it did not help users detect two types of phishing attacks (picture-in-picture and homograph attacks), even after receiving education about the UI.

Sobey et al. [33] analyzed Firefox 3's EV indicator as well as their own new EV design. In a lab study of 28 participants, they found that users did not notice Firefox 3's new EV indicator, but half did notice their new design. However, only a small number of participants seemed to use the newly designed indicator for decision-making.

These studies provide evidence that browser EV indicators are not effective, but they study only a small number of participants in an artificial lab scenario. Moreover, they study the very earliest EV indicators; little work has been done recently to study EV in modern browser UIs. Our work updates and expands these studies by providing large-scale in situ browser telemetry data, as well as survey data from over 1,000 participants, using modern browser UIs.

**Designing EV for reassurance and understanding.** Biddele et al. [8] studied Internet Explorer 7's EV indicator, comparing it to a new EV indicator of the researchers' design. Surveying 40 participants, the researchers found that their new design improved users' confidence, ease of finding information, and ease of understanding. However, they did not evaluate whether the new design helped users identify the attacks we considered. It remains an open question whether a redesigned EV indicator can effectively prevent phishing and social engineering attacks.

#### 7.1.2 Attack proofs of concept

Researchers have recently demonstrated flaws in the EV validation procedures. The researchers obtained misleading certificates that can undermine the effectiveness of EV.

One researcher obtained a certificate for a company named "Identity Verified" [10]. This demonstrated that a malicious website could abuse the EV indicator's privileged position in browser UI to make the attack website seem more legitimate.

Another researcher obtained an EV certificate for a company named "Stripe, Inc.", mimicking the payments company but incorporated in a different state [11]. This demonstrated that EV certificates are subject to cross-jurisdiction collisions in which a user may not be able to distinguish two

identical company names (one legitimate and one malicious) incorporated in different jurisdictions.

Our work is complementary to these attacks. We are primarily concerned with whether users notice and understand the EV indicator, rather than with how it can be attacked and abused. However, we do lend credence to the cross-jurisdiction collision demonstration by evaluating whether users notice cross-jurisdiction collisions (Section 4).

### 7.2 URL comprehension

Our work analyzes whether simple tweaks to browser URL display can help users identify fraudulent sites. Several prior studies have examined whether users understand URLs and can use them to detect attacks.

Lin et al. [28] asked 22 participants to identify fraudulent sites with and without explicit instruction to look at the browser address bar. While their user education effort was successful to an extent, it was not effective for many users and cannot be relied upon as a sole defense. Similarly, Wu et al. [39] and Dhamija et al. [12] found that neither browser address bars nor various supplemental security toolbars helped users detect phishing. In a lab study with a think-aloud protocol, Jakobsson et al. [25] concluded that users look at URLs in the process of determining whether a website is authentic, but they can be easily fooled by tricky URLs.

Xiong et al. [40] expanded Lin et al.'s work to include a control condition that did not highlight the domain in the UI, as well as a larger, more representative participant group and eye-tracking data. They found that instructing participants to look at the address bar led to a modest improvement in their ability to detect fraudulent sites, but the domain highlighting in the browser UI had no detectable effect. Their eye-tracking data suggested that explicit instructions about the browser address bar can draw users' attention to the URL, but does not give them the information or understanding that they need to draw accurate security conclusions from it.

Our work extends Xiong et al.'s study by testing multiple UI variations. Our URL formatting survey (Section 5) corroborates the existing findings that drawing users' attention to the URL bar does not help them make accurate security decisions. We contribute new findings that various UI modifications do not succeed in the goal of making the URL more noticeable and comprehensible.

### 7.3 Other web security UIs

Other security UIs on the web have been examined through user studies, browser telemetry, surveys, and eye-tracking.

#### 7.3.1 Connection security indicators

Research results on browser connection security indicators have been mixed. While some studies have found that many users look at and understand them [19,37], others have found that they do not affect user behavior [12,31]. Felt et al. [16] surveyed thousands of users to redesign connection secu-

rity indicators that met modern design constraints and better communicated the intended semantics.

Multiple studies have investigated user understanding of connection security and HTTPS, finding that users, especially those without technical backgrounds, do not have well articulated mental models for how the Internet works [26], and often conflate HTTPS and the lock icon with site security rather than connection security [38]. Krombholz et al. [27] expanded this prior work by exploring end user and administrator mental models of HTTPS, finding many misconceptions about the benefits and threat models of HTTPS among both groups. Particularly relevant for our work here, they found general distrust in HTTPS as a protocol and that security indicators are rarely part of users' mental models.

Our work contributes to this body of evidence that browser identity indicators, like connection security indicators, do not help users make security decisions. While we do not attempt to redesign identity indicators in this paper, the techniques used by Felt et al. to redesign connection security indicators could be useful for redesigning identity indicators.

### 7.3.2 Browser warnings and prompts

A large body of work has examined users' reactions to browser security warnings and prompts. Malkin et al. [29] and Bravo-Lillo et al. [9] conducted Mechanical Turk studies to evaluate UI changes for HTTPS warnings and plugin installation prompts, respectively. Browser security warnings have been found to have high clickthrough rates in lab studies (e.g., [12, 34, 35]), but lower in the wild [7, 14].

### 7.3.3 Website credibility and authenticity

Websites themselves contain security UI, including security and identity indicators. Fogg et al. [17] performed an online study to understand what makes users perceive a website as credible, and Jakobsson et al. [25] conducted a lab study to examine how users determine whether a website is authentic. These studies found that various aspects of a webpage, such as its language and spelling, can contribute to whether users perceive it as credible and/or authentic. Our survey experiments also find that users pay more attention to the website content than to browser UI when making trust decisions.

## 8 Conclusion

Browser identity indicators, including URLs and EV certificates, are supposed to help users identify phishing, social engineering, and other attacks, but prior lab studies and surveys suggested that older browser identity UIs are not effective security tools. In this paper, we sought to understand whether users would act on modern browser identity indicators. We provide naturalistic large-scale data about how users react to the EV indicator. We then survey thousands of users to understand the effects of recent developments in the EV ecosystem, and whether simple tweaks to browsers' URL displays can help users understand URLs better as identity indicators. We conclude that modern browser identity

indicators are not effective. To design better identity indicators, we recommend that browsers consider focusing on active negative indicators, explore using prominent UI as an opportunity for user education, and incorporate user research into the design phase.

## 9 Acknowledgments

Thanks to Devon O'Brien, Jim Bankoski, Parisa Tabriz, Ryan Sleevi, Andrew Whalley, and Chelsea Tanaka for their support and feedback on this work.

# RAZOR: A Framework for Post-deployment Software Debloating

Chenxiong Qian\*, Hong Hu\*, Mansour Alharthi, Pak Ho Chung, Taesoo Kim, Wenke Lee

*Georgia Institute of Technology*

## Abstract

Commodity software typically includes a large number of functionalities for a broad user population. However, each individual user usually only needs a small subset of all supported functionalities. The *bloated* code not only hinders optimal execution, but also leads to a larger attack surface. Recent works have explored *program debloating* as an emerging solution to this problem. Unfortunately, these works require program source code, limiting their real-world deployability.

In this paper, we propose a practical debloating framework, RAZOR, that performs code reduction for deployed binaries. Based on users' specifications, our tool customizes the binary to generate a functional program with minimal code size. Instead of only supporting given test cases, RAZOR takes several control-flow heuristics to infer complementary code that is necessary to support user-expected functionalities. We evaluated RAZOR on commonly used benchmarks and real-world applications, including the web browser FireFox and the close-sourced PDF reader FoxitReader. The result shows that RAZOR is able to reduce over 70% of the code from the bloated binary. It produces functional programs and does not introduce any security issues. RAZOR is thus a practical framework for debloating real-world programs.

## 1 Introduction

*"Entities are not to be multiplied without necessity."*

— Occam's Razor

As commodity software is designed to support more features and platforms to meet various users' needs, its size tends to increase in an uncontrolled manner [16, 39]. However, each end-user usually just requires a small subset of these features, rendering the software *bloated*. The bloated code not only leads to a waste of memory, but also opens up unnecessary attack vectors. Indeed, many serious vulnerabilities are rooted in the features that most users never use [31, 35]. Therefore, security researchers are beginning to explore software *debloating* as an emerging solution to this problem.

\*The two lead authors contributed equally to this work.

Unfortunately, most initial works on software debloating rely on the availability of program source code [40, 15, 44], which is problematic in real-world use. First, most users do not have access to the source code, and even if they do, it is challenging for them to rebuild the software, diminishing the intended benefits of software bloating. Moreover, users may use the same software in drastically different ways, and thus the unnecessary features to be removed will accordingly vary from user to user. Therefore, to obtain the most benefits, the debloating process should take place after software deployment and should be tailored for each individual user.

Making such a *post-deployment* approach beneficial and usable to end-users creates two challenges: 1) how to allow end-users, who have little knowledge of software internals, to express which features are needed and which should be removed and 2) how to modify the software binary to remove the unnecessary features while keeping the needed ones.

To address the first challenge, we can ask end-users to provide a set of sample inputs to demonstrate how they will use the software, as in the CHISEL work [15]. Unfortunately, programs debloated by this approach only support given inputs, presenting a rather unusable notion of debloating: if the debloated software only needs to support an apriori, fixed set of inputs, the debloating process is as simple as synthesizing a map from the input to the observed output. However, from our experiments, we find that even processing the same input multiple times will result in different execution paths (due to some randomization factors). Therefore, the naive approach will not work even under simplistic scenarios.

In order to practically debloat programs based on user-supplied inputs, we must identify the code that is necessary to completely support required functionalities but is not executed when processing the sample inputs, called *related-code*. Unfortunately, related-code identification is difficult. In particular, it is challenging for end-users (even developers) to provide an input corpus that exercises all necessary code that implements a feature. Furthermore, if the user provides some description of all possible inputs (*e.g.*, patterns), it is still hard to identify all reachable code for those inputs. Thus, we be-

lieve that any debloating mechanism in the post-deployment setting will be based on *best-effort heuristics*. The heuristics should help identify the related-code as much as possible, and meanwhile include minimal functionally unrelated code. Note that techniques like dead code elimination [23, 22] and delta debugging [49, 42] do not apply to this problem because they only focus on either removing static dead code or preserving the program’s behavior on a few specific inputs.

We design four heuristics that infer related-code based on the assumption that code paths with more significant divergence represent less related functionalities. Specifically, given one executed path  $p$ , we aim to find a different path  $q$  such that 1)  $q$  has no different instructions, or 2)  $q$  does not invoke new functions, or 3)  $q$  does not require extra library functions, or 4)  $q$  does not rely on library functions with different functionalities. Then, we believe  $q$  has functionalities similar to  $p$  and treat all code in  $q$  as related-code. From 1) to 4), the heuristic includes more and more code in the debloated binary. For a given program, we will gradually increase the heuristic level until the generated program is stable. In fact, our evaluation shows that even the most aggressive heuristic introduces only a small increase of the final code size.

Once all the related-code is identified, we develop a binary-rewriting platform to remove unnecessary code and generate a debloated program. Thanks to the nature of program debloating, our platform does not face the symbolization problem from general binary-rewriting tools [51, 53, 52, 5]. Specifically, a general binary-rewriting tool has to preserve all program functionalities, which is difficult without a reliable disassembling technique and a complete control-flow graph (CFG) [2]. For debloating, we preserve only the functionalities related to the sample inputs, where the disassembling and CFG are available by observing the program execution.

We designed the RAZOR framework to realize the post-deployment debloating. The framework contains three components: **Tracer** monitors the program execution with the given sample inputs to record all executed code; **PathFinder** utilizes our heuristics to infer more related-code from the executed ones; **Generator** generates a new binary based on the output of Tracer and PathFinder. In the RAZOR framework, we implemented three tracers (two based on dynamic binary instrumentation and one based on a hardware tracing feature), four path finding heuristics, and one binary generator.

To understand the efficacy of RAZOR on post-deployment debloating, we evaluated it on three sets of benchmarks: all SPEC CPU2006 benchmarks, 10 coreutils programs used in previous work, and two real-world large programs, the web browser Firefox and the closed-sourced PDF parser FoxitReader. In our evaluation, we performed tracing and debloating based on one set of training inputs and tested the debloated program using a different set of functionally similar inputs. Our results show that RAZOR can effectively reduce 70-80% of the original code. At the same time, it introduces only 1.7% overhead to the new binary. We compared RA-

ZOR with CHISEL on debloating 10 coreutils programs and found that CHISEL achieves a slightly better debloating result (smaller code size), but it fails several programs on given test cases. Further, CHISEL introduces exploitable vulnerabilities to the debloated program, such as buffer overflows resulting from the removed boundary checks. RAZOR does not introduce any security issues. We also analyzed the related-code identified by our path finder and found that different heuristics effectively improve the program robustness.

In summary, we make the following contributions:

- **New approach.** We proposed a practical post-deployment debloating framework that works on program binaries. Besides given test inputs, our system supports more inputs of the required functionalities.
- **Open source.** We designed RAZOR as an end-to-end system to produce a minimal functional executable. We implemented our system on an x86-64 Linux system and will open source RAZOR at <https://github.com/cxreet/razor>.
- **Practical and ready-to-use.** We evaluated RAZOR on real-world programs such as Firefox and FoxitReader and showed that these programs can be significantly debloated, resulting in better security.

## 2 Problem

### 2.1 Motivating Example

Figure 1a shows a bloated program, which is designed to parse image files in different formats. Based on the user-provided options (line 4 and 6), the program invokes function `parsePNG` to parse PNG images (line 5) or invokes function `parseJPEG` to handle JPEG images (line 7). In function `parsePNG`, the code first allocates memory to hold the image content and saves the memory address in `img` (line 10). Then it makes sure `img` is aligned to 16-bytes with the macro `ALIGN` (line 11 and 12). Finally, it invokes function `readToMem` to load the image content from file into memory for further processing. Function `parseJPEG` has a structure similar to `parsePNG`, so we skip its details.

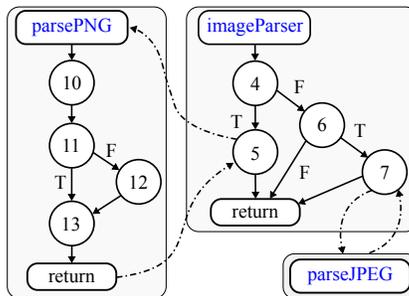

Although the program in Figure 1a merely supports two image formats, it is still bloated if the user only uses it to process PNG files. For example, screenshots on iPhone devices are always in PNG format [27]. In this case, the code is bloated with the unnecessary JPEG parser, which may contain security bugs [18]. Attackers can force it to process malformed JPEG images to trigger the bug and launch remote code execution. In real-world software ecosystem, we can easily find document readers (*e.g.*, Preview on MacOS) that support obsolete formats (*e.g.*, PCX, Sun Raster, TGA). We can debloat these programs to reduce their code sizes and attack surfaces.

```

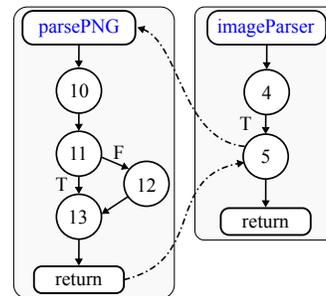

1 #define MAX_SIZE 0xffff
2 #define ALIGN(v,a) (((v+a-1)/a)*a)
3 void imageParser(char *options, char *file_name) {
4     if (!strcmp(options, "PNG"))
5         parsePNG(file_name);
6     else if (!strcmp(options, "JPEG"))
7         parseJPEG(file_name);
8 }
9 void parsePNG(char *file_name) {
10    char * img = (char *)malloc(MAX_SIZE + 16);
11    if ((img % 16) != 0)
12        img = ALIGN(img, 16);
13    readToMem(img, file_name);
14 }
15 void parseJPEG(char *file_name) { ... }

```

(a) A bloated image parser.

(b) Original control-flow graph.

(c) Debloated control-flow graph

**Figure 1:** Debloating an image parser. (a) shows the code of the bloated image parser, where the program invokes different functions to handle PNG or JPEG files based on the options. The control-flow graphs before and after debloating are shown in (b) and (c).

## 2.2 Program Debloating

In this paper, we develop techniques to remove user-specified unnecessary functionalities from bloated programs. Given a program  $P$  that has a set of functionalities  $\mathcal{F} = \{F_0, F_1, F_2, \dots\}$  and a user specification of necessary functionalities  $\mathcal{F}_u = \{F_i, F_j, F_k, \dots\}$ , our goal is to generate a new program  $P'$  that only retains functionalities in  $\mathcal{F}_u$  and gracefully refuses requests of other functionalities in  $\mathcal{F} - \mathcal{F}_u$ .

The program in Figure 1a has two high-level functionalities: parsing PNG images and parsing JPEG images, while the user specification only requires the first functionality. In this case, the goal of debloating is to generate minimal code that only supports parsing PNG files while exiting gracefully if the given images are in other formats. From the simple code we can easily tell that code in the yellow background (*i.e.*, line 6, 7 and 15) is not necessary, so we remove such code in a safe manner: function `parseJPEG` will be simply removed; for line 6 and 7, we should replace the code with fault-handling code to prompt warnings and exit gracefully.

In this paper, we focus on reducing functionalities from software binaries. Specifically, the program  $P$  is given as a binary, while the source code like Figure 1a is not available. Instead, we construct the control-flow graph (CFG) from the executable and use it to guide the binary debloating. Figure 1b and Figure 1c show CFGs of the bloated binary and the debloated one, respectively. Black arrows represent intra-procedural jumps, while dotted arrows stand for inter-procedural calls and returns. Originally, function `imageParser` can execute lines 6 and 7 and invoke function `parseJPEG`. In the debloated binary, these lines and functions are not reachable, and the CFG is simplified to Figure 1c. For the vulnerability in the removed code, the new binary prevents attackers from triggering them in the first place.

## 2.3 Challenges and Solutions

From the previous example, we can find the gap between the user specification and the code removed: users specify

that the functionality of parsing PNG files is necessary (*i.e.*, others are unnecessary), while we finally remove line 6, line 7, and function `parseJPEG`. However, mapping high-level functionalities to low-level code manually is challenging, especially for large programs. Specifically, this leads to two general challenges of program debloating:

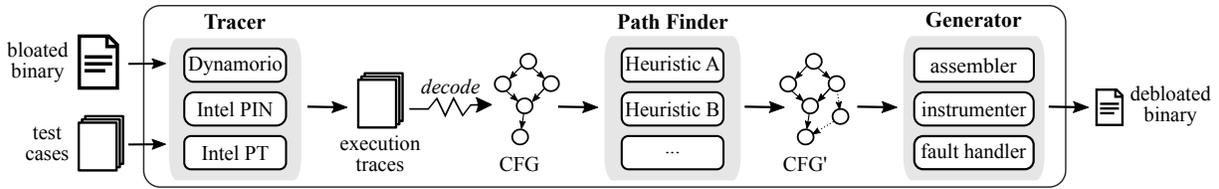

- C1.** How to express unnecessary functionalities;
- C2.** How to map functionalities to program code.

One possible solution is to rely on end-users to provide a set of test cases for each necessary/unnecessary functionality so we can inspect the program execution to learn the related program code. Our problem can be rephrased as follows: given the program binary  $P_b$  and a set of test cases  $T = \{t_i, t_j, t_k, \dots\}$ , where each test case  $t_i$  triggers some functionalities of  $P_b$ , we will create a minimal program  $P'_b$  that supports and only supports functionalities triggered by the test cases in  $T$ .

Test cases help us address challenges **C1** and **C2**. However, it is impossible to provide test cases that cover all related-code of the required functionalities. In this case, some related-code will not be triggered. If we simply remove all never-executed code, the program functionality will be broken. For example, the code at lines 11 and 12 of Figure 1a will make sure the pointer `img` is aligned to 16. Based on the concrete execution context, the return value of `malloc` (at line 10) may or may not satisfy the alignment requirement. If the execution just passes the check at line 11, the simple method will delete line 12 for the minimal code size. However, if the later execution expects an aligned `img`, the program will show unexpected behavior or even crash. Our evaluation in §5.2 shows that simply removing all non-executed code introduces many bugs, even exploitable ones, to the debloated program. Therefore, a test-case-based debloating system faces the following challenge.

- C3.** How to find more related-code from limited test cases.

To address challenge **C3**, we propose control-flow-based heuristics to infer more related-code that is necessary to support the required functionalities but was missed during our

**Figure 2:** Overview of RAZOR. It takes in the bloated program binary and a set of test cases and produces a minimal, functional binary. Tracer collects the program execution traces with given test cases and converts them into a control-flow graph (CFG). PathFinder utilizes control-flow-based heuristics to expand the CFG to include more related-code. Based on the new CFG, Generator generates the debloated binary.

inspection. Suppose the test cases in  $T$  only trigger the execution of instructions in  $\mathcal{S} = \{i_0, i_1, i_2, \dots\}$ , our heuristic will automatically infer more code that is related to the functionalities covered by  $T$ . Specifically, we identify a super set  $\mathcal{S}' = \mathcal{S} \cup \{i_x, i_y, i_z, \dots\}$  and keep all instructions in  $\mathcal{S}'$  while removing others to minimize the code size. When debloating the code in Figure 1a, the execution of given test cases does not cover line 12. However, with our heuristics, we will include this line in the debloated program. The evaluation in §5.3 shows that our heuristic is effective in finding related-code paths and introduces only a small increase in code size.

### 3 System Design

Figure 2 shows an overview of our post-deployment debloating system, RAZOR. Given a bloated binary and a set of test cases that trigger required functionalities, RAZOR removes unnecessary code and generates a debloated binary that supports all required features with minimal code size. To achieve this goal, RAZOR first runs the binary with the given test cases and uses Tracer to collect execution traces (§3.1). Then, it decodes the traces to construct the program’s CFG, which contains only the executed instructions. In order to support more inputs of the same functionalities, PathFinder expands the CFG based on our control-flow heuristics (§3.2). The expanded CFG contains non-executed instructions that are necessary for completing the required functionalities. In the end, with the expanded CFG, Generator rewrites the original binary to produce a minimal version that only supports required functionalities (§3.3).

#### 3.1 Execution Trace Collection

Tracer executes the bloated program with given test cases and records the control-flow information in three categories: (1) executed instructions, including their memory addresses and raw bytes; (2) the taken or non-taken of conditional branches, like `je` that jumps if equal; (3) concrete targets of indirect jumps and calls, like `jmpq %rax` that jumps to the address indicated by register `%rax`. Our Tracer records the raw bytes of executed instructions to handle dynamically gen-

| Executed Blocks                     | Conditional Branches     |
|-------------------------------------|--------------------------|
| [0x4005c0, 0x4005f2]                | [0x4004e3: true]         |
| [0x400596, 0x4005ae]                | [0x4004ee: false]        |
| ...                                 | [0x400614: true & false] |
|                                     | ...                      |
| Indirect Calls/Jumps                |                          |
| [0x400677: 0x4005e6#18, 0x4005f6#6] |                          |
| ...                                 |                          |

**Figure 3:** A snippet of the collected trace. It includes the range of each executed basic block, the taken/non-taken of each condition branch, and the concrete target of indirect jumps/calls. We also record the frequency of each indirect jump/call target (after #).

erated/modified code. However, instruction-level recording is inefficient and meanwhile most real-world programs only contain static code. Therefore, Tracer starts with basic block-level recording that only logs the address of each executed basic block. During the execution, it detects any dynamic code behavior, like both writable and executable memory region (e.g., just-in-time compilation [13]), or overlapped basic blocks (e.g., legitimate code reuse [26]), and switches to the instruction-level recording to avoid missing instructions. A conditional branch may get executed multiple times and finally covers one or both targets (i.e., the fall-through target and the jump target). For indirect jump/call instructions, we log all executed targets and count their frequencies.

Figure 3 shows a piece of collected trace. It contains two executed basic blocks, one at address `0x4005c0` and another at `0x400596`. The trace also contains three conditional branch instructions: the one at `0x4004e3` only takes the `true` target; the one at `0x4004ee` only takes the `false` target; the one at `0x400614` takes both targets. One indirect call instruction at `0x400677` jumps to target `0x4005e6` for 18 times and jumps to target `0x4005f6` for six times. As the program only has static code, Tracer does not include the instruction raw bytes.

We find that it is worthwhile to use multiple tools to collect the execution trace. First, no mechanism can record the trace completely and efficiently. Software-based instrumentation can faithfully log all information but introduces significant overhead [7, 25, 6]. Hardware-based logging can record efficiently [20] but requires particular hardware and may not guarantee the completeness (e.g., data loss in Intel PT [17]). Second, program executions under different tracing environ-

ments will show divergent paths. For example, Dynamorio always expands the file name to its absolute path, leading to different executed code in some programs (e.g., vim). Therefore, we provide three different implementations (details in §4.1) with different software and hardware mechanisms. End-users can choose the best one for their requirement or even merge traces from multiple tools for better code coverage.

**CFG construction.** With the collected execution traces, RAZOR disassembles the bloated binary and constructs the partial control-flow graph (CFG) in a reliable way. Different from previous works that identify function boundaries with heuristics [52, 51, 3, 4, 45], RAZOR obtains the accurate information of instruction address and function boundary from the execution trace. For example, we can find some of all possible targets of indirect jumps and calls.

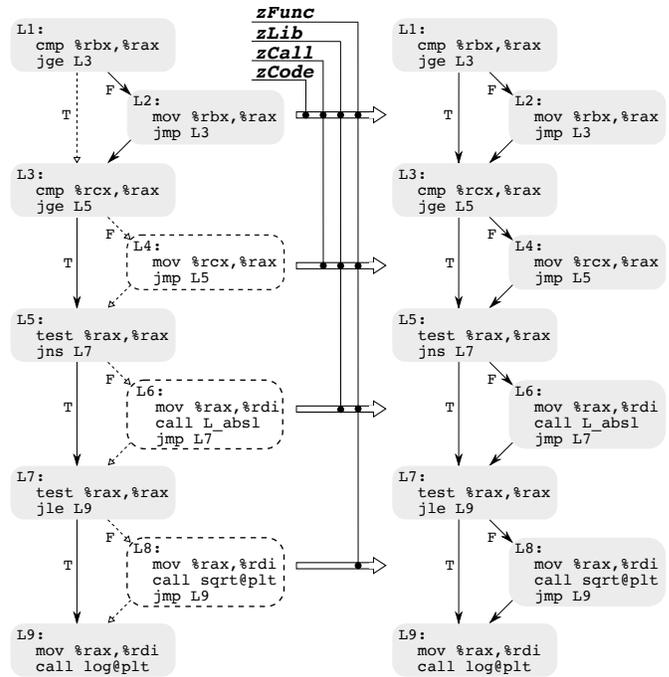

Starting from such reliable information, we are able to identify more code instructions [47]. For conditional branch instructions, both targets are known to us. Even if one target is not executed, we can still reliably disassemble it. For indirect jumps, we can identify potential jump tables with specific code patterns [53]. For example, `jmpq *0x4e65a0(,%rdx,8)` indicates a jump table starting from address `0x4e65a0`. By identifying more instructions, we are able to include them in the binary if our heuristic treats them as related-code.

### 3.2 Heuristic-based Path Inference

Considering the challenge of generating test cases to cover all code, we believe no perfect method can completely identify all missed related-code. As the first work trying to mitigate the problem, we adopt the *best-effort heuristic* approach to include more related-code. Next, we present these heuristics one by one, from the conservative one (including less code) to the aggressive one (including more code):

**(1) Zero-code heuristic (zCode).** This heuristic adds new edges (i.e., jumps between basic blocks) into the CFG. For conditional branch instructions that only have one target taken (the fall-through target or the jump target), PathFinder checks whether the non-taken target is already in the CFG (i.e., reached through other blocks). If so, PathFinder permits the jump from this instruction to the non-taken target. This heuristic does not add any new instructions and thus will not affect the code reduction.

Figure 4 shows an example of related-code identification with heuristics, with the original CFG on the left and the expanded CFG on the right. The code is designed to calculate  $\log(\sqrt{\text{abs1}(\max(\text{rax}, \text{rbx}, \text{rcx}))})$ . Dashed branches and blocks are not executed during tracing, while others are executed. The original execution path is `L1→L2→L3→L5→L7→L9`. Blocks `L4`, `L6`, `L8`, and the branch `L1→L3` are missed in the original CFG. With the `zCode` heuristic, PathFinder adds branch `L1→L3` into the new CFG, as `L3` is the non-taken branch of the conditional jump `jge L3` in `L1` and it is already reached from `L2` in the current CFG.

**Figure 4:** Identifying related-code with different heuristics. Dashed branches and blocks are not executed and thus are excluded from the left CFG, while others are executed.

**(2) Zero-call heuristic (zCall).** This heuristic includes alternative execution paths that do not trigger any function call. With this heuristic, PathFinder starts from the non-taken target of some conditional branches and follows the control-flow information to find new paths that finally merge with the executed ones. If such a new path does not include any `call` instructions, PathFinder includes all its instructions to the CFG. When PathFinder walks through non-executed instructions, we do not have the accurate information for stable disassembling or CFG construction. Instead, we rely on existing mechanisms [53, 3] to perform binary analysis. When applying the `zCall` heuristic on the example in Figure 4, PathFinder further includes block `L4`, and path `L3→L4→L5`, as this new path merges with the original one at `L5` and does not contain any `call` instruction.

**(3) Zero-libcall heuristic (zLib).** This heuristic is similar to `zCall`, except that PathFinder includes the alternative paths more aggressively. The new path may have `call` instructions that invoke functions within the same binary or external functions that have been executed. However, `zLib` does not allow calls to non-executed external functions. In Figure 4, with this heuristic, PathFinder adds block `L6` and path `L5→L6→L7` to the CFG, as that path does not have any call to non-executed external functions.

**(4) Zero-functionality heuristic (zFunc).** This heuristic further allows including non-executed external functions as long as they do not trigger new high-level functionalities. To correlate library functions with functionalities, we check their

12 include = !has\_new\_func(CFG', p, libcall\_groups)  
13 if include:  
14 CFG' = CFG' ∪ p

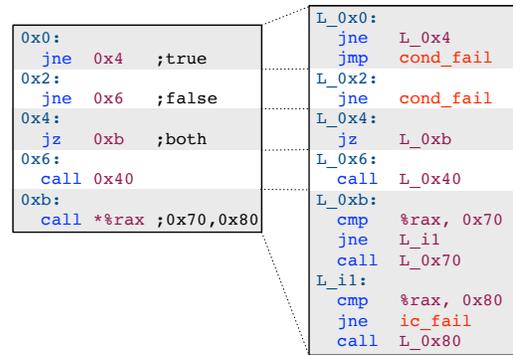

---

descriptions and group them manually. For libc functions, we classify the ones that fall into the same subsection in [32] to the same group. For example, log and sqrt are in the subsection Exponentiation and Logarithms, and thus we believe they have similar functionalities. With this heuristic, PathFinder includes block L8 and path L7→L8→L9, as sqrt has a functionality similar to the executed function log.

Algorithm 1 shows the steps that PathFinder uses to find related-code that completes functionalities. For each conditional branch in the input CFG (line 1), the algorithm invokes the function get\_non\_taken\_branch to get the non-taken branch (line 2). If both branches have been taken, the algorithm proceeds to the next conditional branch (line 3). Otherwise, PathFinder starts to add code depending on the given heuristic (line 4 to 14). If the non-taken branch is reachable in the current CFG (line 4), zCode enables the new branch in the output CFG (line 5). If the heuristic is more aggressive than zCode, PathFinder first gets all alternative paths that start from the non-taken branch and finally merges with some executed code (line 6). Then, it iterates over all paths (line 7) and calls corresponding checking functions (i.e., has\_call, has\_new\_libcall, and has\_new\_func) to check whether or not the path should be included (line 9 to 12). In the end, PathFinder adds the path to the output CFG if it satisfies the condition (line 14).

### 3.3 Debloated Binary Synthesization

With the original bloated binary and the expanded CFG, Generator synthesizes the debloated binary that exclusively supports required functionalities. First, it disassembles the original binary following the expanded CFG and generates a pseudo-assembly file that contains all necessary instructions. Second, Generator modifies the pseudo-assembly to create a valid assembly file. These modifications symbolize basic blocks, concretize indirect calls/jumps, and insert fault han-

**Figure 5:** Synthesize debloated assembly file. Each basic block is assigned a unique label; indirect calls are expanded with comparisons and direct calls; fault handling code is inserted.

dling code. Third, it compiles the assembly file into an object file that contains machine code of the necessary instructions. Fourth, Generator copies the machine code from the object file into a new code section of the original binary. Fifth, Generator modifies the new code section to fix all references to the original code and data. Finally, Generator sets the original code section non-executable to reduce the code size. We leave the original code section inside the debloated program to support the potential read from it (e.g., jump tables in code section for implementing switch [11]). We discuss this design choice in §6.

#### 3.3.1 Basic Block Symbolization

We assign a unique label to each basic block and replace all its references with the label. Specifically, we create the label L\_addr for the basic block at address addr. Then, we scan all direct jump and call instructions and replace their concrete target addresses with corresponding labels. In this way, the assembler will generate correct machine code regardless of how we manipulate the assembly file. Figure 5 shows an assembly file before and after the update, illustrating the effect of basic block symbolization. Before the update, all call and jump instructions use absolute addresses, like jne 0x6 in basic block 0x0. After the symbolization, the basic block at 0x6 is assigned the label L\_0x6, while instruction jne 0x6 is replaced with jne L\_0x6. Similarly, instruction call 0x40 in block 0x06 is replaced with call L\_0x40. One special case is the conditional branch jne 0x6 in basic block 0x2. In the extended CFG, it only takes the fall-through branch, which means that jumping to block 0x6 should not be allowed in the debloated binary. Therefore, instead of replacing 0x6 with symbol L\_0x6, we redirect the execution to the fault handling code cond\_fail (will discuss in §3.3.3). Note that basic block symbolization only updates explicit use of basic block addresses, i.e., as direct call/jump targets. We handle the implicit address use, like saving function address into memory for indirect call, with the indirect call/jump concretization.

### 3.3.2 Indirect Call/Jump Concretization

Indirect call/jump instructions use implicit targets that are loaded from memory or calculated at runtime. We have to make sure all possible targets point to the new code section. For the sake of simplicity, we use the term `indirect call` to cover both indirect calls and indirect jumps.

With the execution traces, Generator is able to handle indirect calls in two ways. The first method is to locate constants from the original binary that are used as code addresses and replace them with the corresponding new addresses, as in [52, 51]. However, this method requires a heavy tracing process that records all execution context and a time-consuming data-flow analysis. Therefore, it is impractical for large programs. The second method is to perform the address translation before each indirect call, as in [53]. In particular, we create a map from the original code addresses to the new ones. Before each indirect call, we map the old code address to the new one and transfer the control-flow to the new address.

Our Generator takes a method similar to the second one, but with different translations for targets within the same module (named local targets) and targets outside the module (named global targets). For local targets, we define a concrete policy for each indirect call instruction. Specifically, we replace the original call with a set of compare-and-call instructions, one for each local target that is executed by *this* instruction at tracing. Then, we call the new address of the matched old addresses. Global targets have different addresses in multiple runs because of the address space layout randomization (ASLR). We use a per-module translation table to solve this problem. Different from previous work that creates a translation table for all potential targets in the module [53], our translation table contains only targets that are ever invoked by other modules. At runtime, if the target address is outside the current module, we use a global translation function to find the correct module and look up its translation table to get the correct new address to invoke.

Figure 5 gives an example of indirect call concretization. In the execution trace, instruction `call %rax` in block `0xb` transfers control to function at `0x70` and `0x80`. Our concretization inserts two `cmp` instructions, one to compare with the address `0x70` and another to compare with `0x80`. For any successful comparison, Generator inserts a direct call to transfer the control-flow to the corresponding new address.

**Security benefit.** Our design achieves a stronger security benefit on control-flow protection over previous methods. For example, the previous work binCFI [53] uses a map to contain all valid code addresses, regardless of which instruction calls them. Thus, any indirect call instruction can reach all possible targets, making the protection vulnerable to existing bypasses [12, 43, 9]. Our design is functionally equivalent to creating one map for each indirect call, which contains both the targets obtained from the trace and the targets inferred by

our PathFinder. For inter-module indirect calls, we limit the targets to a small set that is ever invoked by external modules. In this way, attackers who try to change the control flow will have fewer choices, and the debloated binary will be immune to even advanced attacks.

**Frequency-based optimization.** Depending on the number of executed targets, we may insert many compare-and-call instructions that will slow the program execution. For example, one indirect call instruction in `perlbench` benchmark of SPEC CPU2006 has at least 132 targets, and each target is invoked millions of times. To reduce the overhead, we rank all targets with their execution frequencies and compare the address with high-frequent targets first. The targets inferred from heuristics have a frequency of zero. With this optimization, we can reduce the overhead significantly.

### 3.3.3 Fault Handling

Running a debloated binary may reach removed code or disabled branches for various reasons, such as a user's temporal requirement for extra functionalities or malicious attempts to run unnecessary code. We redirect any such attempt to a fault handler that exits the execution and dumps the call stack. Specifically, for conditional jump instructions with only one target taken, we intercept the branch to the non-taken target to hook any attempt of the invalid jump. Similarly, for indirect call instructions, if no allowed target matches the runtime target, we redirect the execution to the fault handler.

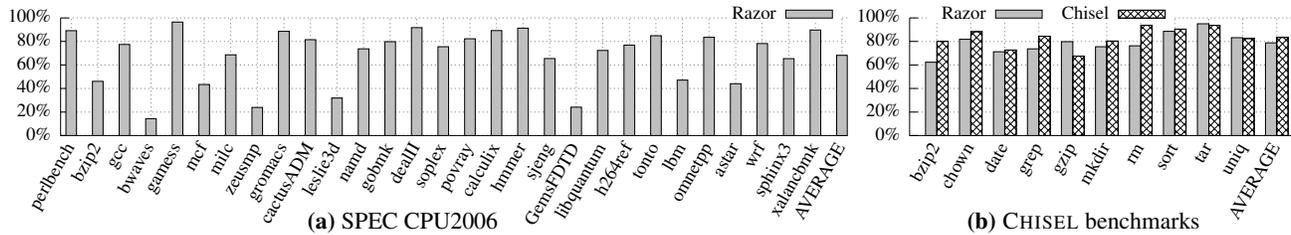

Figure 5 includes examples of hooking failed conditional jumps and indirect calls. For instruction `jne 0x4` in block `0x0`, we insert `jmp cond_fail` to redirect the branch to the fall-through target to the fault handler `cond_fail`. Similarly, we update instruction `jne 0x6` with `jne cond_fail` to prevent jumping to the non-executed target. For conditional branch `jz 0xb` which has both targets taken, we do not insert any code. For instruction `call %rax`, we insert code `jne ic_fail` in the case that all allowed targets are different from the real-time one.

## 4 Implementation

We implement a prototype of RAZOR with 1,085 lines of C code, 514 lines of C++ code, and 4,034 lines of python code, as shown in Table 1. The prototype currently supports x86-64 ELF binaries. Our design is platform-agnostic and we plan to support other binary formats from different architectures. We tried our system on system libraries (e.g., `libc.so`, `libm.so`) and report our findings in §6.

### 4.1 Tracer Implementations

As we discussed in §3.1, each tracing method has different benefits and limitations, such as the tracing efficiency and completeness. We provide three different implementations of

**Figure 6: Code size reduction on two benchmarks.** We use RAZOR to debloat both SPEC CPU2006 benchmarks and CHISEL benchmarks without any path finding and achieve 68.19% and 78.8% code reduction. CHISEL removes 83.4% code from CHISEL benchmarks.

| Component | Tracer | PathFinder | Generator | Total |
|-----------|--------|------------|-----------|-------|
| C         | 1,085  | 0          | 0         | 1,085 |
| C++       | 514    | 0          | 0         | 514   |
| Python    | 218    | 743        | 3,073     | 4,034 |

**Table 1: Implementation of different RAZOR components.**

Tracer in RAZOR so that users can choose the best one for their purpose. In our evaluation, we use software-based instrumentation to collect complete traces for simple programs, and use a hardware-based method to efficiently get trace from large programs.

**Tracing with software instrumentation.** We use the dynamic instrumentation tools Dynamorio [7] and Pin [25] to monitor the execution of the bloated program. Both tools provide instrumentation interfaces at function level, basic block level, and instruction level. We implement three instrumentation passes to collect control-flow information. First, at the beginning of each basic block we record its start address; second, for each conditional jump instruction, we insert two pieces of code between the instruction and its two targets to log the taken information; third, before each indirect call and jump instruction, we record the concrete target for each invocation. At runtime, we remove the basic block instruction immediately after its first execution to avoid unnecessary overhead. Similarly, we remove the instrumentation of conditional branches once that branch has been taken. However, we keep the instrumentation of indirect call and jump instructions, as we do not know the complete set of targets.

**Tracing with hardware feature.** Considering the overhead of software instrumentation, we provide an efficient Tracer built on Intel Processor Trace (Intel PT) [20]. Intel PT records the change of flow information in a highly compressed manner: the TNT packet describes whether one conditional branch is taken or non-taken; the TIP packet records the target of indirect branches, like indirect call and return. As Intel PT directly writes the trace to physical memory without touching the page table or memory cache, it achieves the most efficient tracing. Our Tracer decodes the traces from Intel PT to get necessary control-flow information. We can use other hardware features available on different platforms to implement efficient Tracer, like branch trace store (BTS)

on Intel CPUs or program flow trace (PTM) on ARM CPUs.

## 4.2 Update ELF Exception Handler

ELF binaries generated by gcc and clang adopt the table-based exception handling [46] to provide stack unwind and exception handler information. Specifically, ELF keeps a table in the `.eh_frame_hdr` section, one entry per function. Each entry indicates the location of a frame description entry (FDE) in the `.eh_frame` section, which further specifies the location of the language-specific data area (LSDA). The LSDA region in the `.gcc_except_table` section contains the concrete address of exception handlers, called landingpad.

We have to replace the old value of all landingpads in `.gcc_except_table` with the new ones. However, the challenge is that the value in `.gcc_except_table` is encoded in the LEB128 format – a variable-length encoding that may have different lengths for different values. Since we update the old address with a different one, the encoding of the new address may take more bytes and thus cannot be put into the original location. To solve this problem, we update the section layout of the binary to create more space for the new address. Specifically, we shrink the table inside the `.eh_frame_hdr` section to exclude entries of non-executed functions. Recall that the given test cases only trigger part of the functionalities, and the non-executed functions will not be included in the debloated binary. Then we shift `.eh_frame` and `.gcc_except_table` sections to get more space for our update of landingpad values.

## 5 Evaluation

In this section, we perform extensive evaluation in order to understand RAZOR regarding the following aspects:

- **Code reduction.** How much code can RAZOR reduce from the original bloated binary? (§5.1)
- **Functionality.** Does the debloated binary support the functionalities in given test cases? (§5.2) How effective is PathFinder in finding complementary code? (§5.3)
- **Security.** Does RAZOR reduce the attack surface of the debloated binaries? (§5.4)

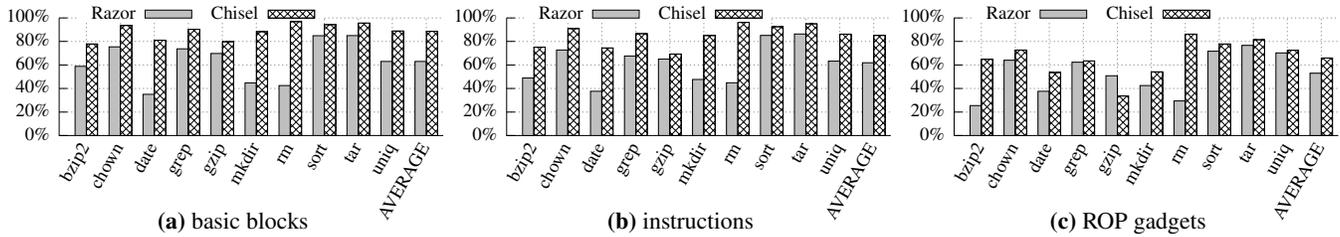

Figure 7: Reduction of basic blocks, instructions, and ROP gadgets, debloated by RAZOR and CHISEL from CHISEL benchmarks.

- **Performance.** How much overhead does RAZOR introduce into the debloated binary? (§5.5)
- **Practicality.** Does RAZOR work on commonly used software in the real world? (§5.6)

**Experiment setup.** We set up three sets of benchmarks to evaluate RAZOR: 29 SPEC CPU2006 benchmarks, including 12 C programs, seven C++ programs, and 10 Fortran programs; 10 coreutils programs used in the CHISEL paper<sup>1</sup> [15]; the web browser Firefox and the close-source PDF reader FoxitReader. We use the software-based tracing tools that rely on Dynamorio and Pin to collect the execution traces of SPEC and CHISEL benchmarks, to get accurate results; for the complicated programs Firefox and FoxitReader, we use the hardware-based tracing tool (relying on Intel PT) to guarantee the execution speed to avoid abnormal behaviors. We ran all the experiments on a 64-bit Ubuntu 16.04 system equipped with Intel Core i7-6700K CPU (with eight 4.0GHz cores) and 32 GB RAM.

## 5.1 Code Reduction

We applied RAZOR on SPEC CPU2006 benchmarks and CHISEL benchmarks to measure the code size reduction. For SPEC benchmarks, we treated the train dataset as the user-given test cases. For CHISEL benchmarks we obtained test cases from the paper’s authors. We did not apply any heuristics of path finding for this evaluation. As RAZOR works on binaries, we cannot measure the reduction of source code lines. Instead, we compare the size of the executable memory region before and after the debloating, specifically, the program segments with the executable permission. Figure 6a shows the code reduction of SPEC benchmarks debloated by RAZOR. Figure 6b shows the code reduction of CHISEL benchmarks, debloated by CHISEL and RAZOR.

On average, RAZOR achieves 68.19% code reduction for SPEC benchmarks and 78.8% code reduction for CHISEL benchmarks. Especially for dealIII, hmmer, gamess, and tar, RAZOR removes more than 90% of the original code. For bwaves, zeusmp, and GemsFDTD, RAZOR achieves less than 30% code reduction. We investigated these exceptions and found that these programs are relatively small and the train

<sup>1</sup>We appreciate the help of CHISEL authors for sharing the source code and their benchmarks.

datasets already trigger most of the code.

Meanwhile, CHISEL achieves 83.4% code reduction on CHISEL benchmarks. For seven programs, CHISEL reduces more code than RAZOR, while RAZOR achieves higher code reduction than CHISEL for the other three programs. CHISEL tends to remove more code as long as the execution result remains the same. For example, variable initialization code always gets executed at the function beginning. CHISEL will remove it if the variable is not used in the execution, while RAZOR will keep it in the debloated binary. Although CHISEL performs slightly better than RAZOR on code reduction, we find that the debloated binaries from CHISEL suffer from robustness issues (§5.2) and security issues (§5.4).

**Other reduction metrics.** We also measured RAZOR’s effectiveness on reducing basic blocks (Figure 7a) and instructions (Figure 7b) from CHISEL benchmarks and compared these results with those achieved by CHISEL. On average, RAZOR removes 53.1% of basic blocks and 63.3% of instructions from the original programs, while CHISEL reduces 66.0% of basic blocks and 88.5% of instructions from the same set of programs. This result is consistent with the code size reduction, where RAZOR reduces less code, as it can neither remove any executed-but-unnecessary blocks or instructions, nor utilize compiler to aggressively optimize the debloated code.

## 5.2 Functionality Validation

We ran the debloated binaries in CHISEL benchmarks against given test cases to understand their robustness. For each benchmark, we compiled the original source code to get the original binary and compiled the debloated source code from CHISEL to get the CHISEL binary. Then, we used RAZOR to debloat the original binary with given test cases, generating the RAZOR binary. Next, we ran the original binary, the CHISEL binary, and the RAZOR binary again with the test cases. We examine the execution results to see whether the required functionalities are retained in the debloated binaries.

Table 2 shows the validation result. RAZOR binaries produce the same results as those from the original binaries for all test cases of all programs (the last column), showing the robustness of the debloated binaries. Surprisingly, CHISEL binaries only pass the tests of three programs (*i.e.*, chown,

| Program | Version | # of Tests | Failed by Chisel |   |   |   | Failed by RAZOR |
|---------|---------|------------|------------------|---|---|---|-----------------|
|         |         |            | W                | I | C | M |                 |
| bzip2   | 1.0.5   | 6          | 2                | - | 2 | - | -(zLib)         |
| chown   | 8.2     | 14         | -                | - | - | - | -(zFunc)        |
| date    | 8.21    | 50         | 5                | - | 3 | - | -(zLib)         |
| grep    | 2.19    | 26         | -                | - | - | 6 | -(zLib)         |
| gzip    | 1.2.4   | 5          | -                | 1 | - | - | -(zLib)         |
| mkdir   | 5.2.1   | 13         | -                | - | - | 1 | -(zLib)         |
| rm      | 8.4     | 4          | 2                | - | - | - | -(zFunc)        |
| sort    | 8.16    | 112        | -                | - | - | - | -(zCall)        |
| tar     | 1.14    | 26         | 3                | - | - | 4 | -(zCall)        |
| uniq    | 8.16    | 16         | -                | - | - | - | -(zCall)        |

**Table 2:** Failed test cases by RAZOR binaries and CHISEL binaries. CHISEL failed some tests with different reasons: **Wrong** operations, **Infinite** loop, **Crashes**, and **Missing** output. For RAZOR binaries, we show the heuristic that makes the program pass all tests.

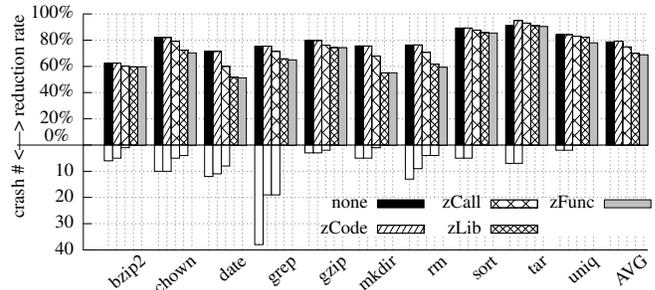

sort, and uniq) and trigger some unexpected behaviors for the other seven programs. Considering that CHISEL verifies the functionality of the debloating binary, such a low passing rate is confusing. We checked these failed cases and the verification process of CHISEL and found four common issues.

**Wrong operation.** The debloated program performs unexpected operations. For examples, bzip2 should decompress the given file when the test case specifies the -d option. However, the binary debloated by CHISEL always decompresses the file regardless of what option is used. We suspect that CHISEL only uses one test case of decompression to debloat the program and thus removes the code that parses command line options.

**Infinite loop.** CHISEL may remove loop condition checks, leading to infinite loops. For example, gzip fails one test case because it falls into a loop in which CHISEL drops the condition check. We believe the reason is that the test case used by CHISEL only iterates the loop one time. The verification step of CHISEL should identify this problem. However, we found that the verification script adopts a small timeout (e.g., 0.1s) and treats any timeout as a successful verification. Therefore, it cannot detect any infinite loops.

**Crashes.** The debloated binary crashes during execution. For example, date crashes three test cases because CHISEL removes the check on whether the parameters of strcmp are NULL. bzip2 crashes three test cases for the same reason.

**Missed output.** CHISEL removes code for printing out on stdout and stderr, leading to missed results. For example, grep fails six test cases, as the binary does not print out any result even through it successfully finds matched strings. We find that in the verification script of CHISEL, all output of the debloated binaries is redirected to the /dev/null device. Therefore, it cannot detect any missing or inconsistent output.

**Figure 8:** Path finding on CHISEL benchmarks with different heuristics. The top part is the code reduction, while the bottom part is the number of crashes. ‘none’ means no heuristic is used.

### 5.3 Effectiveness of Path Finding

We use two sets of experiments to evaluate the effectiveness of PathFinder on finding the related-code of required functionalities. First, we use RAZOR to debloat programs with different heuristics, from the empty heuristic to the most aggressive zFunc heuristic, aiming to find the least aggressive heuristic for each program. Second, we perform N-fold cross validation to understand the robustness of our heuristic. In this subsection, we focus on the first experiment and leave the N-fold cross validation in §5.6.1.

We tested RAZOR on CHISEL benchmarks as follows: (1) design training inputs and testing inputs that cover the same set of functionalities; (2) trace programs with the training inputs and debloat them with none, zCode, zCall, zLib, and zFunc heuristics; (3) run debloated binaries on testing inputs and record the failed cases. The setting of evaluating PathFinder is given in Table 7 of Appendix A. We use the same options for training inputs and testing inputs to make sure that the debloated binaries are tested for the same functionalities as those triggered by the training inputs. The difference is the concrete value for each option or the file to process. For example, when creating folders with mkdir, we use various parameters of the option -m for different file mode sets. For program bzip2 and gzip, we use different files for training and testing.

Figure 8 presents our evaluation result, including the code reduction (the top half) and the number of failed test cases (the bottom half) under different heuristics. We can see that debloating with a more aggressive heuristic leads to more successful executions. All binaries generated without any heuristic fail on some testing inputs. grep fails on all 38 testing inputs, while chown and rm fail more than half of all tests. The zCode heuristic helps mitigate the crash problem, like making grep work on 19 test cases. However, all generated binaries still fail some inputs. The zCall heuristic further improves the debloating quality. For program sort, tar, and uniq, it avoids all previous crashes. With the zLib heuristic, only two programs (i.e., chown and rm) still have a small number of failures. In the end, debloating with the zFunc heuristic

1 int compare(line *a,line *b) {
2   alen = a->length - 1UL;
3   blen = b->length - 1UL;
4   if (alen == 0UL) {
5     diff = -(blen != 0UL);
6   } else {
7     if (blen == 0UL) {
8       diff = 1;
9     } else { ... }
10  }

```

**Figure 11:** A crash case reduced by applying zCall heuristic.

```

1 int main(...) { ...
2   fail = make_dir(...);
3   if (!fail) {
4     if (!create_parents) {
5       if (!dir_created) {
6         tmp_7=gettext("error");
7         error(0,17,tmp_7,tmp_6);
8         fail = 1;
9         ...
10  }}}}

```

**Figure 12:** A crash case reduced by applying zLib heuristic.

reduces all crashes in all programs.

Interestingly, although aggressive heuristics introduce more code to the debloated binary (shown in the top of Figure 8), they do not significantly decrease the code reduction. Without any heuristic, the average code reduction rate of 10 programs is 78.7%. The number is reduced by -0.4%, 3.8%, 8.8%, and 12.6% when applying zCode, zCall, zLib, and zFunc heuristics, respectively. Therefore, even with the most aggressive zFunc heuristic, the code reduction does not decrease heavily. At the same time, all crashes are resolved, showing the benefits of applying heuristics. Note that the zCode heuristic slightly increases the code reduction over the no heuristic case, as it enables more branches of conditional jumps, which in turn reduces the instrumentation of failed branches.

We investigated the failed cases mitigated by different heuristics and show some case studies as follows:

- (1) The **zCode** heuristic enables the non-taken branch for executed conditional jumps. Figure 9 shows part of the function `fillbuf` of program `grep` that fails if we do not use the zCode heuristic. The training inputs always trigger the true branch of the condition at line 2 and jump to line 3, which in turn reach line 4. However, in the execution of testing inputs, the conditional at line 2 takes the false branch (i.e., `minsize > maxsize_off`) and triggers the jump from line 2 to line 4. This branch is not allowed from execution traces. The zCode heuristic enables this branch, as line 4 has been reached in the previous execution.
- (2) The **zCall** heuristic includes alternative paths that do not trigger any `call` instructions. Figure 11 shows an example where the zCall heuristic helps include necessary code in the debloated binary. Function `compare` in program `sort` uses a sequence of comparisons to find whether two text lines are different. Since the training inputs have no empty lines, the condition at line 4 and line 7 always fails. However, the testing inputs contain empty lines, which makes these two conditional jumps take the true branches. The zCode heuris-

**Table 3:** Vulnerabilities before and after debloating by RAZOR and CHISEL. ✓ means the binary is vulnerable to the CVE, while ✗ mean it is not vulnerable. CVEs with \* are evaluated in [15].

tic adds lines 5 and 8 and related branches to the debloated program, which effectively avoids this crash.

- (3) The **zLib** heuristic allows extra calls to native functions or library functions if they have been used in traces. It helps avoid a crash in program `mkdir` when we use the debloated binary to change the file mode of an existing directory. Figure 12 shows the related code, which crashes because of the missing code from line 6 to line 9. Since `mkdir` does not allow changing the file mode of an existing directory, the code first invokes function `gettext` to get the error message and then calls library function `error` to report the error. The zLib heuristic includes this path in the binary because both `gettext` and `error` are invoked by some training inputs.
- (4) The **zFunc** heuristic includes alternative paths that invoke similar library functions. Figure 10 shows the code that causes `rm` to fail without this heuristic. When `rm` deletes a folder that contains both files and folders, it triggers the code at line 3 to check whether it is traversing to the parent directory. Since the training inputs never call `strcmp`, the debloated binary fails even with the zLib heuristic. However, the training inputs ever invoke function `strncmp`, which has the functionality similar to `strcmp` (i.e., string comparison). Therefore, the zFunc heuristic adds this code in the debloated binary.

The results show that PathFinder effectively identifies related-code that completes the functionalities triggered by training inputs. It enhances the robustness of the debloated binaries while retaining the effectiveness of code reduction.

## 5.4 Security Benefits

We count the number of reduced bugs to evaluate the security benefit of our debloating. For each program in the CHISEL benchmark, we collected all its historical vulnera-

| Heuristic | FireFox     |           | FoxitReader |           |
|-----------|-------------|-----------|-------------|-----------|
|           | crash-sites | reduction | crash-PDFs  | reduction |
| none      | 13          | 67.6%     | 39          | 89.8%     |
| zCode     | 13          | 68.0%     | 10          | 89.9%     |
| zCall     | 2           | 63.1%     | 5           | 89.4%     |
| zLib      | 0           | 60.1%     | 0           | 87.0%     |
| zFunc     | 0           | 60.0%     | 0           | 87.0%     |

**Table 4:** Debloating Firefox and FoxitReader with RAZOR, together with different path-finding heuristics.

and FoxitReader require at least the zLib heuristic to obtain crash-free binaries, with 60.1% and 87.0% code reduction, respectively. Without heuristics, Firefox fails on 13 out of 25 websites and FoxitReader fails on 39 out of 40 PDF files. The zCode heuristic helps reduce FoxitReader crashes to 10 PDF files and increases the code reduction by avoiding fault-handling instrumentation. The zLib and the zFunc heuristic eliminate all crashes. Compared with the non-heuristic debloating, the zLib heuristic only decreases the code reduction rate by 7.5% for Firefox and by 2.8% for FoxitReader. Therefore, it is worth using this heuristic to generate robust binaries.

**Performance overhead.** We ran the debloated Firefox (with zLib) on several benchmarks and found that RAZOR introduces  $-2.1%$ ,  $1.6%$ ,  $0%$ , and  $2.1%$  overhead to Octane [33], SunSpider [34], Dromaeo-JS [30], and Dromaeo-DOM [29] benchmarks. For FoxitReader, we did not find any standard benchmark to test the performance. Instead, we used the debloated binaries to open and scroll the testing PDF files and did not find any noticeable slowdown.

**Application – per-site browser isolation.** As one application of browser debloating, we can create minimal versions that support particular websites, effectively achieving per-site isolation [38, 21, 48]. For example, the bank can provide its clients a minimal browser that only supports functionalities required by its website while exposing the least attack surface. To measure the benefit of the per-site browser, we applied RAZOR on three sets of popular and security-sensitive websites: banking websites, websites for electronic commerce, and social media websites. Table 6 shows the debloating result, the used path-finding heuristic and the security benefits over the general debloating in Table 4. As we can see, the banking websites can benefit with at least 5.0% code reduction for the per-site minimal browser. The E-commerce websites will have around 3.0% extra code reduction, a little less because of its high requirement on user interactions. Surprisingly, social media websites can benefit by up to 8.5% extra code reduction and at least 4.2% when supporting all three websites. We believe the minimal web browser through binary debloating is a practical solution for improving web security.

| Train/Test | ID  | #Failed | Reduction | failed websites          |
|------------|-----|---------|-----------|--------------------------|
| 20/30      | T10 | 1       | 59.3%     | wordpress.com            |

|            | T08 | 2       | 59.3%     | wordpress.com, twitch.tv |
|            | T09 | 0       | 59.1%     |                          |

**Table 5: N-fold validation of zLib heuristic on Firefox.** First, we randomly split Alexa’s Top 50 websites into five groups, and select two groups (20 websites) as the training set and others (30 websites) as the test set for 10 times. Second, we randomly split the 50 website into 10 groups, and select five groups (25 websites) as the training set, and others (25 websites) as the test set for 10 times.

### 5.6.1 N-fold Cross Validation of Heuristics

To further evaluate the effectiveness of our heuristics, we conducted N-fold cross validation on Firefox with the zLib heuristic, as it is the least aggressive heuristic that renders Firefox crash-free. We performed two sets of evaluations and show the result in Table 5. First, we randomly split Alexa’s Top 50 websites into five groups, 10 websites per group. We picked two groups (20 websites) for training and used the remaining 30 websites for testing. We performed this evaluation 10 times. The result in the table shows that during one test with ID T11, the debloated Firefox successfully loads and renders 30 testing websites. The debloated Firefox fails two websites (6.7%) seven times and fails one website (3.3%) two times. Second, we randomly split Alexa’s Top 50 websites into 10 groups, five websites per group. We randomly picked five groups (25 websites) for training and used the others (25 websites) for testing. We performed this evaluation 10 times. The result shows that, in five times, the debloated Firefox loads and successfully renders the tested 25 websites. The debloated Firefox fails one (4%) website one time and fails two websites (8%) four times. The code size reduction is consistently round 60%. These results show that our heuristics are effective for inferring non-executed code with similar functionalities of training inputs. Among all the tests, only three websites trigger additional code and the program gracefully exits with warning information. We plan to check these websites to understand the failure reasons.

We also manually checked what code of Firefox

| Type         | Site              | Reduction | Heuristic | Benefits |
|--------------|-------------------|-----------|-----------|----------|
| Banking      | bankofamerica.com | 69.4%     | zCall     | +6.3%    |
|              | chase.com         | 69.6%     | zCall     | +6.5%    |
|              | wellsfargo.com    | 68.8%     | zCall     | +5.7%    |
|              | all-3             | 68.1%     | zCall     | +5.0%    |
| E-commerce   | amazon.com        | 71.4%     | none      | +3.8%    |
|              | ebay.com          | 70.7%     | none      | +3.1%    |

|              | all-3             | 70.4%     | none      | +2.8%    |
| Social Media | facebook.com      | 70.8%     | zCall     | +7.7%    |
|              | instagram.com     | 71.6%     | zCall     | +8.5%    |
|              | twitter.com       | 74.0%     | none      | +6.4%    |
|              | all-3             | 71.8%     | none      | +4.2%    |

**Table 6:** Per-site browser debloating

was removed. We find that code related to features such as record/replay, integer/string conversion, compression/decompression are removed.

## 6 Discussions

**Best-effort path inference.** Mapping high-level functionalities to low-level code is known to be challenging, especially when source code is unavailable. RAZOR empirically adopts control-flow-based heuristics to infer more related-code with its best effort. We understand that such a heuristic cannot guarantee the completeness or soundness of the path inference, and the debloated binary may miss necessary code (*i.e.*, code for handling different environment variables) or include unnecessary ones (like some initialization code). However, we noticed that the heuristic-based method has been widely used in binary analysis and rewriting [53, 52]. With the execution trace, RAZOR is able to mitigate some limitations of these works, such as finding indirect call targets. Further, the evaluation result demonstrates that our control-flow-based heuristics are practically effective.

**CFI and debloating.** Control-flow integrity (CFI) enforces that each indirect control-flow transfer (*i.e.*, indirect call/jump and return) goes to legitimate targets [1]. It prevents malicious behaviors that are unexpected by program developers. In contrast, software debloating removes benign-but-unnecessary code based on users' requirements. For example, if function A is designed to be a legitimate target of an indirect call *i*, CFI will allow the transfer from *i* to A. However, if the user does not need the functionality in A, software debloating will disable the transfer and completely remove the function code. In fact, CFI and debloating are complementary to each other. On the one hand, debloating achieves a coarse-grained CFI where an attacker can only divert the control-flow to remaining code. It also simplifies the analysis required by some CFI works [50, 37] because of a smaller code base. On the other hand, existing CFI works provide fundamental platforms for enforcing debloating. For example, RAZOR makes use of several binary analysis techniques developed in binCFI [53]

for optimization.

**Library debloating.** We tried to use RAZOR to debloat system libraries for each program. Our tool works well on some libraries (*e.g.*, `libm.so` and `libgcc.so`), but fails on others. For example, the debloated `libc.so` triggers a different execution path even if we aggressively include more related-code with the `zFunc` heuristic. After inspecting the failure cases on `libc.so`, we found that its execution path is very sensitive to the change of the execution environment. One reason is that `libc.so` contains a lot of highly optimized code for memory or string operations (*e.g.*, `memcpy`), which, based on the argument value, choose the most efficient implementation. For example, function `strncpy` implements 16 different subroutines to process strings with different alignments. Another reason is that it performs different executions according to the process status. For example, for each memory allocation, `malloc` searches a set of cached chunks and picks up the first available one. Inputs with different sizes may cause `malloc` to walk through a complete non-executed path. From such a preliminary result, we plan to develop library-specific heuristics to handle environment-sensitive executions. For example, we can perform debloating on the function level instead of the current basic block level. We also plan to explore existing library debloating solutions that work on source code [40] and port them into binaries if necessary.

**Removing original code.** The current design of RAZOR keeps the original code section inside the debloated program and changes its permission to read-only to reduce the attack surface. This design simplifies the handling of potential data inside the code section, which the program may read for special purposes. For example, LLVM will emit jump tables in the code section to support efficient `switch` statements [11], and the indirect jump instruction will obtain its targets by reading the table. To further reduce the program size and memory usage, we can completely remove the original code section as follows: 1) during the execution tracing, we set the original code section to execute-only [11] so that any read from the code section will trigger the exception and can be logged by Tracer; 2) we perform backward data-flow analysis to identify the source of the data pointer used for each logged memory access; 3) during the binary synthesization, we relocate the data from the original code section to a new data section and update the new code to visit the new location. In this way, we are able to handle the challenging problem of data relocation during binary rewriting. In fact, we performed a study to understand the prevalence of these problems and found that for all the programs tested in the paper, none of them ever reads any data from the code section, given the test cases we used. In these cases, we can simply remove the original code section to minimize the file size and memory footprint.

**Future work.** We will release the source code of RAZOR. We plan to extend the platform to support binaries in more

formats and architectures, including shared libraries, 32-bit binaries, Windows PE programs, MacOS Mach-O programs, and ARM binaries. At the same time, we will design more security-related heuristics to make RAZOR support various real-world situations.

## 7 Related Work

**Library debloating.** Program libraries are designed to support a large number of functionalities for different users. Library debloating customizes the general code base for each program and leads to significant code reduction. Mulliner *et al.* propose CodeFreeze to remove the unnecessary functionalities from Windows shared libraries [36]. They start from per-library control-flow analysis to identify the code dependency of each exported function. Then they check the program binary to find all required library functions. By stitching program required functions and per-library CFG, they rewrite the library to remove unreachable code region. Similarly, Quach *et al.* [40] present library debloating through piece-wise compilation and loading. Instead of customizing the library for each program, they split the large library into small groups based on the control-flow dependency. At runtime, they use a customized loader to rewrite the library code to remove unnecessary functions. Jiang *et al.* [23, 22] propose to remove dead code from Android Apps, Java Runtime Environment, and SDKs. Our system is different from library debloating in two ways. First, previous work performs the binary rewriting at the beginning of each process, leading to performance overhead for each execution, while RAZOR generates the debloated binary through static binary rewriting, which is only performed once and used forever. Second, library debloating utilizes static analysis to find the unused code and has to conservatively keep all potentially useful code. In contrast, our system relies on a dynamic execution trace to locate the code that is executed during tracing or inferred with our heuristic and removes all others.

**Delta debugging.** Delta debugging is proposed to minimize bug-triggering inputs. For example, Regehr *et al.* [42] propose C-Reduce to generate a smaller test cases efficiently. Sun *et al.* [49] present Perses, which exploits formal syntax to generate smaller and functionally equivalent program in a timely manner. Recently, Heo *et al.* [15] proposed CHISEL to use reinforcement learning for further speeding up the delta debugging process. However, the programs generated by delta debugging only support given test cases, while real-world software usually has an infinite number of test cases for certain functionalities. Instead, RAZOR takes control-flow-based heuristics to infer more related-code that is necessary to complete the required functionalities.

**Source code debloating.** Several recent works use program analysis to debloat programs. Bu *et al.* [8] propose a bloat-ware design paradigm that analyzes Java source code to optimize object allocations to avoid memory usage bloating

at runtime. Sharif *et al.* [44] propose Trimmer, which propagates a user-provided configuration to program code and utilizes the compiler optimization to reduce code size. These systems, as well as [42, 49, 15], rely on the complicated analysis of program source code, which is not always available for deployed programs. In contrast, RAZOR only requires program binaries, making it more practical for deployment.

**Container Debloating.** Containers are becoming more popular, and their code base is bloated. Guo *et al.* [14] proposed a method to monitor the program execution to identify necessary resources and create a minimal container for the traced program. Rastogi *et al.* [41] developed Cimplifier, which uses dynamic analysis to collect resource usages for different programs and partitions the original container into a set of smaller ones based on user-defined policies. The resulting containers only have resources to run one or more executable programs. The design of RAZOR is also applicable for debloating containers or other systems. For example, Intel PT supports tracing operating systems.

**Hardware Debloating.** Nowadays, hardware devices are also bloated. For example, general-purpose processors are overly designed for specific applications, such as implantables, wearables, and IoT devices. Cherupalli *et al.* propose an approach that automatically removes unused gates from the design of a general-purpose processor to generate a bespoke processor for a specific application [10]. On average, the approach can reduce the area by 62% and the power by 50% from the general processor. Currently, software debloating and hardware debloating are performed separately. An interesting direction is to consider both hardware devices and software programs to find more debloating space.

## 8 Conclusion

In this paper, we presented RAZOR, a framework for practical software debloating on program binaries. It utilizes a set of test cases and control-flow-based heuristics to collect necessary code to support user-expected functionalities. The debloated binary has a reduced attack surface, improved security guarantee, robust functionality, and efficient execution. Our evaluation shows that RAZOR is a practical framework for debloating real-world programs.

## Abstract

Today memory analysis plays a fundamental role in computer forensics and is a very active area of research. However, the field is still largely driven by custom rules and heuristics handpicked by human experts. These rules describe how to overcome the semantic gap to associate high level structures to individual bytes contained in a physical memory dump. Structures are then traversed by following pointers to other objects, and the process is repeated until the required information is located and extracted from the memory image.

A fundamental problem with this approach is that we have no way to *measure* these heuristics to know precisely how well they work, under which circumstances, how prone they are to evasions or to errors, and how stable they are over different versions of the OS kernel. In addition, without a method to measure the quality and effectiveness of a given heuristic, it is impossible to compare one approach against the others. If a tool adopts a certain heuristic to list the sockets associated to a program, how do we know if that is the only possible way to extract this information? Maybe other, even better, solutions exist, just waiting to be “discovered” by human analysts.

For this reason, we believe we need to go back to the drawing board and rethink memory forensics from its foundations. In this paper we propose a framework and a set of metrics we can use as a basis to assess existing methodologies, understand their characteristics and limitations, and propose new techniques in a principled way. The memory of a modern operating system is a very large and very complex network of interconnected objects. Because of this, we argue that automated algorithms, rather than human intuition, should play a fundamental role in evaluating and designing future memory forensics techniques.

## 1 Introduction

Computer forensics is often considered an art, as the analyst proceeds by formulating hypothesis about the cause of an incident and uses inductive reasoning to reinforce or discard them based on clues and artifacts collected from the target system.

The way these artifacts are extracted and analyzed is largely based on the experience and on the set of heuristics encoded into the available tools. Memory forensics, i.e. the field focusing on the analysis of snapshots of the physical memory of a machine, is no exception to this rule. Memory forensic tools need to recover the high-level semantic associated with sequences of raw bytes – thus reconstructing the internal state of the operating system (OS) and its applications at the time the memory was acquired. Unfortunately, modern OSs are very complex software whose memory often contains millions or tens of millions of individual objects at any moment in time. Even worse, both the fields and the layout of these objects can change when the kernel is updated or recompiled, and the connections among them evolves very rapidly – with a considerable amount of links and pointers that change every few milliseconds.

Currently memory forensics techniques rely on a large number of rules and heuristics that describe how to navigate through this giant graph of kernel data structures to locate and extract information relevant to an investigation. For example an analyst can use rules — commonly known as *plugins* in the field terminology — to retrieve the list of processes running at acquisition time (including their name, starting time, process ID, and other related information) or the list of open sockets. The result of the analysis depends on the number and accuracy of these rules. However, the field today is still in its infancy and each individual technique is manually written by researchers and practitioners. As a result, it is often unclear why a particular exploration strategy has been chosen, except for the fact that some developers found it reasonable based on their experience. Even worse, how accurate a given heuristic is and how we can compare it with other candidates to decide which strategy is more suitable for a given investigation remains an open question.

In fact, we still do not even know how to properly characterize the accuracy of a technique, as its quality depends on the metric we use to evaluate it, which in turn depends on the goal of the analyst. For instance, in an adversarial environment in which the analyst is investigating a sophisticated attack, a good heuristic would be one that is difficult to evade for an attacker. In a different investigation in which there is no risk of tampered

kernel data, a heuristic that only traverses closely-related (in physical memory) data structures may be preferable as pages acquired far apart may otherwise contain inconsistent information if the dump was not acquired atomically.

**Contribution:** The goal of this paper is to introduce a more principled way to approach the problem of memory analysis and forensics. Our plan is articulated around three main points. The first intuition is that heuristics used to extract information from memory dumps should be automatically generated by computers and not handpicked by humans. As we will show in our experiments, the graph of kernel objects is tightly connected and there are tens of millions of different ways to reach a given structure by starting from a global symbol. The second point is the fact that it is very important to be able to quantitatively measure the properties of each heuristic, so that different options can be compared against one another and an analyst can decide which technique is more appropriate for her investigation. Finally, the analyst should be able to obtain some form of guarantee about the results, to ensure that once a given quality metric has been chosen, a certain technique is the *optimal* solution to navigate the intricacies of runtime OS data structures.

As a step towards these goals, we constructed a complete graph of the internal data structures used at runtime by the Linux kernel. In our graph, nodes represent kernel objects and edges a pointer from one object to another. We chose Linux as the availability of its source code simplifies the creation of our model. However, a similar graph was also extracted in the past by Microsoft for the Windows kernel [4] and could therefore be reused for our purpose. The resulting map of the memory is a giant network (containing over a million nodes) with a very dynamic topology that is constantly reshaped as new data structures get allocated and deallocated.

Memory forensics tools adopts rules to navigate through the data structures present in a memory dump, and these rules can therefore be represented as paths in our kernel graph. Nodes and edges can then be decorated with additional pieces of information that capture different properties an analyst can find important in an analysis routine. In our study we model this phase by introducing and discussing five different metrics: *Atomicity*, *Stability*, *Generality*, *Reliability*, and *Consistency*. We used these metrics to compute a score associated to each path, and therefore to existing memory analysis techniques, as well as to compute the optimal solution according to a chosen set of criteria. We then discuss the intricacies of identifying such optimal paths by performing experiments with 85 different kernel versions and 25 individual memory snapshots acquired at regular time intervals.

Building a map of the kernel memory is a very tedious and time-consuming process. However, we believe this map can have many interesting uses in computer security beyond memory forensics – including virtual machine introspection (VMI), kernel hardening, and rootkit detection. Since both the code and the results of the previous attempts to build this graph [4, 17, 19]

are not publicly available, we decided to release all our data – hoping it will help other researchers to considerably reduce the time required to investigate and validate techniques that require information about the content of a running kernel.

## 2 Motivation

Being quite in its infancy, memory forensics has still many open problems, which have been recently summarized by Case and Richard [6]. The authors divided them in two categories, depending on whether they are related to the *acquisition* or the *analysis* of a memory dump. More precisely, the first category contains all the practical issues of acquiring memory from a device under investigation while the second one deals with the capabilities of memory forensics, such as malware detection and evidence extraction.

One of the main issues belonging the first category is *page smearing*, which is a consequence of the fact that while the acquisition is performed the underlying system is not frozen and thus the dump may contain inconsistent information [12]. While the term was coined in 2004 [5], its actual implications are still unclear to the community. For instance, a recent study from Le Berre [18] pointed out that in real investigations more than the 10% of memory dumps suffer from this problem and thus can not be properly analyzed with existing tools. Our work can help mitigating this issue by assessing how existing techniques are affected by non-atomic acquisitions, and help design new heuristics which are more robust against the presence of inconsistent information.

The second category focuses instead on challenges related to memory analysis. For example, as of today, forensics practitioners lack the necessary tooling for extracting a number of interesting information such as Powershell activity and evidences related to Office applications and private browsing sessions, or to analyze sophisticated userland malware. Finally, a vast range of technologies did not receive any forensics coverage: Apple iOS, Chromebooks, and IoT devices are still out of scope when it comes to memory forensics analysis.

While these issues are very different from one another, most of them share the same underlying assumption: kernel objects must be located, traversed and interpreted by a set of rules. Our approach enables forensics practitioners and researchers to evaluate, under different constraints, the quality of these rules and provide them with a framework to compare and discover new sets of rules.

## 3 Approach

In this section we describe the four-step approach we propose to precisely measure and improve the quality of existing memory forensics techniques. The first step consists of building a precise representation of all data structures that exists in a running kernel and of the way these structures are connected

- ① `[init_task].tasks.prev`  $\circlearrowleft$   $\rightarrow$  `task_struct.mm`  $\rightarrow$  `mm_struct.mmap`  $\rightarrow$  `vm_area_struct.vm_next`  
 $\circlearrowleft$   $\rightarrow$  `vm_area_struct`
- ② `[root_cpuacct].css.cgroup`  $\rightarrow$  `cgroup_root.cgrp.e_csets[2].next`  $\rightarrow$  `css_set.tasks.next`  $\rightarrow$   
`task_struct.mm`  $\rightarrow$  `mm_struct.mmap`  $\rightarrow$  `vm_area_struct.vm_next`  $\circlearrowleft$   $\rightarrow$  `vm_area_struct`

Figure 1: Two different paths that reach the same `vm_area_struct` object.

to one another. The challenges and the process we followed to build this kernel graph are described in details in Section 4. In the second phase we map existing forensic analysis techniques into our model, by representing their algorithms as paths through the kernel graph. We then color the graph according to different properties that are relevant for a forensic investigation, and we employ graph-based algorithms to assess the characteristics of the previously-identified paths and find new ones that may exhibit better properties. Finally, in the fourth and final phase of our methodology we translate our findings back to the memory forensic space by generating improved analysis plugins, thus increasing the number and quality of the rules that are used today to analyze memory dumps.

### 3.1 Memory Forensics as a Graph Exploration Problem

The goal of memory forensics is to bridge the semantic gap between the raw bytes that constitute a physical memory’s snapshot and the high-level abstractions provided by modern operating systems. This task requires the forensic tool to be able to correctly translate virtual to physical memory addresses, as well as to identify the data structures that contain the required information (e.g., the name of the files opened by a given process). The latter is typically achieved in two phases. First, the system locates a known object – either because it resides at a fixed or predictable location, by using symbols information generated by the compiler when the kernel was built, or by carving a particular data structure based on a set of known properties and invariants. Starting from this entry point, the analysis then traverses different memory regions, moving from one data structure to the next by following pointers, until it reaches the required piece of information. For example, we assume the analyst found a suspicious process and she wants to extract its executable code for further analysis. On Linux, this analysis starts from extracting the position of the global kernel variable `init_task` of type `task_struct`. This is one of the most important kernel object in terms of Linux memory forensics since every kernel thread and user space process has its own and it serves as a hub to reach several other relevant pieces of information. After locating `init_task`, the processes list is walked until the `task_struct` belonging to the suspicious process is found. From here, the `mm_struct` is reached by dereferencing the `mm` field. Finally, the list of `vm_area_struct`, each of

which defines a virtual memory area, is retrieved — first by following the `mmap` pointer, then by using the `vm_next` field. With this information, the analyst can find the executable regions of the process and can proceed to save their content to disk.

This procedure can be naturally represented as a path on a graph in which every node is a kernel object, and every link a pointer. While the final node is dictated by a given forensic task, both the first and the intermediate nodes are often the result of handcrafted routines based on the experience and expert judgment of the developers of the forensic tool.

In our graph, the previously presented analysis would correspond to the path ① in Figure 1. The path contains the names of the structures and fields that need to be traversed (in square brackets when they refer to global symbols in the kernel) as well as the type of transition ( $\rightarrow$ : follow a pointer reference,  $\circlearrowleft$ : visit multiple structures of the same type linked together). For simplicity, we report inner structures in our paths as names in the edge and not explicitly as standalone nodes. Also, note that in the example ①, since the suspicious process was freshly spawned, the shortest path in our graph traverses the process list *backwards* — contrarily to the more common *forward* walking.

On top of the previous solution, our approach shows that a stunning 2.5 million different sequences of vertices exist in the kernel graph to reach the very same target object starting from a global variable, *only* counting the paths with no more than 10 edges. For example, path ② in Figure 1 begins from the little-known global symbol `root_cpuacct`, passes through a number of *cgroup*-related objects, before finding the `task_struct` of the suspicious process.

The previous two “rules” are both capable of locating a given process structure in a memory dump. The first is certainly more intuitive and it may also traverse a lower number of data structures. However, this is purely a *qualitative* assessment, and it is unclear if the first solution actually has any clear advantage or whether it provides any better guarantee than the second.

### 3.2 Path Comparison

As we saw in the previous example, if we want to assess the quality of a given solution, we first need to define what “quality” means in our context. In other words, when two paths exist to reach the same target data structure, we need to define a metric that can tell us which one is better to follow from a forensic perspective.

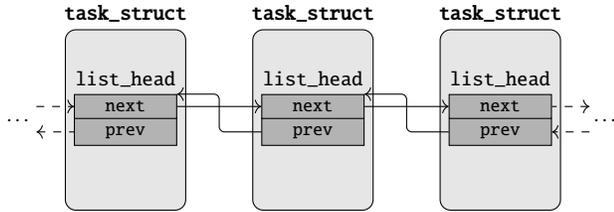

Figure 2: `task_struct`s organized in a doubly linked list.

A developer may favor the shortest path, as it is simpler to implement and may appear to be more robust according to the intuition that the fewer the data structures that need to be parsed, the less likely it is that something can go wrong while doing that. However, this approach raises another important issue about today’s approach for memory analysis: its ad hoc nature and lack of a scientific foundation. In fact, it is not clear today how different exploration techniques can be compared and how they can be evaluated against one another in a precise and measurable way.

A first important observation is that there is not a single, absolute metric that defines the quality of a memory exploration rule. It all depends on the goal of the analyst, the conditions under which the memory snapshot was acquired, and the type of threat that is investigated. For example, in the common case in which a memory snapshot is acquired non-atomically, the analyst may prefer to adopt an approach that only traverses structure closely located in memory, thus minimizing the chances of inconsistencies. On the opposite case in which the memory was acquired atomically in a lab from a virtual machine used to investigate a possible rootkit, the analyst would certainly favor a different approach that traverses structures whose values cannot be tampered with by the attacker. In yet another scenario, an investigator may try to analyze a dump for which she was not able to retrieve a correct OS profile, and therefore she might be interested in paths that traverse structures that have changed very rarely across different kernels, to maximize her probability of success.

Therefore, it is the analyst who needs to select the more appropriate fitness function to compare paths according to any combination of desired properties. And once this function has been chosen, it is possible to use it to compute the optimal path (and therefore the optimal exploration strategy) to traverse the kernel graph. In this paper we explore different possible scenarios by proposing several metrics to enrich the graph (more details about this process are presented in Section 5) and then use this information to evaluate existing approaches and discuss other, non-conventional solutions that can provide better guarantees for the analyst.

## 4 Graph Creation

The first step of our methodology consists in building a model of the operating system kernel, that we can later use

to compare different memory forensic approaches. The model we chose for our analysis is a graph of kernel objects, in which nodes represent kernel data structures and edges represent relationships between objects (for example a pointer from one structure to another).

The core idea is simple and relies on two crucial pieces of information extracted from the kernel debugging symbols. The first one is the layout, in terms of the exact type and offset of each field, of all the `struct` defined and used by the kernel code. The second information is instead related to the address, name, and type of global kernel variables that play the role of entry points for our graph exploration. Starting from these global pointers, our algorithm can recursively traverse other structures, each time following a pointer and casting the target memory to the appropriate type. While this process may seem straightforward at first, there are many special cases that make the construction of a kernel graph a complex procedure that requires multiple phases and several dedicated components.

In the rest of the section we discuss in more details some of these problems and the way we handled them in our study: abstract data types (and the issue with non-homogeneous circular lists), opaque pointers, and the presence of uninitialized or invalid data.

### 4.1 Abstract Data Types

Over the years, to maintain a reasonable quality over its code base, the Linux kernel developers have adopted several design patterns [20]. In particular, the kernel exports a rich set of APIs to manipulate and create complex data structures, such as double-linked lists and trees of various types, thus relieving kernel developers from the burden of reinventing the wheel every time they need to store and organize multiple objects. For this reason, the existing APIs are not tied to a specific type of kernel object but rely instead on predefined data types that can be included in more complex `struct` objects, and in a number of macros to manipulate them.

Figure 2 shows one of the most common example of this pattern, in which several `task_struct` are organized in a doubly linked list using the `list_head` type. While this provides a simple and efficient way to organize data structures, it unfortunately poses a serious challenge to the automated exploration of kernel objects. In fact, if the leftmost `task_struct` in the figure was already identified by other means (for example because it was pointed to from a global variable), simply following the `next` pointer would result in the discovery of the inner `list_head` structure, but *not* of the outer `task_struct`.

In fact, this operation is performed in the source code by using dedicated macros. In the case of the previous example, a developer would invoke:

```
container_of(var, struct task_struct, task)
```

that the compiler pre-processor translates to a snippet of code required to cast the target `list_head` variable `var` to the requested type based on the current offset inside it (as specified

by the field `task`). However, in our analysis we cannot simply mimic the same behavior by subtracting the offset of the list field from `next` pointer and to cast the result to the correct type to obtain a reference to the outer object. In fact, there are many cases in which this approach would lead to wrong results and it is not sufficient to look at the field type or at its value to distinguish these problematic cases. One example is the list rooted in the field `children` of a `task_struct`. While the field points to another `task_struct`, it does so by reaching it at a different offset (in the `sibling` field). Because of this and other similar problems (explained in more details later in the paper) it is not possible to systematically apply the “subtract and cast” strategy.

For each pointer in a data structure we need to know where — in terms of object type and offset in the target structure — it points to. Other works that built a map of the Linux kernel [1, 24, 35] solved the problem by manually annotating the source code. While this was doable for old kernel versions (e.g., 2.4), it would take many weeks of tedious work to annotate a recent kernel — which today uses more than 6000 different data structures and more than a thousand instances of `list_heads`. Moreover, manual annotations are error prone and are tailored to one specific code base, thus requiring to be verified and modified whenever a new kernel version is released. The compiler community has also already extensively studied the points-to problem [9, 14, 15, 22, 30, 34]. Unfortunately, the techniques they proposed are not suitable to our work as they tend to favor speed (an important factor at compile-time) over precision [4] (a more important factor for our analysis). Only four previous studies automatically extracted a type graph of a kernel [4, 17, 19, 29]. However, none of their systems is available: in one case because the authors relied on the internal source code of the Microsoft Windows operating system [4], and in the other because the entire work was lost [17].

For this reason, we decided to implement our own points-to analysis — which consists of a `clang` plugin that reasons on the Abstract Syntax Tree (AST) of each kernel compilation unit. Contrary to standard points-to analysis, our approach focuses only on the *type* information. More precisely, traditional solutions are designed to identify where each pointer points to, while in our case we only need to extract the target structure, and the offset inside that structure. The result is a *type graph* of the kernel under analysis. To extract this information we take advantage of the fact that the information we need can be inferred by analyzing the source code of the kernel that is in charge of manipulating the data structure in question. Our plugin explores the AST until it finds a call to a kernel API related to data structure management. At this point it analyzes the parameters and resolves their structure type and field name. An example of API call and respective AST is given in Figure 3. In the example, a call to the API `list_add` is used to append the new task at the beginning of the list rooted at `head->tasks`. This give us the information that the

field `tasks` of `task_struct` indeed points to the very same type. Our plugin current supports `list_heads`, `hlist_heads` (used in the implementation of hash tables), and `rb_root` (used in the implementation of red-black trees).

Except for those, the most common type that is still not supported by our prototype is `radix_tree`, which however is only used 8 times in the entire kernel code base.

As we will show in Section 4.6, our approach is very effective and was able to resolve the type pointed by 250 global lists and by more than 1110 unique object fields in the Linux kernel 4.8, compiled with the Ubuntu 16.04 kernel configuration. Moreover, while our approach is tailored to the Linux kernel, it can be adapted to work on any other operating system, given the availability of its source code. Finally, since the parameter resolution routine does not perform complex analyses, our analysis does not introduce any significant overhead at compilation time.

### Circular Lists of Non Homogeneous Elements

As we already discussed in the previous section, certain linked list can chain together object of different types. Since the code must have a way to determine to which type the target element belongs to, this pattern is only present in the form of a “root” object which is the first element of a circular list of otherwise homogeneous objects.

As a consequence, these lists can *only* be traversed starting from their root node, as traversing the loop from an intermediary objects can result into unexpectedly reaching the root node (of a different type) when dereferencing one of the `next` pointers. For example, other than the already cited `children` field of `task_struct`, also the `thread_node` field of the same structure points inside a `signal_struct` object.

To avoid this problem, our analysis classifies every `list_head` field in one of the following three categories: *root* pointer, *intermediate* pointer or *homogeneous* pointer. The first two are used to mark `list_head` fields that belong to lists that contain mixed types, while the latter describes the more common case of homogeneous list. For instance, `task_struct.children` is a root pointer, `task_struct.sibling` an intermediate and `task_struct.tasks` a homogeneous one. This classification can be automatically derived from the type graph: whenever two objects of different types are involved we label the first as *root* and the second as *intermediate*, while all the other objects are labeled as *homogeneous*. During the exploration phase, depending on the type of the pointer, we adopt a different strategy:

- *homogeneous* pointers can be explored by our algorithm in any order.
- *root* pointers require instead our algorithm to immediately walk and retrieve the objects of the entire circular list.
- *intermediate* pointers are ignored since we do not know if they point to another intermediate element or to a

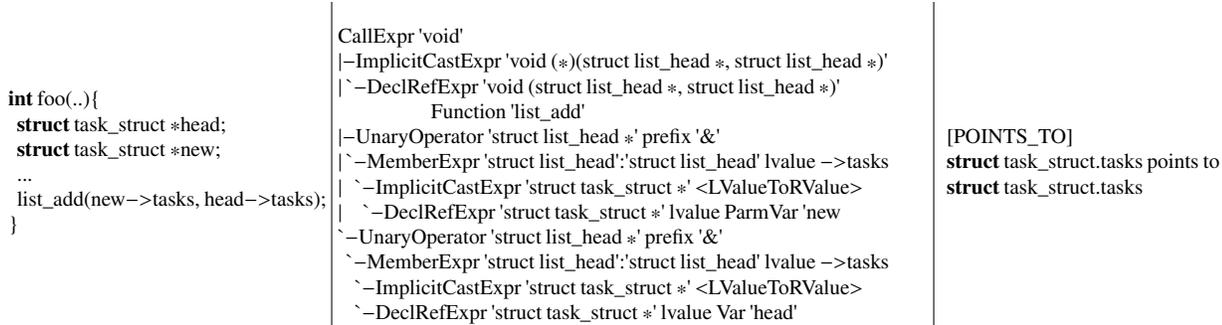

Figure 3: On the left a call to `list_add`, in the center its simplified AST representation, and on the right the plugin output.

root head. This case happens when we enter a circular list from one of its middle elements. This pointer will eventually be explored when the corresponding root node will be visited.

This classification works for every list encountered during the exploration phase, *except* for global `list_head` variables which are always marked as *root* node. In this case, during the very first part of the exploration, these lists are walked entirely and their elements appended to the worklist.

## 4.2 Uninitialized and Invalid Data

During our data structure exploration, there are cases that could potentially introduce false nodes to our graph. This is due to pointers that contain valid memory addresses but are not yet initialized or that were not valid at the time the snapshot was acquired. One common cause for these errors is the fact that most of the memory management kernel APIs do not initialize to zero the allocated memory. As a result, if an object contains an array of pointers there is not way to tell if one element points to an initialized object (except if the pointer has an invalid value). Another source of false-positives comes from the *non quiescent* state in which the kernel might be when the snapshot is taken [16]. In other words, this means that the kernel could have been in the middle of updating a data structure, leaving dangling pointers in the snapshot. Finally, even if very rare, kernel bugs can contribute to the generation of similar errors.

For these reasons we implemented two sets of heuristics to check if an object is valid or not. The first *soft* rule checks that the number of valid pointers in a kernel object is greater or equal than the number of invalid ones (after removing null pointers and the pointers which normally point to userspace memory, such as the ones contained in `struct sigaction`). The second, more precise, heuristic immediately flags an object as invalid if certain conditions are not verified (such as kernel objects that contain a negative spinlock, or those with function pointers that do not point in the executable sections of the kernel). Finally, we require that, whenever present, a `list_head` has to be valid, i.e. its `next` and `prev` pointer

must point to addressable memory. If these rules are not met, we consider the object invalid and discard it from our analysis.

## 4.3 Opaque Pointers

Opaque pointers, as represented by `void*` fields or by long long integers that contain at runtime the address of other objects, are traditionally one of the hardest obstacle to build a complete map of kernel objects. Luckily, this is not the case in our particular scenario. Since we are interested in using our graph to analyze and improve existing memory forensic techniques, opaque pointers play a very marginal role (if any at all) in this space. As they can point to potentially any structure, and the actual target type can change over time, traversing these pointers can be unpredictable during a post-mortem analysis. Even if none of the heuristics we encountered in our experience make use of them, we decided to include them in our graph. After the exploration ends, in case the target of an opaque pointer was discovered by other means, we create the resulting edge, clearly marking it. In this way, we are able to detect if any of these edges are traversed during our experiments. Finally, it is important to understand that these limitations cannot lead to “wrong” results (since they cannot create erroneous paths in the graph), but nonetheless restrict the guarantees of optimality we discuss in the next sections to the constructed graph.

## 4.4 Limitations and Manual Fixes

Like all previous attempts to build a map of the kernel memory, two particular limitations also affect our solution: unions, and dynamically allocated arrays. Handling the latter case would require more sophisticated code analysis techniques to identify the variable number of elements contained in the arrays, which are beyond the scope of this paper. Nevertheless, we identified few cases of dynamically allocated arrays that contain information that can be relevant for memory forensics and we decided to handle them by hardcoding a custom logic. The first cases are global hash tables where often the size is not inferable from the hash table itself. For example, the `pid_hash` hash table, used by the kernel to quickly locate a process given its

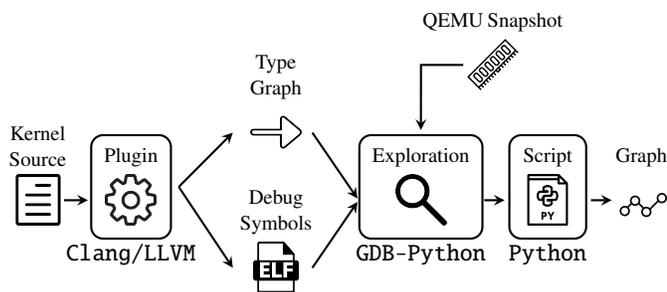

Figure 4: System Overview.

process id, is implemented by using a dynamically allocated array where the size is specified in another global variable (`pidhash_shift`). The second cases are instead dynamically allocated arrays pointed by a kernel object. For example, the file descriptor table associated with each process, which contains the files opened by a process (field `fd` of `struct fdtable`). Once again, this is a dynamically allocated array of `struct file` pointers, and the size can be retrieved from the field `max_fds` of the same structure.

Finally, the handling of `per_cpu` pointers was also hardcoded in our implementation. These are special pointers that, thanks to a double indirection mechanism when dereferenced, give to each processor a different copy of the same variable.

However, we want to stress that this limitation does not invalidate our findings since the graph extracted by our approach is *not* incorrect, but only potentially incomplete.

## 4.5 Implementation

Our final system is illustrated in Figure 4. It consists of an LLVM compiler plugin to perform the *points-to analysis* on the kernel code at compile-time and a set of python `gdb` extensions that combine the information extracted in the previous step with the information provided by kernel debug symbols to identify all kernel objects contained in a memory snapshot acquired using the QEMU emulator. The kernel exploration routine starts by loading a QEMU snapshot, parsing the type graph, and appending the global object symbols to an internal worklist. At this point the real exploration begins: an object is fetched from the worklist and analyzed using the heuristics we adopted to identify invalid or uninitialized memory. If it is well-formed, each of its field are processed to identify structures, pointers to other structures, or arrays of either type. All them are retrieved and appended to the worklist – paying attention to implement the techniques described above to handle abstract data types. These objects are then processed by a separate component responsible to build the final kernel graph that we will later use to carry out our experiments.

## 4.6 Final Kernel Graph

We built our kernel graph using *graph-tool* [23], a python library designed to handle large networks. To reduce the size of the graph, we chose to represent with one vertex each *outer* structure identified during the exploration. In other terms we decided to group together, in a single vertex, all the nested structures (but we keep the nesting information as it is needed when we need to move from the graph space back to the memory analysis heuristics). This transformation also makes the graph directed, and result in only one type of edges that represent pointers from a structure to another. As we will thoroughly discuss in Section 5 we assign a number of different weights to each node and edge to allow for several comparisons among different paths.

Figure 5 shows a kernel graph counting 109,000 nodes and 846,000 edges, plotted using Gephi [2]. This graph contains more than 41,000 strongly connected components with the vast majority (95%) containing only one node. On the other hand, the largest one contains 53% of the vertices and has a diameter of 272 nodes. As we will discuss in Section 6, this has important consequences for memory analysis, as it results in a multitude of available paths to move from one node to almost anything else in the kernel memory. The vertex with the highest in-degree is of type `super_block`, pointed by more than 11,000 `inodes` and 11,000 `dentries`. If we exclude the file system, the node with the highest degree is a `vm_operations_struct`, pointed by more than 4200 `vm_area_structs`.

In the picture, the size of labels and node is adjusted according to the betweenness centrality of a node. This type of centrality counts how many shortest path between every pair of nodes pass through a node. In other terms, the larger the size the more often a node is present inside every shortest path. The node color depends instead on the kernel subsystem the object belongs to. By using the name of the file where the object is defined we were able to classify them in roughly 7 classes, from file system to object related to memory or process management.

## 5 Metrics

In the previous section we described how we extracted a global map of a running kernel that can serve as basis for our analysis. However, without any further information, the only way we can compare two paths on the graph is by looking at their *length*, computed by counting either the total number of nodes or the total number of unique structures that need to be traversed. In fact, this simple approach may resemble the one adopted today by most of the memory forensic tools, where the most straightforward path is often chosen by the developers. However, this solution does not tell anything about the *quality* of a given path, nor about the presence of better options to solve the same problem. To get a solid foundation on which we can compare different techniques we need therefore to define a metric. And since the idea of having an absolute metric is

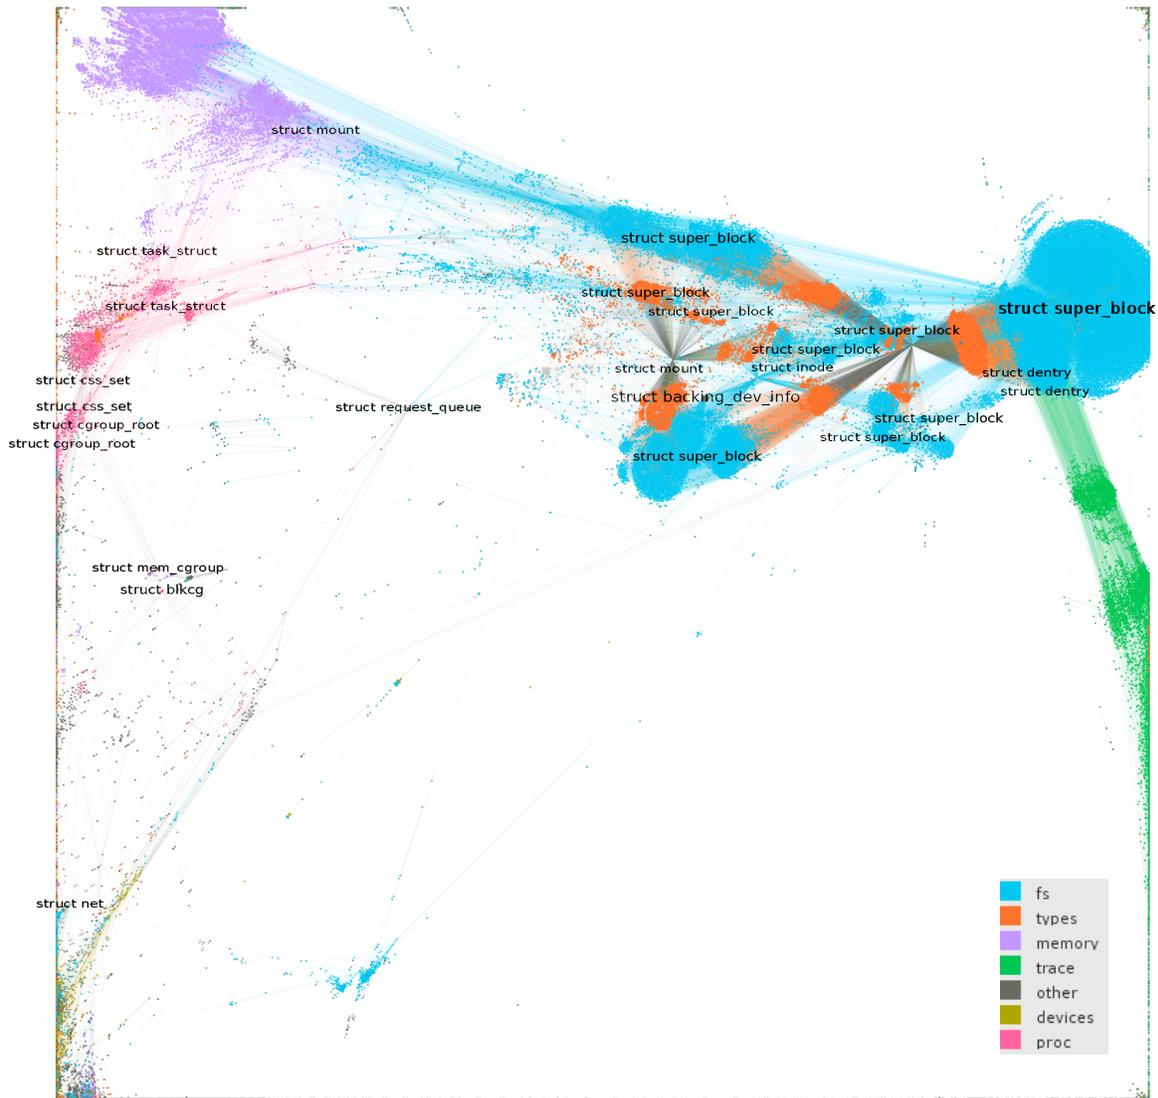

Figure 5: Kernel Graph

unrealistic, multiple different metrics can be plugged on our graph to study the characteristics of each path.

For our experiments we decided to investigate and add to our graph three numerical and two boolean weights, related to the atomicity, stability, generality, reliability, and consistency of a path. As described below, all of them capture different but important aspects of what an analyst may expect from a memory analysis routine.

#### Atomicity (numerical)

This weight express the distance in physical memory between two interconnected kernel objects. While this metric is ex-

pressed in terms of distance among physical pages, for an easier interpretation we often express it in seconds (as distance in time between the acquisition of the two pages). The atomicity is a very important aspect in most of today's investigation that rely on *non-atomic* dumps. In fact, moving across objects located far apart in memory - and thus acquired far apart on the time scale - can introduce inconsistencies. Intuitively, by using this metric the best path between a pair of nodes is the one which minimize the time-delta among all visited structures, thus passing only thorough objects acquired very close in time. More precisely, we can adopt three distinct ways to measure Atomicity:

- Acquisition Window (AW) – this is the total window

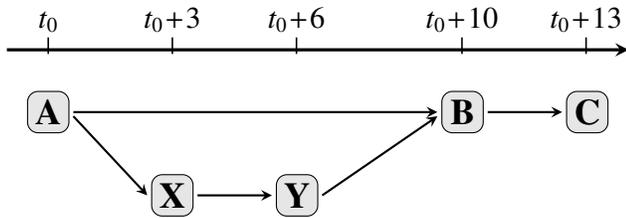

Figure 6: Time acquisition of nodes belonging to two paths.

that covers all data structures traversed in the path. E.g., one path may walk fifteen objects, all of which were acquired in a period of 23 seconds.

- **Cumulative Time Gap (CTG)** – this is the sum of the time difference of each edge traversed in the path. For instance, if a path visits three consecutive nodes (*A*, *B*, and *C*) and the difference between the acquisition time of the pointer in *A* and the content of *B* was 7 seconds and the difference between *B* and *C* was 3, the CTG would be 10 seconds.
- **Maximum Time Gap (MTG)** – this just takes into account the longest “jump” in a path. In the previous example, this would be 7 seconds.

All three measures are related to the Atomicity, but they capture different aspects. If it is important than none of the visited structures have changed during the acquisition, AW is the best metric. CTG gives instead a cumulative probability that things can go wrong by following links. The more edges are traversed, and the more far apart are the objects on the end of those edges, the more likely it is than a link can be corrupted due to the non-atomicity of the dump. Finally, MTG provides an estimation of the single most fragile edge in a path. This can be an important information, as traversing 10 edges each one a second apart can be a better option than traversing a single link with a nine seconds delay in the acquisition.

This can lead to some counter-intuitive results. For example, let suppose our graph analysis identifies two paths to reach a certain target structure *C* namely {*A* → *B* → *C*} and {*A* → *X* → *Y* → *B* → *C*} (for simplicity we ignore the name of the pointers). Both paths start from a structure *A* but the first traverses a single node *B* before reaching the destination while the second takes a detour through two other intermediate data structures *Y* and *Z* before re-joining the first path. Figure 6 shows the two paths on a time scale, that represent at which time the memory containing each data structure was collected.

While the second path is obviously a longer variation of the first, and therefore seems logical to believe that has nothing better to offer, it is very well possible that the detour reduces the probability of incurring in broken links. The pointer *A* → *B* was in fact collected 10 seconds before the object *B*, while the longest path decreases these time gaps to a maximum of four seconds. Whether this is an advantage or not depends

on how often those pointers are modified in a running kernel, which we capture with our next metric.

### Stability (numerical)

This weight expresses the stability over time of a given node or edge on the graph. Some structures are allocated at boot time and are never modified afterwards, while other parts of the graph are very ephemeral and contain structures that get allocated and de-allocated multiple times per second. By computing a heat-map of the stability of each edge (extracted by processing a number of consecutive snapshots), this weight can provide a valuable information on how the kernel map evolves over time, on which paths are more stable, and on which are instead more ephemeral and may only exists for short periods of time.

We measure Stability by computing the **Minimum Constant Time (MCT)** of all links in a path. The MCT can tell, for instance, that over a certain number of memory images all edges traversed by a certain heuristic remain constant for a minimum time of 30 seconds. In our experiments, we computed this metric by taking a snapshot of the same system at seconds 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 20, 30, 40, 50, 60, 100, 200, 350, 700, 1000, 3000, 5000, 8000 and 12000.

Surprisingly we found that the 81% of edge are stable, i.e., they never change across our experiments. The majority of them are objects related to the file system (*inode* and *dentry*), which the kernel caches for performance reasons. But this does not mean the graph does not evolve, actually quite the opposite. For example, we saw an increase of more than 60% of both nodes and edges between the graph built at  $t=0$  and the one built at  $t=700$ .

Moreover, if we exclude the filesystem subsystem and the paths that remained stable over all our experiments, 11% of the edges changed in less than 10 seconds, 12.5% in less than a minute, and 97% in the first hour.

### Generality (numerical)

This weight captures another important problem of memory forensics: the constant change in the layout of kernel objects. This is due to several factors. First of all the kernel is always under active development which means that fields are continuously added to and removed from kernel objects definitions. Moreover, the layout is also influenced by the configuration options chosen at compile time. Existing tools mitigate this problem by requiring additional compile-time information (part of what it is normally called an *OS Profile*). Unfortunately, there are cases in which this information is not available, which today greatly complicate (if not completely preclude) the ability of analyzing a particular memory dump. Therefore, it would be interesting to compute analysis paths that traverse structures which change very rarely across different distributions, kernel versions, and enabled kernel options.

For this reason we downloaded 85 kernels from the Ubuntu repository, spanning from version 4.4.0-21 to 4.15.0-20. For every object defined in each of these kernels we extracted the offset of the fields required for navigation – such as structure pointers or array of structures. We aggregated this information in a single `Kernels Counter` (KC) weight computed by counting over how many of the 85 kernels an entire path would remain constant (i.e., all its traversed link were present at the same offsets in their corresponding structures).

### Reliability (boolean)

This is a very important aspect in memory forensics and captures how tamper-resistant is a given path on the graph, assuming an attacker is capable of reading and writing arbitrary kernel memory. Some paths are very easy for an attacker to modify, and therefore cannot be trusted by an analyst whenever she suspects the attacker might have gained admin privileges on the machine. On the other hand, other paths are more robust, as breaking them would make the system unstable. This can potentially result in programs malfunction or termination and, in the worst case, in a crash of the entire operating system. The robustness of individual data structures has already been studied in the past by several works [1, 10, 25]. But here we are instead interested in the reliability of a path, i.e., not in the fact that individual fields (such as a file name) can be modified, but whether an attacker can tamper with the edges that need to be traversed to prevent a certain heuristic to reach its destination (to the best of our knowledge, this problem has never been addressed in the literature). Being able to compute a path on the graph that only traverses tamper-resistant edges may have a great impact on memory forensics. While today we still do not have enough information to color the entire graph according to this metric, we can still compute the reliability on demand. This means that we cannot compute the optimal solution according to its reliability, but once we have a candidate solution we can perform experiments to verify it.

### Consistency (boolean)

As a final property in this list we want to show how metrics can also be aggregated to capture more complex properties of a path. For this example we chose to combine the *stability* and *atomicity* of a path in a single measure that captures how likely it is for a given path to traverse consistent information. Intuitively, traversing a path whose nodes were acquired over a period of 20 seconds may be acceptable if those structures change very rarely, but completely unacceptable if its links are modified every few milliseconds. We capture this aspect by consider a path *consistent* if and only if the acquisition gap of each edge is lower than the minimum change time of the edge as computed in all our snapshots.

## 6 Experiments

We now discuss how our graph-based framework can be used in different scenarios, in which we investigate existing techniques used by Volatility [33], we discuss the intricacies of computing optimal paths, and we discover new solutions to reach all processes running in a system. In any case, these are only examples of what can be achieved by adopting a more systematic approach to memory forensics, and many more applications can benefit from our framework.

All experiments were conducted on a QEMU machine equipped with 2GB of RAM and 4 virtual CPUs, running `wordpress` on top of a LAMP stack. Before and between the acquisitions, we generated some activity by visiting the CMS pages and performing basic system administration task, such as logging in via `ssh` and updating the list of packages.

### 6.1 Scenario 1

In the first scenario we want to apply our methodology to study the quality of current memory forensics techniques. For our example we selected seventeen Volatility plugins that explore different subsystems (process, network, and filesystem) and mapped them as *paths* in our kernel graph. To achieve this we manually analyzed each plugin and extracted which global variables and kernel objects are traversed. With this information we were able to write a python script which automatically extracts these paths from our graph. Note that many plugins traverse similar kernel structures (e.g `linux_pslist` and `linux_pstree`) so, to avoid duplicates, we only report results for a subset that rely on different information. The final list of the plugins we analyzed is reported in Table 1.

Before looking at the individual metrics, we wanted to investigate to which degree the structures traversed by these heuristics are interconnected. The total number of unique objects used by this heuristics depends on the size of the graph. In our experiments they vary from 20 to hundreds of thousands. As we already introduced in Section 4.6, by averaging over the 25 graphs we created, more than 96% of the nodes used by the heuristics belong to a single giant *strongly* connected component that contains on average 53% of all the nodes in the graph. By combining this information with the nodes visited by Volatility, we found that this component contains all the information related to running processes, such as their mapped memory and open files, but also the information related to the `arp` table and the `ttys`. The remaining 4% of the nodes used by the Volatility rules are instead scattered among several other components. The biggest one, which contains only 0.5% of the heuristics nodes, contains the information related to the installed modules and, more in general, to the `kobjects` subsystem. Finally, the rest of the nodes belong to components containing only a single node. These are the nodes representing, for example, the global `pid_hashtable` and its associate `hlist_heads`.

Table 1: Comparison of Volatility plugins implemented as paths in our graph

| Name                | Description                                               | # Nodes | Atomicity |            |       | Stability MCT | Generality KC | Consistency |      |
|---------------------|-----------------------------------------------------------|---------|-----------|------------|-------|---------------|---------------|-------------|------|
|                     |                                                           |         | AW        | CTG        | MTG   |               |               | Fast        | Slow |

This is an important finding, as it means that the vast majority of the information needed for forensic purposes is interconnected and reachable from one another. Translated in practical terms, the presence of this giant connected component means that is enough to locate a single kernel object to reach all the other interesting ones only by dereferencing pointers. This might be beneficial in scenarios where the position of global kernel objects is not available to the analyst. In such cases, one entry point can often be located by memory carving and then used as starting point for every other analysis.

By looking at the atomicity metrics (columns four-to-six in Table 1) the first thing that stands out is that the values for the Acquisition Window (AW) and the Maximum Time Gap (MTG) are very similar and relatively constant across all commands. After further investigation we discovered that this is due to the fact that, when compiled with normal configurations, Linux kernel global variables are located in the low part of the physical memory while kernel objects are allocated in the higher end. Since all heuristics start from global symbols, the very first edge already accounts for the maximum gap between two consecutive kernel objects. This also influences the acquisition window, since one of the two farthest objects is always the global variable from where the heuristic starts from. On the other hand, the Cumulative Time Gap (CTG) shows more variations as it is also influenced by the number of traversed objects.

To better understand this phenomenon, in Figure 7 we plotted the content of the physical memory as a Hilbert curve. In the graph, each pixel represents a physical page and its color shows if the page is traversed by the Volatility heuristics (red in the graph) or if it contains at least one node of our connected component of the kernel graph (green). It is clear that the relevant data structures are not spread equally on the entire physical memory. Instead, they clearly aggregated around three main clusters, which we marked respectively as C1, C2, and C3. In our experiments the kernel global variables are all located in C1 while other information are often stored in C2 and C3. Therefore, most heuristics start from C1 and

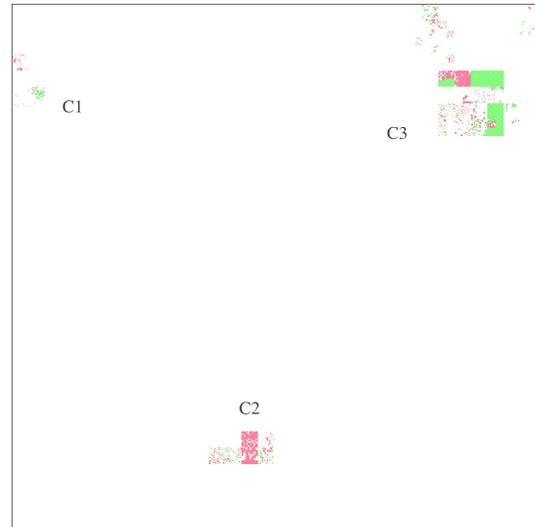

Figure 7: View as Hilbert curve of physical memory.

then eventually traverse an edge towards one of the other regions - which alone is responsible for the entire AW and MTG metrics. This physical distribution is also very important for the third scenario presented in Section 6.3, where we will encounter heuristics that need to hop back and forth from the three clusters, significantly impacting the atomicity metrics.

The second surprising result of this first scenario is the fact that the Kernel Counters (KC) of six plugins *never* changed across all the different kernel versions we used in our analysis. This means that, even when fields were added or removed from these object, the offsets of the fields used by the plugins remained constant. This has important implications for current memory forensics tools where a *profile* of the kernel is needed to analyze a memory dump. Our experiment suggests that, at least for locating certain information, a generic structure layout can be used across almost 100 kernel versions, released

as far as 2 years apart.

Another important propriety we evaluated in this first scenario is the consistency of the selected techniques. This is especially useful to better understand how the continuous modifications of kernel objects might impact memory dumps taken in a non-atomic fashion. This was recently listed by Case et al. [6] as “*one of the most pressing issues*” of memory forensics. While Case focused on page smearing (an inconsistency between the page tables and the referred physical memory), with this experiment we show that this problem does not affect only page tables but also references among kernel objects. The most important variable that influence the consistency of the memory is the duration of the acquisition process. To align with real world scenarios we run two different tests, by setting the acquisition ratio respectively to the fastest and to the slowest tool as reported by McDown et al. [21]. In that study, the authors compared seven different memory acquisition tools, chosen from a survey conducted over 41 companies specialized in memory forensics.

Interestingly, out of the 17 plugins we tested, three have a stability of 12,000 seconds, which means that none of the links they traversed *ever* changed over a period of more than three hours. At the other end of the spectrum, eleven plugins walked links that remained stable for less than a minute (and in five cases even less than one second). In this case, this may result in wrong pointers depending on how far in the physical memory were the page containing the link and the page containing the linked object. In fact, the last column of Table 1 shows that our analysis found inconsistencies in five (when the fastest tool to acquire the memory was used) or seven (in the case of the slowest solution was used) plugins. The affected plugins interest different parts of the kernel, but they can be divided to three distinct categories: *Memory* (`linux_proc_maps`, `linux_proc_maps_rb`), *File system* (`linux_check_fop`, `linux_find_file`, `linux_lsof`, `linux_mount`) and *Process* (`linux_pidhashtable`)

In the Memory category we found respectively 33 inconsistencies that affected the connections among `vm_area_struct` of a process, which are kept both in a linked list and in a red-black tree. These errors affected five instances of `apache`, one of `systemd-login` and one of `agetty`. The filesystem category included 40 unique inconsistencies in the hierarchy of dentries (fields `d_subdirs` and `d_child`) 53 in the mapping from a dentry to an inode (field `d_inode`). The latter object was also involved in 43 cases of inconsistency towards its `file_operations` object (field `i_fop`), while 23 `file` object had inconsistent edges pointing to their dentry and its mount objects. (field `f_path.dentry` and `f_path.mnt`). The most interesting cases of inconsistencies in this category – 10 in total – involved the array containing the pointers to the files opened by a process. This array belonged to three distinct instances of `apache`, one of `systemd` and one of the `mysql` database. In the process category, we only detected one case of inconsistent edge between a `struct pid` and the

pointed `task_struct`.

To systematically understand if these inconsistent paths can be avoided, we used once again our kernel graph – this time by filtering out *all* the 5,000 inconsistent edges, and searching for alternative paths to reach the same objects used by the affected plugins. Our graph exploration was able to discover alternative paths for 107 out of 213 inconsistent edges. For example, in the case of inconsistent array of opened files for the `systemd` process the alternative path — which traversed 11 additional nodes — was able to reach the target `file` by first locating the `task_struct` of the same process, then accessing its corresponding `files_struct` and from here reaching the `file` via the `fd_array` field (an array only used when the process opens less than 64 files). While these detours were sufficient in our experiments to retrieve the missing information, more experiments are required to understand if those alternative paths can be generalized to other scenarios. In any case, they show once more that the giant connected component that hosts most of the relevant data structures may allow analyst to find alternatives solution to mitigate the presence of wrong pointers and inconsistent information. Sadly, almost 50% of the affected pointers did not allow for an alternative path, thus emphasizing again the severe consequences that the lack of atomicity can have on memory analysis.

## 6.2 Scenario 2

In our second case study we want to understand if we can employ the kernel graph to find new heuristics for common forensics tasks. In particular, we focus on the starting point of many forensics investigation: listing the processes running at the acquisition time. Currently Volatility implements three different plugins<sup>1</sup> to list the processes, respectively by walking the process list, by using the `pidhash` hashtable, and by parsing the kernel memory allocator. However, the latter is only applicable if the kernel uses the SLAB allocator. Unfortunately, many distributions, such as Ubuntu and Debian, ships by default with the SLUB allocator, which is not supported by Volatility and which does not keep track of full `slabs` – thus making this technique not applicable anymore.

The main reason for looking for alternative solutions is that previous research already pointed out that rootkits are already capable of removing a process from the process list, but also to unlink a process from the `pid` hashtable [19,26,27] thus leaving the forensic analyst without a reliable method to list processes. Moreover, as we already discussed in the previous scenario, the lack of atomicity of a memory dump can introduce inconsistencies and result in broken pointers also in the list of running processes. For these reason, it is important to find new ways to locate processes, so that their output can be compared with other techniques to spot inconsistencies or hidden processes.

<sup>1</sup>Volatility also includes a plugin to carve `task_struct` objects by using a signature, but this is a parallel approach that does not require exploring memory but relies instead on pattern-matching.

Table 2: Comparison between different heuristics used to find processes

| Category   | Root Node                     | New | # Nodes | # task_struct | AW    | Atomicity CTG | MTG   | Stability MCT | Generality KC | Reliability | Consistency |
|------------|-------------------------------|-----|---------|---------------|-------|---------------|-------|---------------|---------------|-------------|-------------|

|            | init_task (linux_threads)     | ✗   | 156     | 156           | 16.27 | 280.68        | 16.24 | 30.00         | 31/85         | ✗           | ✓           |
|            | pid_hash (linux_pidhashtable) | ✗   | 469     | 156           | 16.67 | 451.87        | 16.67 | 30.00         | 30/85         | ✗           | ✓           |

This scenario is also interesting as it is harder to translate into a graph exploration problem. In fact, since we are looking for techniques to list all (or a part of) the running processes, this is equivalent to a *collection* of, possibly not homogeneous, paths. As a result, listing all processes is not simply equivalent to a path, but more to an *algorithm* to explore the graph.

Our approach to find new heuristics is the following. First, we discarded all the global roots that do not have a path to reach all the `task_struct`s in *every* graph we created. As a result, we were left with 621 global roots (out of more than 8000 we started with). Second, we modified the graph to remove the edges already used by known techniques, such as the `tasks` field. This helps removing all those paths that would just find a different way to reach a single process, and then walk the list like the existing plugins already do. While not useless per se, our goal is to find *new* solutions and not variations of the existing ones.

By only considering the *shortest* paths from every root node to every task structure, our system found more than 100 million distinct paths, generated from a set of more than 966,000 sequences of vertices. This is possible because, as we later discovered, the graph contained many parallel edges connecting the same nodes. In fact, by putting things in perspective, on average every sequence of vertices from a root node to a target object generates more than 100 unique paths. The good news is that this makes extremely difficult for attackers to modify all edges required to completely hide a process. On the other hand though, this also makes very hard the task of identifying interesting patterns in this multitude of options. For simplicity, we first decided to filter out all *similar* edges – i.e., parallel edges that shares the same metrics (and that therefore are equivalent for our purpose). This operation removed more than 300,000 edges, some of which played an important role in the path explosion. For example, many entries of the array `e_cset_node` of the `css_set` object pointed multiple times to the same vertex. After this operation the number of different paths decreased to about 7.5 millions paths.

We then merged similar paths into *templates*, constructed by keeping only the type of the objects present in the path, and by also removing adjacent nodes with the same type

(which capture the  $\odot$  link discussed in Section 3). Finally, we removed templates that were subset of other templates, resulting in a final set of 4067 path templates.

By manually exploring these options, we soon realized that they belong to only four main families, depending on the kernel subsystem they live in. The first one is related to the *cgroup* subsystem, the second to the *memory* subsystem through the `mm_struct` structure, the third passes through the *work queues* to reach kernel workers, and the last traverses the `struct rq` and follows the `curr` field, a per-cpu runqueue. The results are summarized in Table 2.

Unfortunately, there are no alternative paths that can improve the atomicity. In fact, the bulk of the time gap (16.24 seconds) is due to the difference in the acquisition time of the global entry points (located in C1 in Figure 7) and the first task structure (located in C2 and C3). However, all these edges are very stable and in only one case (for the `css_set_table`) the value of this first connection ever changed during our memory acquisition.

The memory-based heuristics walked a red-black tree (`i_mmap`) that is very ephemeral and, while exploring it, we found more than 30 edges that could be inconsistent if the memory dump is not taken atomically. A similar problem affects the scheduler, whose structures also contain links that change very rapidly. We observed an interesting phenomenon in the *cgroup*-related heuristics. The first is inconsistent as it traverses a pointer with a very large time gap. However, the second avoid this problem by reaching the same `css_set` structures by taking a detour through several intermediate objects which act as a bridge to lower the time gap. This is an example of the counter-intuitive behavior we introduced in Section 5 (Figure 6), where we predicted that the most direct path might not always be the best in term of consistency. The worker-related approach was the best in terms of stability, consistency, and generality. However, its goal is to list all active kernel workers and therefore this heuristic is unable to capture normal userspace processes. Finally, the two heuristics in the process category, which represent the Volatility plugins `linux_pslis` and `linux_threads`, had both a stability of 30 seconds. This is strange, as several processes should have started during this

time frame. However, new processes were all appended to the tail of the process list without altering the intermediate nodes.

To test the Reliability of the heuristics we wrote a kernel module that tries to hide an userspace process by unlinking it from the path required by each heuristic. As a result, each case required a custom hiding technique. For the cgroup heuristics we deleted the processes from the `cg_list` linked list. For the memory we first found every non-anonymous, i.e. backed by a file, `vm_area_structs`. We then delete all this structures from the red black tree rooted in the `inode`, which keeps track of all the `vm_area_struct` which are currently mapping this file. For the first two process heuristics, we removed the process from the process list (by unlinking `task_struct.tasks`), while for the `pid_hash` we removed the `struct pid` from the hashtable. For the workqueue we instead created a custom workqueue and queued a simple work function that mimicked the behavior of the userspace process we used in our test. We then proceeded by unlinking the worker from the linked list rooted at `worker_pool.workers`.

In all the cases our program continued to run without observable side-effects – showing that each path we listed so far can be tampered with by a properly written rootkit. As we also discussed in Section 5, we believe that more experiments are needed to improve the assessment of a path’s reliability. While it is true that our program continued to run, there can be a multitude of events (e.g. the kernel starting to swap memory) that might compromise the stability of the altered system.

### 6.3 Scenario 3

In the third scenario we show how we can compute optimal paths, with respect to the different metrics we proposed in this work. As running example, we picked this time the problem of finding the files opened by a given process (identified by its `task_struct`).

To run our experiments we collected all the `task_struct` and all the associated `file` objects and analyzed the paths Volatility would take to move from the first to the second. However, we immediately run into a strange behavior, as the metrics were returning very different results for different files. To understand the reason we had to look closer at how the physical pages were assigned to the different kernel objects.

Figure 7 explains very well the three classes of behavior we identified in our experiments. Since the clusters (C1, C2 and C3) are located far apart in memory (and therefore they can be acquired far apart in time), whenever a heuristic moves from one structure contained in one cluster to another contained in a different one, it needs to take a “jump” with associated a considerable time gap. If a `task_struct` and all the intermediate objects needed to reach the open files are located inside the same cluster, then time gaps are extremely small and path are always consistent. In this case paths are already optimal and there is no much room for improvement. If they are instead located in two different clusters, then the atomicity increase by almost nine

seconds. However, the picture shows that also in this case it is not possible to find better alternatives, as all paths would need to cross the gap between the clusters– incurring in the same penalty. Finally, there are examples in which the `task_struct` and the `file` objects were located in the same cluster, but the intermediate structures traversed by Volatility resided in the other one. In this case the Volatility heuristic needs to jump across clusters twice, incurring twice in the risk of inconsistent links. But in this third case it might be possible to use our graph to find an alternative path that is fully contained in the same cluster.

An example of each of these three cases is shown in Table 3, along with the metrics computed on the Volatility heuristic and those computed on the optimal paths extracted from our graph. Regarding the cumulative time gap (CTG), our insight was correct and only paths belonging to the third category could be considerably improved. In fact, the table shows that from more than 17 seconds in the Volatility case, the optimal path had a CTG of less than 0.01 seconds. Accordingly, also the MTG decreased with the same magnitude. As we discussed in the previous scenario, finding a consistent path for this particular problem is sometimes possible. Indeed, when this is the case, we were able to find a path that remained stable for all our experiments. Interestingly, for the second case, one of the paths with maximum stability has also higher generality than the one used by Volatility but, since it passes through more nodes, it has an higher CTG. On the other hand, maximizing the generality of a path has a serious impact to its consistency and stability. In fact, while we were able to find paths which are constant over 50 kernels, none of them was consistent, independently to the speed of acquisition.

## 7 Discussion and Future Directions

The goal of our work is to provide a principled way to think about memory forensics as a graph-related optimization task. This way of modeling the problem opens the door to a multitude of different possibilities to evaluate and compare existing techniques, design algorithms to compute new alternative solutions, validate the consistency of kernel structures, or propose heuristics customized to different experiments setup and acquired dump.

We tried to discuss some of these opportunities through our experiments, but we are aware that many questions are still open and new research is needed to shed light to each individual use case. For this reason, we decided to release our code and data to other researchers, hoping that this will facilitate new experiments in this field and accelerate new findings based on our methodology.

In this paper we focused on the analysis of traditional computers. This choice was simply dictated by the fact that this is the area where memory forensics is more mature and for which most of the heuristics have been designed so far. Nevertheless, we believe that our system could be used to help researchers to better design and implement future forensic

Table 3: Optimal paths compared with Volatility paths

| Name                                                                             | # Nodes | Atomicity |              |              | Stability    | Generality   | Consistency |      |

frameworks tailored to emerging technologies such as mobile devices and the Internet of Things (IoT).

**Main findings:** our experiments show that a large part of the kernel graph belongs to a giant connected component. This means there are thousands, or even millions of possible paths that allow an analyst to move from one node to another. It also means that it is very difficult for an attacker to completely hide some piece of information from all possible paths.

Another consequence of the interconnected topology of the graph is that it is hard for an analyst to simply inspect all possible paths, looking for new techniques to implement in memory forensic tools. We tried to do this in our second scenario, and run into a path explosion problem even by considering only all shortest paths. However, this effort allowed us to discover two new promising techniques (one based on `cgroups` and one on `workqueues`) that can complement those used today by Volatility<sup>2</sup>.

Sadly, the problem of finding an optimal path turned out to be very delicate and dependent on multiple factors. In fact, the exact memory layout when the snapshot is acquired may affect the metrics associated to different links (e.g., one path may be optimal for one dump but poor in another). This may suggest that maybe, instead of relying on a single solution, new techniques should try to explore the graph by following many parallel paths.

Moreover, we are aware that some of the metrics we proposed in this paper turned out to be ineffective in the evaluation. However, we decided to include them anyway in the paper for two reasons. First, because we did not know in advance that (for example the Maximum Time Gap) would be

irrelevant in the analysis of common Linux kernels. This has nothing to do with the heuristic itself, but with the fact that the kernel allocates global variables (entry points) very far from other objects. We believe this fact to be an interesting finding which came as a consequence of applying our framework. Second, while this is true in our experiments, it is probably not the case on other operating systems or OS kernels. So, we believe it is still interesting to implement and discuss those ineffective metrics in our framework.

Finally, we want to stress the fact that our main contribution is not the discovery of new technique, but the introduction of a model that can be used to *reason* about memory analysis, explore its complexity, and perform quantitative measurements.

**Future Work:** In this paper we discuss a number of metrics an analyst can use to compare different solutions. However, the list is certainly not exhaustive and we expect more to be defined in the future. More work is also needed to understand which metric is better at capturing certain aspects of an investigation.

Reliability is certainly one of the most important characteristic of an analysis technique. Unfortunately, it is also the only one we discussed that cannot be extracted with automated experiments. More research is needed to fill this gap and enable to compute the reliability of a large amount of links among kernel objects.

Finally, to be useful in practice, our prototype should be applied to a larger number of memory dumps taken from different systems. This could help generalize the results and customize the analysis to an environment that resemble the one under investigation.

<sup>2</sup>We implemented both as Volatility plugins

## 8 Related Work

The analysis of kernel objects and their inter-dependencies has attracted the interest of both the security and the forensics community. While the common goal, namely ensuring the integrity of the kernel against malware attacks using the inter-dependencies between kernel object, is shared by the majority of works on this topic, the methods and the tools used to achieve it are often different. Several research papers have also been published on reconstructing and analyzing data structure graphs of user-space applications [3, 7, 28, 31]. However, most of these techniques are not directly applicable to kernel-level data structures, because they do not take in account the intricacies present in the kernel, such as resolution of ambiguous pointers to handle custom data structures. For this reason they will not be discussed in this Section.

To better highlight the different approaches, we decided to divide them in two distinct categories. The first one covers approaches which presented the analysis of a *running* kernel. The second category is focusing instead on *static* approaches, which require only a memory snapshot or the OS binary.

### Dynamic Analysis

One of the first example of dynamic kernel memory analysis was presented by Rhee et al. in 2010 [26]. The tool, named LiveDM, places hooks at the beginning and at the end of every memory-related kernel functions, to keep track of every allocation and deallocation event. When these hooks are triggered, the hypervisor notes the address and the size of the allocated kernel object and the call site. The latter information is used, along with the result of an offline static analysis of the kernel source code, to determine the type of the allocated object. A work built on top of LiveDM is SigGraph [19]. In this paper the authors generate a signature for each kernel object, based on the pointers contained in the data structure. These signatures are then further refined during a profiling phase, where problematic pointers - such as null pointers - are pruned. The result can then be used by the final user to search for a kernel object in a memory dump. The major concern about signature-based scheme is their uniqueness, that avoids problems related to isomorphism of signatures. The authors found that nearly the 40% of kernel object contains pointers and - among this objects - nearly 88% have unique SigGraph signatures. Unfortunately the uniqueness was reported *prior* the dynamic refinement, so it is unclear the percentage of non-isomorphic signatures. For this reasons a kernel graph built using the approach adopted by SigGraph would only retrieve a *partial* view of the entire memory graph.

Another work focused on signatures to match kernel objects in memory was done by Dolan-Gavitt et al in 2009 [10]. The main insight of this work is that while kernel rootkits can modify certain fields of a structure - i.e. to unlink the malicious process from the process list - other fields (called *invariants*) can not be tampered without stopping the malicious behavior or causing a kernel crash. The invariant are determined in a two steps approach. During the first one every access to a data

structure is logged, using the stealth breakpoint hypervisor technique [32]. Then, the most accessed field identified in the previous step are fuzzed and the kernel behavior is observed. If the kernel crashes then there are high chances that this field can not be modified by a rootkit. On the other hand, if no crash is observed, than the field is susceptible to malicious alteration. The direct results of these two phases is that highly accessed field which result in a crash when fuzzed are good candidates to be used as *strong* signatures. While this approach looks very promising is not easily adaptable to our context since, as also noted by the authors, creating a signature for small structures can be difficult. Furthermore, generating a signature requires to locate at least one *instance* of a structure in memory, which might not be straightforward.

Xuan et al. [35] proposed *Rkprofiler*. This tool combine a trace of read and write operations of malicious kernel code with a pre-processed kernel type graph, to identify the tampered data. The problem of ambiguous pointers is overcome by annotating the type graph with the real target of a list pointer. While it is not clearly stated in the paper, it seems the annotation was manually done. As we discussed in Section 4 the Linux kernel uses a large amount of ambiguous pointers, thus making the manual annotation approach not feasible anymore.

While more focused on kernel integrity checks, OSck [16] uses information from the kernel memory allocator (*slab*) to correctly label kernel address with their type. The integrity check are run in a kernel thread, separated by the hypervisor. This two components allow OSck to write custom checkers that are periodically run. While this approach seems promising, only a small subset of frequently-used structures are allocated using *slab* (such as `task_struct` or `vm_area_struct`), and thus is unsuitable for our needs.

Another approach to create a Windows kernel object graph is *MACE* [11]. Using a pointer-constrain model generated from dynamic analysis on the memory allocation functions and unsupervised learning on kernel pointers, MACE is able to correctly label kernel objects found in a memory dump. Once again, while the output of the work is a kernel object graph for Windows, the application only focuses on rootkit detection.

### Static Analysis

One of the most prominent work in this field is KOP [4], and its subsequent refinement MAS [8]. Very similarly to our approach, the authors use a combination of static and memory analysis techniques respectively on the kernel code and on a memory snapshot. In the first step they build a precise *field-sensitive* points-to graph, which is then used during the memory analysis phase to explore and build the kernel objects graph. Contrary to this solution, ours does not make *any* assumption about the kernel memory allocator. While the Windows kernel has only one allocator, the Linux kernel has three different ones (`slab`, `slub`, and `slob`). Moreover, only a predefined subset of kernel objects are allocated in custom slabs, while the vast majority is sorted in generic slabs based on their size.

Gu et al. [13] presented OS-Sommelier<sup>+</sup>, a series of tech-

niques to fingerprint an operating system from a memory snapshot. In particular, one of these techniques is based on the notion of *loop-invariants*: a chain of pointers rooted at a given kernel object that, when dereferenced, points back to the initial object. Once a ground truth is generated from a set of known kernels, this loop invariant *signatures* can be used to fingerprint unknown kernels. Unfortunately the paper does not mention the problem of ambiguous pointers, and we believe our graph generation approach could improve OS-Sommelier<sup>+</sup> detection.

Finally, as we already discussed, none of the tools to automatically build a graph of kernel objects was publicly available.

## 9 Conclusion

Memory forensics focuses on locating and extracting artifacts from a memory snapshots, using a broad set of custom rules. However, the quality of the existing heuristics is difficult to measure and it is largely based on the experience of the researchers who wrote them. As a result, analysts are left without any clear guidelines on how to compare and evaluate different approaches and how to assess the results they produce.

For these reasons, in this paper we proposed a method to study memory forensics techniques in a principled way. Our solution is based on a graph representation that captures the relationships between all kernel objects, enriched with a set of metrics that covers different aspects of memory forensics. We believe that our framework can help researchers to measure the quality of existing memory forensics techniques, but also to extract qualitatively better heuristics.

# Detecting Missing-Check Bugs via Semantic- and Context-Aware Criticalness and Constraints Inferences

Kangjie Lu, Aditya Pakki, and Qiushi Wu  
*University of Minnesota*

## Abstract

Missing a security check is a class of semantic bugs in software programs where erroneous execution states are not validated. Missing-check bugs are particularly common in OS kernels because they frequently interact with external untrusted user space and hardware, and carry out error-prone computation. Missing-check bugs may cause a variety of critical security consequences, including permission bypasses, out-of-bound accesses, and system crashes. While missing-check bugs are common and critical, only a few research works have attempted to detect them, which is arguably because of the inherent challenges in the detection—whether a variable requires a security check depends on its semantics, contexts and developer logic, and understanding them is a hard problem.

In this paper, we present CRIX, a system for detecting missing-check bugs in OS kernels. CRIX can scalably and precisely evaluate whether any security checks are missing for critical variables, using an inter-procedural, semantic- and context-aware analysis. In particular, CRIX’s modeling and cross-checking of the semantics of conditional statements in the peer slices of critical variables infer their *criticalness*, which allows CRIX to effectively detect missing-check bugs. Evaluation results show that CRIX finds missing-check bugs with reasonably low false-report rates. Using CRIX, we have found 278 new missing-check bugs in the Linux kernel that can cause security issues. We submitted patches for all these bugs; Linux maintainers have accepted 151 of them. The promising results show that missing-check bugs are a common occurrence, and CRIX is effective and scalable in detecting missing-check bugs in OS kernels.

## 1 Introduction

Security checks are a class of conditional statements that validate program execution states. Security checks play an important role in ensuring the security of OS kernels. Not only do OS kernels accept arbitrary untrusted inputs, but they

also perform complicated tasks such as concurrent resource management and multi-user/capability access control. Therefore, OS kernels often enter into erroneous states and require security checks to capture them.

A missing-check bug exists when an intended security check is not enforced for a critical variable. Examples of such critical variables include the ones used to indicate potential erroneous execution states, e.g., the return value of `kmalloc()`, and the ones used in critical operations, e.g., the size variable in `memcpy()`. [Figure 1](#) shows a concrete example of missing-check bugs. `ib_get_client_data()` may fail and return `NULL`. Since `smcibdev` is not checked, the following uses of it may cause multiple problems—`NULL`-pointer dereferences, failures in removing and unregistering devices, and memory leaks. To fix the problem, a security check should be enforced between lines 6 and 8 to ensure that `smcibdev` is not `NULL`.

```
1 /* Linux: net/smc/smc_ib.c */
2 static void smc_ib_remove_dev(struct ib_device *ibdev...)
3 {
4     struct smc_ib_device *smcibdev;
5     /* ib_get_client_data may fail and return NULL */
6     smcibdev = ib_get_client_data(ibdev, &smc_ib_client);
7     // ERROR1: NULL-pointer dereference
8     list_del_init(&smcibdev->list);
9     /* ERROR2: device cannot be removed or unregistered */
10    smc_pnet_remove_by_ibdev(smcibdev);
11    ib_unregister_event_handler(&smcibdev->event_handler);
12    /* ERROR3: memory leak */
13    kfree(smcibdev);
14    /* No return value: caller cannot know the errors */
15 }
```

**Figure 1:** Example: A new missing-check bug found by CRIX. The missed check against variable `smcibdev` will cause multiple problems, as annotated in the code.

Missing-check bugs may cause critical security impacts because security checks are a main means for OS kernels to ensure their security and reliability. To understand the importance of security checks, we first studied recently reported security vulnerabilities in the National Vulnerabilities Database (NVD). We found that 59.5% security vulnerabilities stem

from missing-check bugs, which were all fixed by inserting security checks. We then investigated these vulnerabilities and found that at least 52% (excluding denial-of-service cases) of them will cause severe security impacts such as permission bypass, memory corruption, system crashes/hangs.

Although missing-check bugs are critical and prevalent, only a few research works have attempted to detect them in OS kernels and have several limitations. In particular, Vanguard [32] assumes that some critical operations should always be checked. It however detects missing-check bugs for only four specified critical operations such as arithmetical division and array indexing. Some other approaches (e.g., Chucky [46], Juxta [23], Kremenek et al. [19], and Dillig et al. [7]) employ cross-checking, inconsistency analysis, or machine learning to reduce false positives in detecting bugs. These approaches have non-trivial limitations. First, the manual specification for critical variables covers only a small set of critical variables. This leads to significant false negatives. Second, most of these approaches are not semantic- or context-aware. For example, they tend to treat any conditional statement (i.e., an `if` or a `switch` statement) as a security check. In fact, whether a variable requires a security check highly depends on its semantics and contexts, without considering which, the detection would suffer from high false-negative and false-positive rates.

The lack of effective research in detecting missing-check bugs is arguably because of several inherent challenges. (1) Critical variables that require security checks take diverse forms. For example, a critical variable can be a parameter of a critical function (e.g., the `size` variable in `memcpy()`), a global variable, or a return value of a function call that is used in only security checks but not others such as arithmetic operations (this case is missed by Vanguard [32]). Therefore, generally checking for different kinds of critical variables is hard.

(2) Identifying security checks requires semantic understanding. Treating any conditional statement as a security check will cause both significant false positives and false negatives. In fact, according to our study §6, the majority (about 70%) of conditional statements are not security checks but some normal selectors in which both branches of the conditional statements lead to normal execution. (3) Missing-check bugs are context dependent, and the detection should be context aware. For example, an error code may not require a security check at all if it is used in a debugging function. As such, missing-check detection should be context aware. (4) Last but not least, OS kernels are extremely large and complex. Checking every variable will not scale, and corner cases such as hand-written assembly will make the analysis error-prone.

In this paper, we present CRIX (Criticalness and constraints Inferences for detecting missing checks), a system that overcomes the aforementioned challenges to effectively detect missing-check bugs in OS kernels. At a high level, CRIX first employs an automated approach to identify critical variables as the analysis targets. For each critical variable, CRIX con-

structs *peer* slices that share similar semantics and contexts. After that, CRIX models constraints of conditional statements in each slice. By cross-checking the modeled constraints of the peer slices of a critical variable, CRIX finally identifies deviations as potential missing-check bugs and reports them for further confirmation.

While the high-level idea of CRIX is intuitive, it entails overcoming multiple technical challenges. We thus have developed multiple new techniques to tackle these challenges. (1) We first propose a two-layer type analysis to identify indirect-call targets, which serves as a foundation of our data-flow analysis engine. In addition to the function-type analysis (the first layer) employed by traditional control-flow integrity (CFI) techniques [4, 25, 40], the two-layer type analysis further uses struct-type analysis, which is also employed by Ge et al. [10], to refine indirect-call targets. (2) We then develop an automated analysis that identifies security-checked variables as potential critical variables, which not only narrows down the analysis scope and thus scales the detection to OS kernels, but also significantly reduces false reports by filtering out non-critical variables. (3) We further propose peer-slice construction to collect slices of a critical variable that share similar semantics and contexts. The set of peers enables effective cross-checking for potential missing check cases of the critical variable. (4) At last, to precisely detect missing-check cases, we construct constraints from the conditional statements in the peer slices and model them based on their semantics (e.g., the condition type in conditional statements). The modeled constraints allow CRIX to cross-check slices for detecting missing-check bugs, in a semantic-aware manner.

With the new techniques, CRIX's analysis is scalable, semantic- and context-aware, and the data-flow analysis engine in CRIX is inter-procedural, flow-, context-, and field-sensitive. By focusing on the small set of automatically identified critical variables, CRIX can scale to large programs like the Linux kernel. The peer-slice construction allows CRIX to reason about potential missing-check cases in a semantic- and context-aware manner, and the constraint modeling and cross-checking enable CRIX to infer the criticalness of critical variables. As a result, CRIX is able to effectively and precisely detect missing-check bugs in complex and large system software such as the Linux kernel.

We have implemented CRIX on top of LLVM as multiple static-analysis passes. We chose the Linux kernel as the experimental target given its prevalence and complexity (more than 25 million SLOC). CRIX finished the analysis for the whole Linux kernel in about one hour and reported many missing-check cases. By manually investigating the top 804 missing-check cases reported by CRIX, we confirmed 278 new missing-check bugs. We also submitted patches for all of them to the Linux maintainers. Out of these patches, 151 have been accepted, with 134 applied to the mainline Linux kernel and 17 confirmed. The results show that CRIX is highly scalable and effective in finding missing-check bugs. We also

discuss CRIX’s portability in §6 and believe that CRIX can be easily extended to detect missing-check bugs in other system software.

We make the following contributions in this paper.

- **A new system for missing-check bug detection.** Missing-check bugs constitute the root cause of the majority (59.5%) of recent security vulnerabilities. We propose a semantic- and context-aware approach to scalably and effectively detect missing-check bugs in OS kernels. The resulting system, CRIX, is open sourced<sup>1</sup>.
- **Multiple new general techniques.** We propose multiple new general techniques in CRIX, which would benefit other research. In particular, the peer-slice construction identifies code paths that share similar semantics and contexts, which is useful for general differential analysis. The automated critical-variable inference finds a small set of targets that deserve precise analysis and protection, which narrows down target scope and could improve the performance for techniques such as fuzzing and data-flow integrity. The two-layer type analysis refines indirect-call targets, without introducing false negatives, which is also useful for inter-procedural static analysis, control-flow integrity, and program debloating.
- **Numerous new bugs in the Linux kernel.** With CRIX, we found a large number of new missing-check bugs in the Linux kernel, which may cause critical security and reliability issues to the Linux kernel used by billions of devices. We reported these new bugs and have worked with Linux maintainers to fix many of them.

The rest of this paper is organized as follows. We present the study on missing check bugs in §2, the design of CRIX in §4, implementation of CRIX in §5, evaluation of CRIX in §6. We further discuss the extension and limitations of CRIX in §7. We present related work in §8, and conclude in §9.

## 2 Missing Checks in OS Kernels

To propose an effective approach to finding missing-check bugs, we first study the characteristics of previously reported missing-check bugs.

**Bug-set collection.** We collect previously reported missing-check bugs from NVD [26]. We first selected the recent 200 vulnerabilities that were reported during 2017 and 2018. Out of them, we then selected the ones fixed by enforcing security checks, which returned us 119 (59.5%) vulnerabilities. We finally took the missing-check bugs leading to these vulnerabilities as the bug set for our study.

<sup>1</sup><https://github.com/umnsec/crix/>

### 2.1 Impact of Missing-Check Bugs

To assess the impact of missing-check bugs, we investigated (1) what percent of security vulnerabilities are caused by missing-check bugs, (2) common classes of security vulnerabilities caused by missing-check bugs, and (3) severe security impact of missing check-related vulnerabilities.

**Percent of missing check-related vulnerabilities.** As we mentioned in the bug-set collection, a majority (59.5%) of recent security vulnerabilities were caused by missing-check bugs. This is expected because common vulnerabilities such as out-of-bound access and access-control errors are typically fixed with security checks.

**Common classes of missing-check impact.** We then classified the security impact of the 119 missing-check bugs based on the classification provided by CVEDetails [48]. We found that missing-check bugs can introduce at least ten classes of vulnerabilities. Table 1 shows the six most common classes. In particular, more than half of the missing-check bugs may result in denial-of-services, and more the 52% of them may result in other severe impacts. Some missing-check bugs may have multiple impacts, so the total number is > 100%.

| DoS   | Over flow | Bypass privi. | Info leak | Memory corrupt | Code exec. |
|-------|-----------|---------------|-----------|----------------|------------|
| 51.2% | 16.0%     | 14.3%         | 11.7%     | 6.7%           | 3.4%       |

Table 1: Common security impacts of missing-check bugs.

**Severe security impact.** We also looked into the most severe vulnerabilities from 2017 to 2018 that have a CVSS (Common Vulnerability Scoring System) score 10 (the highest severity level) from the Linux kernel. We in total found 15 such vulnerabilities. Specifically, we found that 11 of these vulnerabilities are caused by missing-check bugs. The targets of the missing checks in these vulnerabilities include buffer length, function return value, pointer value, and permissions. Correspondingly, the missing-check bugs will cause severe impacts, including buffer overflow, use-after-free, memory corruption, permission pass, which will finally result in data losses, information leaks, and even attackers control of the whole system. Figure 2 shows an example of a severe missing-check bug (CVE-2017-18017) with a CVSS 10. The attacker-controllable `len` and `tcp_hdrlen` are used as a loop-termination condition for memory access. Missing the security checks for these variables will result in denial of service, information leak, and memory corruption.

### 2.2 Targets of Security Checks

According to our analysis of the missing-check bugs, generally, security checks have two classes of targets: state variables and critical-use variables.

```

1 /* Linux: net/netfilter/xt_TCPMSS.c (CVE-2017-18017) */
2 static int tcpmss_mangle_packet(struct sk_buff *skb,
3     unsigned int tcphoff, ...) {
4     tcp_h = (struct tcp_hdr *) (skb_network_header(skb) + tcphoff);
5     tcp_hdrlen = tcp_h->doff * 4;
6     /* Security checks for both "len" and "tcp_hdrlen" */
7     if (len < tcp_hdrlen || tcp_hdrlen < sizeof(struct tcp_hdr))
8         return -1;
9 }

```

**Figure 2:** A missing-check bug causing multiple severe security impacts: denial of service, information leak, and memory corruption. The bug is assigned with ID CVE-2017-18017.

**State variables.** State variables indicate if the current execution is in an erroneous state, e.g., if an operation is successful or not. According to the C programming convention, a return value of a function often serves as an indicator of execution states. State variables are prevalent in OS kernels because kernel operations are error-prone. OS kernels have to frequently use and check state variables to ensure that an operation is successful. A special feature of state variables is that they are often used in only security checks but not any other function-related operations such as arithmetic operations. Line 4 in Figure 3 is an example of checking the state variable `ret`, which is used only in the security check at line 4. In function `btrfs_search_slot()`, different error codes are returned for indicating various erroneous states, which should be checked in callers.

**Critical-use variables.** Variables used in critical operations are another common class of check targets. Intuitively, variables should be checked before being used in a critical operation. Common critical-use variables include pointers in dereferencing, offsets in array indexing, operands of binary operations such as arithmetic division, and parameters in critical functions (e.g., `memcpy()`) that may cause security issues. Line 9 in Figure 3 is an example of checking the variable `tx_out` before it is being used in the critical function `dmaengine_submit()` which internally dereferences `tx_out`.

```

1 /* Linux: fs/btrfs/inode-map.c */
2 ret = btrfs_search_slot(NULL, root, &key, path, 0, 0);
3 /* "ret" is a state variable for the search operation */
4 if (ret < 0)
5     goto out;
6
7 /* Linux: drivers/crypto/omap-des.c */
8 /* "tx_out" is checked before "dmaengine_submit" uses it */
9 if (!tx_out)
10     return -EINVAL;
11 dmaengine_submit(tx_out);

```

**Figure 3:** Examples of check targets. `ret` is a state variable checked in line 4, and `tx_out` is checked at line 9 because it is used by the critical function `dmaengine_submit()`.

### 3 Overview of CRIX

The goal of CRIX is to detect missing-check bugs in OS kernels. To this end, CRIX automatically infers whether a vari-

able in the target OS kernel requires a security check. The detection of missing-check bugs, in general, is to answer the following questions: (1) does a variable require a security check, (2) if possible, what security check should be enforced for the variable, and (3) is such a security check present. Answering these questions requires the understanding of the contexts and semantics of the code, which is challenging. Prior research [41] has shown the promise of statistical inferences in finding bugs. Such inferences identify inconsistent cases as potential bugs, which avoids the hard problem of understanding contexts and semantics. It makes sense that a deviation from common patterns is often problematic and thus is likely a potential bug, given that a majority of the code is correct. In CRIX, we also employ the general idea of statistical inference to find missing-check bugs. However, compared to the previous detection, CRIX is context and semantic aware.

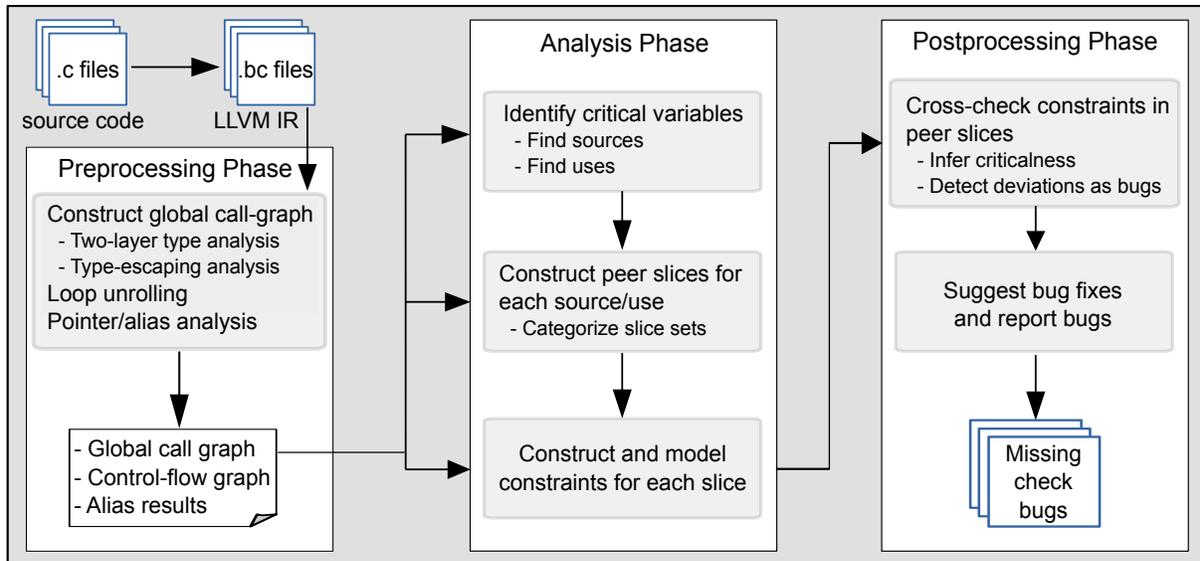

Figure 4 shows the overview of CRIX. CRIX consists of three phases: (1) preprocessing phase which prepares a global call graph, control-flow graph, and alias results; (2) analysis phase which performs the key analyses to identify critical variables, construct peer slices for them, and construct constraints for peer slices, and (3) postprocessing phase which cross-checks constraints of peer slices and reports missing-check bugs.

In the first phase, given the LLVM IR (intermediate representation), CRIX constructs a precise global call graph, which is not only foundational to all the following data-flow analysis, but also enables the peer-slice construction, as will be presented in §4.3. Since LLVM does not provide targets of indirect calls, CRIX employs a technique, namely two-layer type analysis, to precisely find indirect-call targets.

In the second phase, CRIX first identifies critical variables. Because a large number of variables are non-critical in OS kernels, conservatively checking all variables would cause significant scalability and false-positive issues. CRIX therefore first identifies critical variables (see §2.2). The intuition behind the critical-variable identification is that security-checked variables are typically critical. Therefore, CRIX identifies the security-checked variables as critical variables, which however requires CRIX to first identify security checks. Since the majority of conditional statements are not security checks [43], CRIX employs an approach to identify security checks, as presented in §4.2.1.

Since the critical variables identified through security checks have already been checked in the current code paths, CRIX instead tries to identify missing-check bugs in the peer code paths. To this end, CRIX constructs peer slices that share similar semantics and contexts with the current code path checking the critical variable. To find substantial peer slices, given a critical variable, CRIX identifies the sources and uses of the critical variable, and employs data-flow analysis to find slices for each source and each use (see §4.3).

A slice of a source or a use of a critical variable may or may not contain a security check. A naive approach is to iden-

**Figure 4:** The overview of CRIX. CRIX has three phases. It takes as input LLVM IR and produces missing-check bug reports.

tify any slices that do not have a security check as potential missing-check bugs. This will however introduce significant false positives because (1) the source or the use may not be very “critical”; (2) even if security checks are present in some slices, they may not be semantically equivalent. To address this problem, CRIX first extracts the constraints from the conditional statements in the peer slices and models them in a special way (see §4.4) that can both preserve the semantics and facilitate the following bug detection.

With the modeled constraints extracted from conditional statements, in the last phase, CRIX cross-checks (statistical analysis) them to infer the “criticalness” of the source or the use based on how common the constraints are, i.e., how frequently the source or use is checked in its peer slices. If the criticalness is significant, not having a constraint would be identified as a deviation, and a slice that does not have the constraint would be identified as a potential missing-check bug. In the end, CRIX suggests bug fixes based on the constraints in the peer slices and reports the details for further manual confirmation.

## 4 Design of CRIX

In this section, we present the design of the key techniques in CRIX, including the identification of indirect-call targets, construction of peer slices, construction and modeling of constraints, and statistical analysis of constraints for reporting missing-check cases. Other techniques such as alias analysis and loop unrolling will be presented in the implementation section (§5).

### 4.1 Identifying Targets of Indirect Calls

A precise call graph serves as a foundation for a variety of program analyses and security defense mechanisms. In particular, any inter-procedural data- and control-flow analysis requires a precise call graph. Control-flow integrity (CFI) [1, 9, 10, 25] and software debloating [28] techniques also require a precise call graph. Unfortunately, in large programs, constructing a precise call graph is an open problem in general because of the challenge of finding the targets of indirect calls. At compilation time, it is hard to know which address-taken functions would be valid targets of an indirect call.

Existing approaches for finding the targets of indirect calls can be classified into two categories: pointer analysis [2, 3, 8, 22, 36, 37] and type analysis [4, 9, 25, 40, 42]. Pointer analysis–based approaches aim to find the point-to-relationships between dereferenced function pointers and address-taken functions. Such approaches have fundamental limitations. While unsound pointer analysis will miss valid function targets, sound pointer analysis often introduces a large number of false positives—many unrelated functions are included as potential targets of an indirect call. Further, the pointer analysis *itself* requires a precise call graph. Whenever the pointer analysis encounters an indirect call, an expensive recursive analysis must be employed to find the targets.

Due to the limitations with pointer analysis–based approaches, recent CFI research opted for type analysis. Type analysis–based approaches try to match the number and types of arguments of an address-taken function with the ones of an indirect call. Matched functions are considered potential targets of the indirect call. Such approaches have been used in practice. For example, LLVM-CFI [4] employs such a type analysis. Type analysis–based approaches are conservative in

that all possible targets are included as long as function-type casting, which is rare, is handled properly [25]. However, they tend to suffer from false positives—many unrelated functions are included as valid targets. This will cause significant inaccuracy in the following data-flow analysis. The problem becomes even more critical in CRUX because the construction of peer slices heavily relies on a precise call graph.

To the best of our knowledge, the hybrid approach proposed by Ge et al. [10] for finding indirect-call targets in OS kernels is the most precise one. It employs both taint analysis and type analysis to find the targets. Specifically, it first taint-tracks the propagations of function pointers to identify indirect-call targets. Moreover, for function pointers stored in struct-type objects, because the function pointers should typically be loaded from the objects of the same struct type, the approach uses the struct type to further restrict the indirect-call targets. To avoid false negatives, the approach has two assumptions: (1) the only allowed operation on a function pointer is assignment, and (2) there exists no data pointer to a function pointer. The approach uses static taint analysis to detect and report violations which will be fixed manually. In addition to the hybrid analysis, the approach also analyzes assembly code, which further restricts the indirect-call targets.

#### 4.1.1 Two-Layer Type Analysis

To improve the existing type analysis-based approaches in finding indirect-call targets, we propose *two-layer type analysis*, which aims to dramatically refine the targets produced by previous type analyses. The first-layer type analysis uses function types to restrict indirect-call targets. The second-layer type analysis instead uses struct type to further restrict the targets, which is based on a similar observation as in the approach proposed by Ge et al. [10]. Specifically, in large systems such as OS kernels, the majority of taken addresses (e.g., 88% for the Linux kernel, according to our study in §6) of functions are first stored to a function-pointer field of a struct, and later, to dereference the addresses in indirect calls, they must be loaded from the struct. In LLVM IR, the type information of the struct in both store and load operations is present. Intuitively, in these cases, function addresses that are *never* stored in the specific struct will not be valid targets of the indirect calls that load the function addresses from the struct. This way, by further matching the struct types in the store and load operations, we can further refine the indirect-call targets. 12% of function addresses in the Linux kernel are not stored to struct. A common example in the Linux kernel is that a function address is stored to a function-pointer variable which is further used as an argument of another function. Indirect calls dereferencing these function pointers will not benefit from the second-layer struct-type matching.

Figure 5 shows an example, in which the addresses of functions `adp5589_reg` and `adp5585_reg` are stored in the

`reg` field of a struct with type `adp_constants`, in line 10 and 16, respectively. Later on, the addresses are loaded from the field of the struct of the same type and dereferenced at line 4. Our two-layer type analysis finds exactly only *two* targets for the indirect call because there are no any other functions whose addresses are ever stored to the field of the struct type. In comparison, since the indirect call has only one argument of a basic type, traditional one-layer type analysis matches 20 functions as targets for the indirect call, 18 of which are false positives.

A struct may have multiple fields that hold function pointers. To further improve the analysis accuracy, our type analysis is field-sensitive. That is, it recognizes which field is holding the particular function pointer, by analyzing the offset of the field in the data struct. In some rare cases, when the offset is undecidable because the indices are non-constant, we roll back the analysis to be field-insensitive.

```

1 /* drivers/input/keyboard/adp5589-keys.c */
2 static int adp5589_gpio_add(...) {
3     /* Indirect call: "kpad->var" is of type "adp_constants" */
4     kpad->var->reg(ADP5589_GPIO_DIRECTION_A);
5 }
6
7 unsigned char adp5589_reg(unsigned char reg)
8 static const struct adp_constants const_adp5589 = {
9     // address of "adp5589_reg" assigned to the field "reg"
10    .reg = adp5589_reg,
11 };
12
13 unsigned char adp5585_reg(unsigned char reg)
14 static const struct adp_constants const_adp5585 = {
15     // address of "adp5585_reg" assigned to the field "reg"
16    .reg = adp5585_reg,
17 };

```

Figure 5: An example of how a function pointer is stored to and later loaded from a field of a struct.

#### 4.1.2 Type-Escaping Analysis for False Negatives

Our two-layer type analysis is sound as long as the struct types holding function addresses do not escape—we cannot decide what function addresses a struct can hold. When a struct, say `structA`, has escaped, a function address stored to a different struct, say `structB`, can be loaded from the memory with `structA`; however, in this case, the function address will be missed by the type analysis because we cannot find that the function address is ever stored to `structA` but only `structB`. Such escaping cases exist when (1) the struct holding the function addresses is cast to or from a different type; (2) the function-pointer field of struct is stored to with a value of a different type (e.g., `unsigned long`). These cases may make the function addresses a struct can hold *undecidable*.

To handle this problem, we use conservative type analysis to find all store and casting operations and analyze the types in the sources and destinations based on the aforementioned criteria for deciding escaping cases. When an escaped type

is found, we conservatively discard the type in our two-layer type analysis. That is, if the function pointer of an indirect call is loaded from an escaped type, we use only one-layer type analysis for this indirect call. This way, we ensure that our two-layer type analysis does not introduce extra false negatives to existing one-layer type analysis.

Although CRIX shares the similar insight into further restricting indirect-call targets with the approach proposed by Ge et al. [10], CRIX differentiates itself from the approach. CRIX employs a two-layer design that allows the type analysis to be elastic. Whenever the second-layer type analysis fails, CRIX falls back to the first-layer type analysis. Second, the escaping analysis conservatively finds and discards invalid types to ensure the soundness.

## 4.2 Identifying Critical Variables

System software has a large number of variables. Conservatively checking all of them is not only unscalable but also generates an overwhelming number of false reports. Intuitively, important variables are often protected with security checks. We say that a variable is a (potential) critical variable if it is validated in a security check. By identifying security checks and their targets, we can identify critical variables. Note that a critical variable has different levels of *criticalness*. As will be shown §4.4, the criticalness is inferred based on check ratio of the occurrences of the critical variable. In this section, we first focus on identifying critical variables.

### 4.2.1 Identifying Security Checks for Critical Variables

Since we define validated variables in security checks as critical variables, CRIX first identifies security checks using a similar approach proposed in LRSan [43]. Specifically, checking failures typically require failure handling which has clear patterns: returning an error code or calling an error-handling function. We say that an `if` statement is a security check if its two branches satisfy the following two conditions: (1) one branch handles a checking failure, and (2) the other branch continues the normal execution. Note that an `if` statement whose two branches both handle checking failures is not a security check. Therefore, the key step to identify security checks is to determine whether the branches have the failure-handling patterns. Two typical failure-handling primitives are returning an error code and calling an error-handling function. Since LRSan supports only error-returning cases, we extend the idea by supporting error-handling functions.

System software such as the Linux kernel has a small number of basic error-handling functions. Such functions are often critical and implemented in assembly. For example, `BUG()`, `panic()`, and `dump_stack()` in Unix-like OS kernels are functions for handling unrecoverable errors. Moreover, functions such as `pr_err()` and `dev_err()` are used for reporting error messages, which have clear patterns. Specifically, such func-

tions typically have a name or an argument with a severity level (e.g., `KERN_ERR`, `KERN_CRIT`, and `KERN_EMERG`). Moreover, such functions take a variable number of parameters. Detecting these patterns is straightforward for a static analysis tool. To ensure that our heuristic-based approach reports correct error-handling functions, we manually investigated the results and filter out false-positive cases. In total, we found 531 error-handling functions (available in the code repository). In comparison, while LRSan reports only 131K security checks, CRIX reports 308K security checks. Once we identify security checks, we extract the checked targets as critical variables.

### 4.2.2 Identifying Sources and Uses of Critical Variables

In the next step, CRIX collects the sources and uses of the critical variables (i.e., checked variables). It is important to identify sources (where a critical variable propagates from) and uses (where a critical variable is used) of critical variables for two reasons. First, criticalness of a variable can propagate. When a critical variable is moved to another variable, the destination variable also becomes critical. By identifying the sources and uses, we can identify families of critical variables that propagate from the same sources or propagate to the same uses. Second, by identifying a family of critical variables, we can analyze how frequently they are checked, which is used to infer the criticalness of a source or a use. We realize the identification of sources and uses through a standard *inter-procedural* data-flow analysis—backward analysis for identifying sources and forward analysis for identifying uses. The inter-procedural data-flow analysis uses the following definitions to identify sources and uses.

**Definition of sources.** If a value is never critical, we do not need to include it for further analysis. Therefore, we include only potentially-critical values as sources. The inter-procedural backward data-flow analysis collects the following variables as sources.

- Constants. Constants such as error codes are critical.
- Return values and parameters of certain functions. Input functions (e.g., `copy_from_user` and `get_user`) obtain inputs from the external entities, which are untrusted. In addition, functions implemented as handwritten assembly often perform critical operations. We include the corresponding parameters or return values of such functions as sources.
- Global variables. Global variables may contain critical values that may propagate to the whole program.
- Others. When CRIX cannot find a predecessor instruction, the current values are marked as sources.

Note that we do not include allocations as a source because they become critical only when critical values are written to the allocated memory.

**Definition of uses.** Further, the following operations are defined as potentially critical uses of critical variables.

- Pointer dereference. Any pointer dereferencing operation is a critical use of the pointer variable.
- Indexing in memory accesses. Using the offset variable in memory access is also a critical use.
- Binary operations. We conservatively treat binary operations such as arithmetic division as critical uses.
- Functions calls. When none of the above is found, we take the closest function call that takes the critical variable as a parameter as a critical use.
- None. If none of the above is found, we deem that this critical variable does not have any use. This is common for critical variables that are error codes.

---

**Algorithm for identifying sources and uses.** Based on the definition of sources and uses, the algorithm presented in [AL-](#)

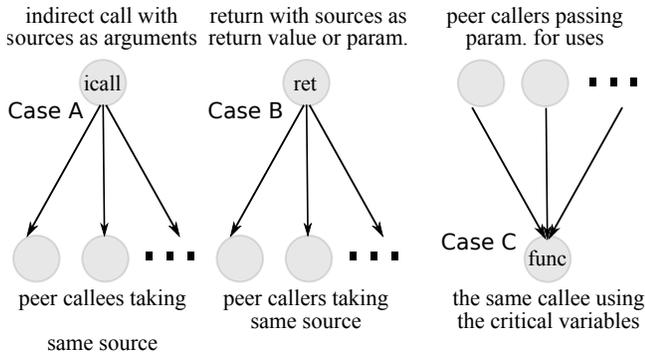

[gorithm 1](#) collects all potentially critical sources and uses. The algorithm takes as input the set of critical variables (CVSet), and set of functions (FuncSet). CVSet are the checked variable extracted from a security check, and FuncSet is the set of pre-collected input functions (e.g., `copy_from_user`) and assembly functions. FuncSet is collected in the pre-processing phase of the CRUX, concurrently with security-check identification, as will be shown in §5. The algorithm then produces two sets as the output: SrcSet and UseSet, the source and use sets, respectively. CVUseSet contains the immediate and forward uses of the current CV, which are returned by LLVM’s `value.users()` function. As shown in [Algorithm 1](#), the analysis is recursive and inter-procedural. Note that the algorithm is used to collect potentially critical sources and uses, but not to infer criticalness. Criticalness is instead inferred by measuring how frequently a critical variable is checked before being used, as will be shown in §4.4.

### 4.3 Constructing Peer Slices

At this step, we have the sources and uses of critical variables. Seemingly, we can construct slices for the critical variables forwardly from their sources and backwardly from their uses, and cross-check the slices to find check deviations as potential missing-check cases. Such a naive approach will suffer from at least two problems. First, the slicing will easily lead to path explosion [15] given the complexity of OS kernels. Second, if slices do not share similar semantics and contexts, we cannot effectively detect missing-check bugs because missing a check in an unrelated slice does not necessarily indicate a potential bug. Consequently, such an approach will lead to significant false positives.

To solve these problems, for a source or a use, we must construct its peer slices. Such peer-slice construction should satisfy two requirements: (1) the construction should yield sufficient peer slices to enable cross-checking; (2) the peer slices should share similar semantics and contexts. Given a control-flow graph, we observed that `call` (both direct and indirect) and return instructions often generate peer paths. In particular, for sources, indirect calls and return instructions often have substantial targets. As the example shown in [Figure 5](#), indirect call `pad->var->reg()` serves as a dispatcher that may target multiple semantically similar callee functions (e.g., `adp5589_reg` and `adp5585_reg`). Since the arguments in the callee functions all come from the same caller, they also share the similar contexts. For uses, when the used critical variable comes from an argument of the current function, direct calls to the function also generate substantial edges from the callers to the function (callee). Since the arguments passed from various callers to the same callee function, they are used as similar semantics in similar contexts.

[Figure 6](#) illustrates how we find different classes of peer paths for sources and uses. For each critical-variable source, we perform forward data-flow analysis for it. When encoun-

**Figure 6:** Different cases generating peer paths. `icall` is indirect call; `func` is the callee taking critical variables from peer callers.

tering an indirect call that takes the source as a parameter, we collect all the indirect-call callees as a set of peer paths. Similarly, when encountering a return instruction, we analyze whether the critical variable is returned or written into the memory pointed to by an argument (in this case, the critical variable may be further used in the callers through a pointer parameter). If so, we collect callers (starting from the next instruction following the call) as a set of peer paths. Our analysis is recursive. That is, the forward data-flow analysis continues to find more sets of peer paths until the end of the propagation of the critical variable or a critical use of the variable is found. For uses, we instead perform backward data-flow analysis from a use of a critical variable. If the critical variable comes from an argument of the current function, all callers of the function are collected as peer paths. The backward analysis is also recursive and ends until the source of the critical variable is found. Since a peer path may further contain multiple sub-paths, we use a simple BFS algorithm to flatten all sub-paths. Therefore, each peer path can be viewed as a single path. Finally, we construct peer slices by slicing the peer paths. The slicing ends at a conditional statement or the end of the path. Therefore, each slice has at most one conditional statement. Note that ending at the closest conditional statement would not cause false negatives because the slices sets are collected in a recursive manner, and our detection in §4.4.2 will cross-check each peer set.

For each critical-variable source and use, the peer-slice construction produces multiple sets of peer slices and categorizes them into four classes, each corresponds to a case in Figure 6.

- Source-Ret corresponds to case B. A critical variable is returned as the return value to multiple peer callers.
- Source-Param also corresponds to case B. However, in this case, a critical variable is “returned” an output parameter to multiple peer callers.
- Source-Arg corresponds to case A. A critical variable is passed to peer callees through an indirect call.
- Use-Param corresponds to case C. A critical variable used in a function is passed in from multiple peer callers.

## 4.4 Constructing and Cross-Checking Check Constraints

Until now, CRIX has produced multiple sets of peer slices of different classes for each critical-variable source and use. Each slice may or may not contain a conditional statement. The next step of CRIX is to cross-check the slices to detect deviations in the absence of security checks as potential missing-check cases. We choose to cross-check conditional statements instead of security checks (a subset of conditional statements) in this step for two reasons. First, the security-check identification part in CRIX have false negatives and may not identify all security checks; cross-checking security checks only may have significant false negatives because deviations can be normalized. Second, although cross-checking all conditional statements may introduce false positives, our fine-grained modeling for conditional statements can mitigate this issue.

A simple approach to cross-check slices for deviations is to treat conditional statements equally and quickly find deviating slices that do not have any conditional statement. Such coarse-grained analysis may have false negatives because conditional statements may have completely different semantics, and having a conditional statement does not mean the slice has checked the source or use. On the other hand, exactly comparing concrete values in conditional statements would be too restrictive, leading to false positives. For example, when two slices have `if (len < 8)` and `if (len < 16)`, respectively, treating them as different checks is too aggressive because both of them indeed enforce length checks. To avoid these problems, we must “qualitatively” understand the semantics of conditional statements in the slices. To this end, we propose to construct and model constraints from conditional statements. Note that the modeling focuses on the semantics of conditional statements, which does not consider their positions in the slices.

### 4.4.1 Modeling Conditional Statements as Constraints

As described in §4.3, a slice is flattened as a single code path using BFS, and a slice has at most one conditional statement. The goal of this step is to answer what classes of semantics a conditional statement has, with a proper granularity. We thus use two empirical rules to model the conditional statements based on the semantics of typical conditions and comparison operators. The modeled conditional statements will be cross-checked for missing-check bugs, as shown in §4.4.2.

1. If the conditional statement checks the return value of a function call, we identify the function’s signature as the constraint. For example, if a variable is checked in a conditional statement, `if (IS_ERR(ret))`, we model the constraint as “IS\_ERR(int)”. This is, the slice uses `IS_ERR()` to check the source or use.
2. Otherwise, we model the conditional statement as “<opcode\_type, operand\_type>”, where `opcode_type`

represents the type of the comparison, such as `eq`, `ne`, and `lt`; and `operand_type` represents the type of the condition operand. The type can be `var` (a variable), `zero`, `positive` constant, and `negative` constant. For example, if a condition statement is `if (len < 8)`, the constraint will be modeled as “`lt positive`”.

#### 4.4.2 Detecting Deviations as Potential Bugs

With the modeled constraints for all slices in a set, we cross-check them to find deviations. The idea of the detection is to calculate the relative frequency (RF) [18] for each constraint in the set. Since different constraints have different frequency distributions, we calculate the RF for each constraint in the set separately. More specifically, given a constraint, we define  $N_{nc}$  as the number of slices that do not have the constraint, and define  $N_t$  as the total number of slices in the set. With these two numbers, the RF is defined as in Equation 1.

$$RF = \frac{N_{nc}}{N_t} \quad (1)$$

The detection works as follows. Given a constraint in a peer-slice set, the detection counts how many slices do not have this *particular* constraint. Note that a slice that has a different constraint will also be counted. The count serves as  $N_{nc}$ . Since  $N_t$  is the total number of slices in the set, we can quickly obtain it and calculate the RF for the given constraint. If the RF is very small, i.e., most slices have the constraint, the detection reports slices that do not have the constraint as potential missing-check cases. A slice set may have multiple constraints, and the detection will go through the steps for each constraint in the slice set.

## 5 Implementation

We have implemented CRIX as multiple passes on top of LLVM, including a pass for constructing call graph and unrolling loops, a pass for finding security checks and critical variables, and a pass for detecting and reporting missing-check cases. CRIX’s source code contains 4.5K lines of C++ code. The rest of the section describes some interesting implementation details in each phase.

### 5.1 Preprocessing Phase

**Disabling inlining and IR pruning.** To facilitate peer-slice construction, we aim to preserve callsites as much as possible. To this end, we chose to disable inlining by modifying Clang. A side effect of disabling inlining is that *inline* functions defined in header files will be copied to each module that uses them, leading to significant redundancy in LLVM IR. To prune the IR, we leverage debugging information to map the functions to its source code. This way, we can figure out multiple functions in IR share the same source code, and if

so, we keep only one copy in the IR and discard all other copies. The pruning strategy reduces the original size of IR by approximately 30%.

**Identifying indirect-call targets.** To realize the two-layer type analysis, we first identify all store operations (either a store instruction in LLVM or a struct initializer) that assign a function address to a variable. We then analyze the type of the *memory* holding the variable. At this step, our analysis is conservative: the variable must be loaded from a pointer, and the pointer must be pointing to a field of a data structure. That is, the pointer must be a `GetElementPtrInst` in LLVM. With the type information in LLVM IR, we can then extract the base struct type from the pointer. Note that, we do not recursively find the struct type; if the pointer is not `GetElementPtrInst`, or the base type of the `GetElementPtrInst` is not a struct or is an aggregated type (e.g., `union`), we stop the analysis for the particular function address and roll back to the traditional one-layer type analysis. The field-sensitive analysis is realized by analyzing the indices in the `GetElementPtrInst` which includes the index of the accessed field into the base type. The process of this step goes through all address-taken functions in all modules. The output of this step is a map from the hash of the type to the function addresses.

A challenge in implementing the two-layer type analysis to conservatively capture escaping types. As described in §4.1.2, we have a conservative policy to identify escaping types. To implement the type-escaping analysis, we analyze the operand types in cast and store operations (both instructions and global static initializers). If the operand types satisfy the policy, we identify them as escaping types.

After that, we match the second layer type for indirect calls. Similarly, we analyze the type of the *memory* holding the function pointer (address) in the same way—analyzing the corresponding `GetElementPtrInst`. By querying the map, we can find the matched functions for the indirect call. If we cannot find a match, we again roll back to the one-layer type analysis for the indirect call.

**Unrolling loops.** To avoid path explosion, we chose to unroll loops by treating `for` and `while` statements as `if` statements, which is a common strategy used in practice [45]. A loop has two special basic components: header block, latch block. A header block is the entrance node for a loop; a latch block contains an edge back to the header block. In order to unroll loops, we delete the back edge and add a new edge from the latch block and the successor block of the loop.

**Pointer analysis.** We perform points-to analysis for each pointer to a memory location within a function, relying on LLVM’s `AliasAnalysis` infrastructure. The `MayAlias` results conservatively include pointers that may refer to the same object; two pointers referring to different fields of an object may also be included as aliases. To refine the results, we perform field-sensitive data-flow analysis for each pointer that is ever used in memory load/store or function calls as

parameters. Pointers that are validated to refer to different fields are excluded from the `MayAlias` results. A second issue with the points-to analysis is its significant runtime overhead, and we observed that this is mainly caused by a small number of objects that have a large number of pointers. We mitigate the problem by limiting the maximum number of pointers an object can alias simultaneously. By setting the number to 1000, our results showed that only 23 functions in the Linux kernel have aliased memory pointers with size greater than this limit. After applying the two improvements, the running time for points-to analysis is reduced from 103 minutes to only 24 minutes, and the average number of alias pointers of an object is reduced by 65%.

## 5.2 Analysis Phase

**Modeling input functions and collecting assembly functions.** In CRIX, specific return values and parameters of input functions and assembly functions are defined as sources (§4.2.2). As such, we need to collect a set of such functions. We define a function as input function if it may fetch data from outside. For example, `copy_from_user(dst, src, size)` copies the content from user-space memory `src` into the kernel-space memory `dst`. In total, we empirically collected 36 input functions (Table 3). We also specified which parameter or if the return value of these functions holds the inputs. Similarly, the kernel contains lots of assembly code as optimizations for performance reasons. Such functions are typically critical. Since LLVM does not support analysis of assembly code, we also model the assembly functions and treat them as sources. Identification of assembly functions is realized by scanning through LLVM IR files for `isa<InlineAsm>` instructions.

## 5.3 Postprocessing Phase

**Selecting threshold for relative frequency.** Missing checks within the Linux kernel are identified using various strategies described in §4. A case in a peer-slice set that has low relative frequency will be reported as a potential missing-check bug. The relative frequency is the ratio of occurrences of a constraint or “non-constraint” to the size of the peer-slice set. A uniform threshold for different categories might skew the results in favor of a particular type of bugs. To solve this challenge, we provided the relative frequency field as a tuning parameter and tested the results on various runs for various categories. We observed that the relative frequency works best between [0.1, 0.15] to detect sufficient missing-check bugs with reasonably low false reports, for all the categories.

**Generating bug-fixing suggestions.** Peer slices of the same critical variable can reveal many interesting details about the implementation. For each peer, we are able to reason about the constraints of the critical variable. Since we have constraints for each of the peer slices, one can suggest a possible

security check in a possible location for missing-check cases. Statistically analyzing the “suggestions” returns us a reasonable bug fix. As such, CRIX always reports the most common suggestion to facilitate bug fixing. The report includes the most common constraint and which function the constraint should be applied to.

**Bug Reporting.** After collecting the constraints from the peer slices and using a user-defined relative frequency, we rank the missing-check output based on the relative frequency, we format the report to output the line contains the relative frequency, the Linux source code, the module containing the code, the number of times security check was checked, times missed among the peers, and most importantly, the bug-fixing suggestion. As expected, reported cases in the top of the ranking are more likely to be true bugs.

## 6 Evaluation

We extensively evaluate the scalability and effectiveness of CRIX using the Linux kernel. We also evaluate the effectiveness of our two-layer type analysis. The experiments were performed on Ubuntu 16.04 LTS with LLVM version 8.0 installed. The machine has a 64GB RAM and an Intel CPU (Xeon R CPU E5-1660 v4, 3.20GHz) with 8 cores. We tested the bug detection efficiency of CRIX, on the Linux kernel version 4.20.0-rc5 with the top git commit number `b72f711a4efa`, the latest patch as on Dec 6, 2018. Using the `allyesconfig`, we generated 17,343 LLVM IR bitcode files to cover as many modules as possible.

### 6.1 Precision in Finding Indirect-Call Targets

**Results.** In total, out of 57,299 indirect calls, 45,840 (80%) enjoyed our two-layer type analysis. 5,019 (8.8%) indirect calls suffer from type escaping thus disqualify the two-layer type analysis. Others indirect calls do not load function pointers from a struct thus do not trigger the two-layer type analysis. The high percentage confirms our observation that most function pointers are stored to and loaded from memory through data struct. We then calculate the average number of targets for an indirect call before and after applying our two-layer type analysis. The results show that the average number over all indirect calls for traditional type analysis is 134 while it is only 33 for our two-layer type analysis. We further calculate the average numbers over indirect calls that can benefit the two-layer type analysis. The results show that the average target number is 129 and 9 (i.e., 7%) before and after using our two-layer type analysis, respectively, which confirms that the analysis can dramatically refine the indirect-call targets.

Measuring the false positives of indirect-call targets is a challenging problem because of the complexity of pointer propagation and point-to relationships. Existing CFI tech-

niques use the average number of targets to represent the accuracy of target refinement. Given that CRIX reports only an average number of 9 for indirect calls that benefited from the two-layer type analysis, we expect the false-positive rate of our analysis to be low. In comparison, the hybrid approach proposed by Ge et al. [10] reports an average number of 6.64 for indirect calls in FreeBSD, and, the number is calculated over all indirect calls. We believe that the accuracy of the approach benefits from the combination of taint analysis and type analysis.

## 6.2 Analysis Performance and Numbers

CRIX completed the analyses of the kernel for missing-check cases in 64 minutes, of which pointer analysis required 24 minutes and the remaining analysis to identify and report missing-check cases required 28 minutes. By running CRIX over the whole kernel, with a threshold of 0.15, the output contained 308K security checks from 1,028K conditional statements, and reported 804 cases.

## 6.3 Bug Findings

Table 2 presents the bug detection statistics of CRIX, running on the entire Linux kernel with a constant relative frequency of 0.15, across categories. We used a fixed number for relative frequency to avoid inconsistencies while comparing similar bugs across the various categories. CRIX reported 804 potential bugs and manual analysis confirmed 278 new bugs. To manually analyze all the bugs, it took three researchers, a total of 36 man-hours. We found that the cross-checking results over peer slices can significantly relieve the manual analysis by suggesting how and why peers enforce the security checks. The manual effort was mainly spent in checking if the critical variable is actually checked because the check may have been missed by CRIX due to issues such as aliasing. In most cases, the “suggested” source-check or check-use chains are across one or two functions, so the manual analysis overall is straightforward.

We submitted patches for all the bugs. Linux maintainers accepted 151 of the submitted patches to be applied to the latest Linux version or future releases. Maintainers confirmed 99 patches within a week of submission confirming the criticalness of fixing missing-check bugs. Figure 1 shows an example of the new bugs found by CRIX, which can cause multiple security issues such as NULL-pointer dereferencing. A detailed list of all the bugs is available in Table 4 and in Table 5, in the Appendix section. During our interaction with the maintainers, we not only fixed missing-check bugs determined by CRIX, but also fixed some other relevant bugs present in the error paths of security checks including but not limited to missing/incorrect error handling, missing resource releases, use-after-free, and dead code.

Further 76 bugs are included in more than one bug category. That is, these 76 bugs were detected twice, once each while generating the source and use constraints. However, these duplicates are within the chosen 804 cases, used to evaluate CRIX. Accounting for the duplicate bug reporting, the false-positive rate of CRIX is 65%. We believe this is an acceptable number for critical software such as OS kernels.

The distribution of bugs is heavily skewed towards driver code. The report showed 195 bugs in the driver modules and at least 27 driver modules had more than one missing-check. These bugs reinforce previous research studies that the driver code is indeed buggy as well as confirm the effectiveness of CRIX in detecting new missing checks. Second, we also computed the latent period of the detected bugs and the average time between the initial patch and detection is 1,675 days or approximately 4 years and 7 months. A significant observation is 27 out of these 278 bugs have a latent period of greater than 10 years and 6 patches’ latent period is greater than 13 years.

The third interesting finding of our bugs involves the type of bugs. A total of 79 bugs involve memory allocation on the heap. Linux developers strictly maintain that every pointer returned by an alloc-like function be checked for emptiness. Interestingly, CRIX identified 11, 5, 11, and 12 calls of (`kzalloc`, `kmalloc`, `kcalloc` and `kmempdup`) respectively; all missing a check on the pointer to the allocated memory for emptiness. All these bugs can crash a system while dereferencing the NULL pointer, as well as provide an attack vector to launch a denial of service attack by unauthorized users. The numerous missing-check bugs confirm the effectiveness of CRIX in identifying security vulnerabilities.

One reason of concern in the output report is the duplication of bugs across various categories. CRIX performs backward data-flow analysis from use, and a forward data-flow analysis from source to identify missing-check bugs in various categories. With a constant relative frequency, a true missing-check bug will often be reported in both directions. To simplify our analysis, we ran CRIX performing both analyses at the same time and then eliminated the duplicate records. While this action does not impact the accuracy of the system, we observed a non-trivial difference in ranking order of the bug, when evaluating each category individually.

## 6.4 False Positives

As presented in §6.3, CRIX has false positives. We have investigated the causes of false positives. In this section, we present the main classes of causes.

**Inaccurate points-to analysis.** Pointer analysis [14] is a hard problem. CRIX’s data-flow analysis engine generally relies on the Alias Analysis. However, the alias results provided by LLVM are often inaccurate. Although we have refined the MayAlias results, there are still over 48% of false positives that are caused by the inaccuracy of pointer analysis. We will

| Category     | Example bug (related function)                             | Latent Period | R   | A   | C   |
|--------------|------------------------------------------------------------|---------------|-----|-----|-----|
| Source-Ret   | drivers/net/hyperv/netvsc_drv.c +1377 (kvmalloc_array)     | 4y 10m        | 449 | 300 | 156 |
| Use-Param    | net/ncsi/ncsi-netlink.c +253 (nla_nest_cancel)             | 2y 10m        | 247 | 150 | 115 |
| Source-Param | drivers/gpu/drm/i810/i810_dma.c +307 (drm_legacy_ioremap)  | 4y 1m         | 83  | 42  | 4   |
| Source-Arg   | drivers/dma/ti/omap-dma.c +1056 (omap_dma_prep_dma_cyclic) | 10y           | 25  | 8   | 3   |

**Table 2:** Bug detection statistics of CRIX on Linux kernel with relative frequency = 0.15. Columns R= bugs reported, A = Analyzed bugs, C = Confirmed bugs. The Latent Period is the average time differential for all confirmed bugs(C), within the category.

discuss potential improvements of pointer analysis in §7.

**Inconsequential checks.** While checks are necessary to guarantee the state of the kernel, programmers often ignore security checks in cases such as debugging code, failure-handling paths, driver-shutdown functions, resource cleanup functions, unlikely failures (e.g., `kmalloc` with `__GFP_NOFAIL`) or code that is already protected by synchronization primitives. Checks are redundant in these cases as an erroneous state has already existed or a valid state is guaranteed by the kernel. Such cases account for 25% of false positives.

**Implicit checks.** Programmers can reason about the state of the variable in an implicit way. For example, to test if an allocation of an object is successful, developers may use the object, without a security check, in a function, and use the return values of the function to test if the object was allocated successfully. In this case, although the object itself is never explicitly checked, the function call checks the object implicitly. Such cases contribute about 8% of the false positives. A potential solution to mitigating this problem is to maintain a list of “checker” functions.

**Other causes.** Besides these above-mentioned causes, false positives can also be caused by complex programmer logic, imprecise static analysis techniques, etc. All these account for the remaining 19% of the false positives.

## 6.5 False Negatives

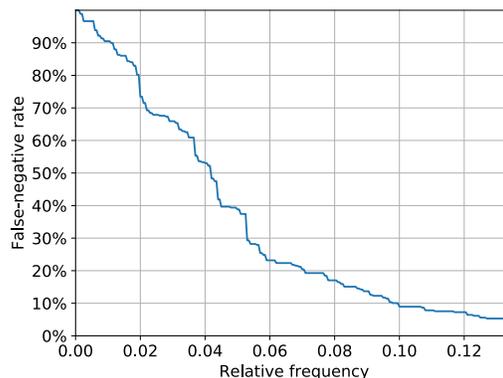

CRIX provides a tuning parameter, the threshold of RF, while detecting missing-check cases. In other words, the threshold can influence the false-negative rate. In this section, we evaluate (1) the absolute false negatives that are missed when the RF threshold is set to 1; and (2) the relationship between the false-negative rate and the RF threshold.

In §2, we collected 119 missing-check bugs that have a clear security impact. To make the false-negative evaluation more robust, we collect 231 recently reported missing-check bugs in the Linux kernel based on its Git patch history. The patches containing the fixes of these 350 missing-check bugs are evaluated in our false-negative study. To reproduce these bugs, we revert the patches in the Linux kernel to the version used in our experiments.

By setting the RF threshold to 1, we determined 14 (4%) patches as absolute false negatives. Absolute false negatives are caused by two factors. First, the checked critical variables

are not captured by CRIX because the error code or error-handling functions are not identified as part of a security check. Second, inaccurate pointer analysis identifies incorrect aliases for the critical variables. These aliases are mistakenly identified as valid security checks, bypassing the identification of actual missing-check bugs.

Second, we also evaluate the relationship between the threshold and false-negative rate, presented in Figure 7. We find that, as RF threshold increases, the false-negative rate decreases as prior false negatives are identified as missing-check bugs. We found that when the threshold is set to 0.13, the false-negative rate is 5% and reaches its elbow point. Further tuning the threshold has no impact on the false negative rate.

**Figure 7:** Relationship between the relative frequency (RF) threshold and the false-negative rate.

## 6.6 Portability

A program-specific component of CRIX is identifying security checks. Determining if a conditional statement is a security check, while scanning the kernel relies on the identification of error handling functions, and error codes. Identifying the error handling functions requires a limited amount of experience with the target code base. In Unix-like kernels, these functions share similar patterns, called “Single Unix Specification” [35], as presented in §4.2.1. All these kernels, also have a single global header file that defines the standard error codes.

Similarly, other kernels and programs like browsers also have corresponding header files containing the error codes.

Besides this step, the idea to generate an error control flow graph is generic to adapt to other systems. Once security checks, described in §4, are identified, the algorithm for identifying missing checks is easily adaptable to other software systems such as BSD kernels and C++ code base such as web browsers.

## 7 Discussion

**Two-layer type analysis for more types.** The current implementation of two-layer type analysis supports only struct type because it is the most commonly used type for memory holding function pointers. To further exploit the two-layer type analysis, we could extend it to support more types such as array, global variable, and vector. The type-escaping analysis in CRIX will ensure to eliminate false negatives when any type casting occurs or function pointers are moved across different types.

**RF threshold.** We discussed the false positives and false negatives of CRIX in §6. To balance false positives and false negatives, we suggest setting the RF threshold to a value between 0.1 and 0.15 for the Linux kernel. CRIX cross-checks peer slices to detect deviations. CRIX may have higher false-report rates in smaller target programs because they have small sets of peer slices.

**Pointer analysis.** Another major cause of false reports is the inaccuracy of alias analysis. To mitigate this problem, we intend to use Andersen pointer analysis [13] and Steensgaard pointer analysis [34] in the future. Given that, pointer analysis is used extensively in CRIX, we believe that this addition can significantly improve the overall accuracy.

**Inconsequential checks.** Besides alias analysis, the next major portion of false positives are due to programmer intended missing checks. Based on our interaction with Linux maintainers, we found that they are reluctant to fix missing-check cases in resource-release paths such as driver shutdown or state reset. Previous work by Saha et.al [31] proposed a pattern-based approach to find resource-release paths. As a potential solution, we may leverage the approach to filter out cases in resource-release paths and thus reduce the false positives in CRIX.

**Determining exploitability and security impact of missing-check bugs.** To automatically determine the exploitability of missing-check bugs, one can employ symbolic execution [29] and a theorem prover like Z3 [6] to generate inputs to trigger a missing-check bug. In addition, fuzzers can complement the limitations with symbolic execution. To automatically determine the security impact, one can analyze the uses of the checked variable to understand the potential security impact. For example, if a checked variable is used as the size variable in `memcpy()`, the potential impact can be memory corruption or information leak. For the identified new bugs, we found that more than half of them will cause Denial-

of-Service, and quite a few of them will cause out-of-bound access, as shown in Table 4 and Table 5.

In general, automatically determining exploitability and security impact of a bug is a challenging research problem. A number of recent works [47] have investigated into this problem. If we can automatically decide the exploitability and security impact of a potential miss-check case, we can automatically confirm a missing-check bug/vulnerability and thus automatically eliminate false positives. We will leave such an analysis for future work.

## 8 Related Work

**Missing-check detection.** The most closely related works to CRIX are about missing-check detection. LRSan [43] detects lacking-recheck bugs, a subclass of missing-check bugs. CRIX detects general missing-check bugs that include lacking-recheck bugs. Juxta [23] detects semantic bugs using cross-checking between semantically equivalent implementations of file systems. Most bugs found by Juxta are missing-check bugs. CRIX can detect missing-check bugs in all subsystems in the OS kernels and do not require multiple implementations of a subsystem. Other works utilizing complementary implementation techniques to detect missing-check include Vanguard [32], Chucky [46], AutoISES [38], Rolecast [33], and MACE [24]. To the best of our knowledge, none of the tools are scalable to a system as large as the OS kernel nor have an equivalent technique to reason about the semantics and contexts of a critical variable.

**Error-code propagation and handling.** To detect missing-check bugs, CRIX relies on error-handling primitives to find critical variables. Techniques in error-code propagation and handling, within the Linux kernel, include EIO [12], Hector [31], and by Rubio-González et al.[30]. Similarly, APEx [17], ErrDoc [39], and EPEX [16] reason about the error-code propagation in open source SSL implementations, either automatically or via user definitions. Unlike CRIX, all the above systems target a limited range of error returning code specifications and thus have significant false negatives. Further, these techniques do not consider error-handling cases that do not return any error code. According to our study, such error-handling cases are common.

**OS-kernel analysis.** Given the complexity, analysis targeting the entire OS kernels is challenging. Recent advances on kernel analysis can be mainly categorized into kernel source-code analysis and static IR analysis. Smatch [5] and Coccinelle [27] find bugs in the Linux kernel. While Smatch [5] relies on syntax tree-based intra-procedural analysis to find simple bugs such as NULL-pointer dereferences. Coccinelle [27] performs code-pattern matching to find specified bugs. In comparison, CRIX leverages flow-sensitive, context-sensitive, and field-sensitive inter-procedural analyses to identify missing check bugs.

To benefit from rich analysis passes in LLVM, recently,

many tools analyze OS kernels on LLVM IR. K-Miner [11] improves the efficiency of data-flow analysis by partitioning the kernel code along separate execution paths starting from system-call entry points. Dr. Checker [21] is also a static data-flow analysis tool that identifies bugs in the drivers. While K-Miner and Dr. Checker serve as general bug detection tools, there are also some detection tools specialized for detecting a specific class of bugs in OS kernels. KINT [44] detects integer overflows using taint analysis; UniSan [20] detects information leaks caused by uninitialized data reads, also using taint analysis.

## 9 Conclusion

Missing-check bugs are a common cause of critical security vulnerabilities. In this paper, we have presented CRIX, a scalable and effective system for detecting missing-check bugs in OS kernels. CRIX's detection is semantic- and context-aware with an inter-procedural and context-, flow- and field-sensitive data-flow analysis engine. We realized the detection by proposing multiple new and general techniques. In particular, the two-layer type analysis can dramatically improve the precision in finding direct-call targets. The automated critical-variable inference narrows down the analysis to a very small scope, thus scaling expensive analyses to OS kernels. The peer-slice construction and constraint modeling for conditional statements enable semantic- and context-aware analysis. With these techniques, CRIX has reasonably low false-report rates and outstanding analysis performance. By applying CRIX to the Linux kernel, we found 278 new bugs and maintainers accepted 151 of our submitted patches. The evaluation results show that CRIX is scalable and effective in finding missing-check bugs in OS kernels.

## 10 Acknowledgment

We would like to thank our shepherd, Trent Jaeger, and the anonymous reviewers for their helpful suggestions and comments. We are also grateful to Stephen McCamant for providing valuable comments and to Linux maintainers for providing prompt feedback on patching bugs. This research was supported in part by the NSF award CNS-1815621. Any opinions, findings, conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of NSF.

**Table 4:** List of new bugs (1-142) detected with CRIX. LP = Latent Period of bugs in years. Column Category specifies the category of peer-slice set used to identify the bugs. A, P, S, and U indicate categories Source-Arg, Source-Param, Source-Ret, and Use-Param respectively. The S, C, A in the Status field represent patch status, Submitted, Confirmed, Applied, respectively.

| Subsystem   | Filename             | Line# | Impact          | Category | Status | LP |

## Abstract

Value set analysis (VSA) is one of the most powerful binary analysis tools, which has been broadly adopted in many use cases, ranging from verifying software properties (*e.g.*, variable range analysis) to identifying software vulnerabilities (*e.g.*, buffer overflow detection). Using it to facilitate data flow analysis in the context of postmortem program analysis, it however exhibits an insufficient capability in handling memory alias identification. Technically speaking, this is due to the fact that VSA needs to infer memory reference based on the context of a control flow, but accidental termination of a running program left behind incomplete control flow information, making memory alias analysis clueless.

To address this issue, we propose a new technical approach. At the high level, this approach first employs a layer of instruction embedding along with a bi-directional sequence-to-sequence neural network to learn the machine code pattern pertaining to memory region accesses. Then, it utilizes the network to infer the memory region that VSA fails to recognize. Since the memory references to different regions naturally indicate the non-alias relationship, the proposed neural architecture can facilitate the ability of VSA to perform better alias analysis. Different from previous research that utilizes deep learning for other binary analysis tasks, the neural network proposed in this work is fundamentally novel. Instead of simply using off-the-shelf neural networks, we introduce a new neural network architecture which could capture the data dependency between and within instructions.

In this work, we implement our deep neural architecture as DEEPVSA, a neural network assisted alias analysis tool. To demonstrate the utility of this tool, we use it to analyze software crashes corresponding to 40 memory corruption vulnerabilities archived in Offensive Security Exploit Database. We show that, DEEPVSA can significantly improve VSA with respect to its capability in analyzing memory alias and thus escalate the ability of security analysts to pinpoint the root cause of software crashes. In addition, we demonstrate that

our proposed neural network outperforms state-of-the-art neural architectures broadly adopted in other binary analysis tasks. Last but not least, we show that DEEPVSA exhibits nearly no false positives when performing alias analysis.

## 1 Introduction

Despite the best efforts of developers, software inevitably contains flaws that may be leveraged as security vulnerabilities. Modern operating systems integrate various security mechanisms to prevent software faults from being exploited [18, 36, 51, 53]. To bypass these defenses and hijack program execution, an attacker therefore needs to constantly mutate an exploit and make many attempts. While in their attempts, the exploit triggers a security vulnerability and makes the running process terminate abnormally.

To analyze the unexpected termination (*i.e.*, program crash) and thus pinpoint the root cause, software developers or security analysts need to perform backward taint analysis [17, 20, 39], track down how a bad value is passed to the crashing site and thus pinpoint the statements that led to the crash. Technically speaking, this process can be significantly facilitated – and even automated – if the control and data flows pertaining to the crash are available upon its termination.

Recently, a large amount of research has demonstrated that program execution can be recorded through hardware tracing (*e.g.*, [30, 55]) in a least intrusive manner. As a result, a software developer can easily restore the control flow pertaining to a program crash. However, the recovery of data flow from the execution trace alone is still challenging, especially when source code is not available. As it has been discussed in recent research [55], this is primarily because data flow construction is highly dependent upon the capability of memory alias analysis [4, 5].

Of all the memory alias analysis techniques proposed in past research, value-set analysis (VSA) is the most *effective* and *efficient* technique and has been broadly adopted to facilitate the ability of identifying memory alias at the binary

\*Equal Contribution.

level [6]. Applied in the context of postmortem program analysis, it however exhibits an insufficient capability in handling memory alias identification. Technically speaking, this is mainly because VSA needs to infer memory references based on the context of a control flow. However, accidental termination of a running program only leaves behind incomplete control flow information, making memory alias analysis clueless.

To address this technical issue, we introduce a deep neural network to enhance the capability of VSA in memory alias analysis, especially in the context of software failure diagnosis. More specifically, we use this neural network to learn the memory regions that each memory access refers to. The rationale behind this approach is as follows. VSA divides the address space of a process into several non-overlapping regions (*i.e.*, stack, heap, and global) and deem pairs of memory references to different regions as non-alias. With incomplete control flow information pertaining to a software crash, VSA loses the execution context of a crashing program and typically exhibits bad performance in assigning memory references to different memory regions. Using deep learning, we can learn complex execution patterns pertaining to memory region accesses, restore the memory regions that VSA fails to infer through incomplete control flow, and finally enhance the capability of alias analysis for postmortem program analysis.

Different from previous research that utilizes deep learning to tackle other binary analysis problems (*e.g.*, [15, 48, 49, 56]), the deep neural network used in this work is novel. Instead of simply applying an off-the-shelf neural architecture to our problem domain, we propose a new neural network architecture. To be specific, our proposed solution first utilizes an instruction embedding network to capture the semantic of each instruction. Then, it employs a bi-directional sequence-to-sequence neural architecture to learn the dependency between the instructions and predict the memory access for each individual instruction. With this new design practice, we could capture the dependency relationship within and between instructions and thus accurately predict the memory regions that each instruction attempts to access. As we will discuss and demonstrate in Section 3 and 4, this perfectly reflects the characteristic of binary code analysis and significantly benefits alias analysis in the context of software failure diagnosis.

We implemented our proposed technique as DEEPVSA<sup>1</sup>, a neural network-assisted alias analysis tool for postmortem program analysis. To the best of our knowledge, DEEPVSA is the first tool that takes advantage of deep learning to improve alias analysis in the context of postmortem program analysis. We manually analyzed program crashes corresponding to 40 memory corruption vulnerabilities gathered from the Offensive Security Exploit Database Archive [47] and compared our manual analysis with the analysis conducted by DEEPVSA.

<sup>1</sup>The code, data and models of DEEPVSA are available at <https://github.com/Henrygwb/deepvsa/>.

```

1  sub    esp, 0x14
2  call  malloc
   .....
3  ret
4  mov   [eax], test
5  mov   [esp+0x8], eax
   -----
6  push  eax
7  call  child
8  push  ebp
9  mov   ebp, esp
10 mov   [0xC8], 0x0
11 mov   eax, [ebp+0x8]
12 mov   [eax], 0x1
13 mov   [eax+0x4], 0x2
14 mov   eax, 0
15 pop  ebp
16 ret
17 mov   eax, [esp+0xC]
18 call  [eax]          <--- crash site

```

Figure 1: An example instruction trace prior to a program crash.

We observed that DEEPVSA can accurately resolve approximately 35% of unknown memory relationships that VSA fails to identify when performing analysis on a crashing execution. In addition, we discovered that the escalation in alias analysis significantly improves the capability in tracking down the root cause of software crashes. For about 75% failure cases, DEEPVSA is capable of assisting backward taint analysis in identifying the root causes of their crashes. Compared with the broadly adopted neural networks in other binary analysis tasks, we also demonstrate that our new neural network architecture introduces no false positives in memory alias identification.

In summary, this paper makes the following contributions:

- We discover that deep neural networks are a viable approach towards addressing alias analysis issues in the context of software failure diagnosis.
- We propose a new neural network architecture which could be used to improve alias analysis for VSA and thus escalate the ability to diagnose the root cause of software crashes.
- We implement our deep learning technique as DEEPVSA—a tool for alias analysis facilitation—and demonstrate its effectiveness by using 40 distinct software crashes covering approximately 1.6 million lines of execution trace in total.

The rest of the paper is organized as follows. Section 2 provides an overview of value-set analysis and its limitations in postmortem program analysis. Section 3 presents the deep neural network we propose to improve alias analysis. Section 4 describes our implementation and evaluation, demonstrating the utility of DEEPVSA. Section 5 surveys related work. Finally, we conclude this work in Section 6.

Table 1: The results of value-set analysis against the instruction trace shown in Figure 1.

## 2 Background and Problem Scope

As is described and discussed in many recent research works (e.g. [19, 55]), new hardware components could trace program execution in a least intrusive fashion. With this capability, security analysts could easily obtain the control flow pertaining to a software crash. Using the execution trace, it is however still challenging to pinpoint the root cause of the crash (i.e., the instructions truly attributive to the crash). On the one hand, this is because a security analyst barely has the access to the source code of the crashing program. On the other hand, this is because a security analyst needs to analyze the data flow of the crashing trace which involves memory alias analysis at the binary level. To tackle this challenge, value-set analysis (VSA) can be adopted. In this section, we first introduce how software instrumentation and hardware tracing are used to record program execution. Second, we briefly describe how

to perform value-set analysis on a recorded execution trace. Third, we specify how to use the derived value set to perform alias analysis and thus diagnose the root cause of a software crash. Finally, we provide a more in-depth discussion about why VSA behaves poorly in many real-world applications.

### 2.1 Program Tracing for Software Debugging

Software instrumentation techniques have long been used to fully record program execution and thus facilitate the root cause diagnosis for a crashing program (e.g., [38, 37]). However, such an approach imposes significant overhead to a software normal operation. In order to minimize additional overhead, some lightweight instrumentation techniques have been proposed (e.g., [41, 40]). While they are less intrusive and informative for assisting software debugging, such a lightweight approach cannot be used to fully restore the

control flow pertaining to a software crash.

Recently, the advance in hardware-assisted processor tracing significantly ameliorates this situation. With the emergence of brand new hardware components, such as Intel PT [27] and ARM ETM [2], software developers and security analysts can trace instructions executed with nearly no overhead and save them in a circular buffer. At the time of a program crash, an operating system includes the trace into a crash dump. Since this post-crash artifact contains both the state of crashing memory and the execution history (*i.e.*, the last  $N$  instructions executed prior to the crash), software developers not only can inspect the program state at the time of the crash, but also fully reconstruct the control flow that led to the crash.

In this work, we focus on using an enhanced value-set analysis technique to analyze such an aforementioned post-crash artifact and thus facilitate the root cause diagnosis of a crashing program. It should be noted that the aforementioned lightweight software instrumentation approach is out of the scope of this research because they cannot provide a complete instruction trace for value-set analysis to identify memory alias and thus pinpoint the root cause of the crash.

## 2.2 Value-set Analysis

Value-set analysis is an algorithm designed for analyzing assembly code or an instruction trace in a static fashion. Based on the observation that memory layout generally follows, VSA partitions memory into 3 disjoint memory regions – global<sup>2</sup>, stack and heap – and assigns instructions to the regions, accordingly. For some instructions, VSA achieves region assignment by examining the semantics of the instructions. For example, from a binary code perspective, accesses to global and stack variables appear as [absolute-address] and [esp-offset]. Thus, VSA can easily link the global and stack regions to the instructions `mov edx, [0x8050684]` and `lea eax, [esp+4]`, respectively. For other instructions, VSA performs a simple forward data flow analysis to determine the regions tied to instructions in a conservative fashion<sup>3</sup>. Take for example the instruction trace shown in Figure 1. The instruction at line 4 indicates a write to the target memory [eax]. Through a forward data flow analysis, VSA could easily pinpoint that the value of `eax` was passed through line 3 because the library function `malloc` places its return value in the register `eax`. Given that the semantics of `malloc` is to allocate a memory region on the heap and then return its reference to the caller function, VSA could easily assign the heap region to the instruction at line 4.

<sup>2</sup>Note that the global region consists of initialized and uninitialized data segments.

<sup>3</sup>By ‘conservative fashion’, we refer to the fact that VSA does not actively infer the value held in a memory cell if the data flow propagation is blocked by an unknown memory reference.

In addition to assigning instructions to memory regions in the ways above, VSA tracks down variable-like entities referred to as *a-locs*. By convention, an *a-loc* could be a register, a memory cell on the stack, on the heap, or in the global region. Take the instruction trace shown in Figure 1 as an example. The register *a-locs* contain all the registers `esp`, `eax` and `ebp`. The global *a-locs* contain [0xC8]. The stack *a-locs* include [esp], [esp+0x8], [esp+0xC] and [ebp+0x8]. The heap *a-locs* consist of [eax] and [eax+0x4]. It should be noticed that, as is illustrated in Table 1b, VSA represents a non-register *a-loc* as a combination of the value held by a memory cell and the value set indicating the address of that memory cell. For example, the instruction `mov [esp+0x8], eax` accesses the stack memory, and VSA specifies its corresponding stack *a-loc* as [esp+0x8] ( $\perp$ , [-0xC, -0xC],  $\perp$ ). Here, [esp+0x8] indicates the name of the stack memory cell, and ( $\perp$ , [-0xC, -0xC],  $\perp$ ) is the value set of the memory address or, in other words, the values that `esp+0x8` could potentially equal to at the site of that instruction.

For each *a-loc* identified, VSA computes a value set, indicating the set of values that each *a-loc* could potentially equal to. By convention, VSA represents such a value set as a 3-tuple pertaining to the three memory regions partitioned. For each element in the tuple, VSA specifies a range of offsets which indicates the values that the *a-loc* could equal to with respect to the corresponding memory region.

To illustrate this, we take the register *a-loc* `esp` as an example. As depicted in the first row of Table 1b, VSA specifies its value set as a 3-tuple (`global`  $\mapsto \perp$ , `stack`  $\mapsto [-0x14, -0x14]$ , `heap`  $\mapsto \perp$ ), for brevity ( $\perp$ , [-0x14, -0x14],  $\perp$ ). In this set,  $\perp$  is a symbol denoting the empty set of offsets (*i.e.*,  $\emptyset$ ). It reflects the fact that the register `esp` is the stack pointer in x86 architecture and cannot refer to any memory cells on the heap or global region. Since the semantics of the first instruction is to offset `esp` by 0x14 from the starting point of the stack, VSA assigns the value set  $\{-0x14\}$  to the register *a-loc* `esp`, and attaches this set to the stack. It should be noticed that for specification consistency we write the value sets  $\{-0x14\}$  tied to the stack as [-0x14, -0x14].

## 2.3 Alias Analysis and Root Cause Diagnosis

**Alias Analysis.** Given a control flow specified as a sequence of instructions executed prior to a program crash, VSA can track down *a-locs*, derive value sets, and perform memory alias analysis by examining the value set tied to each of the *a-locs*. To illustrate this, we again take the instruction trace depicted in Figure 1 as an example and assume they represent the entire execution trace prior to a program crash. Supposing that Table 1b indicates the value set tied to each of the *a-locs* identified from the instruction trace, we can easily observe that [esp] at line 6 and [ebp+0x8] at line 11 refer to the same memory region or in other words they are alias of each other. In addition, we can observe [eax]

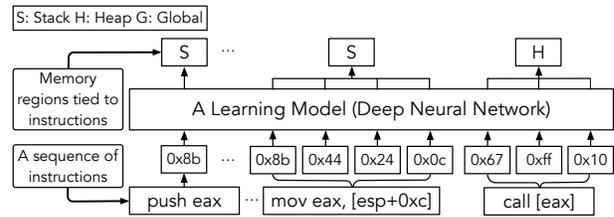

at line 4, 12 and 18 are also alias between each other. This is simply because the *a-locs* tied to these memory regions carry the overlapping value set corresponding to their addresses, *i.e.*,  $(\perp, [-0x18, -0x18], \perp)$  for `[esp]` and `[ebp+0x8]`;  $(\perp, \perp, [0,0])$  for `[eax]`. To better understand the effect of VSA on alias analysis, we derive all the alias and non-alias relationships from the value sets specified in Table 1b, and depict them in the upper triangular portion of the matrix shown in Table 1a.

**Root Cause Diagnosis.** With the alias analysis results and the value sets in hand, it is relatively easy to perform a backward taint analysis and thus track down the root cause of a program crash. To illustrate this process, we continue the example shown in Figure 1. Given that the program crashes at line 18 when the program performs an indirect call, we can easily discover that the bad destination `[eax]` was passed through the instruction at line 12 in which memory `[eax]` is assigned with a constant `0x1`. As is described above, `[eax]` at line 12 and 18 are the alias of each other. Therefore, we can safely conclude the bad destination originally comes from the instruction `mov [eax], 0x1` in line 12. Through this backward analysis, we could deem the instruction `mov [eax], 0x1` as the root cause of the crash.

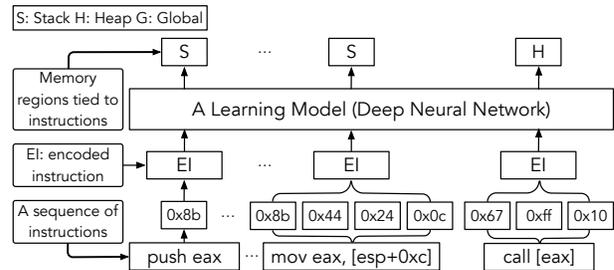

## 2.4 Problem Scope

As is described in the aforementioned example, VSA exhibits perfect performance in alias analysis and we could identify the root cause of the crash successfully. However, this does not imply that VSA could significantly resolve the memory alias issue and thus perfectly facilitate postmortem program analysis. To demonstrate this, we again take for example the instruction trace shown in Figure 1. However, different from the setup specified above, we assume the trace is available only starting from line 6. As is described in Section 2.1, hardware tracing components store a instruction trace in a circular buffer with limited size. As a result, it is commonplace that a security analyst cannot obtain a complete crashing trace but only a partial execution chronology prior to a program crash. By truncating the trace in our example, we emulate the scenario where there are only last *N* instructions recorded in a post-crash artifact.

In Table 1b, we also show the *a-locs* identified from this truncated trace. Compared with the value set derived from the full execution trace shown in the same figure, we can easily observe that nearly all the value sets tied to the *a-locs* are varied. This is because VSA performs an over-approximation in value-set construction and the missing context limits the capability of VSA with respect to reasoning memory regions or offsets within a region. Take the *a-loc* indicated by `[eax+0x4]` ( $\top, \top, \top$ ) as an example. Without the complete execution context of the crashing program, VSA conservatively assumes `eax` could equal to any value. Thus, memory `[eax+0x4]` could refer to any memory regions with an arbitrary offset

(a) A neural network taking machine code as its input.

(b) A neural network taking as input encoded instructions.

Figure 2: Two neural networks that identify memory region accesses pertaining to each instruction by taking as input a sequence of machine code and a sequence of encoded instructions respectively.

indicated by the symbol  $\top$ . As is shown in the instruction in line 13, the value of `[eax+0x4]` is assigned by a value from a global region. Therefore, the value set tied to this *a-loc* can be represented as  $([0x2, 0x2], \perp, \perp)$ . From the *a-locs* identified from the truncated trace along with their value set, we follow the aforementioned approach to examine value set intersection, and illustrate the alias and non-alias relationships in the lower triangular portion of the matrix shown in Table 1a. As we can easily observe, without the full execution trace, VSA over-approximates value sets tied to *a-locs*, and conservatively deems many memory pairs as may-alias relationships. Since may-alias represents uncertainty relationship, Table 1a illustrates them as the question symbol ‘?’’. Using such results to derive the data flow for software crash diagnosis, it is not difficult to observe that a security analyst can barely yield any useful results or in other words pinpoint the root cause of the program crash for the simple reason that VSA has the limited capability in tracking down the memory alias.

## 3 Technical Approach

To address the problem above, we propose a technical approach driven by a deep neural network. In this section, we first discuss why deep learning could potentially facilitate VSA and thus improve software crash analysis. Second, we briefly describe neural network architectures commonly used in other binary analysis tasks. Third, we discuss the limita-

tion of these existing neural networks and then specify how to design a new neural architecture to better tackle our problem. Finally, we present the detail of our new neural architecture and specify how to integrate it into conventional VSA.

### 3.1 Overview

Recall that, when a crashing trace is incomplete, VSA exhibits an insufficient capability in alias analysis and thus fails root cause diagnosis. As is demonstrated above, this is because the missing context restricts the ability of VSA to determine the region of memory accesses for some instructions. To address this pitfall, we leverage a deep neural network to enhance VSA with the ability to infer memory region(s) for instructions. In the following, we describe the rationale behind this idea and illustrate why it could benefit the diagnosis of software crashes.

**Rationale behind our idea.** In many previous applications (*e.g.*, speech recognition [24] and API generation [25]), it has been demonstrated that some sequence-to-sequence neural network architectures can be used to learn patterns from a sequence of inputs, thus facilitating the determination of a label for each individual input. As a result, in order to augment conventional VSA with the ability to infer the memory region(s) that each instruction refers to, intuition suggests that we can view an execution trace as a sequence of machine code or instructions, partition memory into disjoint regions (*e.g.*, stack, heap and global), treat each region as an individual label tied to each instruction and eventually use a sequence-to-sequence deep neural network to predict that label for each instruction. For example, given the instruction `push 0x68732f2f` represented by machine code `[0x68, 0x2f, 0x2f, 0x73, 0x68]`, we could determine the stack region is tied to this instruction by using either of the two designs shown in Figure 2. As is depicted in the figure, the two designs take the input differently, one with machine code as the input directly to a deep learning model and the other with the encoded instructions as the input to a model. In Section 3.3, we compare these two designs and describe why we choose one over the other. In Section 4, we show their performance difference.

**Effect upon root cause diagnosis.** With the augmentation above, VSA could typically perform better alias analysis and thus benefit the diagnosis of a software crash. We illustrate this by again taking for example the instruction trace shown in Figure 1. Recall that, without the complete execution context, conventional VSA cannot determine the memory region that `eax` refers to. Therefore, it assumes `[eax]` and `[eax+0x4]` could represent any memory regions, assigns `eax` and `eax+0x4` with value-set  $(\top, \top, \top)$  and eventually fails the root cause diagnosis of that crash.

Given the sequence of the instructions tied to the crashing trace, assume a deep neural network could correctly infer that, the register `eax` at `line 6` refers to a memory region at the heap. Then, VSA could assign `eax` with value-set  $(\perp,$

$\perp, [X, X])$  where  $[X, X]$  denotes an unknown address on the heap. With this, VSA could further update the value sets for corresponding *a-locs*. We show the updated value sets in Table 1b under the column “*Incomplete Trace with DL*”. As we can observe, the memory reference `[eax]` at `line 12` and `18` are aliased to each other because they both refer to the same memory address  $[X, X]$  on the heap. With this alias analysis result, VSA could quickly assist backward taint in tracking down the instruction at `line 12` – the root cause of the crash – even though this crashing trace is partial and incomplete.

## 3.2 Existing Neural Architectures

To perform binary analysis with deep learning, previous research typically utilized three types of recurrent neural networks (RNNs) – vanilla RNN [33], long short-term memory (LSTM) [22] and gated recurrent units (GRU) [13]. Here, we briefly describe them in turn.

### 3.2.1 Vanilla Recurrent Neural Network

A vanilla RNN (RNN for brevity) is specialized for processing a sequence of values  $x^{(1)}, \dots, x^{(t)}$ . When trained to perform a prediction from the past sequence of inputs, it typically maps the sequence to a fixed length vector  $h^{(t)}$  through a function  $g^{(t)}$ :

$$\begin{aligned} h^{(t)} &= g^{(t)}(x^{(t)}, x^{(t-1)}, x^{(t-2)}, \dots, x^{(2)}, x^{(1)}), \\ &= f(h^{(t-1)}, x^{(t)}; \theta). \end{aligned}$$

As we can observe from this equation, the function  $g^{(t)}$  takes the whole past sequence as input and produces a summary  $h^{(t)}$  for that sequence. In an RNN,  $h^{(t)}$  refers to a hidden state. As is illustrated in Figure 3a, an RNN can be unfolded as a chain structure where each hidden state is connected to the previous one [23]. As such,  $g^{(t)}$  can be factorized into the repeated application of a function  $f$ , which controls the transition from the previous hidden state to the next one (*i.e.*, the recurrent neuron). For example, assuming the length of the chain to be 3 – indicating a finite number of hidden states – we can then obtain

$$\begin{aligned} h^{(3)} &= f(h^{(2)}; \theta), \\ &= f(f(h^{(1)}; \theta); \theta). \end{aligned}$$

To make predictions using the chain structure depicted in Figure 3a, an RNN follows a forward propagation in which it begins with an initial state  $h^{(0)}$  and then utilizes the update equations below to compute the prediction  $\hat{y}^{(t)}$  accordingly.

$$\begin{aligned} a^{(t)} &= \mathbf{W}h^{(t-1)} + \mathbf{U}x^{(t)} + b, \\ h^{(t)} &= \tanh(a^{(t)}), \\ o^{(t)} &= \mathbf{V}h^{(t)} + c, \\ \hat{y}^{(t)} &= \text{softmax}(o^{(t)}). \end{aligned}$$

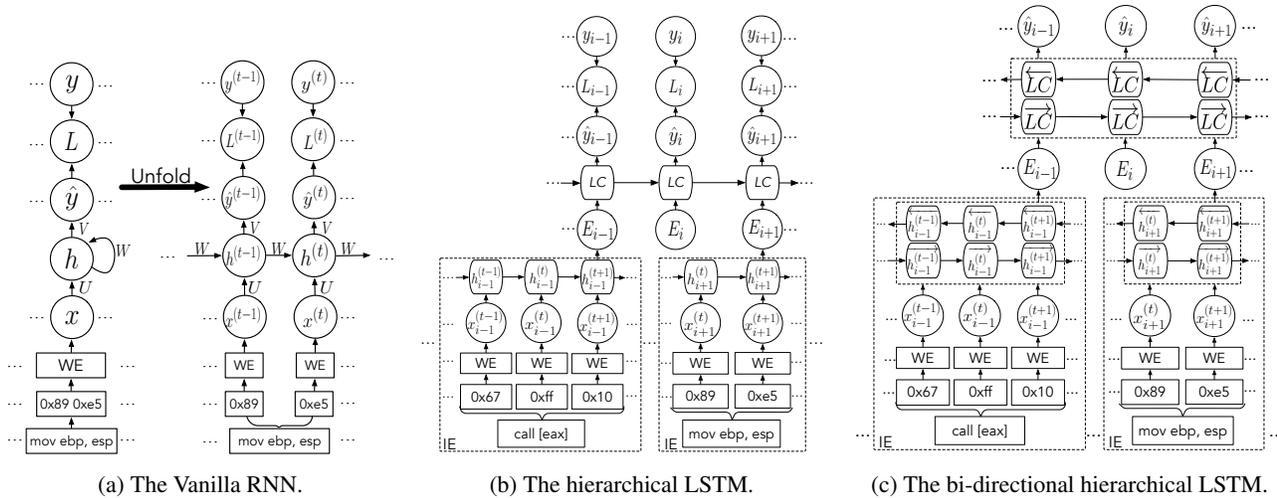

Figure 3: Recurrent neural networks with various architectures serving for different purposes. Note that “LC” indicates LSTM cell, “IE” stands for the embedding for each instruction and “WE” refers to the word embedding.

Here, bias vectors  $b$  and  $c$  are parameters.  $\tanh(\mathbf{W}h^{(t-1)} + \mathbf{U}x^{(t)} + b)$  is the detailed form of the recurrent neuron  $f$  in which  $\tanh$  is an activation function [54]. Softmax refers to the softmax classifier [10]. Along with the weight matrices  $U$ ,  $V$  and  $W$ , pertaining to input-to-hidden, hidden-to-output, and hidden-to-hidden connections respectively, the bias vectors can be learned by minimizing the loss function described below

$$\begin{aligned}
 L^{(t)} &= L(x^{(1)}, x^{(2)}, \dots, x^{(t)}, y^{(1)}, y^{(2)}, \dots, y^{(t)}) \\
 &= \sum_t L^{(t)} \\
 &= - \sum_t \log p_{model}(y^{(t)} | x^{(1)}, x^{(2)}, \dots, x^{(t)}),
 \end{aligned}$$

where  $p_{model}(y^{(t)} | x^{(1)}, \dots, x^{(t)})$  is the probability from the prediction vector  $\hat{y}^{(t)}$  corresponding to the entry for the true label vector  $y^{(t)}$ . Similar to other neural networks commonly used (e.g., multi-layer perceptron [44] and convolution neural networks [32]), the minimization of the aforementioned loss function can be achieved by using different kinds of optimization algorithms (e.g., stochastic gradient descent [11], ADAM [31], RMSprop [52]) with respect to the bias parameters and weight matrices. The details of these optimization algorithms can be found in [45].

### 3.2.2 Long Short-Term Memory

In the cybersecurity community, recent works have demonstrated that a vanilla RNN has already demonstrated great performance when performing binary analysis (e.g., [15, 48]). However, it has been noted that, as is used in other applications such as speech recognition and machine translation, such an ordinary recurrent architecture is not sufficient in processing a long sequence of inputs. This is because a vanilla

RNN naturally struggles to remember information for long periods of time or, in other words, suffers from derivative vanishing and explosion problems [26]. To address this issue, other works have used a long short-term memory (LSTM) model to carry out binary analysis.

Similar to a vanilla RNN depicted in Figure 3a, LSTM also has a chain structure. However, it replaces the aforementioned hidden states with LSTM cells, and each cell carries a set of parameters and a system of gating units that controls the flow of information. In an LSTM network, each cell has a state unit  $s^{(t)}$  as well as three gating units – a forget gate unit  $f^{(t)}$ , an external input gate unit  $g^{(t)}$ , and an output gate  $q^{(t)}$  – which together control the output  $h^{(t)}$  of the LSTM cell via the following equation

$$\begin{aligned}
 s^{(t)} &= f^{(t)} \odot s^{(t-1)} + g^{(t)} \odot \sigma(\mathbf{W}h^{(t-1)} + \mathbf{U}x^{(t)} + b), \\
 h^{(t)} &= q^{(t)} \odot \tanh(s^{(t)}).
 \end{aligned}$$

Here,  $\sigma(\cdot)$  denotes a sigmoid function [29] which sets a value between 0 and 1, and  $\odot$  represents the element-wise multiplication.  $b$ ,  $U$  and  $W$  respectively indicate the biases, input weights, and recurrent weights into an LSTM cell. To compute the gate units, one could follow the equations below

$$\begin{aligned}
 g^{(t)} &= \sigma(\mathbf{W}^g h^{(t-1)} + \mathbf{U}^g x^{(t)} + b^g), \\
 f^{(t)} &= \sigma(\mathbf{W}^f h^{(t-1)} + \mathbf{U}^f x^{(t)} + b^f), \\
 q^{(t)} &= \sigma(\mathbf{W}^q h^{(t-1)} + \mathbf{U}^q x^{(t)} + b^q),
 \end{aligned}$$

where  $\{b^f, b^g, b^q\}$ ,  $\{\mathbf{U}^f, \mathbf{U}^g, \mathbf{U}^q\}$  and  $\{\mathbf{W}^f, \mathbf{W}^g, \mathbf{W}^q\}$  are respectively: biases, input weights, and recurrent weights for the forget, external input, and output gates. Similar to  $b$ ,  $U$  and  $W$ , they are also the parameters that can be learned via the optimization algorithms mentioned above. Again, more details of parameter computation can be found at [23].

### 3.2.3 Gated Recurrent Units

As is described in previous research [15], gated recurrent units (GRU) can also be used for some of binary analysis tasks. GRU is an alternative LSTM which can also capture long term dependency. The main difference between GRU and LSTM is that GRU replaces the forget gate  $f$  and output gate  $q$  in LSTM with one update gate. More specifically, it integrates both forget and output gates into a single gating unit  $u^{(t)}$ . As a result, it reduces the parameters that a network has to learn and thus poses a lower computational cost. The following equations indicate how to compute the output  $h^{(t)}$  of a GRU cell:

$$\begin{aligned}r^{(t)} &= \sigma(\mathbf{W}^r h^{(t-1)} + \mathbf{U}^r x^{(t)} + b^r), \\u^{(t)} &= \sigma(\mathbf{W}^u h^{(t-1)} + \mathbf{U}^u x^{(t)} + b^u), \\h^{(t)} &= u^{(t)} \odot h^{(t-1)} + (1 - u^{(t)}) \odot \tanh(\mathbf{W}(r^{(t)} \odot h^{(t-1)}) + \mathbf{U}x^{(t)} + b).\end{aligned}$$

Here,  $r^{(t)}$  stands for a reset gate which controls the influence of the past sequences of inputs upon the current one.  $\{b^r, \mathbf{U}^r, \mathbf{W}^r\}$  and  $\{b^u, \mathbf{U}^u, \mathbf{W}^u\}$  are gate weights. Along with the bias  $b$  and weights  $\mathbf{U}$ ,  $\mathbf{W}$ , they need to be learned through the aforementioned optimization algorithms.

## 3.3 Our Neural Network Architecture

As we described in Section 3.1, we could utilize two different design mechanisms to predict the memory region that each instruction refers to. For the design shown in Figure 2a, we could simply leverage any of the aforementioned recurrent neural networks to take as input the sequence of machine code, learn the pattern hidden behind the machine code sequence and predict the memory region for each instruction. As they have already demonstrated in other binary analysis tasks (e.g., [48, 15]), we could expect this design could perform reasonably well in memory region identification. However, following the intuition described below, we do not utilize this design. Rather, we develop our technique by using the alternative design shown in Figure 2b.

Take for example the instruction sequence `push ebp; mov ebp, esp` indicated by the byte sequence `[0x55, 0x89, 0xe5]`. An existing neural network model could take this machine code sequence as input and make predictions for their corresponding memory accesses based on the dependency between the bytes. It is not too difficult to observe that this simple approach neglects the semantics and contexts of these instructions. As is described in Section 2, in binary analysis, the semantics and contexts of instructions could be used as indicators to infer the memory accesses tied to instructions. Therefore, intuition suggests that it could be potentially beneficial for memory region identification if we could build a neural network with the ability to capture not only the dependency between the bytes but also that between instructions.

Inspired by this, we choose the design depicted in Figure 2b and build a hierarchical LSTM architecture. We depict the structure of this learning model in Figure 3b. As we can observe, similar to existing neural networks used for other binary analysis tasks, it first maps each byte into a vector by using a word embedding mechanism [9]. Then, it groups the bytes per each instruction and utilizes an embedding network to convert each group of bytes into an instruction embedding (i.e., an encoded vector). Taking the instruction embedding as the input, our neural architecture further employs a sequence-to-sequence network [50] to predict the memory region tied to each instruction.

In comparison with the aforementioned off-the-shelf recurrent architectures largely adopted by other binary analysis tasks, the proposed hierarchical LSTM architecture is composed of two networks. The embedding network models the correlation of bytes in one instruction and the sequence-to-sequence network captures the dependency between instructions. By designing the model structure in this fashion, our neural network model is able to perform memory access predictions at the instruction level and learn the dependency between and within instructions at the same time.

However, it is not difficult to note that this new recurrent architecture cannot represent a backward analysis procedure, where the memory region(s) tied to an instruction is determined by the consecutive instructions. Yet we note that this backward analysis is feasible. To illustrate this, we take the following execution trace as an example.

```
00015670 <malloc>:
53          push  ebx
...
89 44 24 04  mov  DWORD PTR [esp+0x4],eax
e8 6d b1 fe ff call 800 <_libc_memalign@plt>
83 c4 18    add  esp,0x18
5b          pop   ebx
c3          ret
```

As is illustrated above, the trace indicates the instructions and corresponding machine code executed while invoking the `malloc` function. Here, the highlighted instruction and machine code indicate the last definition of `[eax]` prior to the return of the function call. Given that the call to `malloc` places the return value in the register `eax`, indicating an address on the heap, we can reversely perform inference and conclude that the memory access tied to the highlighted instruction is within a heap region.

To enable our design with the capability of inferring memory regions in both forward and backward ways, we further upgrade our hierarchical LSTM model to a bi-directional chain structure [46]. As is shown in Figure 3c, our bi-directional chain structure is applied to both the embedding network and the sequence-to-sequence network. With respect to the embedding network, our neural architecture combines a network that moves forward, beginning from the start of the corresponding byte sequence, with another network that moves backward, starting from the end of the corresponding byte

sequence. Regarding the sequence-to-sequence network, our architecture concatenates the output of a forward embedding network with the output of a backward embedding network. Then, it takes the concatenation as input and performs memory access prediction for each individual instruction based on the sequence of instructions executed before and after that instruction.

### 3.4 Detail of Our Neural Architecture

Here, we describe more details of our proposed neural network architecture. More specifically, we specify how we process a crashing trace, perform corresponding computation, train the neural network and eventually utilize it to facilitate VSA.

**Padding and word embedding.** As is described above, our neural network utilizes a bi-directional embedding to encode each instruction prior to making predictions for their memory accesses. Before passing machine code to that embedding network, we process them as follows.

Assume we have a crashing trace containing  $n$  instructions  $I_{1:n}$ . For each instruction  $I_i$ , it could be represented as  $m$  bytes of machine code  $b_i^{(1:m)}$ . For an x86 machine, instructions do not share the same length. To design the same structure of embedding networks for instructions, we therefore pad instructions to a fixed length. To do this, we first convert each individual byte into an integer based on its value (e.g., encoding machine code 55 to its integer form 85). Then, we pad that instruction with integer 256. In this way, we could ensure our padding does not introduce ambiguity to a target instruction. After the padding, we also utilize a word embedding to further process the padded crashing trace. In our work, our word embedding converts each byte into a one-hot vector with a dimensionality of 257. Then, the vector is multiplied with a matrix projecting the byte into a new vector (i.e.,  $x_i^{(1:m)}$ ) typically with lower dimensionality.

**Instruction embedding.** For each instruction, we use a bi-directional LSTM model to further encode its word embedding and then generate an individual instruction embedding. Technically speaking, we achieve this by integrating the outputs of the forward and backward networks. More specifically, we utilize the following equations to compute the output of the forward network.

$$\begin{aligned} \overrightarrow{h}_i^{(t)} &= \text{LSTM}(\overrightarrow{h}_i^{(t-1)}, x_i^{(t)}), \\ \overrightarrow{E}_i &= \overrightarrow{h}_i^{(m)}. \end{aligned}$$

Similarly, we compute the output for the backward network as follows.

$$\begin{aligned} \overleftarrow{h}_i^{(t)} &= \text{LSTM}(\overleftarrow{h}_i^{(t+1)}, x_i^{(t)}), \\ \overleftarrow{E}_i &= \overleftarrow{h}_i^{(1)}. \end{aligned}$$

Here,  $\overrightarrow{E}_i$  and  $\overleftarrow{E}_i$  are the forward and backward embeddings of the instruction  $I_i$ , respectively. LSTM denotes an LSTM cell

introduced above. As we can observe from the two sets of equations above, the hidden representation of the first and last bytes of the instruction,  $h_i^{(m)}$  and  $h_i^{(1)}$ , contain the information that flows from the previous and consecutive bytes.

To combine the outputs of both forward and backward networks, we concatenate both representations in the form of  $E_i = [\overrightarrow{E}_i, \overleftarrow{E}_i]$ . Technically, it should be noted that we can use one single embedding network for all instructions, or employ different embedding networks for instructions. With the consideration of lowering computational overhead, our neural network architecture follows the first approach.

**Sequence-to-sequence network.** Given a sequence of instruction embeddings pertaining to the instructions in a crashing trace, we then use a sequence-to-sequence model mentioned above to predict the label (i.e., , memory access region(s)) for each instruction. To be specific, the model takes as input the instruction embeddings  $E_{1:n}$  and utilizes a bi-directional LSTM as the hidden layer of our neural architecture<sup>4</sup>. At the output layer of our neural network, it uses a softmax classifier to assign a corresponding label for each hidden state (i.e., the hidden representation of each instruction). Different from previous deep neural network used in other binary analysis technique, which assigns a label to each byte, our new architecture gives us the ability to attach an individual prediction to each instruction.

**Training strategy.** Similar to the recurrent neural networks summarized in Section 3.2, we also need to leverage aforementioned optimization algorithms to estimate the parameters for our neural network. In binary analysis tasks, the training dataset is often significantly large, e.g., one execution trace carries millions of lines of instructions. Using conventional gradient descent algorithms – like stochastic gradient descent – against a large data set, parameter estimation would experience significant computation overhead. To address this issue, we take advantage of mini-batch gradient descent, a variation of the gradient descent algorithm [28]. Technically speaking, this approach splits the training dataset into small batches, uses them to calculate model error through loss function and updates model parameters accordingly. Compared with other approaches, particularly stochastic gradient descent, mini-batch provides a computationally efficient process and enables parallel computations.

In addition to mini-batch gradient descent, we adopt RMSprop [34] to accelerate the optimization process needed for gradient descent computation. To be specific, we adjust the learning rate by dividing it by an exponentially decaying average of squared gradients. For more details, the reader could refer to an unpublished article available at Geoff Hinton’s class [34]. Last but not least, we also pad the remaining sequences in the last batch with vectors where each element equals 256. In this way, we can represent each batch as a

<sup>4</sup>Note that we can also use GRU as an alternative to LSTM for the encoding network and the sequence to sequence network.

matrix with fixed size, making it capable of being efficiently processed at the same time.

**Integration into VSA.** Without the facilitation of a deep learning model and the clue of which memory region an instruction accesses, VSA initializes *a-locs* and value-set with  $(\top, \top, \top)$ , indicating the memory access in that instruction could refer to any memory regions. Using our deep neural architecture introduced above, we could have the neural network output the memory region that instruction accesses (*i.e.*, global, stack or heap). As is illustrated in Section 3.1, with this capability, we could initialize *a-locs* and value-set with  $([X, Y], \perp, \perp)$ ,  $(\perp, [X, Y], \perp)$  or  $(\perp, \perp, [X, Y])$ , denoting a memory access in that instruction could refer to a particular memory area ranging from X to Y at a global, stack or heap region. Then, starting from the first instruction in the crashing trace, VSA could regularly perform forward analysis and update the value for X and Y. For example, as we have shown in Table 1b, when analyzing the instruction at line 6, our deep learning model initializes *eax* with value-set  $(\perp, \perp, [X, Y])$  and VSA updates X and Y with  $X=Y$  indicating the register *eax* refers to the memory address X at the heap region.

## 4 Evaluation

In this section, we describe our implementation, the dataset we utilized, set up our experiment, and summarize our experimental results. Through this evaluation, we seek to answer the following questions. ❶ Does our problem require a deep learning model or could it be resolved with conventional machine learning techniques? ❷ Can our proposed technique correctly link memory regions to instructions or, more precisely, identify the memory regions that instructions dereference? ❸ Compared with commonly adopted recurrent neural architectures that take as input the raw machine code, does the proposed neural network architecture (taking encoded instructions as the input to a neural network) exhibit better performance in terms of memory region identification? ❹ Can the memory regions identified improve the ability of VSA with respect to memory alias analysis and thus bring the positive impact upon the capability in software crash diagnosis?

### 4.1 Implementation

To answer the questions above, we must first train many deep neural network architectures. This requires a large training data set containing various instruction traces as well as the memory reference tied to each instruction. To facilitate the collection of the instruction traces as well as the corresponding memory accesses, we first implemented a tracing system which provides us with the ability to not only record the instructions that a target program executes but also the memory region each instruction refers to. While both Intel PT and

ARM ETM could trace program execution, in this work, we utilize Intel Pin [35] to complete the implementation of our tracing system. This is because, in order to train a neural network, we have to obtain the ground truth of which memory regions instructions access but both hardware components do not provide us with such a capability (*i.e.*, recording memory regions referred by instructions).

In addition to the tracing system, we customized a VSA system which implemented an instruction parser using `libdisasm` and 84 distinct instruction handlers to perform value-set calculation. Going beyond alias analysis, the implementation of our customized VSA system also contains a backward taint component which takes the results of alias analysis and performs the root cause diagnosis for a crashing program. In total, our VSA implementation contains about 9,500 lines of C code. It should be noticed that the value-set calculation for instructions with similar semantics (*e.g.*, `ja`, `jb`, `jc`) were taken care of by a unique handler.

Recall that our ultimate goal is to use a deep neural network to facilitate VSA with respect to alias analysis and thus improve the effectiveness of software crash diagnosis. Last but not least, we therefore prototyped a neural network assisted VSA system and named it after DEEPVSA. In our implementation, DEEPVSA first utilizes a pre-trained deep neural network to predict memory accesses for each instruction. Then, it determines non-aliasing relationships based on the prediction by following the approach introduced in Section 3. Combining the results of the conventional value-set analysis with this non-aliasing analysis, our DEEPVSA finally performs backward taint analysis and thus pinpoints the root cause of a program crash. In this work, we ran all the aforementioned systems on a 32-bit Linux system with Linux kernel 4.4.0 running on an Intel i7-6600 quad-core processor with 16 GB RAM. We trained all the deep neural networks in this work on 2 Nvidia Tesla K40 GPUs and 4 Nvidia GTX 1080Ti GPUs using the Keras package [14] and with Tensorflow [1] as backend, amounting to about 2,000 lines of Python code. Upon the acceptance of this submission, we will release all of our systems along with our data set described below.

### 4.2 Data Set

As is mentioned above, we need to train many deep neural networks with various execution traces along with their corresponding memory accesses. In this work, we construct our training data set by using 78 unique programs in a package of GNU software – `coreutils`, `ineutils` and `binutils`. More specifically, we ran these programs by following their documentation and running examples. Using the aforementioned tracing system, we then gathered their execution traces along with their memory accesses. In total, these 78 programs generate a training data set with 96 distinct execution traces covering 49,193,919 lines of instructions.

To test our neural network and demonstrate the effective-

Table 2: The list of program crashes corresponding to memory corruption vulnerabilities. “Root cause” specifies whether the result of alias analysis successfully facilitate the root cause identification of software crashes. The percentages under VSA and DEEPVSA represent the amount of non-alias memory pairs identified. The number shown along with “non-alias” indicates the length of the trace prior to the site of the root cause instruction.

ness of DEEPVSA in alias analysis and root cause diagnosis, we exhaustively searched the Exploit Database Archive [47] and randomly selected 40 distinct vulnerability reports corresponding to 38 unique versions of software running on Linux. Following the description of each report, we compiled vulnerable programs<sup>5</sup>, configured the underlying systems and ran the PoC programs tied to corresponding vulnerabilities. In this way, we triggered software failures, recorded their crashing traces and treated these traces as our testing data set. Using these crashing traces, we benchmarked DEEPVSA and examined the effectiveness of our proposed technique. Recall that the execution trace is stored in a circular buffer with a

<sup>5</sup>In other binary analysis research works using deep learning, the binary is typically compiled with various optimization options. In this work, we compiled programs mostly with O2 option because many vulnerabilities cannot be reproduced if compiled with other options. Note that this does not influence the generalization of our approach because O2 is the default compilation options for most software.

limited size (4KB) and that buffer is shared by multiple running processes. Since different lengths of an instruction trace stored in that shared buffer might influence memory alias identification, we retained different lengths of instructions for each of our test cases. This gives us the ability to identify the optimal memory size needed for a running process.

In Table 2, we present all the crashing programs selected<sup>6</sup>. From the table, we have the following observations. First of all, we can observe that the programs listed in the table has less overlaps with the programs in our training data set. This implies the dissimilarity between our training and testing data sets and thus avoids the possibility of using the same or similar data for model training and testing. Considering programs could invoke functions in the same shared library (e.g., glibc), and too many of such invocations could potentially

<sup>6</sup>Note that we present the corresponding CVE/EDB-IDs as well as the length of each crashing trace in Appendix.

Table 3: The overall performance of different machine learning models.

introduce the risk of using the same data for training and testing, we further examine the instruction traces in the testing data set with those in the training. We discover that there are 14.02% of overlapping functions, appearing both in our test cases and the cases in our training set. In order to ensure our training and testing data sets do not share instructions, we eliminate the commonly shared instruction sequences from the training data set. This further avoids the situation where we perform alias analysis against a target crashing trace by using the model trained with itself.

Second, we can observe, the programs in the table cover a wide spectrum, ranging from sophisticated software like `gdb-7.5.1` with over 1.6M lines of code to lightweight software such as `o3read-0.0.3` and `corehttp-0.5.3.1` with less than 1K lines of code. To some extent, this diversity of our test cases imposes different levels of difficulty upon alias analysis and root cause diagnosis. Last but not least, we manually examine the memory access behaviors and observe that our test corpus encloses a variety of memory access behaviors, manifested as different amounts of memory dereferences across four disjoint memory regions (see Table 4 in Appendix). It should be noted that apart from the three memory regions that conventional VSA typically separates, we introduce ‘*other*’ which represents the memory region pertaining to the text and global sections tied to dynamic libraries. This is an useful addition because the involvement of this region could allow us to extend conventional VSA to consider the following two memory access practices. ❶ An instruction dereferences a memory cell which held a piece of read-only data in the text section. ❷ A running process and dynamic library do not share the same global section and an instruction of the process accesses a memory cell indicating the global section of the dynamic library.

### 4.3 Experimental Setup

Using the systems mentioned in Section 4.1 as well as the data sets described in Section 4.2, we set up a series of experiments to evaluate our proposed technique and thus answer the four questions presented above.

To answer the first three questions (❶, ❷ and ❸) mentioned at the beginning of this section, we first trained 6 different machine learning models by using the training data set mentioned above. As is specified in Table 3, two of them are conventional machine learning models – Hidden Markov Model (HMM) as well as Conditional Random Field (CRF). While there are other machine learning approaches, such as decision tree or logistic regression, which might also work for our task, we select HMM and CRF as our baseline approaches and compare them with our proposed deep learning technique. This is because, by design, the approaches of our choice could take a sequence of input and yield a sequence of predictions, whereas other traditional machine learning approaches need to involve sophisticated feature engineering efforts in order to process a sequence of data input. In addition to conventional learning models, Table 3 depicts our proposed neural network architecture that takes instruction embedding as the input to a neural network as well as three aforementioned neural architectures that take as input the raw machine code. In this work, we compare the performance of these different neural architectures and examine whether the design of feeding instructions to a neural network outperforms that of taking raw machine code<sup>7</sup>.

To obtain the performance measure of each machine learning models mentioned above, we applied the learning models to the aforementioned testing data set, used them to predict the memory region each instruction refers to and compare their prediction with the true labels (i.e., the memory regions a corresponding instruction truly refers to). For each memory access in the execution traces of the testing data set, we define a prediction as a correct identification if and only if the predicted memory regions aligns the true memory regions that the corresponding instruction refers to. With this definition, we further computed the precision, recall and F1 score for each machine learning model. To be more specific, we use the equations  $\frac{P_M \cap T_M}{P_M}$ ,  $\frac{P_M \cap T_M}{T_M}$  and  $2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}$  to compute precision, recall and F1 score, respectively. Here,  $P_M$  represents the set of memory accesses predicted to refer to memory region  $M$  where  $M \in \{\text{stack}, \text{heap}, \text{global}, \text{other}\}$ .  $T_M$  denotes the set of memory accesses truly referencing memory region  $M$ .

To explore the answer to our last question (❹), we further set up our experiment as follows. For each trace in our testing data set, we first applied our proposed neural network model to predict the memory regions tied to corresponding

<sup>7</sup>It should be noted that all the neural networks shown in the table are bi-directional. This is because previous research [48] indicates the bi-directional structure outperforms those designed with a single-directional chain particularly when using deep learning to performing binary analysis.

instructions. With these prediction results, we then utilized DEEPVSA. As is mentioned above, DEEPVSA is an extension of VSA. It is built with the additional ability to take the region prediction and determine non-alias relationships that the conventional VSA originally fails to identify. In addition, it leverages the results of alias analysis to perform backward taint analysis and thus pinpoint the root cause of the corresponding crash. Using these capabilities, our experiment compares the non-alias pairs that DEEPVSA and conventional VSA identified. Then, using the alias analysis results that DEEPVSA and conventional VSA derive, our experiment further examines their corresponding capability in facilitating the root cause diagnosis. When conducting our experiments, we also investigate the impact of the instruction trace length upon the non-alias identification. To be specific, we preserve different lengths of instructions prior to the root cause site (*i.e.*, 200, 400, 800, 1600, 3200, 6400, 12800 and 19600) and measure how different lengths impact alias identification. It should be noted we utilize 4KB of execution trace for our study if hardware cannot enclose the root cause site in its circular buffer.

#### 4.4 Experimental Results

**Performance of machine learning models.** Table 3 shows the precision, recall and F1 score of various machine learning models, which demonstrate their capability of assigning correct memory regions to instructions. As we can easily observe, all deep neural network models significantly outperform traditional machine learning models. This is because a crashing trace is relatively long and deep learning approaches naturally have stronger capability than HMM and CRF in learning the patterns hidden in a long sequence. Of all the neural network models, we can also observe that our proposed neural network model (specified as ‘our model’) exhibits the highest classification performance (*i.e.*, with the highest F1 score). This indicates that, in comparison with the model taking as input the raw machine code, a learning model that takes instruction embedding as the input to a neural network could better capture the dependency hidden between instructions.

From Table 3, we also find that, in comparison with other deep learning models, our model typically demonstrates the performance improvement with only about 1% ~ 12%. However, this does not imply that the utility of our model is only slightly better than those of other neural network models. In our binary analysis task, the crashing traces are relatively long. Using a neural network with even only 0.1% of improvement in precision, for example, we could reduce the amount of false positives or negatives by thousands. Given a long crashing trace containing hundreds of thousands of instructions, our performance improvement indicates a significant reduction in the memory regions mistakenly assigned by neural networks.

**Performance of memory alias analysis.** In addition to showing the superior performance of our model when conducting

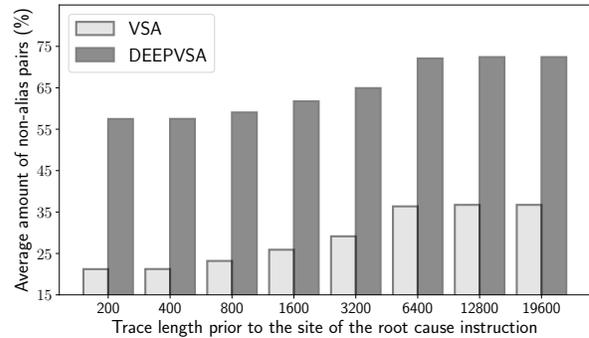

Figure 4: The average amount of non-alias memory pairs vs. the length of instructions retained.

memory region identification, we demonstrate the performance of our model in terms of its ability to facilitate VSA with respect to memory alias analysis. In Table 2, we specify the percentage of non-alias pairs that VSA and DEEPVSA track down when given different lengths of crashing traces (400, 800, 3200, 6400, 12800). As we can observe, on average, conventional VSA tracks down about 21.23% ~ 36.73% non-alias pairs compared with 57.49% ~ 72.40% of non-alias pairs identified by DEEPVSA. This is more than a 35% increase in non-alias memory reference determination. These results perfectly reflect how conventional VSA generally fails to accurately identify memory regions when execution traces are incomplete. With the assistance of a deep neural network, VSA’s ability to perform memory region identification can be enhanced resulting in a significant benefit for memory alias analysis.

In Table 2 and Figure 4, we further specify the impact of the execution trace length upon the ability to perform alias analysis. We observe that, for some crashing programs (*e.g.*, `poppler-0.8.4` and `JPegToAvi-1.5`), the length of the execution trace stored in the circular buffer influences the capability of VSA and DEEPVSA upon determining memory alias relationships. With the increase in the length of an execution trace, we discover that both VSA and DEEPVSA demonstrate the improvement in their ability to analyze memory alias. This is because both techniques rely upon an execution context to perform alias analysis and a longer execution trace provides them with more abundant contexts. In addition, we observe that the capability of performing alias analysis converges when the length of the instructions (prior to the root cause instruction site) exceeds 12,800. This indicates that, even though DEEPVSA significantly improves VSA’s capabilities for alias analysis, it does not completely address alias identification issues for a crashing trace. We believe there is still a room for future exploration in this space, particularly because VSA utilizes both memory regions and offsets to perform alias analysis while DEEPVSA only simply extends VSA with the consideration of coarse-grained memory region differences.

Recall that our DEEPVSA performs alias analysis by using a deep learning approach which cannot predict a memory region access with 100% of accuracy. As a result, along with the influence of a trace length upon alias analysis, we also investigate if inaccurate prediction actually causes DEEPVSA to incorrectly – or mistakenly – track down a non-memory alias pair and thus fail root cause diagnosis. We discover that, similar to conventional VSA, DEEPVSA exhibits zero error rate across all test cases shown in the table. This implies that DEEPVSA does not introduce unsoundness to alias analysis while our proposed deep neural network might mistakenly assign an incorrect region to an instruction. We believe the reason behind this surprising observation is as follows. Given a crashing trace, there is only a tiny portion of memory references that are truly aliased to each other. Even though our deep learning model mistakenly predicts regions for instructions, and DEEPVSA takes that inaccurate prediction as a strong indicator for determining non-alias relationships, the possibility of propagating that error to alias analysis is still extremely low.

**Performance of root cause diagnosis.** Going beyond specifying the facilitation of alias analysis, Table 2 also illustrates how the analysis of memory alias benefits backward taint analysis and thus the root cause identification. As we can observe from the table, compared with VSA – with which backward taint could successfully pinpoint the root cause of the crash for 27 test cases – DEEPVSA demonstrates superior performance in facilitating root cause diagnosis. We can observe that, with only 3 test cases, DEEPVSA fails to help backward taint to track down the root cause of a software crash. To understand the reasons behind the failure, we look closely into the instructions tainted. With respect to `Overkill-0.16` and `ClamAV-0.93.3`, we note that the failure results from the nature of the hardware which has only 4KB memory storage to record all execution traces. Even if we allocate this entire storage to the crashing process, the hardware is still not able to enclose the instructions pertaining to the root cause of the crash. Regarding the test case `aireplay-ng-1.2beta3`, we discover the crashing program invoked the system call `sys_read` which writes a data chunk to a certain memory region. Since both the size of the data chunk and the address of the memory are specified in registers, which value-set analysis fails to restore, `sys_read` intervenes the propagation of data flow, making the output of DEEPVSA less informative to failure diagnosis.

## 5 Related Work

This research work mainly focuses on analyzing memory alias in the binary level. Regarding the techniques we employed and the problems we addressed, the lines of works most closely related to our own include machine learning in binary analysis and memory alias analysis for assembly. In this section, we summarize previous studies and discuss their

limitation in turn.

**Memory alias analysis for assembly.** There is a long history of research about analyzing memory alias in binary code. As pioneering research works, Debray *et al.* [21] and Cifuentes *et al.* [16] both propose the same type of technical approaches that compute the values a set of registers can hold at each program point and then use the values held in the registers to determine alias. Considering such techniques determine only the possible values held in each register, but not reason about values across memory operations, Brumley *et al.* propose a logic-based approach which derives all possible alias relationships by finding an over-approximation of the set of values that each memory location and register can hold at each program point [12]. At the high level, this logic-based approach is similar to value set analysis [7, 6, 42] because they both perform value reasoning across memory operations. However, different from the work proposed in [12], value set analysis neither assumes that all memory cells and register locations must be of a single fixed width, nor assumes reads and writes have to be no overlapping. As such, value set analysis is more practical for real-world applications, whereas the logic-based approach [12] has been tested only against simple toy examples.

In a recent research work [19], Cui *et al.* propose a practical debugging system REPT. Technically, it first ignores memory alias in data flow analysis and then utilizes an error correction mechanism to rectify the mistakes caused by memory alias. This approach has demonstrated its effectiveness and efficiency in dealing with some real world crashes. However, as is stated in [19], it inevitably introduces inaccurate analysis results. This is because the proposed correction mechanism does not always catch the occurrence of memory alias, which could sometimes result in incorrectness in root cause diagnosis for a crashing program. In addition, similar to value set analysis, incomplete execution trace imposes the difficulty for REPT in performing alias analysis. In this work, we proposed new deep-learning-based approach which not only inherits the capability of VSA in providing high-fidelity analysis results but more importantly enhances its ability to analyze memory alias.

**Machine learning in binary analysis.** There is an extensive body of work leveraging machine learning to perform binary analysis. Technically speaking, they can be categorized into two types – conventional machine learning based approaches as well as deep learning based ones.

With respect to the works using conventional machine learning techniques, their research focus is mainly on identifying the function boundary in the binary level. For example, Rosenblum *et al.* utilize conditional random fields to formulate function boundary identification [43] and demonstrate decent performance in terms of pinpointing function entry points. In a recent research work, Bao *et al.* propose ByteWeight [8] which significantly improves the performance for function boundary identification by using weighted

prefix trees.

Regarding the research works adopting deep learning techniques, their research focus includes identifying function boundary [48], pinpointing function type signature [15], tracking down similar binary code [56] and performing memory forensics [49]. Using a bi-directional recurrent neural network, Shin *et al.* improve function boundary identification and achieve a nearly perfect performance with respect to function boundary recognition [48]. Going beyond simply identifying function boundary, Chua *et al.* explore recurrent neural networks with respect to its ability to track down the arguments and types of functions in binary [15]. In recent work, deep learning techniques have also been utilized for binary code similarity detection, in which Xu *et al.* employ Multi-Layer Perception (MLP) to encode a control flow graph and then use the encoding to pinpoint vulnerable code fragments [56]. Last but not least, Song *et al.* use a graph based deep learning approach to derive abstract representations for kernel objects so that one could recognize those objects from raw memory dumps efficiently [49].

In this work, we also use machine learning for binary analysis. Different from the aforementioned research, we however focus on leveraging deep learning to improve memory alias identification. Technically speaking, our work is also unique. Unlike the works above, which mostly use an off-the-shelf deep neural architecture, our work introduces a new recurrent neural architecture, which takes the consideration of the data dependency residing in binary code. As is shown in Section 4, our proposed neural network significantly outperforms neural networks largely adopted in other binary analysis tasks.

## 6 Conclusion

In this paper, we introduce a new deep neural network architecture to facilitate value-set analysis for alias analysis and thus improve the capability in software crash analysis. We show that this new neural architecture can significantly improve value-set analysis with respect to its capability in handling memory alias analysis and benefit data flow analysis in the context of postmortem program analysis. Since the design of our proposed neural network architecture takes into consideration not only the semantics of instructions but also their contexts, it can better capture the dependency within and between the instructions in a sequence of machine codes, making alias identification more effective.

We implemented our proposed technique as DEEPVSA— a deep neural network assisted tool for alias analysis and crash diagnosis – and demonstrated its utility using real-world software crashes covering about 1.6 million lines of instructions. We showed that DEEPVSA can facilitate the determination of non-alias relationships with no false positives and benefit the diagnosis of program crashes. In addition, we demonstrated that our newly designed neural network outperforms off-the-shelf neural architectures. Following these findings, we safely

conclude deep learning can be used for the facilitation of memory alias analysis and root cause diagnosis at the binary level. We expect this work can inspire further advancements in alias analysis and postmortem program analysis through deep neural networks.

## Acknowledgement

We would like to thank our shepherd Konrad Rieck and the anonymous reviewers for their helpful feedback. This project was supported in part by NSF grants CNS-1718459, TWC-1409915. In addition, this work was partially supported by the CLTC (Center for Long-Term Cybersecurity), and FORCES (Foundations of Resilient CybErPhysical Systems) which is supported by NSF under the grants CNS-1238959, CNS-1238962, CSN-1239054 and CSN-1239166.

Table 4: The detail of crashing programs. The CVE/EDB column specifies the vulnerability identifiers. In this column, NA indicates those vulnerabilities with an EDB identifier but not a CVE Identifier). “Trace Len” describes the number of instructions from the root cause site to the crashing site. The numbers under “statistics” indicate the amount of memory dereferences across 4 disjoint memory regions.

## Appendix

**Detail of crashing programs and their crashing trace.** As is described in Section 4, for our evaluation, we select 40 crashing traces corresponding to 38 distinct versions of vulnerable software. Table 4 describes the detail of these selected programs, including the CVE/EDB identifiers tied to these programs as well as the length of their crashing traces. In addition, the table shows the memory access behaviors of each program. They are retrieved from the execution trace which

Table 5: The overall performance of different machine learning models trained with the execution traces without the elimination of common instruction sequences.

combines the trace from the root cause site to the crashing site and its 19,200 prefix instructions. We have already made all of the selected programs publicly available. They can be downloaded from our project website [3]. It should be noted that Table 2 and 4 share the same index.

**Learning model performance without the elimination of commonly-shared data.** As is specified in Section 4, in order to avoid the risk of using the same data to train and test a learning model, we eliminate – from the training data set – the instruction sequences commonly shared by both our training and testing sets, and show the performance of the learning models trained on non-overlapping data set. As a comparison, we also conduct an experiment in which we do not eliminate the 14.02% of shared data from the training set, and train all the learning models over the overlapping data set. In Table 5, we depict the model performance under this setting. As we can observe from the table, the model performance is actually comparable regardless whether we trim off the commonly shared instruction sequences. This implies that the shared data has nearly no impact upon model classification and thus memory alias analysis.

# CONFIRM: Evaluating Compatibility and Relevance of Control-flow Integrity Protections for Modern Software

## Abstract

CONFIRM (CONtrol-Flow Integrity Relevance Metrics) is a new evaluation methodology and microbenchmarking suite for assessing compatibility, applicability, and relevance of *control-flow integrity* (CFI) protections for preserving the intended semantics of software while protecting it from abuse. Although CFI has become a mainstay of protecting certain classes of software from code-reuse attacks, and continues to be improved by ongoing research, its ability to preserve intended program functionalities (*semantic transparency*) of diverse, mainstream software products has been under-studied in the literature. This is in part because although CFI solutions are evaluated in terms of performance and security, there remains no standard regimen for assessing compatibility. Researchers must often therefore resort to anecdotal assessments, consisting of tests on homogeneous software collections with limited variety (e.g., GNU Coreutils), or on CPU benchmarks (e.g., SPEC) whose limited code features are not representative of large, mainstream software products.

Reevaluation of CFI solutions using CONFIRM reveals that there remain significant unsolved challenges in securing many large classes of software products with CFI, including software for market-dominant OSes (e.g., Windows) and code employing certain ubiquitous coding idioms (e.g., event-driven callbacks and exceptions). An estimated 47% of CFI-relevant code features with high compatibility impact remain incompletely supported by existing CFI algorithms, or receive weakened controls that leave prevalent threats unaddressed (e.g., return-oriented programming attacks). Discussion of these open problems highlights issues that future research must address to bridge these important gaps between CFI theory and practice.

## 1 Introduction

Control-flow integrity (CFI) [1] (supported by vtable protection [29] and/or software fault isolation [73]), has emerged as

one of the strongest known defenses against modern control-flow hijacking attacks, including return-oriented programming (ROP) [60] and other code-reuse attacks. These attacks trigger dataflow vulnerabilities (e.g., buffer overflows) to manipulate control data (e.g., return addresses) to hijack victim software. By restricting program execution to a set of legitimate control-flow targets at runtime, CFI can mitigate many of these threats.

Inspired by the initial CFI work [1], there has been prolific new research on CFI in recent years, mainly aimed at improving performance, enforcing richer policies, obtaining higher assurance of policy-compliance, and protecting against more subtle and sophisticated attacks. For example, between 2015–2018 over 25 new CFI algorithms appeared in the top four applied security conferences alone. These new frameworks are generally evaluated and compared in terms of performance and security. Performance overhead is commonly evaluated in terms of the CPU benchmark suites (e.g., SPEC), and security is often assessed using the RIPE test suite [80] or with manually crafted proof-of-concept attacks (e.g., COOP [62]). For example, a recent survey systematically compared various CFI mechanisms against these metrics for precision, security, and performance [13].

While this attention to performance and security has stimulated rapid gains in the ability of CFI solutions to efficiently enforce powerful, precise security policies, less attention has been devoted to systematically examining which general classes of software can receive CFI protection without suffering compatibility problems. Historically, CFI research has struggled to bridge the gap between theory and practice (cf., [84]) because code hardening transformations inevitably run at least some risk of corrupting desired, policy-permitted program functionalities. For example, introspective programs that read their own code bytes at runtime (e.g., many VMs, JIT compilers, hot-patchers, and dynamic linkers) can break after their code bytes have been modified or relocated by CFI.

Compatibility issues of this sort have dangerous security ramifications if they prevent protection of software needed in mission-critical contexts, or if the protections must be weak-

\*These authors contributed equally to this work.

ened in order to achieve compatibility. For example, due in part to potential incompatibilities related to *return address introspection* (wherein some callees read return addresses as arguments) the three most widely deployed compiler-based CFI solutions (LLVM-CFI [69], GCC-VTV [69], and Microsoft Visual Studio MCFG [66]) all presently leave return addresses unprotected, potentially leaving code vulnerable to ROP attacks—the most prevalent form of code-reuse.

Understanding these compatibility limitations, including their impacts on real-world software performance and security, requires a new suite of CFI functional tests with substantially different characteristics than benchmarks typically used to assess compiler or hardware performance. In particular, CFI relevance and effectiveness is typically constrained by the nature and complexity of the target program’s *control-flow paths* and *control data dependencies*. Such complexities are not well represented by SPEC benchmarks, which are designed to exercise CPU computational units using only simple control-flow graphs, or by utility suites (e.g., GNU Coreutils) that were all written in a fairly homogeneous programming style for a limited set of compilers, and that use a very limited set of standard libraries chosen for exceptionally high cross-compatibility.

To better understand the compatibility and applicability limitations of modern CFI solutions on diverse, modern software products, and to identify the coding idioms and features that constitute the greatest barriers to more widespread CFI adoption, we present CONFIRM (CONtrol-Flow Integrity Relevance Metrics), a new suite of CFI tests designed to exhibit code features most relevant to CFI evaluation.<sup>1</sup> Each test is designed to exhibit one or more control-flow features that CFI solutions must guard in order to enforce integrity, that are found in a large number of commodity software products, but that pose potential problems for CFI implementations.

It is infeasible to capture in a single test set the full diversity of modern software, which embodies myriad coding styles, build processes (e.g., languages, compilers, optimizers, obfuscators, etc.), and quality levels. We therefore submit CONFIRM as an extensible baseline for testing CFI compatibility, consisting of code features drawn from experiences building and evaluating CFI and randomization systems for several architectures, including Linux, Windows, Intel x86/x64, and ARM32 in academia and industry [7, 33, 45, 47, 75, 77–79].

Our work is envisioned as having the following qualitative impacts: (1) CFI designers (e.g., compiler developers) can use CONFIRM to detect compatibility flaws in their designs that are currently hard to anticipate prior to full scale production. This can lower the currently steep barrier between prototype and distributable product. (2) Defenders (e.g., developers of secure software) can use CONFIRM to better evaluate code-reuse defenses, in order to avoid false senses of security. (3) The research community can use CONFIRM to

identify and prioritize missing protections as important open problems worthy of future investigation.

We used CONFIRM to reevaluate 12 publicly available CFI implementations published in the open literature. The results show that about 47% of solution-test pairs exhibit incompatible or insecure operation for code features needed to support mainstream software products, and a *cross-thread stack-smashing* attack defeats all tested CFI defenses. Microbenchmarking additionally reveals some performance/compatibility trade-offs not revealed by purely CPU-based benchmarking.

In summary, our contributions include the following:

- We present CONFIRM, the first testing suite designed specifically to test compatibility characteristics relevant to control-flow security hardening evaluation.
- A set of 20 code features and coding idioms are identified, that are widely found in deployed, commodity software products, and that pose compatibility, performance, or security challenges for modern CFI solutions.
- Evaluation of 12 CFI implementations using CONFIRM reveals that existing CFI implementations are compatible with only about half of code features and coding idioms needed for broad compatibility, and that microbenchmarking using CONFIRM reveals performance trade-offs not exhibited by SPEC benchmarks.
- Discussion and analysis of these results highlights significant unsolved obstacles to realizing CFI protections for widely deployed, mainstream, commodity products.

Section 2 begins with a summary of technical CFI attack and defense details important for understanding the evaluation approach. Section 3 next presents CONFIRM’s evaluation metrics in detail, including a rationale behind why each metric was chosen, and how it impacts potential defense solutions; and Section 4 describes implementation of the resulting tests. Section 5 reports our evaluation of CFI solutions using CONFIRM and discusses significant findings. Finally, Section 6 describes related work and Section 7 concludes.

## 2 Background

CFI defenses first emerged from an arms race against early code-injection attacks, which exploit memory corruptions to inject and execute malicious code. To thwart these malicious code-injections, hardware and OS developers introduced Data Execution Prevention (DEP), which blocks execution of injected code. Adversaries proceeded to bypass DEP with “return-to-libc” attacks, which redirect control to existing, abusable code fragments (often in the C standard libraries) without introducing attacker-supplied code. In response, defenders introduced Address Space Layout Randomization (ASLR), which randomizes code layout to frustrate its abuse. DEP and ASLR motivated adversaries to craft even

<sup>1</sup><https://github.com/SoftwareLanguagesSecurityLab/ConFIRM>

more elaborate attacks, including ROP and Jump-Oriented Programming (JOP) [11], which locate, chain, and execute short instruction sequences (gadgets) of benign code to implement malicious payloads.

CFI emerged as a more comprehensive and principled defense against this malicious code-reuse. Most realizations consist of two main phases: (1) A program-specific *control-flow policy* is first formalized as a (possibly dynamic) control-flow graph (CFG) that whitelists the code's permissible control-flow transfers. (2) To constrain all control flows to the CFG, the program code is instrumented with guard code at all computed (e.g., indirect) control-flow transfer sites. The guard code decides at runtime whether each impending transfer satisfies the policy, and blocks it if not. The guards are designed to be uncircumventable by confronting attackers with a chicken-and-egg problem: To circumvent a guard, an attack must first hijack a control transfer; but since all control transfers are guarded, hijacking a control transfer requires first circumventing a guard.

Both CFI phases can be source-aware (implemented as a source-to-source transformation, or introduced during compilation), or source-free (implemented as a binary-to-binary transformation). Source-aware solutions typically benefit from source-level information to derive more precise policies, and can often perform more optimization to achieve better performance. Examples include WIT [5], NaCl [81], CFL [11], MIP [48], MCFI [49], RockJIT [50], Forward CFI [69], CCFI [42],  $\pi$ CFI [51], MCFG [66] CFIXX [14] and  $\mu$ CFI [35]. In contrast, source-free solutions are potentially applicable to a wider domain of software products (e.g., closed-source), and have a more flexible deployment model (e.g., consumer-side enforcement without developer assistance). These include XFI [26], Reins [78], STIR [77], CCFIR [84], bin-CFI [87], BinCC [74], Lockdown [54], TypeArmor [72], OCFI [45], OFI [75] and  $\tau$ CFI [47].

The advent of CFI is a significant step forward for defenders, but was not the end of the arms race. In particular, each CFI phase introduces potential loopholes for attackers to exploit. First, it is not always clear which policy should be enforced to fully protect the code. Production software often includes complex control-flow structures, such as those introduced by object-oriented programming (OOP) idioms, from which it is difficult (even undecidable) to derive a CFG that precisely captures the policy desired by human developers and users. Second, the instrumentation phase must take care not to introduce guard code whose decision procedures constitute unacceptably slow runtime computations [34]. This often results in an enforcement that imprecisely approximates the policy. Attackers have taken advantage of these loopholes with ever more sophisticated attacks, including Counterfeit Object Oriented Programming (COOP) [62], Control Jujutsu [28], and Control-Flow Bending [15].

These weaknesses and threats have inspired an array of new and improved CFI algorithms and supporting technologies in

recent years. For example, to address loopholes associated with OOP, *vtable protections* prevent or detect virtual method table corruption at or before control-flow transfers that depend on method pointers. Source-aware vtable protections include GNU VTV [68], CPI [40], SAFEDISPATCH [37], Readactor++ [19], and VTrust [82]; whereas source-free instantiations include T-VIP [29], VTint [83], and VfGuard [58].

However, while the security and performance trade-offs of various CFI solutions have remained actively tracked and studied by defenders throughout the arms race, attackers are increasingly taking advantage of CFI compatibility limitations to exploit unprotected software, thereby avoiding CFI defenses entirely. For example, 88% of CFI defenses cited herein have only been realized for Linux software, but over 95% of desktops worldwide are non-Linux.<sup>2</sup> These include many mission-critical systems, including over 75% of control systems in the U.S. [39], and storage repositories for top secret military data [53]. None of the top 10 vulnerabilities exploited by cybercriminals in 2017 target Linux software [25].

While there is a hope that small-scale prototyping will result in principles and approaches that eventually scale to more architectures and larger software products, follow-on works that attempt to bridge this gap routinely face significant unforeseen roadblocks. We believe many of these obstacles remain unforeseen because of the difficulty of isolating and studying many of the problematic software features lurking within large, commodity products, which are not well represented in open-source codes commonly available for study by researchers during prototyping.

The goal of this research is therefore to describe and analyze a significant collection of code features that are routinely found in large software products, but that pose challenges to effective CFI enforcement; and to make available a suite of CFI test programs that exhibit each of these features on a small scale amenable to prototype development. The next section discusses this feature set in detail.

### 3 Compatibility Metrics

To measure compatibility of CFI mechanisms, we propose a set of metrics that each includes one or more code features from either C/C++ source code or compiled assembly code. We derived this feature set by attempting to apply many CFI solutions to large software products, then manually testing the functionalities of the resulting hardened software for correctness, and finally debugging each broken functionality step-wise at the assembly level to determine what caused the hardened code to fail. Since many failures manifest as subtle forms of register or memory corruption that only cause the program to crash or malfunction long after the failed operation completes, this debugging constitutes many hundreds

Table 1: CONFIRM compatibility metrics

| Compatibility metric        | Real-world software examples                                                                                                                                                                           |
|-----------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Function Pointers           | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, Skype, TeXstudio, UPX, Visual Studio, Windows Defender, WinSCP |
| Callbacks                   | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, TeXstudio, Visual Studio, Windows Defender, WinSCP             |
| Dynamic Linking             | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, Skype, TeXstudio, UPX, Visual Studio, Windows Defender, WinSCP |
| Delay-Loading               | Adobe Reader, Calculator, Chrome, Firefox, JVM, MS Paint, MS PowerPoint, PotPlayer, Visual Studio, WinSCP                                                                                              |
| Exporting/Importing Data    | 7-Zip, Apache, Calculator, Chrome, Dropbox, Firefox, MS Paint, MS PowerPoint, PowerShell, TeXstudio, UPX, Visual Studio                                                                                |
| Virtual Functions           | 7-Zip, Adobe Reader, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, TeXstudio, Visual Studio, Windows Defender, WinSCP                     |
| CODE-COOP Attack            | Programs built on GTK+ or Microsoft COM can pass objects to trusted modules as arguments.                                                                                                              |
| Tail Calls                  | Mainstream compilers provide options for tail call optimization. e.g. /O2 in MSVC, -O2 in GCC, and -O2 in LLVM.                                                                                        |
| Switch-Case Statements      | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, MS Paint, MS PowerPoint, PotPlayer, PuTTY, TeXstudio, Visual Studio, WinSCP                                                    |
| Returns                     | Every benign program has returns.                                                                                                                                                                      |
| Unmatched Call/Return Pairs | Adobe Reader, Apache, Chrome, Firefox, JVM, MS PowerPoint, Visual Studio                                                                                                                               |
| Exceptions                  | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, Skype, TeXstudio, Visual Studio, Windows Defender, WinSCP               |
| Calling Conventions         | Every program adopts one or more calling convention.                                                                                                                                                   |
| Multithreading              | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, Skype, TeXstudio, UPX, Visual Studio, Windows Defender, WinSCP |
| TLS Callbacks               | Adobe Reader, Chrome, Firefox, MS Paint, TeXstudio, UPX                                                                                                                                                |
| Position-Independent Code   | 7-Zip, Adobe Reader, Apache, Calculator, Chrome, Dropbox, Firefox, JVM, Notepad, MS Paint, MS PowerPoint, PotPlayer, PowerShell, PuTTY, Skype, TeXstudio, UPX, Visual Studio, Windows Defender, WinSCP |
| Memory Protection           | 7-Zip, Adobe Reader, Apache, Chrome, Dropbox, Firefox, MS PowerPoint, PotPlayer, TeXstudio, Visual Studio, Windows Defender, WinSCP                                                                    |
| JIT Compiler                | Adobe Flash, Chrome, Dropbox, Firefox, JVM, MS PowerPoint, PotPlayer, PowerShell, Skype, Visual Studio, WinSCP                                                                                         |
| Self-Unpacking              | Programs decompressed by self-extractors (e.g., UPX, NSIS).                                                                                                                                            |
| Windows API Hooking         | Microsoft Office family software, including MS Excel, MS PowerPoint, MS PowerPoint, etc.                                                                                                               |

Table 2: Source code compiled to indirect call

| Source code              | Assembly code         |
|--------------------------|-----------------------|
| 1 void foo() { return; } |                       |
| 2 void bar() { return; } |                       |
| 3 void main() {          |                       |
| 4 void (*fptr)();        | 1 ...                 |
| 5 int n = input();       | 2 call _input         |
| 6 if (n)                 | 3 test eax, eax       |
| 7 fptr = foo;            | 4 mov edx, offset_foo |
| 8 else                   | 5 mov ecx, offset_bar |
| 9 fptr = bar;            | 6 cmovnz ecx, edx     |
| 10 fptr();               | 7 call ecx            |
| 11 }                     | 8 ...                 |

of person-hours amassed over several years of development experience involving CFI-protected software.

Table 1 presents the resulting list of code features organized into one row for each root cause of failure. Column two additionally lists some widely available, commodity software products where each of these features can be observed in non-malicious software in the wild. This demonstrates that each feature is representative of real-world software functionalities that must be preserved by CFI implementations in order for their protections to be usable and relevant in contexts that deploy these and similar products.

### 3.1 Indirect Branches

We first discuss compatibility metrics related to the code feature of greatest relevance to most CFI works: indirect branches. Indirect branches are control-flow transfers whose destination addresses are computed at runtime—via pointer arithmetic and/or memory-reads. Such transfers tend to be of high interest to attackers, since computed destinations are more prone to manipulation. CFI defenses therefore guard indirect branches to ensure that they target permissible destinations at runtime. Indirect branches are commonly categorized into three classes: indirect calls, indirect jumps, and returns.

Table 2 shows a simple example of source code being compiled to an indirect call. The function called at source line 5 depends on user input. This prevents the compiler from generating a direct branch that targets a fixed memory address at compile time. Instead, the compiler generates a register-indirect call (assembly line 7) whose target is computed at runtime. While this is one common example of how indirect branches arise, in practice they are a result of many different programming idioms, discussed below.

**Function Pointers.** Calls through function pointers typically compile to indirect calls. For example, using gcc with the -O2 option generates register-indirect calls for function pointers, and MSVC does so by default.

**Callbacks.** Event-driven programs frequently pass function pointers to external modules or the OS, which the receiving code later dereferences and calls in response to an event. These callback pointers are generally implemented by using function pointers in C, or as method references in C++. Callbacks can pose special problems for CFI, since the call site is not within the module that generated the pointer. If the call site is within a module that cannot easily be modified (e.g., the OS kernel), it must be protected in some other way, such as by sanitizing and securing the pointer before it is passed.

**Dynamic Linking.** Dynamically linked shared libraries reduce program size and improve locality. But dynamic linking has been a challenge for CFI compatibility because CFG edges that span modules may be unavailable statically.

In Windows, *dynamically linked libraries* (DLLs) can be loaded into memory at load time or runtime. In load-time dynamic linking, a function call from a module to an exported DLL function is usually compiled to a memory-indirect call targeting an address stored in the module's *import address table* (IAT). But if this function is called more than once, the compiler first moves the target address to a register, and then generates register-indirect calls to improve execution performance. In run-time dynamic linking, a module calls APIs, such as `LoadLibrary()`, to load the DLL at runtime. When loaded into memory, the module calls the `GetProcAddress()` API to retrieve the address of the exported function, and then calls the exported function using the function pointer returned by `GetProcAddress()`.

Additionally, MSVC (since version 6.0) provides linker support for delay-loaded DLLs using the `/DELAYLOAD` linker option. These DLLs are not loaded into memory until one of their exported functions is invoked.

In Linux, a module calls functions exported by a shared library by calling a stub in its *procedure linkage table* (PLT). Each stub contains a memory-indirect jump whose target depends on the writable, lazy-bound *global offset table* (GOT). As in Windows, an application can also load a module at runtime using function `dlopen()`, and retrieve an exported symbol using function `dlsym()`.

Supporting dynamic and delay-load linkage is further complicated by the fact that shared libraries can also export data pointers within their export tables in both Linux and Windows. CFI solutions that modify export tables must usually treat code and data pointers differently, and must therefore somehow distinguish the two types to avoid data corruptions.

**Virtual Functions.** Polymorphism is a key feature of OOP languages, such as C++. Virtual functions are used to support runtime polymorphism, and are implemented by C++ compilers using a form of late binding embodied as *virtual tables* (vtables). The tables are populated by code pointers to virtual function bodies. When an object calls a virtual function, it indexes its vtable by a function-specific constant, and flows control to the memory address read from the table.

At the assembly level, this manifests as a memory-indirect call. The ubiquity and complexity of this process has made vtable hijacking a favorite exploit strategy of attackers.

Some CFI and vtable protections address vtable hijacking threats by guarding call sites that read vtables, thereby detecting potential vtable corruption at time-of-use. Others seek to protect vtable integrity directly by guarding writes to them. However, both strategies are potentially susceptible to COOP [62] and CODE-COOP [75] attacks, which replace one vtable with another that is legal but is not the one the original code intended to call. The defense problem is further complicated by the fact that many large classes of software (e.g., GTK+ and Microsoft COM) rely upon dynamically generated vtables. CFI solutions that write-protect vtables or whose guards check against a static list of permitted vtables are incompatible with such software.

**Tail Calls.** Modern C/C++ compilers can optimize tail-calls by replacing them with jumps. Row 8 of Table 1 lists relevant compiler options. With these options, callees can return directly to ancestors of their callers in the call graph, rather than to their callers. These mismatched call/return pairs affect precision of some CFG recovery algorithms.

**Switch-case Statements.** Many C/C++ compilers optimize switch-case statements via a static dispatch table populated with pointers to case-blocks. When the switch is executed, it calculates a dispatch table index, fetches the indexed code pointer, and jumps to the correct case-block. This introduces memory-indirect jumps that refer to code pointers not contained in any vtable, and that do not point to function boundaries. CFI solutions that compare code pointers to a whitelist of function boundaries can therefore cause the switch-case code to malfunction. Solutions that permit unrestricted indirect jumps within each local function risk unsafety, since large functions can contain abusable gadgets.

**Returns.** Nearly every benign program has returns. Unlike indirect branches whose target addresses are stored in registers or non-writable data sections, return instructions read their destination addresses from the stack. Since stacks are typically writable, this makes return addresses prime targets for malicious corruption.

On Intel-based CISC architectures, return instructions have one of the shortest encodings (1 byte), complicating the efforts of source-free solutions to replace them in-line with secured equivalent instruction sequences. Additionally, many hardware architectures heavily optimize the behavior of returns (e.g., via speculative execution powered by shadow stacks for call/return matching). Source-aware CFI solutions that replace returns with some other instruction sequence can therefore face stiff performance penalties by losing these optimization advantages.

**Unmatched call/return Pairs.** Control-flow transfer mechanisms, including exceptions and `setjmp/longjmp`, can yield flows in which the relation between executed call instructions

and executed return instructions is not one-to-one. For example, exception-handling implementations often pop stack frames from multiple calls, followed by a single return to the parent of the popped call chain. Shadow stack defenses that are implemented based on traditional call/return matching may be incompatible with such mechanisms.

## 3.2 Other Metrics

While indirect branches tend to be the primary code feature of interest to CFI attacks and defenses, there are many other code features that can also pose control-flow security problems, or that can become inadvertently corrupted by CFI code transformation algorithms, and that therefore pose compatibility limitations. Some important examples are discussed below.

**Multithreading.** With the rise of multicore hardware, multithreading has become a centerpiece of software efficiency. Unfortunately, concurrent code execution poses some serious safety problems for many CFI algorithms.

For example, in order to take advantage of hardware call-return optimization (see §3.1), most CFI algorithms produce code containing guarded return instructions. The guards check the return address before executing the return. However, on parallelized architectures with flat memory spaces, this is unsafe because any thread can potentially write to any other (concurrently executing) thread's return address at any time. This introduces a TOCTOU vulnerability in which an attacker-manipulated thread corrupts a victim thread's return address after the victim thread's guard code has checked it but before the guarded return executes. We term this a cross-thread stack-smashing attack. Since nearly all modern architectures combine concurrency, flat memory spaces, and returns, this leaves almost all CFI solutions either inapplicable, unsafe, or unacceptably inefficient for a large percentage of modern production software.

**Position-Independent Code.** *Position-independent code* (PIC) is designed to be relocatable after it is statically generated, and is a standard practice in the creation of shared libraries. Unfortunately, the mechanisms that implement PIC often prove brittle to code transformations commonly employed for source-free CFI enforcement. For example, PIC often achieves its position independence by dynamically computing its own virtual memory address (e.g., by performing a call to itself and reading the pushed return address from the stack), and then performing pointer arithmetic to locate other code or data at fixed offsets relative to itself. This procedure assumes that the relative positions of PIC code and data are invariant even if the base address of the PIC block changes.

However, CFI transforms typically violate this assumption by introducing guard code that changes the sizes of code blocks, and therefore their relative positions. To solve this, PIC-compatible CFI solutions must detect the introspection and pointer arithmetic operations that implement PIC and

adjust them to compute corrected pointer values. Since there are typically an unlimited number of ways to perform these computations at both the source and native code levels, CFI detection of these computations is inevitably heuristic, allowing some PIC instantiations to malfunction.

**Exceptions.** Exception raising and handling is a mainstay of modern software design, but introduces control-flow patterns that can be problematic for CFI policy inference and enforcement. Object-oriented languages, such as C++, boast first-class exception machinery, whereas standard C programs typically realize exceptional control-flows with `gotos`, `longjumps`, and signals. In Linux, compilers (e.g., `gcc`) implement C++ exception handling in a table-driven approach. The compiler statically generates read-only tables that hold exception-handling information. For instance, `gcc` produces a `gcc_except_table` comprised of *language-specific data areas* (LSDAs). Each LSDA contains various exception-related information, including pointers to exception handlers.

In Windows, *structured exception handling* (SEH) extends the standard C language with first-class support for both hardware and software exceptions. SEH uses stack-based exception nodes, wherein exception handlers form a linked list on the stack, and the list head is stored in the *thread information block* (TIB). Whenever an exception occurs, the OS fetches the list head and walks through the SEH list to find a suitable handler for the thrown exception. Without proper protection, these exception handlers on the stack can potentially be overwritten by an attacker. By triggering an exception, the attacker can then redirect the control-flow to arbitrary code. CFI protection against these SEH attacks is complicated by the fact that code outside the vulnerable module (e.g., in the OS and/or system libraries) uses pointer arithmetic to fetch, decode, and call these pointers during exception handling. Thus, suitable protections must typically span multiple modules, and perhaps the OS kernel.

From Windows XP onward, applications have additionally leveraged *vectored exception handling* (VEH). Unlike SEH, VEH is not stack-based; applications register a global handler chain for VEH exceptions with the OS, and these handlers are invoked by the OS by interrupting the application's current execution, no matter where the exception occurs within a frame.

There are at least two features of VEH that are potentially exploitable by attackers. First, to register a vectored exception handler, the application calls an API `AddVectoredExceptionHandler()` that accepts a callback function pointer parameter that points to the handler code. Securing this pointer requires some form of inter-module callback protection.

Second, the VEH handler-chain data structure is stored in the application's writable heap memory, making the handler chain data directly susceptible to data corruption attacks. Windows protects the handlers somewhat by obfuscating them using the `EncodePointer()` API. However, `EncodePointer()` does not implement a cryptographically secure function (since doing so would impose high overhead);

it typically returns the XOR of the input pointer with a process-specific secret. This secret is not protected against memory disclosure attacks; it is potentially derivable from disclosure of any encoded pointer with value known to the attacker (since XOR is invertible), and it is stored in the *process environment block* (PEB), which is readable by the process and therefore by an attacker armed with an information disclosure exploit. With this secret, the attacker can overwrite the heap with a properly obfuscated malicious pointer, and thereby take control of the application.

From a compatibility perspective, CFI protections that do not include first-class support for these various exception-handling mechanisms often conservatively block unusual control-flows associated with exceptions. This can break important application functionalities, making the protections unusable for large classes of software that use exceptions.

**Calling Conventions.** CFI guard code typically instruments call and return sites in the target program. In order to preserve the original program's functionality, this guard code must therefore respect the various calling conventions that might be implemented by calls and returns. Unfortunately, many solutions to this problem make simplifying assumptions about the potential diversity of calling conventions in order to achieve acceptable performance. For example, a CFI solution whose guard code uses EDX as a scratch register might suddenly fail when applied to code whose calling convention passes arguments in EDX. Adapting the solution to save and restore EDX to support the new calling convention can lead to tens of additional instructions per call, including additional memory accesses, and therefore much higher overhead.

The C standard calling convention (`cdecl`) is caller-pop, pushes arguments right-to-left onto the stack, and returns primitive values in an architecture-specific register (EAX on Intel). Each architecture also specifies a set of caller-save and callee-save registers. Caller-popped calling conventions are important for implementing variadic functions, since callees can remain unaware of argument list lengths.

Callee-popped conventions include `stdcall`, which is the standard convention of the Win32 API, and `fastcall`, which passes the first two arguments via registers rather than the stack to improve execution speed. In OOP languages, every nonstatic member function has a hidden *this pointer* argument that points to the current object. The `thiscall` convention passes the *this pointer* in a register (ECX on Intel).

Calling conventions on 64-bit architectures implement several refinements of the 32-bit conventions. Linux and Windows pass up to 14 and 4 parameters, respectively, in registers rather than on the stack. To allow callees to optionally spill these parameters, the caller additionally reserves a *red zone* (Linux) or 32-byte *shadow space* (Windows) for callee temporary storage.

Highly optimized programs also occasionally adopt non-standard, undocumented calling conventions, or even blur function boundaries entirely (e.g., by performing various

forms of function in-lining). For example, some C compilers support language extensions (e.g., MSVC's *naked* declaration) that yield binary functions with no prologue or epilogue code, and therefore no standard calling convention. Such code can have subtle dependencies on non-register processor elements, such as requiring that certain Intel status flags be preserved across calls. Many CFI solutions break such code by in-lining call site guards that violate these undocumented conventions.

**TLS Callbacks.** Multithreaded programs require efficient means to manipulate thread-local data without expensive locking. Using *thread local storage* (TLS), applications export one or more TLS callback functions that are invoked by the OS for thread initialization or termination. These functions form a null-terminated table whose base is stored in the PE header. For compiler-based CFI solutions, the TLS callback functions do not usually need extra protection, since both the PE header and the TLS callback table are in unwritable memory. But source-free solutions must ensure that TLS callbacks constitute policy-permitted control-flows at runtime.

**Memory Protection.** Modern OSes provide APIs for memory page allocation (e.g., `VirtualAlloc` and `mmap`) and permission changes (e.g., `VirtualProtect` and `mprotect`). However, memory pages changed from writable to executable, or to simultaneously writable and executable, can potentially be abused by attackers to bypass DEP defenses and execute attacker-injected code. Many software applications nevertheless rely upon these APIs for legitimate purposes (see Table 1), so conservatively disallowing access to them introduces many compatibility problems. Relevant CFI mechanisms must therefore carefully enforce memory access policies that permit virtual memory management but block code-injection attacks.

**Runtime Code Generation.** Most CFI algorithms achieve acceptable overheads by performing code generation strictly statically. The statically generated code includes fixed runtime guards that perform small, optimized computations to validate dynamic control-flows. However, this strategy breaks down when target programs generate new code dynamically and attempt to execute it, since the generated code might not include CFI guards. *Runtime code generation* (RCG) is therefore conservatively disallowed by most CFI solutions, with the expectation that RCG is only common in a few, specialized application domains, which can receive specialized protections.

Unfortunately, our analysis of commodity software products indicates that RCG is becoming more prevalent than is commonly recognized. In general, we encountered RCG compatibility limitations in at least three main forms across a variety of COTS products:

1. Although typically associated with web browsers, *just-in-time* (JIT) compilation has become increasingly relevant as an optimization strategy for many languages,

including Python, Java, the Microsoft .NET family of languages (e.g., C#), and Ruby. Software containing any component or module written in any JIT-compiled language frequently cannot be protected with CFI.

2. Mobile code is increasingly space-optimized for quick transport across networks. *Self-unpacking executables* are therefore a widespread source of RCG. At runtime, self-unpacking executables first decompress archived data sections to code, and then map the code into writable and executable memory. This entails a dynamic creation of fresh code bytes. Large, component-driven programs sometimes store rarely used components as self-unpacking code that decompresses into memory whenever needed, and is deallocated after use. For example, NSIS installers pack separate modules supporting different install configurations, and unpack them at runtime as-needed for reduced size. Antivirus defenses hence struggle to distinguish benign NSIS installers from malicious ones [21].
3. Component-driven software also often performs a variety of obscure *API hooking* initializations during component loading and clean-up, which are implemented using RCG. As an example, Microsoft Office software dynamically redirects all calls to certain system API functions within its address space to dynamically generated wrapper functions. This allows it to modify the behaviors of late-loaded components without having to recompile them all each time the main application is updated.

To hook a function  $f$  within an imported system DLL (e.g., `ntdll.dll`), it first allocates a fresh memory page  $f'$  and sets it both writable and executable. It next copies the first five code bytes from  $f$  to  $f'$ , and writes an instruction at  $f' + 5$  that jumps to  $f + 5$ . Finally, it changes  $f$  to be writable and executable, and overwrites the first five code bytes of  $f$  with an instruction that jumps to  $f'$ . All subsequent calls to  $f$  are thereby redirected to  $f'$ , where new functionality can later be added dynamically before  $f'$  jumps to the preserved portion of  $f$ .

Such hooking introduces many dangers that are difficult for CFI protections to secure without breaking the application or its components. Memory pages that are simultaneously writable and executable are susceptible to code-injection attacks, as described previously. The RCG that implements the hooks includes unprotected jumps, which must be secured by CFI guard code. However, the guard code itself must be designed to be rewritable by more hooking, including placing instruction boundaries at addresses expected by the hooking code ( $f + 5$  in the above example). No known CFI algorithm can presently handle these complexities.

### 3.3 Compositional Defense Evaluation

Some CFI solutions compose CFI controls with other defense layers, such as randomization-based defenses (e.g., [8, 9, 18, 45, 52, 77]). Randomization defenses can be susceptible to other forms of attack, such as memory disclosure attacks (e.g., [27, 63–65]). CONFIRM does not test such attacks, since their implementations are usually specific to each defense and not easy to generalize.

Evaluation of composed defenses should therefore be conducted by composing other attacks with CONFIRM tests. For example, to test a CFI defense composed with stack canaries, one should first simulate attacks that attempt to steal the canary secret, and then modify any stack-smashing CONFIRM tests to use the stolen secret. Incompatibilities of the evaluated defense generally consist of the union of the incompatibilities of the composed defenses.

## 4 Implementation

To facilitate easier evaluation of the compatibility considerations outlined in Section 3 along with their impact on security and performance, we developed the CONFIRM suite of CFI tests. CONFIRM consists of 24 programs written in C++ totalling about 2,300 lines of code. Each test isolates one of the compatibility metrics of Section 3 (or in some cases a few closely related metrics) by emulating behaviors of COTS software products. Source-aware solutions can be evaluated by applying CFI code transforms to the source codes, whereas source-free solutions can be applied to native code after compilation with a compatible compiler (e.g., gcc, LLVM, or MSVC). Loop iteration counts are configurable, allowing some tests to be used as microbenchmarks. The tests are described as follows:

**fptr.** This tests whether function calls through function pointers are suitably guarded or can be hijacked. Overhead is measured by calling a function through a function pointer in an intensive loop.

**callback.** As discussed in Section 3, call sites of callback functions can be either guarded by a CFI mechanism directly, or located in immutable kernel modules that require some form of indirect control-flow protections. We therefore test whether a CFI mechanism can secure callback function calls in both cases. Overhead is measured by calling a function that takes a callback pointer parameter in an intensive loop.

**load\_time\_dynlnk.** Load-time dynamic linking tests determine whether function calls to symbols that are exported by a dynamically linked library are suitably protected. Overhead is measured by calling a function that is exported by a dynamically linked library in an intensive loop.

**run\_time\_dynlnk.** This tests whether a CFI mechanism supports runtime dynamic linking, whether it supports retrieving symbols from the dynamically linked library at runtime,

and whether it guards function calls to the retrieved symbol. Overhead is measured by loading a dynamically linked library at runtime, calling a function exported by the library, and unloading the library in an intensive loop.

**delay\_load** (*Windows only*). CFI compatibility with delay-loaded DLLs is tested, including whether function calls to symbols that are exported by the delay-loaded DLLs are protected. Overhead is measured by calling a function that is exported by a delay-loaded DLL in an intensive loop.

**data\_syml.** Data and function symbol imports and exports are tested, to determine whether any controls preserve their accessibility and operation.

**vtbl\_call.** Virtual function calls are exercised, whose call sites can be directly instrumented. Overhead is measured by calling virtual functions in an intensive loop.

**code\_coop.** This tests whether a CFI mechanism is robust against CODE-COOP attacks. For the object-oriented interfaces required to launch a CODE-COOP attack, we choose Microsoft COM API functions in Windows, and gtkmm API calls that are part of the C++ interface for GTK+ in Linux.

**tail\_call.** Tail call optimizations of indirect jumps are tested. Overhead is measured by tail-calling a function in a loop.

**switch.** Indirect jumps associated with switch-case control-flow structures are tested, including their supporting data structures. Overhead is measured by executing a switch-case statement in an intensive loop.

**ret.** Validation of return addresses (e.g., dynamically via shadow stack implementation, or statically by labeling call sites and callees with equivalence classes) is tested. Overhead is measured by calling a function that does nothing but return in an intensive loop.

**unmatched\_pair.** Unmatched call/return pairs resulting from exceptions and setjmp/longjmp are tested.

**signal.** This test uses signal-handling in C to implement error-handling and exceptional control-flows.

**cppeh.** C++ exception handling structures and control-flows are exercised.

**seh** (*Windows only*). SEH-style exception handling is tested for both hardware and software exceptions. This test also checks whether the CFI mechanism protects the exception handlers stored on the stack.

**veh** (*Windows only*). VEH-style exception handling is tested for both hardware and software exceptions. This test also checks whether the CFI mechanism protects callback function pointers passed to `AddVecoredExceptionHandler()`.

**convention.** Several different calling conventions are tested, including conventions widely used in C/C++ languages on 32-bit and 64-bit x86 processors.

**multithreading.** Safety of concurrent thread executions is tested. Specifically, one thread simulates a memory corrup-

tion exploit that attempts to smash another thread's stack and break out of the CFI-enforced sandbox.

**tls\_callback** (*Windows source-free only*). This tests whether static TLS callback table corruption is detected and blocked by the protection mechanism.

**pic.** Semantic preservation of position-independent code is tested.

**mem.** This test performs memory management API calls for legitimate and malicious purposes, and tests whether security controls permit the former but block the latter.

**jit.** This test generates JIT code by first allocating writable memory pages, writing JIT code into those pages, making the pages executable, and then running the JIT code. To emulate behaviors of real-world JIT compilers, the JIT code performs different types of control-flow transfers, including calling back to the code of JIT compiler and calling functions located in other modules.

**api\_hook** (*Windows only*). Dynamic API hooking is performed in the style described in Section 3.

**unpacking** (*source-free only*). Self-unpacking executable code is implemented using RCG.

## 5 Evaluation

### 5.1 Evaluation of CFI Solutions

To examine CONFIRM's effect on real CFI defenses, we used it to reevaluate 12 major CFI implementations for Linux and Windows that are either publicly available or were obtainable in a self-contained, operational form from their authors at the time of writing. Our purpose in performing this evaluation is not to judge which compatibility features solutions should be expected to support, but merely to accurately document which features are currently supported and to what degree, and to demonstrate that CONFIRM can be used to conduct such evaluations.

Table 3 reports the evaluation results. Columns 2–6 report results for Windows CFI approaches, and columns 7–14 report those for Linux CFI. All Windows experiments were performed on an Intel Xeon E5645 workstation with 24 GB of RAM running 64-bit Windows 10. Linux experiments were conducted on different versions of Ubuntu VM machines corresponding to the version tested by each CFI framework's original developers. All the VM machines had 16GB of RAM with 6 Intel Xeon CPU cores. The overheads for source-free approaches were evaluated using test binaries compiled with most recent version of gcc available for each test platform. All source-aware approaches were applied before or during compilation with the most recent version of LLVM for each test platform (since LLVM provides greatest compatibility between the tested source-aware solutions).

Table 3: Tested results for CFI solutions on CONFIRM

| Test                        | LLVM (Windows) |             |        |         | LLVM (Linux) |         |        |             |         |           |                 | Lockdown  |           |
|-----------------------------|----------------|-------------|--------|---------|--------------|---------|--------|-------------|---------|-----------|-----------------|-----------|-----------|
|                             | CFI            | ShadowStack | MCFG   | OFI     | Reins        | GCC-VTV | CFI    | ShadowStack | MCFI    | $\pi$ CFI | $\pi$ CFI (nto) |           | PathArmor |
| fptr                        | 6.35%          | △           | 20.13% | 4.35%   | 4.08%        | △       | 6.97%  | △           | X       | -14.00%   | -13.79%         | △         | 174.92%   |

(nto) stands for *no tail-call optimization*

%: CFI defense passes compatibility and security test, and microbenchmark yields indicated performance overhead

✓: same as %, but this test provides no performance number

△: CFI defense passes compatibility but not security check

X: test does not compile (compilation error), or crashes at runtime

N/A: test is not applicable to the CFI mechanism being tested

⊠: test is Windows-only

\$: test is only for source-free defenses

Two forms of compatibility are assessed in the evaluation: A CFI solution is categorized as *permissively compatible* with a test if it produces an output program that does not crash and exhibits the original test program’s non-malicious functionality. It is *effectively compatible* if it is permissively compatible and any malicious functionalities are blocked. Effective compatibility therefore indicates secure and transparent support for the code features exhibited by the test.

In Table 3, Columns 2–3 begin with an evaluation of LLVM CFI and LLVM ShadowCallStack on Windows. With both CFI and ShadowCallStack enabled, LLVM on Windows enforces policies that constrain impending control-flow transfers at every call site, except calls to functions that are exported by runtime-loaded DLLs. Additionally, LLVM on Windows does not secure callback pointers passed to external modules not compiled with LLVM, leaving it vulnerable CODE-COOP attacks. Although ShadowCallStack protects against return address overwrites, its shadow stack is incompatible with unmatched call/return pairs.

Column 4 of Table 3 reports evaluation of Microsoft’s MCFG, which is integrated into the MSVC compiler. MCFG provides security checks for function pointer calls, vtable calls, tail calls, and switch-case statements. It also passes all tests related to dynamic linking, including `load_time_dynlnk`, `run_time_dynlnk`, `delay_load`, and `data_syml`. As a part of MSVC, MCFG provides transparency for generating position-independent code and handling various calling conventions. With respect to exception handling, MCFG is permissively compatible with all relevant features, but does not protect vectored exception handlers. MCFG’s most significant shortcoming is its weak protection of return addresses. In addition, it generates call site guard code at compile-time only. Therefore, code that links to immutable modules or modules compiled with a different protection scheme remains potentially insecure. This results in failures against callback corruption and CODE-COOP attacks.

Columns 5–6 of Table 3 report compatibility testing results for Reins and OFI, which are source-free solutions for Windows. Reins validates control-flow transfer targets for function pointer calls, vtable calls, tail calls, switch-case statements, and returns. It supports dynamic linking at load time and runtime, and is one of the only solutions we tested that secures callback functions whose call sites cannot be directly instrumented (with a high overhead of 114.84%). Like MCFG, Reins fails against CODE-COOP attacks. However, OFI extends Reins with additional protections that succeed against CODE-COOP. OFI also exhibits improved compatibility with delay-loaded DLLs, data exports, all three styles of exception handling, all tested calling conventions, and TLS callbacks. Both Reins and OFI nevertheless proved vulnerable against attacks that abuse position-independent code and memory management API functions.

The GNU C-compiler does not yet have built-in CFI support, but includes *virtual table verification* (VTV). VTV is

first introduced in gcc 4.9.0. It checks at virtual call sites whether the vtable pointer is valid based on the object type. This blocks many important OOP vtable corruption attacks, although type-aware COOP attacks can still succeed by calling a different virtual function of the same type (e.g., supertype). As shown in column 7 of Table 3, VTV does not protect other types of control-flow transfers, including function pointers, callbacks, dynamic linking for both load-time and run-time, tail calls, switch-case jumps, return addresses, error handling control-flows, or JIT code. However, it is permissively compatible with all the applicable tests, and can compile any feature functionality we considered.

As reported in Columns 8–9, LLVM on Linux shows similar evaluation results as LLVM on Windows. It has better effective compatibility by providing proper security checks for calls to functions that are exported by runtime loaded DLLs. LLVM on Linux overheads range from -6.93% (for switch control structures) to 20.88% (for protecting returns).

MCFI and  $\pi$ CFI are source-aware control-flow techniques. We tested them on x64 Ubuntu 14.04.5 with LLVM 3.5. The results are shown in columns 10–12 of Table 3.  $\pi$ CFI comes with an option to turn off tail call optimization, which increases the precision at the price of a small overhead increase. We therefore tested both configurations, observing no compatibility differences between  $\pi$ CFI with and without tail call optimizations. Incompatibilities were observed in both MCFI and  $\pi$ CFI related to callbacks and runtime dynamic linking. MCFI additionally suffered incompatibilities with the function pointer and virtual table call tests. For callbacks, both solutions incorrectly terminate the process reporting a CFI violation. In terms of effective compatibility, MCFI and  $\pi$ CFI both securely support dynamic linking, switch jumps, return addresses, and unmatched call/return pairs, but are susceptible to CODE-COOP attacks. In our performance analysis, we did not measure any considerable overheads for  $\pi$ CFI’s tail call option (only 0.3%). This option decreases the performance for dynamic linking but increases the performance of vtable calls, switch-case, and return tests. Overall,  $\pi$ CFI scores more compatible and more secure relative to MCFI, but with slightly higher performance overhead.

PathArmor offers improved power and precision over the other tested solutions in the form of contextual CFI policy support. Contextual CFI protects dangerous system API calls by tracking and consulting the control-flow history that precedes each call. Efficient context-checking is implemented as an OS kernel module that consults the last branch record (LBR) CPU registers (which are only readable at ring 0) to check the last 16 branches before the impending protected branch. As reported in column 13, our evaluation demonstrated high permissive compatibility, only observing crashes on tests for C++ exception handling and signal handlers. However, our tests were able to violate CFI policies using function pointers, callbacks, virtual table pointers, tail-calls, switch-cases, return addresses, and unmatched call/return pairs, resulting

Table 4: Overall compatibility of CFI solutions

| Tests                           | LLVM (Windows)* | MCFG    | OFI    | Reins  | GCC-VTV | LLVM (Linux)* | MCFI   | $\pi$ CFI | $\pi$ CFI (nto) | Path-Armor | Lock-down |

| <i>Effective compatibility</i>  | 57.14%          | 59.09%  | 70.83% | 37.50% | 33.33%  | 66.67%        | 50.00% | 66.67%    | 66.67%          | 31.58%     | 57.89%    |

\*Compatibility of LLVM is measured with both CFI and ShadowCallStack enabled.

in a lower effective compatibility score. Its careful guarding of system calls also comes with high overhead for those calls (1221.48%). This affects feasibility of dynamic loading, whose associated system calls all receive a high performance penalty per call. Similarly, load-time dynamic linking exhibits a relatively high 74.54% overhead.

Lockdown enforces a dynamic control-flow integrity policy for binaries with the help of symbol tables of shared libraries and executables. Although Lockdown is a binary approach, it requires symbol tables not available for stripped binaries without sources, so we evaluated it using test programs specially compiled with symbol information added. Its loader leverages the additional symbol information to more precisely sandbox interactions between interoperating binary modules. Lockdown is permissively compatible with most tests except callbacks and runtime dynamic linking, for which it crashes. In terms of security, it robustly secures function pointers, virtual calls, switch tables, and return addresses. These security advantages incur somewhat higher performance overheads of 85.85–227.82% (but with only 1.45% load-time dynamic loading overhead). Like most of the other tested solutions, Lockdown remains vulnerable to CODE-COOP and multi-threading attacks. Additionally, Lockdown implements a shadow stack to protect return addresses, and thus is incompatible with unmatched call/return pairs.

## 5.2 Evaluation Trends

CONFIRM evaluation of these CFI solutions reveals some notable gaps in the current state-of-the-art. For example, all tested solutions fail to protect software from our cross-thread stack-smashing attack, in which one thread corrupts another thread’s return address. We hypothesize that no CFI solution yet evaluated in the literature can block this attack except by eliminating all return instructions from hardened programs, which probably incurs prohibitive overheads. By repeatedly exploiting a data corruption vulnerability in a loop, our test program can reliably break all tested CFI defenses within seconds using this approach.

Since concurrency, flat memory spaces, returns, and writable stacks are all ubiquitous in almost all mainstream architectures, such attacks should be considered a significant open problem. Intel Control-flow Enforcement Technology

(CET) [36] has been proposed as a potential hardware-based solution to this; but since it is not yet available for testing, it is unclear whether its hardware shadow stack will be compatible with software idioms that exhibit unmatched call-return pairs.

Memory management abuse is another major root of CFI incompatibilities and insecurities uncovered by our experiments. Real-world programs need access to the system memory management API in order to function properly, making CFI approaches that prohibit it impractical. However, memory API arguments are high value targets for attackers, since they potentially unlock a plethora of follow-on attack stages, including code injections. CFI solutions that fail to guard these APIs are therefore insecure. Of the tested solutions, only PathArmor manages to strike an acceptable balance between these two extremes, but only at the cost of high overheads.

A third outstanding open challenge concerns RCG in the form of JIT-compiled code, dynamic code unpacking, and runtime API hooking. RockJIT [50] is the only language-based CFI algorithm proposed in the literature that yet supports any form of RCG, and its approach entails compiler-specific modifications to source code, making it difficult to apply on large scales to the many diverse forms of RCG that appear in the wild. New, more general approaches are needed to lend CFI support to the increasing array of software products built atop JIT-compiled languages or linked using RCG-based mechanisms—including many of the top applications targeted by cybercriminals (e.g., Microsoft Office).

Table 4 measures the overall compatibility of all the tested CFI solutions. Permissive and effective compatibility are measured as the ratio of applicable tests to permissively and effectively compatible ones, respectively. All CFI techniques embedded in compilers (*viz.* LLVM on Linux and Windows, MCFG, and GCC-VTV), are 100% permissively compatible, avoiding all crashes. LLVM on Linux, LLVM on Windows, and MCFG secure at least 57% of applicable tests, while GCC-VTV only secures 33%.

OFI scores high overall compatibility, achieving 83% permissive compatibility and 71% effective compatibility on 24 applicable tests. Reins has the lowest permissive compatibility score of only 50%. PathArmor and Lockdown are permissively compatible with 84% and 74% of 19 applicable tests. However PathArmor can only secure 32% of the tests, giving it the lowest effective compatibility score.

Table 5: Correlation between SPEC CPU and CONFIRM performance

| SPEC CPU Benchmark | CFI Solution |       |         |          |       |           |                 |           |          | Benchmark Correlation |

### 5.3 Performance Evaluation Correlation

Prior performance evaluations of CFI solutions primarily rely upon SPEC CPU benchmarks as a standard of comparison. This is based on a widely held expectation that CFI overheads on SPEC benchmarks are indicative of their overheads on real-world, security-sensitive software to which they might be applied in practical deployments. However no prior work has attempted to quantify a correlation between SPEC benchmark scores and overheads observed for the addition of CFI controls to large, production software products. If, for example, CFI introduces high overheads for code features not well represented in SPEC benchmarks (e.g., because they are not performance bottlenecks for CFI-free software and were therefore not prioritized by SPEC), but that become real-world bottlenecks once their overheads are inflated by CFI controls, then SPEC benchmarks might not be good predictors of real-world CFI overheads. Recent work has argued that prior CFI research has unjustifiably drawn conclusions about real-world software overheads from microbenchmarking results [70], making this an important open question.

To better understand the relationship between CFI-specific operation overheads and SPEC benchmark scores, we therefore computed the correlation between median performance of CFI solutions on CONFIRM benchmarks with their performances reported on SPEC benchmarks (as reported in the prior literature). Although CONFIRM benchmarks are not real-world software, they can serve as microbenchmarks of features particularly relevant to CFI. High correlations therefore indicate to what degree SPEC benchmarks exercise code features whose performance are affected by CFI controls.

Table 5 reports the results, in which correlations between each SPEC CPU benchmark and CONFIRM median values are computed as Pearson correlation coefficients:

$$\rho_{x,y} = \frac{(\sum_{i=1}^n x_i \times y_i) - (n \times \bar{x} \times \bar{y})}{(n-1) \times \sigma_x \times \sigma_y} \quad (1)$$

where  $x_i$  and  $y_i$  are the CPU SPEC overhead and CONFIRM median overhead scores for solution  $i$ ,  $\bar{x}$  and  $\bar{y}$  are the means, and  $\sigma_x$  and  $\sigma_y$  are the sample standard deviations of  $x$  and  $y$ , respectively. High linear correlations are indicated by  $|\rho|$  values near to 1, and direct and inverse relationships are indicated by positive and negative  $\rho$ , respectively.

The results show that although a few SPEC benchmarks have strong correlations (namd, xalancbmk, astar, soplex, and povray being the highest), in general SPEC CPU benchmarks exhibit a poor correlation of only 0.36 on average with tests that exercise CFI-relevant code features. Almost half the SPEC benchmarks even have negative correlations. This indicates that SPEC benchmarks consist largely of code features unrelated to CFI overheads. While this does not resolve the question of whether SPEC overheads are predictive of real-world overheads for CFI, it reinforces the need for additional research connecting CFI overheads on SPEC benchmarks to those on large, production software.

## 6 Related Work

### 6.1 Prior CFI Evaluations

We surveyed 54 CFI algorithms and implementations published between 2005–2019 to prepare CONFIRM, over half

of which were published within 2015–2019. Of these, 66% evaluate performance overheads by applying SPEC CPU benchmarking programs. Examples of such performance evaluations include those of PittSFIeld [43], NaCl [81], CPI [40], REINS [78], bin-CFI [87], control flow locking [10], MIP [48], CCFIR [84], ROPecker [16], T-VIP [29], GCC-VTV [69], MCFI [49], VTint [83], Lockdown [54], O-CFI [45], CCFI [42], PathArmor [71], BinCC [74],  $\pi$ CFI [51], VTI [12], VTrust [82], VTPin [61], TypeArmor [72], PITYPAT [24], RAGuard [85], GRIFFIN [30], OFI [75], PT-CFI [33], HCIC [86],  $\mu$ CFI [35], CFIXX [14], and  $\tau$ CFI [47].

The remaining 34% of CFI technologies that are not evaluated on SPEC benchmarks primarily concern specialized application scenarios, including JIT compiler hardening [50], hypervisor security [41,76], iOS mobile code security [22,55], embedded systems security [2–4], and operating system kernel security [20,31,38]. These therefore adopt analogous test suites and tools specific to those domains [17,23,56,57,67].

Several of the more recently published works additionally evaluate their solutions on one or more large, real-world applications, including browsers, web servers, FTP servers, and email servers. For example, VTable protections primarily choose browsers as their enforcement targets, and therefore leverage browser benchmarks to evaluate performance. The main browser benchmarks used for this purpose are Microsoft’s Lite-Brite [44] Google’s Octane [32], Mozilla’s Kraken [46], Apple’s Sunspider [6], and RightWare’s BrowserMark [59].

Since compatibility problems frequently raise difficult challenges for evaluations of larger software products, these larger-scale evaluations tend to have smaller sample sizes. Overall, 88% of surveyed works report evaluations on 3 or fewer large, independent applications, with TypeArmor [72] having the most comprehensive evaluation we studied, consisting of three FTP servers, two web servers, an SSH server, an email server, two SQL servers, a JavaScript runtime, and a general-purpose distributed memory caching system.

To demonstrate security, prior CFI mechanisms are typically tested against proof-of-concept attacks or CVE exploits. The most widely tested attack class in recent years is COOP. Examples of security evaluations against COOP attacks include those reported for  $\mu$ CFI [35],  $\tau$ CFI [47], CFIXX [14], OFI [75], PITYPAT [24], VTrust [82], PathArmor [71], and  $\pi$ CFI [51].

The RIPE test suite [80] is also widely used by many researchers to measure CFI security and precision. RIPE consists of 850 buffer overflow attack forms. It aims to provide a standard way to quantify the security coverage of general defense mechanisms. In contrast, CONFIRM focuses on a larger variety of code features that are needed by many applications to implement non-malicious functionalities, but that pose particular problems for CFI defenses. These include a combination of benign behaviors and attacks.

## 6.2 CFI Surveys

There has been one prior survey of CFI performance, precision, and security, published in 2016 [13]. It surveys 30 previously published CFI frameworks, with qualitative and quantitative comparisons of their technical approaches and overheads as reported in each original publication. Five of the approaches are additionally reevaluated on SPEC CPU benchmarks.

In contrast, CONFIRM establishes a foundation for evaluating *compatibility* and *relevance* of various CFI algorithms to modern software products, and highlights important security and performance impacts that arise from incompatibility limitations facing the state-of-the-art solutions.

## 7 Conclusion

CONFIRM is the first evaluation methodology and micro-benchmarking suite that is designed to measure applicability, compatibility, and performance characteristics relevant to control-flow security hardening evaluation. The CONFIRM suite provides 24 tests of various CFI-relevant code features and coding idioms, which are widely found in deployed COTS software products.

Twelve publicly available CFI mechanisms are reevaluated using CONFIRM. The evaluation results reveal that state-of-the-art CFI solutions are compatible with only about 53% of the CFI-relevant code features and coding idioms needed to protect large, production software systems that are frequently targeted by cybercriminals. Compatibility and security limitations related to multithreading, custom memory management, and various forms of runtime code generation are identified as presenting some of the greatest barriers to adoption.

In addition, using CONFIRM for microbenchmarking reveals performance characteristics not captured by metrics widely used to evaluate CFI overheads. In particular, SPEC CPU benchmarks designed to assess CPU computational overhead exhibit an only 0.36 correlation with benchmarks that exercise code features relevant to CFI. This suggests a need for more CFI-specific benchmarking to identify important sources of performance bottlenecks, and their ramifications for CFI security and practicality.

## Abstract

As the Tor network has grown in popularity and importance as a tool for privacy-preserving online communication, it has increasingly become a target for disruption, censorship, and attack. A large body of existing work examines Tor's susceptibility to attacks that attempt to block Tor users' access to information (e.g., via traffic filtering), identify Tor users' communication content (e.g., via traffic fingerprinting), and de-anonymize Tor users (e.g., via traffic correlation). This paper focuses on the relatively understudied threat of denial-of-service (DoS) attacks against Tor, and specifically, DoS attacks that intelligently utilize bandwidth as a means to significantly degrade Tor network performance and reliability.

We demonstrate the feasibility of several bandwidth DoS attacks through live-network experimentation and high-fidelity simulation while quantifying the cost of each attack and its effect on Tor performance. First, we explore an attack against Tor's most commonly used default bridges (for censorship circumvention) and estimate that flooding those that are operational would cost \$17K/mo. and could reduce client throughput by 44% while more than doubling bridge maintenance costs. Second, we explore attacks against the TorFlow bandwidth measurement system and estimate that a constant attack against all TorFlow scanners would cost \$2.8K/mo. and reduce the median client download rate by 80%. Third, we explore how an adversary could use Tor to congest itself and estimate that such a congestion attack against all Tor relays would cost \$1.6K/mo. and increase the median client download time by 47%. Finally, we analyze the effects of Sybil DoS and deanonymization attacks that have costs comparable to those of our attacks.

## 1 Introduction

Tor [28] is the most popular anonymous communication system ever deployed, with an estimated eight million daily active users [59]. These users depend on Tor to anonymize their connections to Internet services and distributed peers, and also to circumvent censorship by local authorities that control network infrastructure. Tor is used by ordinary citi-

zens and businesses to protect their privacy online, by journalists and activists to more freely access and contribute digital content [7], and by criminals to perform illegal activities while avoiding identification [67].

As a result of its popularity, open-source codebase [9], and transparent development processes [10], Tor has gained significant attention from researchers who explore attacks that aim to deanonymize its users by gaining an advantageous view of network traffic [13]. Research directions for Tor attacks include website fingerprinting [18, 41, 42, 56, 69, 70, 77, 84, 85], routing [15, 16, 79, 81, 83], end-to-end correlation [54, 57, 58, 65, 66], congestion [31, 34, 51, 64], and side channels [43, 63]. Many of these attacks represent realistic threats for Tor users: some attacks are reported to have been launched by state sponsors against Tor in the wild [21, 22, 73, 76]. However, relatively understudied but arguably more viable is the threat of denial-of-service (DoS).

**The Threat of Denial-of-Service:** Bandwidth-based DoS against Tor is a relatively understudied but relevant threat. Previous work has explored the exhaustion of Tor relays' memory [51], CPU [14, 71], and socket descriptor resources [35], as well as selective service refusal [16]. While bandwidth-based DoS attacks against a *single target* have been considered [31], we are the first to study the feasibility, cost, and effects of launching such attacks against the *entire Tor network* of relays and other particularly vulnerable Tor components. Given Tor's limited resources and slow performance relative to the open web, further reducing performance through bandwidth DoS attacks also has the potential to reduce security by driving away users who may be unwilling to endure even slower load times [16, 25].

We argue that DoS attacks in general, and bandwidth DoS attacks in particular, are less complex and therefore more viable than many previous deanonymization attacks. Our DoS attacks either can be outsourced to third party "stresser" services that will flood a target with packets for an amortized cost of \$0.74/hr. per Gbit/s of attack traffic (see §3.1), or utilize lightweight Tor clients running on dedicated servers at an amortized cost of \$0.70/hr. per Gbit/s of attack traf-

fic (see §3.2). Nation-states are known to sponsor DoS attacks [60], and the ease of deployment and low cost of our attacks suggest that state actors could reasonably run them to disrupt Tor over both short and long timescales. We speculate that nation-states may, e.g., choose DoS as an alternative to traffic filtering as Tor continues to improve its ability to circumvent blocking and censorship [32]. Non-state actors could also reasonably deploy the attacks since they require only a few servers or can be completely outsourced.

Tor DoS attacks are not a hypothetical threat: existing evidence indicates that DoS attacks against the network have already been successfully deployed [23, 38, 40], requiring Tor to develop a subsystem to mitigate its effects [24, 39] (the subsystem does not mitigate our attacks). Although it may be challenging to detect and counter bandwidth-based DoS attacks, especially those that are designed to mimic realistic and plausible usage patterns, we believe that it is imperative to better understand such a threat as we develop defenses.

**Our Contributions:** This paper focuses on the costs and effects of DoS attacks that intelligently utilize bandwidth as a means to significantly degrade Tor performance and reliability. Following a discussion of the current pricing models for “stresser” (i.e., DoS-for-hire) services (§3.1) and dedicated servers (§3.2), we first explore the threat of a naïve flooding attack in which an adversary uses multiple “stresser” accounts to consume Tor relays’ bandwidth by flooding them with packets (§4). We estimate that the cost to carry out such an attack against the entire Tor network is \$7.2M/mo.

We then demonstrate the feasibility and effects of 3 major bandwidth DoS attacks against Tor in order of decreasing cost. First, we explore in §5 an attack that attempts to disrupt Tor’s censorship circumvention system by flooding Tor’s default bridges with packets, thereby causing bridge users to migrate to non-default bridges or lose access to Tor. We estimate that flooding Tor’s 12 operational default bridges would cost \$17K/mo. and would reduce bridge user throughput by 44% (if 25% of the users migrated to other bridges) while more than doubling meek bridge maintenance costs.

Second, we explore in §6 an attack that attempts to disrupt Tor’s load balancing system by flooding TorFlow bandwidth scanners with packets, thereby causing inaccurate and inconsistent relay capacity measurement results. Through high-fidelity network simulation using Shadow [47], we find that such an attack reduces the median client download rate by 80%. We estimate that a constant flooding attack against Tor’s 5 TorFlow scanners would cost \$2.8K/mo.

Third, we explore in §7 an attack that uses the Tor protocol to consume relay bandwidth resources. In the attack, a Tor client builds thousands of 8-hop circuits and congests relays by downloading large files through the network. Using Shadow, we find that such an attack using 20k circuits increases the median client download time by 120% at an estimated cost of \$6.3K/mo. and achieves a bandwidth amplification factor of 6.7. We also find that a stop reading strat-

egy [51] reduces the estimated cost of a 20k circuit attack to \$1.6K/mo., increases the median client download time by 47%, and achieves a bandwidth amplification factor of 26.

Finally, we analyze in §8 the effects of relay Sybil attacks that have costs comparable to those of our attacks.

**Ethics and Responsible Disclosure:** We emphasize that we do not carry out attacks against the live Tor network. We conduct some measurement experiments on Tor to better understand its composition and performance characteristics. However, we neither observe nor store any information about any Tor users (other than ourselves). We evaluate our attacks using high-fidelity Shadow simulations that are constructed to resemble the live Tor network. Additionally, we discussed our project with Tor developers, shared some of our results before submission of this paper, and sent a pre-print of our paper prior to its acceptance. We anticipate providing support as they develop any mitigations to our attacks.

## 2 Related Work

In this paper we focus specifically on attacks that target the Tor network, noting that attacks that target Internet protocols (e.g., TCP) or resources (e.g., web servers) have been rigorously studied in previous work.

**Anonymity Attacks against Tor:** There is a large body of work that examines attacks against Tor. The majority of these attacks aim to compromise anonymity—that is, to de-anonymize either targeted users or Tor users *en masse*. We highlight that research directions for anonymity attacks include website fingerprinting [18, 41, 42, 56, 69, 70, 77, 84, 85], routing [15, 16, 79, 81, 83], end-to-end correlation [54, 57, 58, 65, 66], congestion [31, 34, 51, 64], and side channels [43, 63]. (The reader may refer to previous work for a more complete taxonomy [13].) Although anonymity attacks are certainly problematic for Tor, the primary focus of this paper is on bandwidth-based DoS attacks that significantly degrade Tor network performance and reliability. Note that we compare our attacks to Sybil attacks that can be used for deanonymizing Tor users in §8.

**Denial-of-Service Attacks against Tor:** We are not the first to explore the network’s susceptibility to DoS. In their seminal work, Evans et al. [31] exploit the lack of an upper bound on the length of Tor circuits in older Tor versions. They show that an attacker can perform a bandwidth amplification DoS attack by creating cyclic, arbitrary length circuits through high bandwidth Tor relays. The congestion created by the DoS attack affects the latency of legitimate circuits which can be used to determine the guard relay on a circuit. To mitigate this attack, Tor has since imposed a cap of eight relays in circuit creation [27, §5.6].

Similarly, Pappas et al. [71] propose an asymmetric, amplification *packet-spinning* DoS attack against legitimate Tor relays. The goal of the attack is to increase the chances of legitimate clients choosing the attacker’s relays by keeping the legitimate relays busy with expensive cryptographic opera-

tions. The attacker uses a malicious relay to create a circular Tor circuit that starts and ends at the malicious relay. Their focus is on de-anonymization and they do not consider DoS attacks against the entire Tor network.

Borisov et al. [16] show that an attacker can de-anonymize a large fraction of Tor circuits by performing selective DoS on honest Tor relays to increase the probability that the attacker's relays will be chosen as guard and exit relays (and thus capable of performing traffic correlation [80]). Tor has since deployed a route manipulation (path bias) detection system to mitigate the effects of such an attack [26, §7].

Barbera et al. [14] propose an asymmetric DoS attack against Tor relays. The attack floods a targeted relay with CREATE cells that require public key operations to decrypt the cell. They show that by strategically targeting important relays, the attacker can slow down the entire Tor network due to overload on the remaining relays that are not under DoS attack. This is similar in aim to our work. However, our focus is less on protocol vulnerabilities and more on enumerating hotspots in Tor that, when attacked, could disrupt the network at large. We explore multiple avenues for causing network-wide performance and disruption.

Geddes et al. [35] demonstrate socket exhaustion attacks against various proposed replacements [12, 37] of Tor's transport protocol. They show that an attacker can disable arbitrary relays by exhausting their socket file descriptors and prevent legitimate connections from succeeding. However, the attack does not apply to the deployed Tor network, which does not employ the vulnerable transport protocols.

Jansen et al. [51] propose the *Sniper Attack*, a memory-based DoS attack that exploits Tor's end-to-end reliable data transport to consume memory by filling up the application level packet queues. Using simulation on Shadow [47], they show that an attacker can sequentially disable 20 exit relays in 29 minutes and make the Tor network unusable, while remaining undetected. The Tor Project has since rolled out defenses against the sniper attack [45]. We use some of the techniques from the sniper attack in our congestion attacks.

### 3 Threat Model and Attacker Costs

We consider an attacker who is determined to deny service to the Tor network. We make few assumptions about the capabilities or makeup of our adversary. In particular, our adversary need not control large regions of the Internet or be able to observe a large fraction of Tor traffic.

Instead, we model an adversary who has some bandwidth and computing capacity at its disposal. Certainly, a nation-state has such resources, but we imagine that such an adversary would likely prefer to avoid attribution and not conduct attacks from its own networks. More generally, our adversary can acquire (or rent) a distributed network of machines capable of sending traffic into the Tor network. We highlight two potential avenues for obtaining the resources necessary to carry out network-wide attacks against Tor: dedicated

DoS “stresser” services (§3.1) and the use of more traditional (and legal) dedicated hosting services (§3.2).

We do not require that the adversary be able to position itself in arbitrary locations on the Internet, although we do assume that some portion of its traffic will reach its intended targets. For some attacks, we additionally require the adversary to operate a Tor relay, but as we describe below, it is advantageous for such attacks to run a relay that provides negligible bandwidth to the Tor network; that is, the relay could be cheaply instantiated on a shared cloud provider or other low-cost hosting service.

**Attacker Goals:** The goal of the attacker is to disrupt either (i) the Tor network in its entirety or (ii) a portion of it that affects an entire subpopulation of Tor users. The latter includes attacks against Tor's *bridge* infrastructure, the set of unpublished relays that permit the participation of users who are otherwise prevented from accessing the Tor network directly (e.g., due to censorship).

In general, we consider an attack successful if it entirely prevents users from accessing Tor or if it degrades performance to such an extent that the anonymity service becomes too burdensome to use. The latter is of course subjective, but informally, we set a high threshold for what we consider unusable performance. We also note that even in the current (non-attacked) Tor network, its slow performance is already perceived as an impediment to its more widespread use [13]. Degrading performance much beyond Tor's current levels may cause many users to abandon the network.

**Attacker Costs:** One of our goals is to estimate the monetary cost of performing various bandwidth DoS attacks against different elements of Tor infrastructure. To estimate such costs to the attacker, we build a cost model from publicly available information on pricing of various online stresser services and dedicated hosting services.

### 3.1 Stresser Services

There is an active online market for stresser (also called DoS-for-hire or booter) services. These provide the capability to launch DoS attacks against any target, using a web-based interface, at a relatively low monthly cost. Most commonly, the attacks use a distributed botnet of compromised hosts to target a single victim, flooding it with requests.

We summarize the stresser service landscape in Table 1, although this table does not likely capture all available stresser sites. (Since such services are illegal in most jurisdictions, they are not widely advertised and there is significant churn in the industry, making it difficult to obtain a comprehensive list.) We emphasize that Table 1 reports *advertised* attack strengths. Although others have empirically evaluated the achieved attack strengths of these services [74, 75], we elected not to repeat their experiments due to ethical concerns (specifically, the strong possibility of incurring collateral damage). Previous work has found them

**Table 1:** The estimated mean hourly cost to flood a single target with 1 Gbit/s using various online stresser services. The amortized cost is the hourly price per Gbit/s of traffic per target.

| Stresser Service                                    | Time (hrs) | Num Attks | Strength (Gbit/s) | \$/mo. (USD) | \$/target/hr. (USD) | Amort. (USD)   |
|-----------------------------------------------------|------------|-----------|-------------------|--------------|---------------------|----------------|
| bootyou.net                                         | 3          | 3         | 45-50             | \$ 40        | \$ 4.44             | \$ 0.10        |
| booter.xyz                                          | 1.67       | 1         | 150-200           | \$ 50        | \$ 30               | \$ 0.20        |

| <b>Mean amortized cost (\$/target/hour/Gbit/s):</b> |            |           |                   |              |                     | <b>\$ 0.74</b> |

capable of launching bandwidth DoS attacks with measured attack rates in hundreds of Gigabits per second [74, 75].

In our analysis in subsequent sections, we consider the average amortized cost of the attacker to flood a single target (i.e., IP address) with 1 Gbit/s of attack traffic for an hour; we found this to be \$0.74. Although at first blush, this may appear unrealistically inexpensive, we note that this is *more* costly than obtaining the equivalent bandwidth from legitimate dedicated hosting providers; see §3.2. In §4, we evaluate the cost of using stresser services to overwhelm the capacity of the Tor network en masse, and consider more efficient and targeted stresser attacks in §5 and §6.

### 3.2 Dedicated Server Costs

Online dedicated hosting services provide customers with remotely located and managed physical machines. Users have full access to the provisioned resources such as CPU, RAM, and disk storage, at a fixed cost. Typically, providers impose some limits on the amount of monthly traffic, and charge different rates for the provisioned network bandwidth. Table 2 reports the pricing schemes for several popular dedicated hosting services. The average amortized hourly cost for transferring data at 1 Gbit/s is \$0.70.

Unlike stresser services, dedicated hosting services do not cater to network attackers. They are much more likely to police their traffic and terminate service for customers who are obviously attempting to perform flooding attacks. We thus do not consider their use for naïve flooding of Tor components (e.g., to overwhelm their capacity).

Dedicated servers are well-suited for an attacker who is looking to disrupt the Tor network by leveraging some aspects of Tor’s design or protocols. The attacker can use the resources provided by dedicated hosting services to launch such application layer bandwidth DoS attacks on Tor. We explore how dedicated hosting services could serve as a platform for causing severe congestion of Tor relays in §7.

**Table 2:** The estimated mean hourly cost to flood a single target with 1 Gbit/s using various dedicated server providers. The amortized cost is the hourly price per Gbit/s of traffic. Prices include 4 CPU cores with minimum 16 GB RAM and 500 GB storage.

| Service                                      | Speed (Gbit/s) | Quota (TB) | \$/mo. (USD) | Amort. (USD)   |
|----------------------------------------------|----------------|------------|--------------|----------------|
| Liquid Web                                   | 1.00           | 5          | \$ 249.00    | \$ 0.35        |
| InMotion                                     | 1.00           | 10         | \$ 166.59    | \$ 0.23        |
| DreamHost                                    | Unkn.          | Unmet.     | \$ 249.00    | –              |
| GoDaddy                                      | 1.00           | Unmet.     | \$ 239.99    | \$ 0.33        |
| BlueHost                                     | 0.10           | 15         | \$ 249.99    | \$ 3.47        |
| 1&1                                          | 1.00           | Unmet.     | \$ 130.00    | \$ 0.18        |

| <b>Mean amortized cost (\$/hour/Gbit/s):</b> |                |            |              | <b>\$ 0.70</b> |

## 4 Naïve Flooding Attacks against Tor Relays

A straightforward method of attacking Tor is to flood relays with spurious traffic. In this section, we analyze the cost of using stresser services to disrupt the entire Tor network.

**Saturating Links:** To simplify our analysis, we assume a model of the Internet in which every node  $i$  has a finite bandwidth capacity  $\mathcal{C}_i$ , measured in bits per second (bit/s). We do not consider asymmetric bandwidth since Tor relays receive and send traffic in roughly equal proportions; if node  $i$  has asymmetric connectivity, we can consider  $\mathcal{C}_i$  to be the minimum of its upstream and downstream capacities.

We assume that an adversary can effectively deny service to a targeted node  $v$  if (i) it can cause traffic to arrive at the target at a rate greater than  $\mathcal{C}_v$  and (ii) such traffic cannot be filtered upstream. Importantly, the second criterion requires the attacker to initiate a distributed DoS attack from multiple sources (i.e., IP addresses) that cannot easily be enumerated or blocked. Additionally, the communication should resemble legitimate traffic (e.g., be directed at a relevant TCP port). Stresser services generally meet these requirements.

Our first assumption—i.e., a node  $v$  effectively becomes unusable if it receives attack traffic at a rate greater than  $\mathcal{C}_v$ —is admittedly an oversimplification. However, we speculate that saturating  $v$ ’s link would induce a high packet loss rate of 50% or more for legitimate clients, since such clients would have to compete for  $v$ ’s connectivity. TCP performs poorly at such high packet loss rates [61, 68].<sup>1</sup> Stresser services offer attack rates that *vastly* exceed the estimated bandwidth capacities of Tor relays.

**Estimating Tor Relay Link Capacity:** For a successful flooding attack, the rate at which the attack traffic arrives at

<sup>1</sup>Computing TCP’s performance for a given packet loss rate is complex since there are a variety of TCP congestion control algorithms (e.g., Tahoe, Reno, etc.). However, we can derive the theoretical network limit based on the Mathis et al. [61] formula: assuming an average RTT of 40ms, an MSS of 1460B, and a 50% loss rate, the maximum possible throughput achievable by TCP is just  $(\text{MSS}/\text{RTT}) \cdot (1/\sqrt{\text{loss}}) = 0.41 \text{ MiB/s}$ .

the target should be equal to or greater than the target’s network link capacity. Importantly, we distinguish between the link capacity  $\mathcal{C}_v$  of a victim relay and its effective throughput, the latter of which depends on rate limiting, its selection probability, etc. The flooding attack instead depends on overwhelming the victim’s actual connectivity, i.e.,  $\mathcal{C}_v$ .

Unfortunately, Tor relays do not publish their link capacities. To estimate a given relay’s link capacity, we consider its bandwidth history as recorded in the previous year (from 2017–11–01 to 2018–11–01) by the Tor Metrics Portal [11]. For each day, we find the maximum observed bandwidth for the relay and map this bandwidth to the next highest value in a fixed set of *bandwidth offerings* that are commonly available: 1, 10, 100, 200, 500, 1,000 and 10,000 Mbit/s. For example, a relay with a maximum observed bandwidth of 1,200 Mbit/s will be considered to have 10 Gbit/s network link. We thus assume that an attacker must direct 10 Gbit/s of attack traffic to overwhelm the relay’s capacity. We again emphasize that this is an estimate; the actual capacity at any given time may vary significantly if relay operators configure Tor bandwidth limitation options (operators can set instantaneous bandwidth rate limits and total monthly usage limits).

**Attack Cost:** We estimate that the total link capacity across the Tor network ranged from 429 to 575 Gbit/s over the year; for our analysis, we use the average of 512.73 Gbit/s. We require that at least one stresser account be used for each Tor relay (since stresser services usually restrict the number of targets to one). Additional stresser accounts are needed to saturate relays with high bandwidth capacities. Applying our cost model, an attacker can use stresser services to flood *all* relays in the Tor network at a cost of about \$10K/hr. (or \$7.2M/mo.). An adversary can roughly halve its costs by targeting only exit relays, which are required for traffic exiting the network. Overall, however, we find that disrupting Tor by renting stresser services is an expensive proposition, only potentially viable for a nation-state adversary.

**Limitations:** A limitation of our analysis is that it is not based on empirical evidence (since we were not willing to use such services) and relies on advertised attack rates. Although Santanna et al. have found such services to reasonably deliver high-bandwidth [74, 75], it is possible that they provide a much lower attack strength than advertised. We also rely on the assumption that packets are not filtered upstream, which may not always be valid (as discussed below).

**Mitigation:** It is possible that ISPs could render such attacks ineffective by filtering traffic. For example, ISPs could discover hosts belonging to the stresser services and filter traffic originating at those hosts. However, such rules may be difficult to maintain given the dynamic nature of the Internet.

Filtering all incoming requests to Tor relays that do not originate at other relays would be an ineffective strategy. In particular, entry relays must allow for clients anywhere on the Internet to initiate a circuit, and any relay may be chosen as an entry by clients implementing non-default path selec-

tion algorithms. Filtering attempts may also be complicated by the churn rate of Tor relays and would interfere with the process of bootstrapping new relays to the network. Finally, dropping packets on the relay is an ineffective defense since the dropped packets have already consumed bandwidth.

Traditional DoS defenses such as the use of CDNs are not compatible with Tor since aggregating relays onto a small number of CDN providers would diminish anonymity; it is also unclear how a relay could operate within a CDN. Relay operators may consider migrating to popular cloud services that offer DoS protection services [1, 2]. However, the security and privacy implications of migrating to such services is unknown and may risk exposure to traffic correlation attacks.

Perhaps the most tractable mitigation strategy is to increase the total relay bandwidth capacity of the network.

## 5 Congesting Tor Bridges

Tor provides anonymous communication to clients, but does not conceal the network locations of its relays, subjecting them to trivial blocking. To counter censors that block access to Tor relays, Tor logically separates *anonymity* (accessing the Internet without revealing network location) from *unblockability* (gaining access to the Tor network). The latter is achieved through the use of *bridge* relays that are not published in the Tor directories. Bridges serve as alternative ingress points into the Tor network for users who cannot directly connect to Tor entry guards.

In this section, we explore the effects of using stresser services (§3.1) to flood Tor bridge relays. We differentiate between three classes of bridges:

**Default Bridges:** The Tor Browser Bundle (TBB) includes a set of 38 hard-coded default bridges (as of version 8.0.3). Users who cannot directly access Tor relays can configure TBB to connect via one of these default bridges.

A special case of default bridges is *meek bridges* [4, 6] that reside on popular cloud providers and communicate with Tor clients via HTTPS. Censors cannot easily distinguish meek traffic from more typical HTTPS traffic entering the cloud. Disrupting meek thus entails entirely blocking access to the cloud provider, which is presumed to impose too high a collateral cost to the censor. Meek bridges, however, are expensive to operate (since cloud services are not free) and are susceptible to cloud providers disallowing their use [17, 33].

**Unlisted Bridges:** Users can also request an unlisted bridge either directly from TBB, via [bridges.torproject.org](https://bridges.torproject.org), or through email. To prevent a censor from trivially enumerating the bridges, Tor limits the amount of bridges it disseminates to a single requesting IP or email address. However, such protections are obviously brittle and numerous techniques exist for discovering unlisted bridges [20, 30].

**Private Bridges:** Finally, private bridges are not disseminated by the Tor Project, either because their operators did not notify the Tor Project that they exist or because the Tor Project opted not to disseminate them.

## 5.1 The State of Tor’s Bridges

We first examine the performance of the network’s bridges. We focus on the 25 default bridges that use the obfs4 obfuscation protocol<sup>2</sup> since 90% of all bridge users use default bridges [62] and obfs4 is the bridge type recommended by Tor. To test their performance, we use a modified version of Tor to download a 6 MiB file through each bridge. Surprisingly, we find that only 48% (12/25) of the obfs4 default bridges included in TBB are operational.

Figure 1 plots the cumulative distribution (y-axis) of the throughput of the functioning obfs4 default bridges (blue line) when downloading a 6 MiB file on 2018-04-10. Each default obfs4 bridge downloaded the 6 MiB file three times; the CDF plots the average of these downloads. For consistency, we fixed the middle and exit relays, choosing relays with high selection probabilities (and thus high bandwidths). The median throughput of the default bridges is 368 KiB/s; there is a large variation over the default bridges however, ranging from 67 KiB/s to 1,190 KiB/s.

To compare against the performance of unlisted bridges, we requested 135 unlisted obfs4 bridges from the Tor Project’s bridge authority via its web and email interfaces. Roughly 70% (95/135) of the acquired unlisted bridges were found to be functional. As shown in Figure 1 (orange line), the unlisted bridges generally outperformed the default bridges, which is expected given Matic et al.’s finding [62] that suggests approximately 90% of bridge traffic is conducted through default bridges. We suspect that the high demand on the few operational default bridges leads to worse performance than the less frequently used unlisted bridges.

As a point of comparison, historical data from the Tor Metrics Portal reveals that non-bridge circuits on Tor during the same time period yielded an average throughput of 786 KiB/s and experienced negligible failure rates [11].

In summary, Tor’s bridges are generally far more brittle compared to the network’s advertised relays, offering much greater failure rates for default (52%) and unlisted (30%) bridges (compared to 0% for Tor relays) and lower average throughput (545 KiB/s and 681 KiB/s for default and unlisted bridges, respectively, versus 786 KiB/s without bridges).

## 5.2 Attacking Default Bridges

Ninety percent of bridge users use default bridges [62], and only 12 working default obfs4 bridges are included in the TBB. We first estimate how costly it would be for an attacker to disrupt all of the default bridges. Then, for various migration models in which some percentage of affected bridge users switch to unlisted bridges, we estimate the performance and pricing effects of the migration.

**Denying Access to the Default Bridges:** Since bridge relays do not publish their bandwidth capacities, our analysis assumes that the distribution of link capacities for  $n$  default

bridge relays is the same as the distribution of link capacities for the fastest  $n$  non-bridge Tor relays. Thus, saturating one default bridge’s Internet connectivity requires an amount of bandwidth equal to the link capacity of the fastest Tor relay, and saturating 10 default bridges’ requires bandwidth equal to the combined link capacity of the fastest 10 Tor relays. Following the link capacity estimates based on bandwidth offerings as described in §4, we estimate that the set of 12 operational default bridges consists of two 10 Gbit/s links and ten 1 Gbit/s links (a total of 30 Gbit/s) and that the full set of 38 default bridges consists of two 10 Gbit/s links and thirty-six 1 Gbit/s links (a total of 56 Gbit/s). Recall from the pricing model in §3.1 that a 1 Gbit/s stresser account costs \$0.74/hr. Attacking the 12 operational obfs4 bridges thus requires 30 of such stresser accounts at a cost of  $\$0.74 \cdot 30 = \$22.20$  for each hour of downtime (or roughly  $\$22.20 \cdot 24 \cdot 31 \approx \$17K$  per month). Repairing the remaining default bridges offers only a small improvement: denying service to 38 bridges requires 56 stresser accounts at a cost of  $\$0.74 \cdot 56 = \$41.44$ /hr. ( $\$41.44 \cdot 24 \cdot 31 \approx \$31K$ /mo.) which we posit is well within the budget of a nation-state adversary. We emphasize that these are estimates since bridges’ true link capacities are unknown.

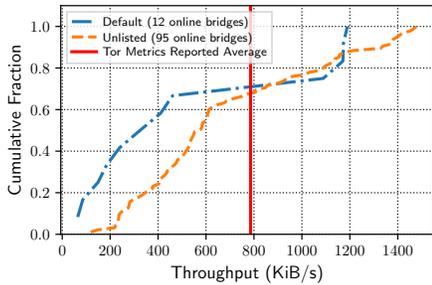

If the default bridges are successfully attacked, there are several potential consequences. In the worst case, the set of default bridges will not be updated and the users who had depended on them will abandon Tor altogether. The Tor Project could also update its list of default bridges (e.g., by pushing an update to TBB), but such a solution is only temporary since an attacker could simply retarget its DoS efforts.

Users who are dependent on bridges may switch to using either unlisted bridges (since they are more plentiful and more difficult to enumerate) or to meek bridges.

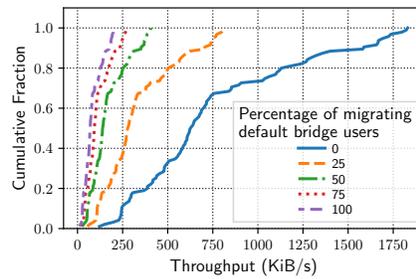

**The Cost of Migrating to Unlisted Bridges:** We base our analysis on (i) the distribution of throughput we measure from unlisted bridges (Figure 1), (ii) the simplifying assumption that how Tor is used by bridge users is independent of the particular type of bridge used to gain entry to the network, and (iii) Matic et al.’s observation that suggests approximately 90% of bridge traffic traverses through default bridges [62]. If all default bridge users switched to unlisted bridges, applying our simplifying assumption, we would therefore expect the load on the unlisted bridges to increase by a factor of nine (since they previously carried just 10% of bridge traffic). More generally, when a fraction  $f$  of default bridge users shift to using unlisted bridges, the unlisted bridges should expect to see a corresponding increase in traffic of a factor of  $9 \cdot f$ . This trend is plotted in Figure 2.

Given that most (90%) of bridge traffic that is handled by the default bridges, even a small migration of default bridge traffic to unlisted bridges has performance consequences. Even if a quarter of previously default bridge users switch to unlisted bridges, their performance will significantly suffer, decreasing from 762 KiB/s to 338 KiB/s in the median.

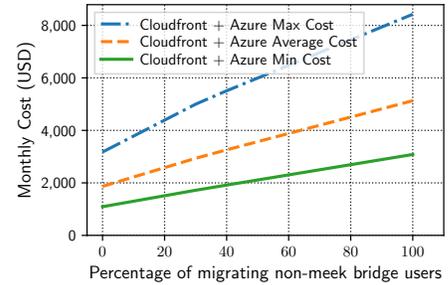

<sup>2</sup>obfs4 obfuscates Tor traffic to appear as a random sequence of bytes, making it hard for DPI systems to classify.

**Figure 1:** Cumulative distribution of bridge throughput when downloading 6 MiB files. The vertical line at 786 KiB/s shows the throughput for clients that directly connect to Tor to download a 5 MiB file.

**Figure 2:** Throughput of Tor users who use unlisted bridges, as a function of the percentage of default bridge users who switch to using unlisted bridges.

**Figure 3:** The minimum, maximum, and average cost of maintaining meek when some fraction of users switch to meek, based on meek usage data and CloudFront and Azure pricing models.

**The Cost of Switching to Meek Bridges:** If the non-meek default bridges become unavailable, we expect some fraction of users to switch to meek bridges. Censors cannot easily disrupt meek bridges without inflicting significant collateral damage since it cannot easily distinguish meek traffic from more typical HTTPS traffic that accesses the cloud provider. However, the increased use of meek incurs a cost (since cloud services are not free).

To estimate the resulting monthly cost of maintaining meek bridges as non-meek users switch over, we estimate the bandwidth consumption of migrating users by constructing a regression model. The bandwidth consumption estimate is required to calculate the cost of operating the meek frontend as cloud providers charge their users based on the bandwidth consumption. To construct the regression model, we first use the statistics from the Tor Metrics Portal to estimate (i) the number of meek users and (ii) the traffic transferred by the meek frontend as reported by meek frontend operators [5] over this same timespan. We use this regression model to estimate the consumed bandwidth as a function of increased traffic from users migrating to meek bridges. We then use the estimated bandwidth usage to derive the expected meek operational cost by applying the current pricing model of the cloud service providers. Unfortunately, the Tor Project stopped providing usage statistics for meek bridges, so we restrict our analysis to usage that occurred between March 2016 and March 2017 (where such data is available [5]). We also note that Amazon and Google stopped supporting the use of domain fronting on their respective cloud services [17, 33]<sup>3</sup>. Given these limitations, our analysis represents a rough approximation.

Figure 3 shows the monthly cost of operating meek bridges as a function of the fraction of non-meek bridge users who switch to using meek bridges. We plot the ranges of estimated monthly costs, since cloud providers charge different amounts based on the locations of clients. We note that

<sup>3</sup>This highlights a particular brittle aspect of meek bridges—they are completely dependent upon the cloud service on which they reside.

if half of non-meek users begin using meek bridges, then *in the best case*, the operational cost of maintaining meek bridges will double. If clients are disproportionately in locations in which providers charge higher rates, then the operational costs could be as high as six times the current amount.

**Mitigation:** Meek bridges offer the best protection against DoS. Unfortunately, supporting a large user base is expensive. One potential strategy for reducing costs is to require bridge users to watch ads or perform small tasks (akin to Mechanical Turk) to finance the cost of their bridge use. Additionally, the recent proliferation of encrypted Server Name Identification (SNI) parameters [36, 44] may enable new methods of domain fronting [32] that are compatible with lower-cost hosting providers.

## 6 Unbalancing Load

In this section, we seek to better understand the extent to which an adversary can disrupt Tor by using stresser services (§3.1) to launch bandwidth DoS attacks on TorFlow [72], a critical component in Tor’s load balancing process.

### 6.1 Relay Performance and Path Selection

As of 2018-11-01, the Tor network contains 6,436 voluntarily operated relays, the status of which is maintained by 9 Tor *directory authorities* in a signed *network consensus document*. When using Tor, clients download and verify a recent consensus, and use it to select paths of relays through which they build *circuits* and tunnel Internet connections.

Tor uses a load-balancing system in order to provide low-latency anonymous communication (i.e., suitable for browsing websites) due to high client resource demand and a large variance in the bandwidth capacities offered by relays (see §4). The load balancing system is composed of two primary components: a relay performance estimation mechanism and a performance-aware path selection algorithm.

**Relay Performance Estimation:** Although Tor initially estimated relay performance according to self-reported *advertised bandwidth* capacities, Bauer et al. showed how a low-resource adversary could attract significant traffic to mali-

cious relays (to improve end-to-end correlation attacks) by lying about their available bandwidth [15]. Perry subsequently designed and published the TorFlow relay measurement system to reduce the extent to which Tor trusts relays to honestly report their bandwidth capacity [72], and Tor has been using it to measure relays for nearly a decade (despite alternative designs [19, 55, 78]).

TorFlow is a measurement tool that scans Tor relays to measure their relative performance. To measure Tor relays, TorFlow (i) sorts the consensus list of relays by their previously-expected performance, (ii) partitions the sorted list into *slices* of 50 relays each, (iii) distributes the slices among 9 subprocesses that run in parallel, (iv) creates 2-hop circuits using pairs of relays that belong to the same slice (and so can provide similar performance), and (v) downloads one of a set of 13 fixed-sized files ( $2^i$  for  $i \in [4, 16]$  KiB) from a known destination through each circuit. TorFlow repeats this process until it has attempted to download through each relay at least 5 times, after which it uses the mean of the measured download completion times to compute a weight for each relay that represents its performance relative to the other measured relays.

The output of the TorFlow measurement process is a *version 3 bandwidth* (V3BW) file specifying the weights and other information about each scanned relay. Currently, 5 of the 9 directory authorities also act as *bandwidth authorities* [3]: they obtain a V3BW file and participate in a voting protocol to determine an authoritative set of relay weights that will appear in the next network consensus. Note that a bandwidth authority operator may obtain a V3BW file by running TorFlow (potentially on a distinct machine from that which runs their directory authority) or by obtaining one from another trusted source that is running TorFlow.

**Performance-Aware Path Selection:** Tor's path selection algorithm biases relay selection to favor those providing more resources and better performance. Clients using the default selection algorithm will choose relays roughly proportional to the weights assigned to them (via the bandwidth authority voting procedure) and listed in the consensus. As a result, client traffic will be driven to the better performing relays. Previous work has shown that Tor's relay selection strategy does a reasonable job of balancing load [82].

## 6.2 Detecting TorFlow Scanners

The TorFlow relay scanners constitute attractive targets for DoS attacks: disrupting the scanners may result in significant variation in relays' weights which could degrade load-balancing and security. If the bandwidth authorities were taken offline, Tor would eventually fall back to an equal weighting (uniformly at random) strategy, which would have a detrimental effect on client performance [82]. Previous work observed the ability to detect TorFlow scanners due to their connection patterns and fixed-size file downloads [55], which we further explore.

TorFlow scanners stand out from normal Tor clients because: (i) they download one of a set of 13 fixed-size files, (ii) they choose new entry relays for each circuit (disabling the guard feature), and (iii) they use two-hop circuits.

To discover the network addresses of the TorFlow scanners, we first determined the range in the number of Tor cells required to download each of the fixed-size files. We then operated a low-bandwidth relay and patched it with a small program that looked for connecting clients (potential candidates for TorFlow scanners) that exhibited similar telltale fetches. To provide some ground truth, we also operated our own TorFlow scanner. Within 48 hours, we were able to identify six IP addresses that fetched files through our relay and fit the pattern of a TorFlow scanner. We operated our TorFlow scanner detection software for 5.5 days, during which it did not identify any additional potential scanners. Although we temporarily stored candidate scanner IP addresses in memory (in order to determine uniqueness), we did not write them to std-out or the filesystem (in order to avoid accidentally recording the IP of a human Tor user). We did, however, record that one of the six identified candidate TorFlow scanners was indeed our own; we posit that the other five correspond to the five scanners operated by the Tor Project.

## 6.3 Attacking TorFlow Scanners

Given that an adversary can identify TorFlow scanners by their IP address, they can use bandwidth DoS attacks to disrupt the relay scanning process and therefore degrade the accuracy of the relay weights produced by TorFlow. A bandwidth DoS attack will clog the TorFlow scanners' links, increasing latency and packet loss on those links and extending the time it takes the scanners to successfully complete file downloads through Tor relays. Therefore, the adversary may effectively manipulate the scanner into believing that relays provide worse performance than they can actually provide. Since TorFlow weights relays by their performance, the adversary can effectively reduce the accuracy of the relay weights which may disrupt the load balancing process.

### 6.3.1 Attack Strategies

We explore several strategies that an adversary may use to conduct bandwidth DoS attacks on TorFlow scanners with a goal of increasing the file download times measured by TorFlow and disrupting the load balancing process. Each strategy will come at a different cost due to the bandwidth required to conduct the attack and the length at which the attack must be sustained.

**Constant:** The most straightforward strategy is to simply flood each TorFlow scanner with bandwidth at a constant rate over time. This brute-force strategy is the easiest to set up and should require minimal monitoring and maintenance by the adversary throughout the duration of attack.

**Periodic:** Since TorFlow produces weights that represent relay performance *relative to other relays*, and because a constant attack strategy may similarly affect all relay measure-

ments, a constant strategy may be suboptimal. Therefore, we also consider a periodic strategy where the adversary floods the victim with bandwidth for a duration of time  $\lambda$  while periodically pausing the attack for a duration of time  $\pi$ . The reasoning behind this strategy is that the scanner will measure normal download times for some relays but significantly reduced download times for others, and the large difference will have a greater impact on the final set of relay weights.

**Targeted:** We also consider a targeted strategy where the adversary carefully selects periods of time during which to run the DoS attack and otherwise does not alter the victim scanner’s network conditions. In particular, we observe that the greatest impact in performance will likely result from significantly depressing the relative weights of the best performing relays. Therefore, the adversary targets the scanner with a bandwidth DoS attack while it is measuring the fastest relays. We discuss below how to determine when the fastest relays are being measured.

### 6.3.2 Attack Strength and Other Assumptions

For any strategy used by the adversary, we assume that it can utilize a stresser service (see §3.1) to limit the victim’s effective bandwidth to rate  $\gamma$  while increasing packet loss on the victim’s link by  $\rho$ . We assume that the adversary can increase or decrease the attack strength to achieve these effects. (See §6.5 for a discussion of cost.) We also assume that the adversary can receive feedback on the attack by closely monitoring the consensus weights and checking how relays’ weights are changing over time. It can monitor the Tor metrics website and data to observe changes in Tor performance. It can iteratively adjust the attack strength and strategy over time in an attempt to produce a greater effect. We also assume that the adversary is capable of setting up and running its own TorFlow scanner instance (the code is open-source), and use it to directly observe how an ongoing attack is affecting the TorFlow measurements and outputs.

The *Targeted* attack strategy depends on being able to target the slice containing the fastest relays. We speculate that the adversary would be able to detect when the fastest slice is being measured by running a fast relay itself and observing when its relay is first measured by a TorFlow scanner. Once detected, the adversary could enable the attack for the time required to measure the slice, which it could estimate empirically by running a TorFlow scanner itself and observing the times to measure the fastest slice over several scan periods. (We ran a TorFlow instance, analyzed its output, and computed the time to measure the fastest slice over 20 scans. We found that the median time to scan the fastest slice was 249 minutes, with an interquartile range of 73 minutes.) Note that these techniques would require additional time, bandwidth, and skill compared to a brute-force attack, and that scan times may be inconsistent over time and network location. See §6.6 for further discussion.

## 6.4 Evaluation

We evaluated the DoS attack strategies and effects in Shadow [47], a high-fidelity network simulation framework that directly executes Tor. We used Shadow to create a private Tor network that is completely contained inside of our lab environment in order to guarantee that our attacks do not harm the safety or privacy of real Tor users or the network. All of the experiments that we present in this section use Shadow v1.13.0 and Tor v0.3.0.10.

**Network Setup:** We used standard Shadow and Tor network generation tools and methods [48] to generate a private Tor network with 100 Tor relays, 3,000 Tor clients, and 1,000 server, and to generate background traffic [53]. 2,619 of the clients are *web* clients that download a 320 KiB file, “think” by pausing for a time selected uniformly at random in the range [1,60] seconds, and then repeat. 81 of the clients are *bulk* clients that repeatedly download a 5 MiB file without pausing between successive downloads. We also run 300 *benchmark* clients that reproduce Tor’s performance benchmarks by occasionally downloading 50 KiB, 1 MiB, and 5 MiB files using fresh circuits throughout each experiment. We use the most recently published Shadow network topology graph [53] to model inter-host latency.

We implemented a TorFlow plugin for Shadow by significantly refactoring and extending previous work [55]. We used the plugin to scan the relays in our network and produce V3BW files which were then added to the consensus and used by the clients to build paths. We first ran one longer experiment allowing TorFlow time to scan through all relays several times, and then we used the final V3BW file that TorFlow produced as the starting point for all other experiments.

**Parameter Settings:** We simulated a bandwidth attack by adjusting TorFlow’s available bandwidth  $\gamma$  and added packet loss  $\rho$ . During each phase where the attack is active, we limit TorFlow’s bandwidth to  $\gamma = 500$  Kbit/s (62.5 KiB/s) and we add a  $\rho = 2\%$  chance of packet loss occurring independently on all incoming and outgoing packets. We set our TorFlow instance to conduct 4 parallel *probes* (2-hop relay measurements), to partition the relays into 10 slices of 10 relays each, and to probe each relay at least 3 times per round before producing a new V3BW file.

We ran a baseline *No Attack* experiment and experiments with each attack strategy. When running the *Constant* attack strategy, the attack is active (the  $\gamma$  and  $\rho$  rates applied) for the duration of the experiment. In the *Periodic* attack strategy, the attack cycles through an active period lasting  $\lambda = 60$  seconds and an inactive period lasting  $\pi = 20$  seconds. In the *Targeted* attack strategy, the attack is active while relays in the slice containing the fastest guard relay in the network are being measured, and inactive otherwise.

**TorFlow Scanner Performance:** The performance of the TorFlow measurement probe downloads across our experiments is shown in Table 3. As shown in the table, our results indicate that the *Constant* attack is the most effective at caus-

**Table 3:** The failure rate of TorFlow probe downloads, and the mean ( $\pm$  standard deviation) download rate for each TorFlow probe download and time to complete a full network scan.

| Strategy  | Fail Rate | Download Rate       | Scan Time        |
|-----------|-----------|---------------------|------------------|
| No Attack | 6.0%      | 390 $\pm$ 381 KiB/s | 47 $\pm$ 21 min. |
| Periodic  | 8.6%      | 256 $\pm$ 292 KiB/s | 59 $\pm$ 20 min. |
| Targeted  | 14%       | 275 $\pm$ 293 KiB/s | 80 $\pm$ 19 min. |
| Constant  | 22%       | 8.7 $\pm$ 5.1 KiB/s | 173* min.        |

\*Only a single scan completed in our 300 minute simulation.

ing TorFlow download errors (which increased to 22% from 6% with *No Attack*). The *Constant* attack is also the most effective at limiting the probe download rate, achieving a reduction in mean download rate of about 381 KiB/s, and intuitively increasing the time to scan all relays in the network by about 126 minutes. We find that the *Periodic* and *Targeted* strategies are less effective than the *Constant* strategy, but still do have a measurable effect on the scanner.

**Relay Performance:** Figure 4(a) shows the relay performance in terms of the distribution of total relay goodput (summed across all relays in the network) over every second during the simulation. We notice a similar trend as with TorFlow performance: in the medians, total relay goodput drops by 86 MiB/s (56%) from 153 MiB/s with *No Attack* to 67 MiB/s with the *Constant* strategy, and relay utilization gets progressively lower with the *Periodic*, *Targeted*, and *Constant* strategies, respectively. Such significant drops in throughput indicates that the new weights produced by TorFlow during the attacks no longer do a good job of balancing client load across relays, and the network is less capable of utilizing its available bandwidth resources.

**Client Performance:** The effects of our attacks on the mean download rate (during active downloads) per client are shown in Figure 4(b). Every attack has a significant effect, with the mean download rate of the median client being reduced by 45 KiB/s from 56 KiB/s with *No Attack* to 11 KiB/s with the *Constant* attack. Client performance also suffers in terms of the download failure rate per client as shown in Figure 4(c): the failure rate for the median client increases by about 23% from about 3% with *No Attack* to about 26% with the *Constant* attack.

Overall, our results show the extent to which an adversary may disrupt Tor performance using straightforward DoS attacks on easy-to-detect TorFlow scanners, and that the simplest constant attack strategy was the most effective.

## 6.5 Attack Cost

We assume that our TorFlow DoS attacks could be launched using a stresser service. In §3.1 we describe that the amortized cost of a stresser service to provide 1 Gbit/s of attack traffic is \$0.74/hr. The *Constant* attack strategy requires that we constantly run the DoS attack on each scanner. Tor runs 5 TorFlow scanners of unknown capacity. If we assume that they all run on 1 Gbit/s links, then the cost to run

the DoS attack on all 5 scanners for one month would be \$0.74 $\cdot$ 5 $\cdot$ 24 $\cdot$ 31 $\approx$ \$2.8K.

## 6.6 Discussion

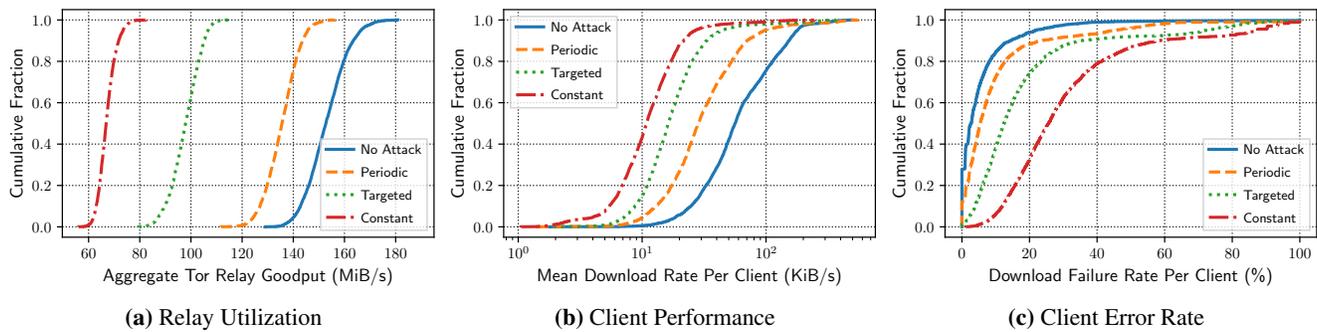

**Limitations:** A limitation of our study of the effects of bandwidth DoS on the TorFlow scanners is that we used a smaller-scale Tor network than that which is publicly accessible (100 relays compared to 6,436). We used a smaller network primarily due to resource limitations and because TorFlow takes a significant amount of time to scan all relays. Using a smaller network allowed us to (i) run longer experiments, (ii) scan the network faster because there are fewer relays to measure, and (iii) complete more scanning rounds.

Due to scale we configured a single TorFlow instance in our experiments measuring 10 relays per slice, using 4 parallel probe subprocesses, and collecting at least 3 probe measurements per relay; Tor runs 5 TorFlow instances measuring 50 relays per slice while using 9 parallel probe subprocesses and collecting at least 5 probe measurements per relay. The process of partitioning a larger set of relays among more slices and more parallel subprocesses could lead to different inconsistencies than those captured by our simulations. We believe that running additional parallel subprocesses would increase the average bandwidth rate of the TorFlow scanner, which may increase the effectiveness of a constant attack strategy. However, the adversary would require additional bandwidth to attack all or a majority of scanners in parallel.

The *Targeted* attack requires the ability to estimate when the fastest slice is being measured and the amount of time required to measure that slice. These estimates may be complicated by TorFlow’s inconsistent relay partitioning and subprocess assignment functions and its parallel measurement processes. In the worst case, the *Targeted* attack would degrade to a *Constant* attack, which performed best in our experiments anyway and for which we estimated cost in §6.5.

The attacks depend on stresser services delivering a high rate of traffic to the target, which is not a stealthy operation. This could potentially trigger automated or manual DoS mitigation techniques, and we did not consider how such defenses would affect the attacks. We rely on the assumption that packets are not filtered upstream from the target scanner, which may not always be valid (as we will discuss below).

**Attack Extension:** Our focus in this paper is on relatively simple and straightforward bandwidth-based DoS attacks. However, it is possible to extend the attack if we consider a more powerful adversary. For example, a network-level adversary that can observe connections from a TorFlow scanner can selectively disrupt TorFlow as it is scanning a target set of relay IP addresses. This would allow an adversary to selectively increase the time to scan the target set of relays, causing the scanner to detect that those relays are “overloaded” and reduce their weights (and therefore the probability that those relays are used by clients) accordingly. Such an attack could be used to drive additional traffic to other mali-

**Figure 4:** Performance metrics as measured when the network is not under attack (*No Attack*) and when the bandwidth authorities are attacked using different strategies (*Periodic*, *Targeted*, and *Constant*): (a) the distribution of aggregate Tor relay goodput per second (summed across all relays for every second); (b) the distribution of mean download rates per client; and (c) the distribution of download failure rates per client.

cious relays, improving the ability of an adversary to conduct attacks on anonymity, e.g., traffic correlation attacks [66].

**Mitigation:** Since the attacks rely on stresser services, the mitigation strategies discussed in §4 also apply here. Specifically, it is possible that ISPs could render attacks against the bandwidth authorities ineffective by filtering traffic en route. For example, ISPs could discover hosts belonging to the stresser services and filter traffic originating at those hosts, or ISPs could install custom rules to filter incoming traffic to the bandwidth authorities since they need only make outgoing connections (in case they are not run alongside Tor relays). However, filtering attempts may be complicated by packet spoofing. (Note that dropping packets on the bandwidth authority is an ineffective defense since the dropped packets already consumed bandwidth.)

Perhaps the best mitigation is to migrate to a decentralized bandwidth measurement system that does not share TorFlow’s security problems. For example, TorFlow’s centralized scanning approach can be easily detected because it uses fingerprintable traffic signatures from a small set of static IP addresses. While it may be difficult to obfuscate the source, destination, and traffic signature while still providing accurate results [55], a system that utilizes distributed trust may help thwart malicious behavior. For example, a peer-based measurement system run by existing relays would preclude the need for centralized measurement infrastructure that is vulnerable to DoS and could complicate scanner and measurement detection [55, 78].

## 7 Congesting Tor Relays

In §4, §5, and §6 we evaluated the effects of using stresser services (§3.1) to flood Tor relays, Tor bridges, and Tor bandwidth authorities, respectively. In this section, we move away from stresser services and explore the extent to which an adversary might degrade Tor network performance by using the Tor protocol itself to congest Tor relays. The attack strategies that we discuss in this section utilize dedicated servers (§3.2) and modified Tor clients.

### 7.1 Relay Usage

All non-bridge Tor relays are publicly known and distributed to Tor clients in network consensus documents in order to facilitate the Tor client path selection and circuit building processes. By default, clients select 3-hop Tor paths and use them to build circuits that are usable for 10 minutes. Clients must use an *exit relay* that allows exiting the Tor network on the desired TCP port as the last relay in their Tor circuits in order to communicate with Internet peers that are not Tor-aware. Additionally, by default, clients use *guard relays* as their entry into the Tor network, and *guard* or *middle relays* (i.e., non-guard, non-exit relays) in the middle position of their circuits. As discussed in §6, each relay is assigned a weight by the directory authorities corresponding to its performance relative to all other relays as measured by TorFlow [72]. Clients use these weights during path selection to bias their choice of relays toward those providing better performance.

### 7.2 Abusing Relay Bandwidth

The Tor protocol contains features that offer protocol flexibility, but also allow for abuse. Although exits are required to be used in the last position of circuits exiting Tor, the Tor protocol technically allows any relay to be used in any non-exit position. Additionally, the Tor protocol technically allows circuits containing up to 8 relays. To utilize these features, a client may select its own custom path of relays and build circuits through them either by modifying their Tor client code directly, or by interacting with Tor using the Tor control interface and protocol. Note that building custom circuits is already supported by existing Tor control clients like stem [8].

#### 7.2.1 Attack Strategies

Given the above features, an adversary may conduct a concerted bandwidth consumption DoS attack by building custom circuits and downloading large files through them.

**Long Paths:** The most basic form of our Tor bandwidth DoS attack makes use of the ability to create 8-hop Tor circuits.

For every byte of data downloaded by a client through such a *long path*, relays in the Tor network will download and upload that byte 8 times in total. This amplification works significantly in favor of the adversary.

**Tunneling:** Tor previously allowed infinite-length circuits until it was shown that long paths (e.g., 24 hops) could be used to congest Tor relays and deanonymize clients [31]. Although the Tor protocol now restricts circuits to 8 relays in length [27, §5.6], paths of unrestricted length are still technically possible by using multiple Tor clients and tunneling each client’s TCP onion connection to its entry relay through another client’s circuit<sup>4</sup> [51].

**Stop Reading:** In order to decrease the cost of downloading large files, the adversary may use a *Stop Reading* strategy. Using this strategy, the adversary first creates a new TCP onion connection to the first-hop relay in its chosen long path, even if a connection to that relay already exists. The adversary then builds an attack circuit using its chosen path and waits for it to complete successfully, making sure to assign the circuit to the new TCP connection. Once the circuit is built, the adversary sends a request for a large data blob from some public server (e.g., the Internet Archive), measures the time to download the first 25 KiB, and then instructs Tor to stop reading from the circuit’s TCP connection to the entry relay (immediately after receiving 25 KiB). Although the client stopped reading, it can still write: the adversary uses the measured time to download the first 25 KiB to estimate the frequency with which it should send Tor circuit and stream SENDME flow control cells<sup>5</sup> which instruct the exit relay to continue to send data toward the client. (Estimating the circuit throughput rate is important, because sending more SENDME cells than is expected by the exit will cause the exit to abort the circuit.)

A stop reading strategy was first described and used as part of the Sniper Attack [51], but we are the first to observe that each attack circuit should use a new and unique TCP connection in order to limit interference with other circuits built in parallel. This requires minor modifications to the Tor client code since Tor by default multiplexes circuits over existing TCP connections. We show in §7.3 that our bandwidth DoS attack scales to thousands of circuits using this approach.

## 7.2.2 Attack Targets

**Single Relay:** An adversary may use an 8-hop long path to conduct a congestion attack on a target victim relay by including the victim in the same circuit multiple times. Since an honest relay will not extend a circuit to the same relay that extended to it, the victim  $v$  must be placed in circuit positions such that two distinct honest relays  $h_1$  and  $h_2$  are placed in subsequent positions before repeating the victim

<sup>4</sup>Tor will tunnel TCP onion connections through a proxy (e.g., another Tor client) when using the `Socks4Proxy` or `Socks5Proxy` torrc options.

<sup>5</sup>A stream SENDME cell is sent for every 50 received cells (25 KiB) and a circuit SENDME for every 100 received cells (50 KiB).

(i.e.,  $v \rightsquigarrow h_1 \rightsquigarrow h_2 \rightsquigarrow v$ , etc.). Therefore, a victim may appear in the same circuit a maximum of 3 times (either in positions 1, 4, and 7, or 2, 5, and 8).

**Relay Subgroups:** An adversary may also target specific subgroups of relays that represent particularly attractive targets. Such subgroups may include the group of all exit relays (since their resources are the most scarce), the group of all publicly known bridges (we explored the impact of such an attack in §5), hidden service directories, and the group of 9 directory authorities (which also serve as relays).

**All Relays:** An adversary may also attempt to congest the entire Tor network with the goal of degrading performance to the extent that Tor becomes unusable to a majority of its user base, which would significantly reduce Tor’s security in addition to its performance [25]. In order to congest all relays, the adversary makes a weighted selection of relays following the weights published in the network consensus. In other words, the adversary uses the same path selection policy as honest clients do by default. This will ensure that the adversary will choose and congest relays with the same distribution that clients attempt to use them: the DoS attack will cause more congestion on relays that are chosen more often by clients, and should therefore impact more users.

## 7.2.3 Attack Strength

The strength of our attack can be described in terms of the number of long path circuits  $\phi$  that the adversary builds in parallel. Each circuit should use at least 2 parallel streams (i.e., downloads) in order to fully utilize the circuit flow control mechanism (the circuit window is 1,000 cells, twice that of the stream window). Whenever circuits close or downloads finish (complete or time out), circuits are replaced with new ones in order to maintain the attack strength over time.

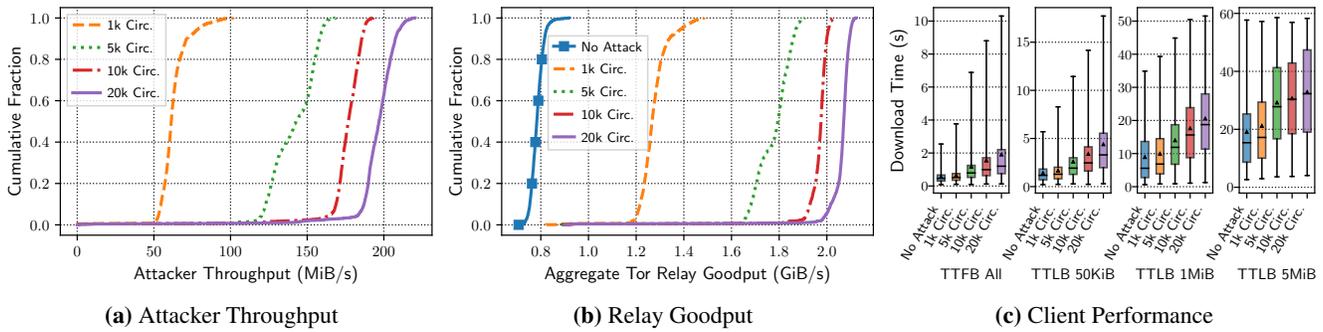

## 7.3 Evaluation

As in §6.4, we use Shadow [47] to safely measure the effects of our DoS attacks in a private Tor network. All experiments in this section use Shadow v1.13.0 and Tor v0.3.1.10.

**Network Setup:** We use the same tools and methods as described in §6.4 to generate a Tor network containing 634 relays (10% of the size and capacity of the public network), 15,000 clients (14,259 *web* clients, 441 *bulk* clients, and 300 *benchmark* clients), and 2,000 servers. Node behaviors are also as described in §6.4.

We implemented our DoS attacks in a C program containing 3,265 lines of code (LoC) which we compiled as a Shadow plugin. Our attacks utilize a Tor v0.3.1.10 client that we modified (409 LoC) to support creating new TCP connections for attack circuits as well as commands to stop reading and for sending SENDME cells.

**Parameter Settings:** Throughout our experiments, we explore the effects of the *Long Path* strategy across attack strengths (number of circuits  $\phi$ ) on performance. We parallelize our attack by running  $\phi/1,000$  identical processes on new attack hosts (i.e., 1,000 circuits per host), each of

**Figure 5:** Performance metrics as measured throughout our network-wide DoS attack on Tor relays: (a) the distribution of attacker throughput rates; (b) the distribution of aggregate Tor relay goodput rates (summed over all relays for each second); and (c) the distribution of *benchmark* client download times to first byte (TTFB) and last byte (TTLB) for files of sizes 50 KiB, 1 MiB, and 5 MiB (the box shows the interquartile range, the  $\blacktriangle$  shows the mean, and the lower and upper whiskers extend to the minimum and the 99th percentile values, respectively).

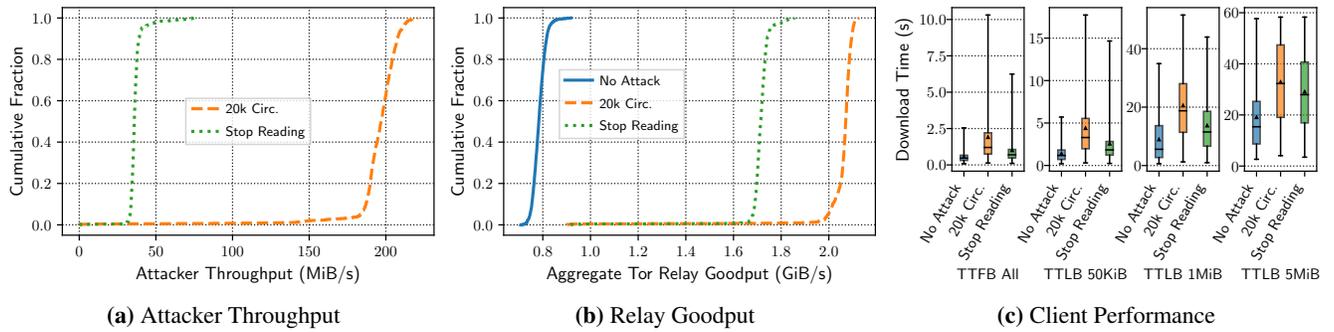

which is configured with a 1 Gbit/s network link to ensure that we could measure the full bandwidth cost of the attack. We attach 2 streams that each request 10 MiB of data to each 8-hop attack circuit whose path is chosen depending on the target (we explore a single relay and all relays as targets). We set each attack circuit to time out if any of its streams either have not completed within 5 minutes, or have not received a byte in the most recent 60 seconds. Finally, we run experiments with and without the *Stop Reading* strategy in order to understand the cost and impact of DoS with and without it. (We did not evaluate the *Tunneling* strategy or a strategy that targets *Relay Subgroups*.)

**Single Relay Attack:** We evaluated the *Long Path* strategy in a *Single Relay* attack against the most highly weighted middle relay in our network. We evaluated attack strengths of 100, 500, and 1,000 circuits. In all cases, the attacker required less than 2.6 MiB/s of throughput to conduct the attack. The victim relay’s throughput increased from 978 KiB/s with no attack to 3.8 MiB/s with 100 attack circuits and 5 MiB/s with both 500 and 1,000 attack circuits (in the medians). Interestingly, 500 circuits was enough to consume all of the victim’s 5 MiB/s capacity. In the medians, the time to download 1 MiB through the victim increased from 3.3 seconds with no attack to 28 seconds with 1,000 circuits, while the download failure rate increased from 0% with no attack to 63% with 1,000 attack circuits. Our results indicate that the attack has a clear effect on both relay throughput and client performance on a small scale.

**All Relays Attack:** We evaluated the *Long Path* strategy in an *All Relays* attack using  $\phi = 1k, 5k, 10k,$  and  $20k$  attack circuits. The performance measured during the attacks and compared to a no attack baseline experiment is shown in Figure 5. Figure 5(a) shows the cumulative distribution of the total attacker throughput used during each attack. Intuitively, the throughput used by the adversary increases with the number of attack circuits: from a median of 61 MiB/s in a  $\phi=1k$

circuit attack to a median of 197 MiB/s in a  $\phi=20k$  circuit attack. Note that the increase in attacker throughput is not linear in  $\phi$ , indicating that we may be reaching relay bandwidth resource limits. Figure 5(b) supports this claim, showing the distribution over each second of Tor network goodput (summed over all relays). In the medians, aggregate relay goodput increases from 802 MiB/s with no attack to 1,297 MiB/s for  $\phi=1k$  (an increase of 495 MiB/s) and 2,120 MiB/s for  $\phi=20k$  (an increase of 1,318 MiB/s). Interestingly, we can see from these results that the effect of  $\phi=10k$  circuits is much greater than the effect of doubling the attack strength to  $\phi=20k$  circuits, suggesting diminishing returns. Finally, the effect of our attack on client performance is shown in Figure 5(c) across a range of download time metrics. Generally, the time to complete downloads of various sizes increases significantly with the attack strength (e.g., TTFB increases by 138% and TTLB increases by 120% in the medians across all downloads for  $\phi=20k$ ), and the variance in performance also increases as attack circuits are added to the network.

Figure 6 shows the effect of the *Stop Reading* strategy on performance. Compared to the regular *Long Path* strategy in the  $\phi=20k$  attack, Figure 6(a) shows that the *Stop Reading* strategy consumed only 36 MiB/s of attacker bandwidth in the median while Figure 6(b) shows that the attack was still able to consume 1,755 MiB/s of total relay bandwidth in the median (an increase of 953 MiB/s over no attack). Figure 6(c) shows that the effect on client performance is also slightly less pronounced (TTFB increases by 48% and TTLB increases by 47% in the medians across all downloads), which is to be expected given that relays are less congested. We expect that we could further increase congestion by scaling up the *Stop Reading* attack at relatively little bandwidth cost to the attacker. A summary of our results in Table 4 shows that the *Stop Reading* strategy achieved the highest bandwidth amplification factor of 26 primarily due to the reduction in attacker bandwidth usage.

**Figure 6:** The effects of the *Stop Reading* attack on the performance metrics as measured throughout our network-wide 20,000 circuit DoS attacks on Tor relays: (a) the distribution of attacker throughput rates; (b) the distribution of aggregate Tor relay goodput rates (summed over all relays for each second); and (c) the distribution of *benchmark* client download times to first byte (TTFB) and last byte (TTFB) for files of sizes 50 KiB, 1 MiB, and 5 MiB (the box shows the interquartile range, the  $\blacktriangle$  shows the mean, and the lower and upper whiskers extend to the minimum and the 99th percentile values, respectively).

**Table 4:** Summary of the total increase in relay bandwidth usage our attack achieved with the given attacker bandwidth usage (all in MiB/s) and the resulting bandwidth amplification factors.

|                             | $\phi=1k$ | $\phi=5k$ | $\phi=10k$ | $\phi=20k$ | Stop* |
|-----------------------------|-----------|-----------|------------|------------|-------|
| <b>Relay Bandwidth</b>      | 495       | 1,035     | 1,221      | 1,318      | 953   |
| <b>Attacker Bandwidth</b>   | 61        | 143       | 177        | 197        | 36    |
| <b>Amplification Factor</b> | 8.1       | 7.2       | 6.9        | 6.7        | 26    |

\* Stop is a  $\phi=20k$  attack using the *Stop Reading* strategy.

## 7.4 Attack Cost

We assume that our DoS attacks could be launched on a dedicated server. In §3.2 we describe that the amortized cost in the dedicated server model for 1 Gbit/s of traffic is \$0.70/hr. (which includes the monthly hardware rental and any bandwidth costs). Our  $\phi=20k$  attack with the *Stop Reading* strategy requires only 288 Mbit/s (36 MiB/s) in our scaled down private Tor network which contains about 10% of both the number of relays in and the bandwidth capacity of the public Tor network (due to the relay sampling approach of Jansen et al. [48]). If we assume that the attack scales linearly with Tor’s bandwidth capacity, then our attack would require  $10 \cdot 288 \text{ Mbit/s} \approx 3 \text{ Gbit/s}$ . The cost to rent three dedicated servers supporting 1 Gbit/s of traffic for one month would then be  $\$0.70 \cdot 3 \cdot 24 \cdot 31 \approx \$1.6K$ . (The regular version of the attack consumes  $\approx 4$  times as much bandwidth, requiring 12 dedicated servers and costing  $\$0.70 \cdot 12 \cdot 24 \cdot 31 \approx \$6.3K/\text{mo.}$ )

Our attack additionally utilizes multiple client IP addresses, each of which is used to maintain an average of  $1,000/634 \approx 1.6$  circuits per relay. If (i) the public Tor network contains  $10 \cdot 634 = 6,340$  relays, (ii) we create  $10 \cdot 20,000 = 200,000$  circuits, and (iii) we maintain the average 1.6 circuits per relay per client IP address rate, then we would require  $200,000/6,340/1.6 \approx 20$  client IP addresses. If we assume that one IP address is provided for each of our three dedicated servers, and the cost is \$5 per additional IP

address, then the additional monthly cost for purchasing 17 more IP addresses is  $17 \cdot \$5 = \$85$ .

Thus, we estimate that the total cost to run a  $\phi=20k$  circuit attack using the *Stop Reading* strategy against the public Tor network is still \$1.6K/mo. due to rounding. (We estimate that the cost of the regular version of the attack is still \$6.3K/mo. due to rounding.)

## 7.5 Discussion

**Limitations:** We used Shadow in order to ethically conduct full-network Tor simulations, and simulation inherently incurs some inaccuracy. However, while no simulator is perfect, Shadow has been shown to exhibit network behavior and performance that is very similar to Linux [50, 52]. Additionally, Shadow has been used to measure performance when Tor is generally overloaded (as in our evaluation) [47, 49, 52], and it has been used to measure the effects of specific DoS attacks against Tor [51].

Our experiments are limited in scale. We simulated a private Tor network with about 10% of both the number of relays in and the bandwidth capacity of the public Tor network. The cost to the adversary to conduct our attack may not scale linearly with the amount of Tor capacity as we assumed in §7.4, or there may be other issues that arise when scaling up our attack. We note that we are limited by the capabilities of our tools and resources and highlight that it would be unethical to conduct this work at scale on the public Tor network.

**Attack Extensions:** We did not evaluate the effects of onion connection tunneling on DoS (i) because Tor could prevent the attack by updating the default exit policy to prevent exiting to a Tor relay, and (ii) in order to provide a more conservative estimate of the bandwidth and monetary costs of performing our bandwidth DoS attack. However, we believe that the technique would be simple to deploy. Additionally, it would be interesting to explore the effects of our attacks on performance when targeting subgroups of relays.

**Mitigations:** It is extremely challenging to mitigate bandwidth DoS attacks on Tor because the circuits that we build in our attack download an amount of traffic that a reasonable client could realistically download. The *Long Path* part of the attack could be mitigated if Tor changes its protocol to further restrict the length of circuits, however, in this case an adversary could switch to using hidden service circuits which are 6 hops by default.

The *Stop Reading* part of our attack uses a separate TCP connection to the entry relay for each attack circuit, and builds many such connections and circuits in parallel. Tor implemented mitigations to this kind of DoS attack and merged them in early 2018 [24, 39] in response to reports of DoS against relays [23, 38, 40]. In the new subsystem, relays will refuse new TCP connections from any IP address that creates more than 3 concurrent connections, and they will refuse new circuits from the IP address if it *also* creates more than 3 circuits per second with an allowable burst of 90 circuits (these were the default settings on 2018-11-01). Our Tor experiments were configured to run with these DoS mitigations in place, and our attacks did not trigger the DoS defense on any relay. Our attacks were able to stay under the connection threshold because we utilize every relay in the network as an entry relay and we maintain only 1,000 circuits per client IP address (1.6 circuits per relay per client IP address on average). While we do believe that the implemented mitigations are effective against some attacks, we note that the proliferation of IPv6 addressing may further reduce their effectiveness.

A defense against the Sniper Attack [45, 51] was merged in Tor v0.2.4.14-alpha (released on 2013-06-13). The defense detects and kills the circuit with the longest waiting cell at the head of the queue if the relay is under memory (RAM) pressure. The defense was active but was not triggered in our experiments since we only download 20 MiB of data through each circuit before abandoning it (our goal is to consume bandwidth rather than a victim’s RAM as in the Sniper Attack, so we do not require long queues).

In order to further limit the impact of the *Stop Reading* strategy, we recommend the implementation and deployment of the authenticated SENDME design as previously described [51] and specified [46]. With authenticated SENDMEs, a client would need to continue reading data in order to continue producing authentic SENDME cells, and the exit would destroy circuits on which it received invalid SENDMEs. This defense would limit a stop reading DoS strategy to 1,000 cells (500 KiB) per circuit, effectively mitigating it.

## 8 Sybil Attacks

We previously explored several bandwidth-based DoS attacks against Tor while estimating the cost to conduct each attack and their effects on Tor performance; we summarize our cost estimates in Table 5. In this section, we compare our DoS attacks with a Sybil attack in which an adversary

**Table 5:** A summary of the costs of our main attacks.

| Attack (Section)       | Service     | Bandwidth | Cost       |
|------------------------|-------------|-----------|------------|
| Bridge Congestion (§5) | stresser    | 30 Gbit/s | \$17K/mo.  |
| Load Unbalancing (§6)  | stresser    | 5 Gbit/s  | \$2.8K/mo. |
| Relay Congestion (§7)  | ded. server | 3 Gbit/s  | \$1.6K/mo. |

**Table 6:** The effective mean aggregate bandwidth resources of Tor relays from 2017-11-01 to 2018-11-01 (in Gbit/s), computed using positional bandwidth weights from 2018-11-01.

| Bandwidth | Entry        | Middle       | Exit         | Total |
|-----------|--------------|--------------|--------------|-------|
| Usage     | 42.4 (36.0%) | 42.9 (36.4%) | 32.5 (27.6%) | 118   |
| Capacity  | 86.7 (35.0%) | 96.7 (39.1%) | 64.0 (25.9%) | 247   |

instead uses its budget to run several high-bandwidth Tor relays in order to affect as much Tor user traffic as possible.

**Relay Resources:** To determine which type of relays would be most advantageous, we computed the effective positional bandwidth usage by and capacity of Tor relays over the year preceding 2018-11-01. The *effective bandwidth* accounts for relay flags and position weights, both of which are used to determine in which position a relay will be selected. From the results shown in Table 6, we can see that exit bandwidth is the scarcest, with only 27.6% of the total bandwidth used and 25.9% of the total bandwidth capacity.

**Sybil DoS Attack:** An adversary could run Sybil relays and then arbitrarily degrade the performance of all traffic forwarded through its Sybils, or deny service by dropping circuits. Note that for such an attack to work, the adversary must (i) maintain a high selection probability by providing high performance during periods in which it is measured by Tor’s bandwidth measurement system, and (ii) not trigger Tor’s abusive relay detection systems (e.g., exit scanners) to avoid getting ejected from the network. We assume that these requirements can be met for the purposes of this analysis.

Due to exit bandwidth scarcity, an adversary can maximize its probability of appearing at least once in a circuit by running all exit relays. We assume that the aggregate bandwidth *usage* (i.e., network load) will remain constant as the adversary adds additional bandwidth *capacity* (i.e., Sybil relays), and that the probability that the adversary serves as the exit in a circuit is approximately equal to its fractional exit capacity (Table 6). Then, Sybil DoS attacks with bandwidth budgets of 30, 5, and 3 Gbit/s (Table 5) could arbitrarily degrade performance for  $30/(30+64) \approx 32\%$ ,  $5/(5+64) \approx 7.2\%$ , and  $3/(3+64) \approx 4.5\%$  of exit circuits, respectively. Comparatively, our attack in §5 affects *all* non-private bridge circuits, and our attacks in §6 and §7 affect *all* circuits.

**Sybil Deanonimization Attack:** If an adversary is able to observe both the entry and exit points in a circuit (its relays are chosen in the first and last circuit positions), then it is generally assumed that the circuit is *vulnerable* to compromise because traffic correlation can be performed to deanonymize the user with high probability [65, 66]. Note

**Table 7:** The fraction of circuits affected by Sybil attacks.

| Bandwidth | Sybil DoS     | Sybil Deanonimization                        |
|-----------|---------------|----------------------------------------------|
| 30 Gbit/s | 32% degraded  | 21% entry · 5.3% exit $\approx$ 1.1% total   |
| 5 Gbit/s  | 7.2% degraded | 4.5% entry · 1.2% exit $\approx$ 0.06% total |
| 3 Gbit/s  | 4.5% degraded | 2.8% entry · 0.8% exit $\approx$ 0.02% total |

that a selective service refusal attack, where an adversary refuses to forward traffic on any circuit it is not in a position to compromise [16], could be mitigated by Tor’s route manipulation (path bias) detection system [26, §7].

In order to observe both ends, an adversary must operate at least one entry guard and at least one exit relay. The entry position is more difficult to obtain since Tor clients use the same guard relay for months at a time [29]. Therefore, previous work has found that a 5:1 guard-to-exit relay bandwidth allocation maximizes the probability of observing both sides of a circuit at least once [54].

A Sybil deanonymization attack with a bandwidth budget of 3 Gbit/s (Table 5) and a 5:1 guard-to-exit relay bandwidth allocation would allow the adversary to observe the entry for  $\frac{5}{6} \cdot 3 / (\frac{5}{6} \cdot 3 + 86.7) \approx 2.8\%$  of Tor clients and observe the exit for  $\frac{1}{6} \cdot 3 / (\frac{1}{6} \cdot 3 + 64.0) \approx 0.8\%$  of circuits built by those clients. Thus, approximately 0.02% of circuits would be vulnerable. Table 7 shows results for other bandwidth budgets and summarizes our Sybil attack analysis.

**Discussion:** Note that Sybil attacks require fixed costs, because relays must generally be fast and reliable in order to be properly utilized by the network. Additionally, attacks that require guard relays can take months to observe a full set of *some* clients (due to guard rotation times), and much longer to observe a set containing *specific* clients. Conversely, our attacks are more flexible because they do not require fixed costs, can be run with clients rather than service providers (relays), and can be repeatedly started and stopped as necessary. Further, our attacks immediately affect all clients (rather than some sample), and our relay congestion attack (§7) benefits from the anonymity that Tor provides.

## 9 Conclusion

This paper performs a multifaceted examination of Tor’s vulnerability to DoS, considering both the efficacy of DoS attacks as well as the adversary’s cost of performing them. On the positive side, we find that Tor’s growth has made it more resilient at least to simple attacks: disrupting the service by naïvely flooding Tor relays using stresser services is an expensive proposition and requires \$7.2M/month.

Unfortunately, however, several aspects of Tor’s design and rollout make it susceptible to more advanced attacks. We find that Tor’s bridge infrastructure is heavily dependent on a small set of fixed default bridges, the operational of which can be disrupted at a cost of \$17K/month. Additionally, Tor’s mechanism for measuring load is too centralized and brittle,

and even inexpensive techniques (e.g., costing \$2.8K/month) can significantly perturb these processes and cause dramatic performance degradation across the network. Finally, attackers can saturate Tor’s capacity by constructing long paths in the network, and exploit protocol vulnerabilities to decrease the costs of such attacks; for example, we find that an attacker can significantly degrade the performance of the network for as little as \$1.6K/month. We also compare our attacks to Sybil attacks and highlight that our load balancing and relay congestion attacks are more effective and flexible than Sybil attacks with the same budget.

For each attack, we describe mitigation strategies that Tor could adopt to improve its resiliency. In particular, we recommend additional financing for meek bridges, moving away from load balancing approaches that rely on centralized scanning, and Tor protocol improvements (in particular, the use of authenticated SENDME cells).

## Acknowledgments

We thank the anonymous reviewers for their valuable feedback that helped to improve this paper. We thank Nikita Borisov for shepherding our paper and David Goulet for discussions about DoS mitigation in Tor. This work has been partially supported by the Office of Naval Research, the National Science Foundation under grant number CNS-1527401, and the Defense Advanced Research Projects Agency (DARPA) under Contract No. HR0011-16-C-0056. ## Abstract

Mix networks are a key technology to achieve network anonymity and private messaging, voting and database lookups. However, simple mix network designs are vulnerable to malicious mixes, which may drop or delay packets to facilitate traffic analysis attacks. Mix networks with provable robustness address this drawback through complex and expensive proofs of correct shuffling but come at a great cost and make limiting or unrealistic systems assumptions. We present *Miranda*, an efficient mix-net design, which mitigates active attacks by malicious mixes. *Miranda* uses both the detection of corrupt mixes, as well as detection of faults related to a pair of mixes, without detection of the faulty one among the two. Each active attack – including dropping packets – leads to reduced connectivity for corrupt mixes and reduces their ability to attack, and, eventually, to detection of corrupt mixes. We show, through experiments, the effectiveness of *Miranda*, by demonstrating how malicious mixes are detected and that attacks are neutralized early.

## 1 Introduction

The increasing number of bombshell stories [27, 19, 10] re-grading mass electronic surveillance and illicit harvesting of personal data against both ordinary citizens and high-ranking officials, resulted in a surge of anonymous and private communication tools. The increasing awareness of the fact that our daily online activities lack privacy, persuades many Internet users to turn to encryption and anonymity systems which protect the confidentiality and privacy of their communication. For example, services like WhatsApp and Signal, which offer protection of messages through end-to-end encryption, gained popularity over the past years. However, such encryption hides only the content but not the meta-data of the message, which carries a great deal of privacy-sensitive information. Such information can be exploited to infer who is communicating with whom, how often and at what times. In contrast, the circuit-based onion routing Tor

network is an example of anonymity systems that protect the meta-data. Tor is currently the most popular system offering anonymity, attracting almost 2 million users daily. However, as research has shown [47, 40, 42, 41], Tor offers limited security guarantees against traffic analysis.

The need for strong anonymity systems resulted in renewed interest in *onion mixnets* [12]. In an onion mixnet, sender encrypts a message multiple times, using the public keys of the destination and of multiple mixes. Onion mixnets are an established method for providing provable protection against meta-data leakage in the presence of a powerful eavesdropper, with low computational overhead. Early mixnets suffered from poor scalability, prohibitive latency and/or low reliability, making them unsuitable for many practical applications. However, recently, researchers have made significant progress in designing mixnets for high and low latency communication with improved scalability and performance overhead [44, 48, 13]. This progress is also visible in the industrial sector, with the founding of companies whose goal is to commercialise such systems [1, 2].

Onion mixnets offer strong anonymity against passive adversaries: a single honest mix in a cascade is enough to ensure anonymity. However, known mixnet designs are not robust against *active* long-term traffic analysis attacks, involving *dropping* or *delaying* packets by malicious mixes. Such attacks have severe repercussions for privacy and efficiency of mix networks. For example, a disclosure attack in which a rogue mix strategically drops packets from a specific sender allows the attacker to infer with whom the sender is communicating, by observing which recipient received fewer packets than expected [4]. Similarly, Denial-of-Service (DoS) attacks can be used to enhance de-anonymization [9], and  $(n - 1)$  attacks allow to track packets over honest mixes [45].

It is challenging to identify and penalize malicious mixes while retaining strong anonymity and high efficiency. Trivial strategies for detecting malicious mixes are fragile and may become vectors for attacks. Rogue mixes can either hide their involvement or worse, make it seem like honest mixes are unreliable, which leads to their exclusion from the net-

work. Several approaches to the problem of active attacks and reliability were studied, however, they have significant shortcomings, which we discuss in Section 8.

In this work, we revisit the problem of making decryption mix networks robust to malicious mixes performing active attacks. We propose *Miranda*<sup>1</sup>, an efficient reputation-based design, that detects and isolates active malicious mixes. We present security arguments that demonstrate the effectiveness of *Miranda* against active attacks. The architectural building blocks behind *Miranda* have been studied by previous research, but we combine them with a novel approach which takes advantage of detecting failure of inter-mix links, used to isolate and disconnect corrupt mixes, in addition to direct detection of corrupt mixes. This allows *Miranda* to mitigate corrupt mixes, without requiring expensive computations.

*Miranda* disconnects corrupt mixes by carefully gathering evidence of their misbehavior, resulting in the removal of links which are misused by the adversary. The design includes a set of secure and decentralized *mix directory authorities* that select and distribute mix cascades once every *epoch*, based on the gathered evidence of the faulty links between mixes. Repeated misbehaviors result in the complete exclusion of the misbehaving mixes from the system (see Figure 1).

We believe that *Miranda* is an important step toward a deployable, practical strong-anonymity system. However, *Miranda* design makes several significant simplifying assumptions. These include (1) a fixed set of mixes (no churn), (2) a majority of benign mixes (no Sybil), (3) reliable communication and efficient processing (even during DoS), and (4) synchronized clocks. Future work should investigate, and hopefully overcome, these challenges; see Section 9.

**Contributions.** Our paper makes the following contributions:

- We present *Miranda*, an efficient, low-cost and scalable novel design that detects and mitigates active attacks. To protect against such attacks, we leverage reputation and local reports of faults. The *Miranda* design can be integrated with other mix networks and anonymous communication designs.
- We propose an encoding for secure *loop messages*, that may be used to securely test the network for dropping attacks – extending traditional mix packet formats for verifiability.
- We show how *Miranda* can take advantage of techniques like community detection in a novel way, which further improves its effectiveness.
- We analyze the security properties of *Miranda* against a wide range of attacks.

<sup>1</sup>“*Miranda* warning” is the warning used by the US police, in order to notify people about their rights before questioning them. Since *Miranda* prevents adversaries from silently (but actively) attacking the mix network, we refer to it as *no right to remain silent*.

**Overview.** The rest of this paper is organized as follows. In Section 2, we discuss the motivation behind our work, and define the threat model and security goals. In Section 3, we present important concepts of *Miranda*. In Sections 4 and 5, we detail the core protocols of *Miranda*, which detect and penalize active attacks. In Section 6, we present improved, *community-based* detection of malicious mixes. In Section 7, we evaluate the security properties of *Miranda* against active attacks. In Section 8, we contrast our design to related work. Finally, we discuss future work in Section 9 and conclude in Section 10.

## 2 The Big Picture

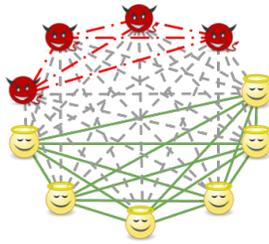

In this section, we outline the general model of the *Miranda* design, define the threat model, and motivate our work by quantifying how active attacks threaten anonymity in mix networks. Then, we summarize the security goals of *Miranda*.

### 2.1 General System Model

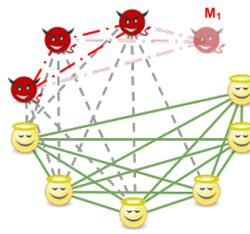

We consider an anonymous communication system consisting of a set of users communicating over the *decryption mix network* [12] operating in synchronous batches, denoted as *rounds*. Depending on the path constraints, the topology may be arranged in separate cascades or a Stratified network [21]. We denote by  $\mathcal{M}$  the set of all mixes building the anonymous network. For simplicity, in this work we assume that the set of mixes  $\mathcal{M}$  is fixed (no churn). See discussion in Section 9 of this and other practical challenges.

Messages are end-to-end *layer encrypted* into a cryptographic packet format by the sender, and the recipient performs the last stage of decryption. Mixes receive packets within a particular round, denoted by  $r$ . Each mix decodes a successive layer of encoding and shuffles all packets randomly. At the end of the round, each mix forwards all packets to their next hops. Changing the binary pattern of packets by removing a single layer of encryption prevents bit-wise correlation between incoming and outgoing packets. Moreover, mixing protects against an external observer, by obfuscating the link between incoming and outgoing packets.

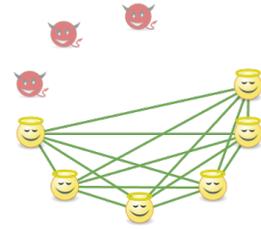

**Message packet format.** In this paper, we use the Sphinx cryptographic packet format [15]. However, other packet formats can be used, as long as they fulfill certain properties. The messages encoded should be of *constant length* and *indistinguishable* from each other at any stage in the network. Moreover, the encryption should guarantee *duplicates detection*, and eliminate tampered messages (*tagging attacks*). The packet format should also allow senders to encode arbitrary routing information for mixes or recipients. We denote the result of encoding a message as  $\text{Pack}(\text{path}, \text{routingInfo}, \text{rnd}, \text{recipient}, \text{message})$ , where  $\text{rnd}$

(a) Connectivity graph in the beginning. All mixes are willing to communicate with each other.

(b) Miranda detects active attacks and removes the links between the honest and dishonest nodes (Section 4.3).

(c) Miranda applies community detection (Section 6) to further detect dishonest nodes and disconnect them from the honest nodes.

Figure 1: High-level overview of the process of isolating malicious mixes in Miranda.

denotes a random string of bits used by the packet format.

## 2.2 Threat Model

We consider an adversary whose goal is to de-anonymize packets traveling through the mix network. Our adversary acts as a *global observer*, who can eavesdrop on all traffic exchanged among the entities in the network, and also, knows the rate of messages that Alice sends/receives<sup>2</sup>. Moreover, all malicious entities in the system collude with the adversary, giving access to their internal states and keys. The adversary may control many participating entities, but we assume a majority of honest mixes and *directory servers* (used for management, see Section 3). We allow arbitrary number of malicious clients but assume that there are (also) many honest clients - enough to ensure that any first-mix in a cascade, will receive a ‘sufficient’ number of messages in most rounds - say,  $2\omega$ , where  $\omega$  is sufficient to ensure reasonable anonymity, for one or few rounds.

In addition, Miranda assumes reliable communication between any pair of honest participants, and ignores the time required for computations - hence, also any potential for Miranda-related DoS. In particular, we assume that the adversary cannot arbitrarily drop packets between honest parties nor delay them for longer than a maximal period. This restricted network adversary is weaker than the standard Dolev-Yao model, and in line with more contemporary works such as XFT [35] that assumes honest nodes can eventually communicate synchronously. It allows more efficient Byzantine fault tolerance schemes, such as the one we present. In practice, communication failures *will* occur; see discussion in Section 9 of this and other practical challenges.

We denote by  $n$  the total number of mixes in the network ( $|\mathcal{M}| = n$ ),  $n_m$  of which are malicious and  $n_h$  are honest ( $n = n_m + n_h$ ). We refer to cascades where all mixes are malicious as *fully malicious*. Similarly, as *fully honest* we refer to cascades where all nodes are honest, and *semi-honest* to

<sup>2</sup>We emphasize that this is a non-trivial adversarial advantage. In reality, the adversary might not know Alice’s rate, and therefore might be more limited regarding de-anonymization attacks.

the ones where only some of the mixes are honest. A link between an honest mix and a malicious mix is referred to as a *semi-honest* link.

## 2.3 What is the Impact of Active Attacks on Anonymity?

Active attacks, like dropping messages, can result in a catastrophic advantage gained by the adversary in linking the communicating parties. To quantify the advantage, we defined a security game, followed by a qualitative and composable measure of security against dropping attacks. To our knowledge, this is the first analysis of such attacks and we provide full details in [34]. Our results support the findings of previous works on statistical disclosure attacks [4] and DoS-based attacks [9], arguing that the traffic analysis advantage gained from dropping messages is significant. We found that the information leakage for realistic volumes of traffic (10–100 messages per round) is quite significant: *the adversary can improve de-anonymization by about 20%*. For larger traffic rates (more than 1000 messages per round) the leakage drops but expecting each client to receive over 1000 messages per round on average seems unrealistic, unless large volumes of synthetic cover traffic is used. The lesson drawn from our analysis and previous studies is clear: it is crucial to design a mechanism to detect malicious nodes and remove them from the system after no more than a few active attacks. The Miranda design achieves this goal.

## 2.4 Security Goals of Miranda

The main goal of a mix network is to hide the correspondence between senders and recipients of the messages in the network. More precisely, although the communication is over cascades that might contain malicious mixes, the Miranda design aims to provide protection which is *indistinguishable from the protection provided by an ‘ideal mix’*, i.e., a single mix node which is known to be honest.

The key goals of Miranda relate to alleviating and discouraging active attacks on mix networks, as they have a significant impact on the anonymity through traffic analysis. This is achieved through the detection and exclusion of misbehaving mixes. The Miranda design offers the following protections against active attacks:

**Detection of malicious nodes.** Every active attack by a corrupt mix is detected with non-negligible probability, by at least one entity.

**Separation of malicious nodes.** Every active attack by a rogue mix results, with a non-negligible probability, in the removal of at least one link connected to the rogue mix - or even removal of the rogue mix itself.

**Reducing attacks impact over multiple epochs.** Repeated application of Miranda lowers the overall prevalence and impact of active attacks by corrupt mixes across epochs, limiting the ability of the adversary to drop or delay packets.

### 3 Rounds, Epochs and Directories

In Miranda, as in other synchronous mixnet designs, time is broken into *rounds*, and in each round, a mix ‘handles’ all messages received in the previous round. However, a more unique element of Miranda is that rounds are collected into *epochs*. Epochs are used to manage Miranda; the beginning of each epoch includes announcement of the set of cascades to be used in this epoch, after a selection process that involves avoidance of mixes detected as corrupt - and of links between two mixes, where one or both of the mixes reported a problem.

The process of selecting the set of cascades for each epoch, is called the *inter-epoch process*, and is performed by a set of  $d$  servers referred to as *directory authorities*, following [14], which maintain a list of available mixes and links between them. We assume that a number  $d_m$  of authorities can be malicious and collude with the adversary or deviate from the protocol, in order to break the security properties. By  $d_h$  we denote the number of honest authorities ( $d = d_m + d_h$ ), which follow the protocol truthfully.

During each epoch, there are multiple rounds where users communicate over the mix network. Both users and mixes report any misbehavior they encounter to the directory authorities. The *directory authorities* process these reports, and, before the beginning of a new epoch, they select a set of cascades available in that epoch. The newly generated cascades will reflect all reported misbehaviors. Namely, cascades exclude links that were reported, or mixes involved in too many reports, or detected via Miranda’s *community-based attacker detection mechanisms*, described in Section 6.

We denote the number of reports which marks a mix as dishonest and causes its exclusion from the network as *thresh* and emphasize that *thresh* is cumulative over rounds and even epochs. In this paper, we simply use  $thresh = n_m + 1$ , which suffices to ensure that malicious mixes cannot cause

Miranda to exclude honest mixes. However, we find it useful to maintain *thresh* as a separate value, to allow the use of larger value for *thresh* to account for a number of failures of honest mixes or links between honest mixes, when the Miranda design is adopted by a practical system.

Significant, although not prohibitive, processing and communication is involved in the inter-epoch process; this motivates the use of longer epochs. On the other hand, during an entire epoch, we use a fixed set of cascades, which may reduce due to failures; and clients may not be fully aware of links and mixes detected as faulty. This motivates the use of shorter epochs. These considerations would be balanced by the designers of an anonymous communication system, as they incorporate the Miranda design.

## 4 Intra-Epoch Process

In this section, we present the mechanisms that operate during an epoch to deter active attacks, including dropping attacks. We start by describing how active attacks are detected and how this deters malicious behavior. Next, we discuss nodes who refuse to cooperate.

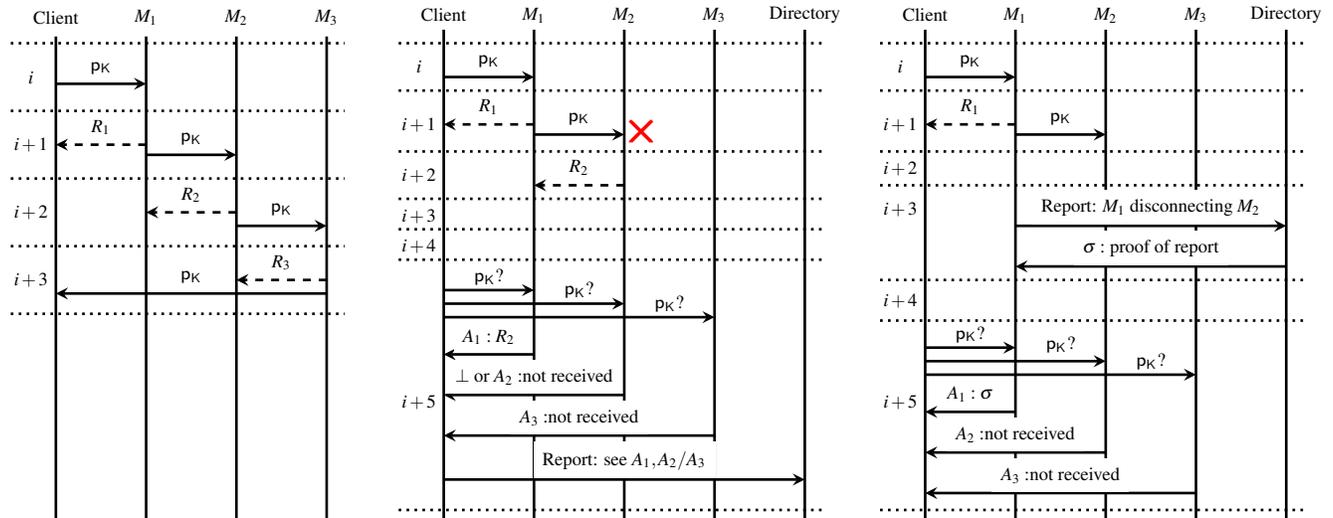

Note that in this section, as in the entire Miranda design, we assume reliable communication between any pair of honest participants. As we explain in Subsection 2.2, a practical system deploying Miranda should use a lower-layer protocol to deal with (even severe) packet losses, and we developed such efficient protocol - see [5].

### 4.1 Message Sending

At the beginning of each epoch, clients acquire the list of all currently available cascades from the directory authorities. When Alice wants to send a message, her client filters out all cascades containing mixes through which she does not wish to relay messages. We denote the set of cascades selected by Alice as  $C_A$ . Next, Alice picks a random cascade from  $C_A$ , which she uses throughout the whole epoch, and encapsulates the message into the packet format. For each mix in the cascade, we include in the routing information the exact round number during which the mix should receive the packet and during which it should forward it. Next, the client sends the encoded packet to the first mix on the cascade. In return, the mix sends back a *receipt*, acknowledging the received packet.

### 4.2 Processing of Received Packets

After receiving a packet, the mix decodes a successive layer of encoding and verifies the validity of the expected round  $r$  and well-formedness of the packet. At the end of the round, the mix forwards all valid packets to their next hops. Miranda requires mixes to acknowledge received packets by sending back receipts. A receipt is a digitally signed [31]

(a) Successful loop packet  $p_k$  sent during round  $i$  and received during round  $i+3$ . Each mix  $M_i$  sends back receipt  $R_i$ .

(b) Example of naive dropping of loop message  $p_k$  by  $M_2$ , which drops  $p_k$  yet sends back a receipt. Since  $p_k$  did not come back the client queries all mixes during round  $i+5$  for the proof of forwarding.  $M_2$  either claims that it did not receive  $p_k$  ( $A_2$ ), thus providing the client a proof that conflicts with the receipt  $R_2$ , or  $M_2$  does not cooperate ( $\perp$ ). In both cases the directory authority verifies received  $A_i$ 's and excludes malicious  $M_2$ .

(c) Loop packet fails to complete the loop due to non-responding mix.  $M_1$  did not receive receipt from  $M_2$  on round  $i+2$  and issues a disconnection in round  $i+3$ . The client performs the query phase on round  $i+5$  and receives the proof of disconnection. The result:  $M_2$  failed to send a receipt to  $M_1$ , and thus lost the link to it.

Figure 2: A diagram illustrating loop packets and isolation process. We denote receipt from mix  $M_i$  as  $R_i$ , and the response as  $A_i$ . Note that both in (b) and (c) the entire query and report phases occur during round  $i+5$ , but it could also be spanned across several rounds, as long as it has a bounded time-frame. For example, if desired, answering the query for  $p_k$  could be done in round  $i+6$  instead of limiting it to the same round.

statement confirming that a packet  $p$  was received by mix  $M_i$ . Receipts must be sent and received by the preceding mix within the same round in which packet  $p$  was sent.

**Generating receipts.** For simplicity, we denote a receipt for a single packet  $p$  as receipt  $\leftarrow \text{Sign}(p \parallel \text{receivedFlag} = 1)$ , where  $\text{Sign}(\cdot)$  is a secure digital signature algorithm, and  $\text{Verify}(\cdot)$  is its matching verification function<sup>3</sup>. However, generating receipts for each packet individually incurs a high computational overhead due to costly public key signature and verification operations.

To reduce this overhead, mixes gather all the packets they received during round  $r$  in Merkle trees [37] and sign the root of the tree once. Clients' packets are grouped in a single Merkle tree  $T_C$  and packets from mix  $M_i$  are grouped in a Merkle tree  $T_{M_i}$ . Mixes then generate two types of receipts: (1) receipts for clients and (2) aggregated receipts for mixes. Each client receives a receipt for each message she sends. Client receipts are of the form: receipt =  $(\sigma_C, \Gamma_p, r)$ , where:  $\sigma_C$  is the signed root of  $T_C$ ,  $\Gamma_p$  is the appropriate information needed to verify that packet  $p$  appears in  $T_C$ , and  $r$  is the round number. Similarly, each mix, except the last one, receives a receipt in response to all the packets it forwarded

<sup>3</sup>Although  $\text{Sign}$  and  $\text{Verify}$  use the relevant cryptographic keys, we abuse notations and for simplicity write them without the keys.

in the last round. However, unlike client receipts, mixes expect back a *single* aggregated receipt for all the packets they sent to a specific mix. An aggregated receipt is in the form of: receipt =  $(\sigma_i, r)$ , where:  $\sigma_i$  denotes the signed root of  $T_{M_i}$  and  $r$  is the round number. Since mixes know which packets they forwarded to a particular mix, they can recreate the Merkle tree and verify the correctness of the signed tree root using a single receipt. Once a mix sent an aggregated receipt, it expects back a signed confirmation on that aggregated receipt, attesting that it was delivered correctly. Mixes record the receipts and confirmations to prove later that they behaved honestly in the mixing operation.

**Lack of a receipt.** If a mix does not receive an aggregated receipt or does not receive a signed confirmation on an aggregated receipt it sent within the expected time slot<sup>4</sup>, the mix disconnects from the misbehaving mix. The honest mix detaches from the faulty mix by informing the directory authorities about the disconnection through a *signed link disconnection receipt*. Note, that the directories cannot identify which of the disconnecting mixes is the faulty one merely based on this message, because the mix who sent the complaint might be the faulty one trying to discredit the hon-

<sup>4</sup>Recall that we operate in a synchronous setting, where we can bound the delay of an acknowledgement.

est one. Therefore, the directory authorities only disconnect the *link* between the two mixes. The idea of disconnecting links was earlier investigated in various Byzantine agreement works [23], however, to our knowledge this approach was not yet applied to the problem of mix network reliability.

**Anonymity loves company.** Note, however, that this design may fail even against an attacker who does not control any mix, if a cascade receives less than the *minimal anonymity set size*  $\omega$ . We could ignore this as a very unlikely event, however, Miranda ensures anonymity also in this case - when the first mix is honest. Namely, if the first mix receives less than  $\omega$  messages in a round, it would not forward any of them and respond with a special ‘under- $\omega$  receipt’ explaining this failure. To prevent potential abuse of this mechanism by a corrupt first mix, which receives over  $\omega$  messages yet responds with under- $\omega$  receipt, these receipts are shared with the directories, allowing them to detect such attacks.

### 4.3 Loop Messages: Detect Stealthy Attacks

In a *stealthy active attack*, a mix drops a message - yet sends a receipt as if it forwarded the message. To deter such attacks, clients periodically, yet randomly, *send loop messages to themselves*. In order to construct a *loop message*, the sender  $S$ , chooses a unique random bit-string  $K_S$ . Loop messages are encoded in the same manner as regular messages and sent through the same cascade  $C$  selected for the epoch, making them *indistinguishable* from other messages at any stage of their routing. The *loop message* is encapsulated into the packet format as follows:

$$p_K \leftarrow \text{Pack}(\text{path} = C, \text{routingInfo} = \text{routing}, \text{rnd} = H(K_S) \\ \text{recipient} = S, \text{message} = \text{“loop”})$$

The tuple  $(S, K_S, C, \text{routing})$  acts as the *opening value*, which allows recomputing  $p_K$  as well as all its intermediate states  $p_K^i$  that mix  $M_i$  should receive and emit. Therefore, revealing the *opening value* convinces everyone that a particular packet was indeed a *loop message* and that its integrity was preserved throughout its processing by all mixes. Moreover, the construction of the *opening value* ensures that only the creator of the loop packet can provide a valid *opening value*, and no third party can forge one. Similarly, nobody can reproduce an opening value that is valid for a non-loop packet created by an honest sender.

If a loop message fails to complete the loop back, this means that one of the cascade’s mixes misbehaved. The sender  $S$  queries all the mixes in the cascade for evidence whether they have received, processed and forwarded the loop packet. This allows  $S$  to isolate the cascade’s problematic link or misbehaving mix which caused the packet to be dropped.  $S$  then reports the isolated link or mix to the directory authorities and receives a signed confirmation on her report. This confirmation states that the link will no longer be used to construct future cascades. We detail the querying

and isolation process in Section 4.3.2.

#### 4.3.1 When to send loop messages?

The sending of loop messages is determined according to  $\alpha$ , which is the required *expected probability of detection* - a parameter to be decided by the system designers. Namely, for every message, there is a fraction  $\alpha$  chance of it being a loop message. To achieve that, if Alice sends  $\beta$  messages in round  $r$ , then  $\lceil \frac{\alpha \cdot \beta}{1 - \alpha} \rceil$  additional loop messages are sent alongside the genuine messages.

This may seem to only ensure  $\alpha$  in the context of the messages that Alice *sends* but not against an attack on messages *sent to* Alice. However, notice that if a corrupt mix  $M_i$  drops messages sent to Alice by an honest sender Bob, then  $M_i$  faces the same risk of detection - by Bob.

If Alice can sample and estimate an upper bound  $\gamma$  on the number of messages that she will *receive* in a particular round, then she can apply additional defense. Let  $x$  be the number of rounds that it takes for a loop message to come back, and let  $r$  denote the current round. Let’s assume that Alice knows bound  $\gamma$  on the maximal number of messages from honest senders, that she will receive in round  $r + x$ . Then, to detect a mix dropping messages sent to her with probability  $\alpha$ , it suffices for Alice to send  $\lceil \frac{\alpha \cdot \gamma}{1 - \alpha} \rceil$  loop messages in round  $r$ . More precisely, given that Alice sends  $\beta$  messages in round  $r$ , in order for the loop messages to protect both messages sent in that round and messages received in round  $r + x$  she should send  $\lceil \frac{\alpha \cdot \max(\beta, \gamma)}{1 - \alpha} \rceil$  loop messages in round  $r$ .

**Within-round timing.** If the Miranda senders would send each message immediately after receiving the message from the application, this may allow a corrupt first mix to distinguish between a loop message and a ‘regular’ message. Namely, this would occur if the attacker knows the exact time at which the application calls the ‘send’ function of Miranda to send the message. To foil this threat, in Miranda, messages are always sent only during the round following their receipt from the application, and after being shuffled with all the other messages to be sent during this round.

#### 4.3.2 Isolating corrupt mixes with loop messages

Since clients are both the generators and recipients of the attack-detecting *loop messages*, they know exactly during which round  $r$  the loop should arrive back. Therefore, if a *loop message* fails to complete the loop back to the sender as expected, the client initiates an *isolation* process, during which it detects and isolates the specific problematic node or link in the cascade. The isolation process starts with the client querying each of the mixes on the cascade to establish whether they received and correctly forwarded the loop packet. During the querying phase, the client first reveals to the respective mixes the packet’s *opening value*, in order

to prove that it was indeed a loop packet. Next, the client queries the mixes for the receipts they received after they delivered that packet. When clients detect a problematic link or the misbehaving mix, they report it to the directory authorities, along with the necessary proofs that support its claim. This is in fact a broadcasting task in the context of the well-known *reliable broadcast problem* and can be solved accordingly [36]. Each directory authority that receives the report verifies its validity, and if it is correct, stores the information to be used in future cascade generation processes. Then, the client chooses another cascade from the set of available cascades and sends future packets and loop messages using the new route. For an illustration of loop packets and the isolation process, see Figure 2.

When a client asks an honest mix to prove that it received and correctly forwarded a packet, the mix presents the relevant receipt. However, if a mix did not receive this packet, it attests to that by returning an appropriate signed response to the client. If a loop message did not complete the loop because a malicious mix dropped it and did not send a receipt back, the honest preceding mix would have already disconnected from the misbehaving mix. Thus, the honest mix can present the appropriate *disconnection receipt* it received from the directory authorities as an explanation for why the message was not forwarded (see Figure 2c).

The malicious mix can attempt the following actions, in order to perform an active attack.

**Naive dropping.** A mix which simply drops a loop packet after sending a receipt to the previous mix can be detected as malicious beyond doubt. When the client that originated the dropped loop packet queries the preceding mix, it presents the receipt received from the malicious mix, proving that the packet was delivered correctly to the malicious node. However, the malicious mix is unable to produce a similar receipt, showing that the packet was received by the subsequent mix, or a receipt from the directories proving that it reported disconnection from the subsequent mix. The malicious mix may simply not respond at all to the query. However, the client will still report to the directories, along with the proofs from the previous and following mixes, allowing the directories to resolve the incident (contacting the suspected mix themselves to avoid any possible ‘framing’) (see Figure 2b).

**Blaming the neighbors.** Malicious mixes performing active dropping attacks would prefer to avoid complete exclusion. One option is to drop the packet, and not send a receipt to the previous mix. However, this causes the preceding mix to disconnect from the malicious one at the end.

Alternatively, the corrupt mix may drop the packet after it generates an appropriate receipt. To avoid the risk of its detection as a corrupt mix, which would happen if it was a loop message, the corrupt mix may disconnect from the subsequent mix - again losing a link. Therefore, a corrupt mix that drops a packet either loses a link, or risks being

exposed (by loop message) and removed from the network.

**Delaying packets.** A malicious mix can also delay a packet instead of dropping it, so that the honest subsequent mix will drop that packet. However, the honest subsequent mix still sends a receipt back for that packet, which the malicious mix should acknowledge. If the malicious mix acknowledges the receipt, the malicious mix is exposed when the client performs the *isolation process*. The client can obtain a signed receipt proving that the malicious mix received the packet on time, and also the acknowledged receipt from the honest mix that dropped the delayed packet. The latter contains the round number when the packet was dropped, which proves the malicious mix delayed the packet and therefore should be excluded. Otherwise, if the malicious mix refuses to sign the receipt, the honest mix disconnects from the malicious one. Therefore, the delaying attack also causes the mix to either lose a link or to be expelled from the system.

The combination of packet receipts, link disconnection notices, the isolation process and loop messages, forces malicious mixes to immediately lose links when they perform active attacks. Failure to respond to the preceding mix or to record a disconnection notice about the subsequent mix in a timely manner creates potentially incriminating evidence, that would lead to a complete exclusion of the mix from the system. This prevents malicious mixes from silently attacking the system and blaming honest mixes when they are queried in the isolation mechanism. The mere threat of loop messages forces malicious mixes to drop a link with an honest mix for each message they wish to suppress, or risk exposure.

## 4.4 Handling missing receipts

Malicious mixes might attempt to circumvent the protocol by refusing to cooperate in the isolation procedure. Potentially, this could prevent clients from obtaining the necessary proofs about problematic links, thus preventing them from convincing directory authorities about problematic links. If malicious mixes refuse to cooperate, clients contact a directory authority and ask it to perform the isolation process on their behalf. Clients can prove to the directory authorities that the loop packet was indeed sent to the cascade using the receipt from the first mix. If all mixes cooperate with the directory authority, it is able to isolate and disconnect the problematic link. Otherwise, if malicious mixes do not cooperate with the directory authority, it excludes those mixes from the system.

We note that a malicious client may trick the directory authorities into performing the isolation process on its behalf repeatedly, against honest mixes. In that case, directory authorities conclude that the mix is honest, since the mix can provide either a receipt for the message forwarded or a disconnection notice. However, this is wasteful for both direc-

tory authorities and mixes. Since clients do not have to be anonymous vis-a-vis directory authorities, they may record false reports and eventually exclude abusive clients. Furthermore, the clients have to send proofs from the following mix of not having received the packet, which cannot be done if there was no mix failure.

**Malicious entry mix.** If a first mix does not send a receipt, the client could have simply chosen another cascade; however, this allows malicious mixes to divert traffic from cascades which are not fully malicious, without being penalized, increasing the probability that clients would select other fully malicious cascades instead. To avoid that, in Miranda, clients *force* the first mix to provide a receipt, by relaying the packet via a trusted *witness*. A witness is just another mix that relays the packet to the misbehaving first mix. Now, the misbehaving node can no longer refuse to produce a receipt, because the packet arrives from a mix, which allows the isolation process to take place. Note that since a witness sends messages on behalf of clients, the witness *relays* messages without the  $\omega$  constraint (as if it was a client).

If the witness itself is malicious, it may also refuse to produce a receipt (otherwise, it loses a link). In that case, the client can simply choose another witness; in fact, if desired, clients can even send via multiple witnesses concurrently to reduce this risk - the entry mix can easily detect the ‘duplicate’ and handle only one message. This prevents malicious mixes from excluding semi-honest cascades without losing a link. Moreover, although the refused clients cannot prove to others that they were rejected, they can learn about malicious mixes and can avoid all future cascades that contain them, including fully malicious cascades, which makes such attacks imprudent.

## 5 Inter-Epoch Process

In this section, we discuss the inter-epoch operations, taking place toward the end of an epoch; upon its termination, we move to a new epoch. The inter-epoch process selects a new random set of cascades to be used in the coming epoch, avoiding the links reported by the mixes, as well as any mixes detected as corrupt.

Until the inter-epoch terminates and the mixes move to the new epoch, the mixes continue with the intra-epoch process as before; the only difference is that newly detected failures, would be ‘buffered’ and handled only in the following run of the inter-epoch process, to avoid changing the inputs to the inter-epoch process after it has begun.

The inter-epoch process consists of the following steps.

### 5.1 Filtering Faulty Mixes

Directory authorities share amongst themselves the evidences they received and use them to agree on the set of

faulty links and mixes. The evidences consist of the reports of faulty links from mixes, clients or authorities performing the *isolation process*. The directory authorities exchange all new evidences of faulty links and mixes, i.e., not yet considered in the previous inter-epoch computation process. Every directory can validate each evidence it received and broadcast it to all other directories. Since we assume majority of honest directories and synchronous operation, we can use known broadcast/consensus protocols, and after a small number of rounds, all honest directory authorities have exactly the same set of faulty links.

Note, that only links connected to (one or two) faulty mixes are ever disconnected. Hence, any mix which has more than *thresh* links disconnected must be faulty (due to the assumption that  $thresh > n_m$ ), and hence the directories exclude that mix completely and immediately. Since the directory authorities share exactly the same set of faulty links, it follows that they also agree on exactly the same set of faulty mixes. We call this exclusion process a *simple malicious mix filtering* step. In Section 6, we discuss more advanced filtering techniques, based on *community detection*.

**Simple malicious mix filtering technique.** To perform the simple malicious mix filtering, each directory authority can build a graph that represents the connectivity between mixes. Namely, consider an undirected graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$  where the vertices map to the mixes in the system ( $\mathcal{V} = \mathcal{M}$ ), and an edge  $(M_i, M_j) \in \mathcal{E}$  means that the link between mixes  $M_i$  and  $M_j$  was not dropped by either mix. Let  $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$  be the complement graph of  $\mathcal{G}$  and let  $\text{Deg}_{\bar{\mathcal{G}}}(M_i)$  denote the degree of the vertex  $M_i$  in graph  $\bar{\mathcal{G}}$ . In the beginning, before any reports of faults have arrived at the directory authorities,  $\mathcal{G}$  is a complete graph and  $\bar{\mathcal{G}}$  is an empty graph. As time goes by,  $\mathcal{G}$  becomes sparser as a result of the links being dropped, and proportionally,  $\bar{\mathcal{G}}$  becomes more dense. The filtering mechanism removes all mixes that lost *thresh* links or more, i.e.,  $\{M_i \mid \forall M_i \in \bar{\mathcal{G}} : \text{Deg}_{\bar{\mathcal{G}}}(M_i) \geq thresh\}$ , where  $thresh = n_m + 1$ . The filtering mechanism checks the degree  $\text{Deg}_{\bar{\mathcal{G}}}(M_i)$  in graph  $\bar{\mathcal{G}}$ , since the degree in  $\bar{\mathcal{G}}$  represents how many links  $M_i$  lost. We emphasize that when such malicious mix is detected and removed, the number of malicious mixes in the system is decreased by one ( $n_m = n_m - 1$ ) and proportionally so does *thresh* ( $thresh = thresh - 1$ ). As a result, whenever the mechanism removes a malicious mix it repeats the mechanism once again, to see whether new malicious mixes can be detected according to the new *thresh* value. An illustration of this process is depicted in Figure 3.

### 5.2 Cascades Selection Protocol

After all directory authorities have the same view of the mixes and their links, they select and publish a (single) set of cascades, to be used by all clients during the coming epoch. To allow clients to easily confirm that they use the correct set of cascades, the directory authorities collectively sign the set

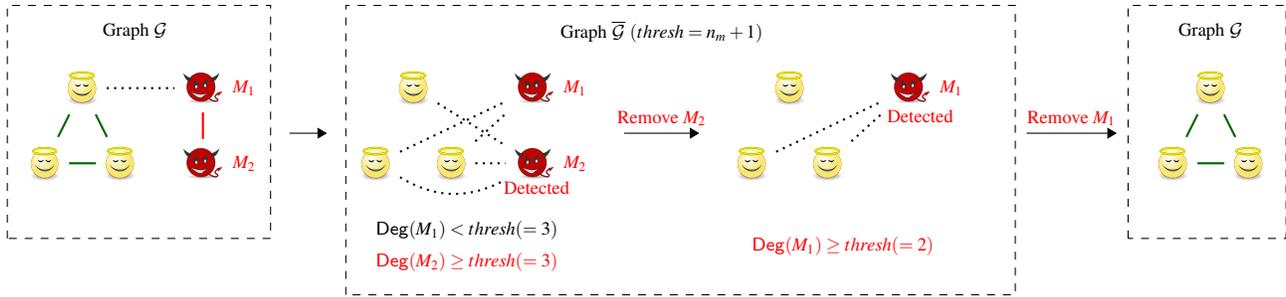

Figure 3: An illustration of the simple malicious mix filtering (without community detection).

that they determined for each epoch, using a threshold signature scheme [46, 25]. Hence, each client can simply retrieve the set from any directory authority and validate that it is the correct set (using a single signature-validation operation).

The *cascades selection protocol* allows all directory authorities to agree on a random set of cascades for the upcoming epoch. The input to this protocol, for each directory authority, includes the set of mixes  $\mathcal{M}$ , the desired number of cascades to be generated  $n_c$ , the length of cascades  $\ell$  and the set of faulty links  $\mathcal{F}_{\mathcal{L}} \subset \mathcal{M} \times \mathcal{M}$ . For simplicity,  $\mathcal{M}$ ,  $n_c$  and  $\ell$  are fixed throughout the execution.

The goal of all directory authorities is to select the same set of cascades  $\mathcal{C} \subseteq \mathcal{M}^{\ell}$ , where  $\mathcal{C}$  is uniformly chosen from all sets of cascades of length  $\ell$ , limited to those which satisfy the selected *legitimate cascade predicates*, which define a set of constraints for building a cascade. In [34], we describe several possible legitimate cascade predicates, and discuss their differences.

Given a specific legitimate cascade predicate, the protocol selects the same set of cascades for all directory authorities, chosen uniformly at random among all cascades satisfying this predicate. This is somewhat challenging, since sampling is normally a random process, which is unlikely to result in exactly the same results in all directory authorities. One way of ensuring correct sampling and the same output, is for the set of directories to compute the sampling process jointly, using a multi-party secure function evaluation process, e.g., [26]. However, this is a computationally-expensive process, and therefore, we present a much more efficient alternative. Specifically, all directories run exactly the same sampling algorithm and for each sampled cascade validate it using exactly the same legitimate cascade predicate. To ensure that the results obtained by all honest directory authorities are identical, it remains to ensure that they use the same random bits as the seed of the algorithm. To achieve this, while preventing the faulty directory authorities from biasing the choice of the seed bits, we can use a coin-tossing protocol, e.g., [7], among the directory authorities<sup>5</sup>.

<sup>5</sup>Note, that we only need to generate a small number of bits (security parameter), from which we can generate as many bits as necessary using a pseudo-random generator.

## 6 Community-based Attacker Detection

So far, the discussion focused on the core behaviour of Miranda and presented what Miranda can do and how it is done. Interestingly, Miranda’s mechanisms open a doorway for advanced techniques, which can significantly improve the detection of malicious mixes. In this section, we discuss several techniques that can leverage Miranda’s faulty links identification into a powerful tool against malicious adversaries. Among others, we use community detection techniques. Community detection has been used in previous works to achieve Sybil detection based on social or introduction graphs [16, 17]. However, we assume that the problem of Sybil attacks is solved through other means, such as admission control or resource constraints. Encouragingly, many other techniques can be employed; yet, we hope that the following algorithms will be also useful in other applications where applicable, e.g., where community detection is needed.

We begin with the following observation.

**Observation 1.** *For every two mixes  $M_i, M_j$  that have an edge in  $(M_i, M_j) \in \bar{\mathcal{E}}$ , at least one of them is a malicious mix.*

Observation 1 stems directly from our assumption that honest mixes never fail. Therefore, a dropped link must be between either an honest mix and a malicious mix or between two malicious mixes. Following this observation, one possible strategy is *aggressive pair removal*, i.e., remove both mixes, if one or both of them report failure of the link connecting them. This strategy seems to provide some benefits - the adversary seems to ‘lose more’, however it comes at an excess cost of possible exclusion of honest nodes. Therefore, we focus on less aggressive techniques that exclude malicious mixes *without* excluding also honest ones.

**Threshold Detection Algorithm.** Since the *aggressive removal* of both mixes connected by the failed link from  $\mathcal{G}$  is not efficient, we adopt the idea of *virtual removal* of the conflicting pair. By *virtually* we mean that virtually removed mixes are not classified as malicious and they are only removed from  $\bar{\mathcal{G}}$  for the duration of the algorithm’s execution, and not from  $\mathcal{G}$  nor  $\mathcal{M}$ . We present the *Threshold Detec-*

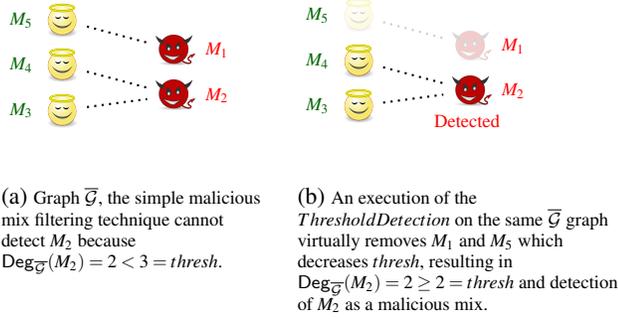

Figure 4: An illustration of how virtually removing mixes from  $\bar{\mathcal{G}}$  can expose malicious mixes. Algorithm 2 refers to the graph in 4b as  $\bar{\mathcal{G}}_1$ , since it is the same graph  $\bar{\mathcal{G}}$  as in 4a but without  $M_1$  and without  $M_1$ 's neighbors.

tion technique in Algorithm 1. The algorithm takes as input graph  $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$ , where an edge  $(M_i, M_j) \in \bar{\mathcal{E}}$  represents the disconnected link between  $M_i$  and  $M_j$ . The algorithm starts by invoking the *SIMPLEMALICIOUSFILTERING* procedure (described in Section 5.1) on the graph  $\bar{\mathcal{G}}$  (line 12). Next, the algorithm invokes the *VIRTUALPAIRREMOVAL* procedure on  $\bar{\mathcal{G}}$  to *virtually* remove a pair of mixes from  $\bar{\mathcal{G}}$  (line 14). Following observation 1, at least one malicious mix was *virtually* removed, thus the *virtual* threshold *thresh'* value is decreased by 1 (line 15). We use the *thresh'* variable to keep track of the virtually removed malicious mixes and the global *thresh* value is decreased only when a malicious mix was actually detected (line 4), and the rest only change the virtual threshold *thresh'*. After that, the algorithm invokes the procedure *SIMPLEMALICIOUSFILTERING* again on the *updated*  $\bar{\mathcal{G}}$  graph, i.e., without the pair of mixes that were virtually removed by the *VIRTUALPAIRREMOVAL* procedure. The algorithm repeats lines 14-16 as long as there are edges in  $\bar{\mathcal{G}}$ . For an illustration why the *ThresholdDetection* algorithm is better than the original *simple malicious mix filtering* see Figure 4.

We next improve upon the detection of malicious mixes by the *ThresholdDetection* algorithm, while still never removing honest mixes. Our improvement is based on Observation 2 below; but before presenting it, we need some preliminaries.

We first define a simple notion which can be applied to any undirected graph. Specifically, let  $G^0 = (V^0, E^0)$  be an arbitrary undirected graph. A sequence  $\{G^j\}_{j=0}^{\mu}$  of subgraphs of  $G^0$  is a *removal sequence* of length  $\mu \geq 1$  of  $G^0$ , if for every  $j: \mu \geq j \geq 1$ ,  $G^j = G^{j-1} - v_j$ . Namely,  $G^j$  is the same as  $G^{j-1}$ , except for removal of some node  $v_j \in G^{j-1}$ , and of all edges connected to  $v_j$ . A removal sequence is *legitimate* if every removed node  $v_j$  has at least one edge.

Let us define the graph  $\bar{\mathcal{G}}_i$  to be the resulting graph after removing from  $\bar{\mathcal{G}}$  the node  $M_i$  together with all its *neighbors*, denoted as  $N(M_i)$ .

---

**Algorithm 1** *ThresholdDetection*( $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$ )

---

```

1: procedure SIMPLEMALICIOUSFILTERING( $\bar{\mathcal{G}}, \text{thresh}'$ )
2:   for every  $M_i \in \bar{\mathcal{G}}$  s.t.  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) \geq \text{thresh}'$  do
3:      $M_i$  is malicious (remove from  $\bar{\mathcal{G}}, \bar{\mathcal{M}}$ ).
4:      $\text{thresh} \leftarrow \text{thresh} - 1$ 
5:      $\text{thresh}' \leftarrow \text{thresh}' - 1$ 
6:
7: procedure VIRTUALPAIRREMOVAL( $\bar{\mathcal{G}}$ )
8:   Pick an edge  $(M_i, M_j) \in \bar{\mathcal{E}}$ .
9:   Remove mixes  $M_i, M_j$  from  $\bar{\mathcal{G}}$ .
10:
11:  $\text{thresh}' \leftarrow \text{thresh}$ .
12: Invoke SIMPLEMALICIOUSFILTERING( $\bar{\mathcal{G}}$ ).
13: while  $\bar{\mathcal{E}} \neq \emptyset$  do
14:   Invoke VIRTUALPAIRREMOVAL( $\bar{\mathcal{G}}$ ).
15:    $\text{thresh}' \leftarrow \text{thresh}' - 1$ .
16:   Invoke SIMPLEMALICIOUSFILTERING( $\bar{\mathcal{G}}$ ).

```

---

**Observation 2.** *If  $\bar{\mathcal{G}}_i$  has a legitimate removal sequence of length  $\mu_i$ , then there are at least  $\mu_i$  malicious nodes in  $\bar{\mathcal{G}}_i$ .*

We use Observation 2 to identify malicious mixes, using the following claim.

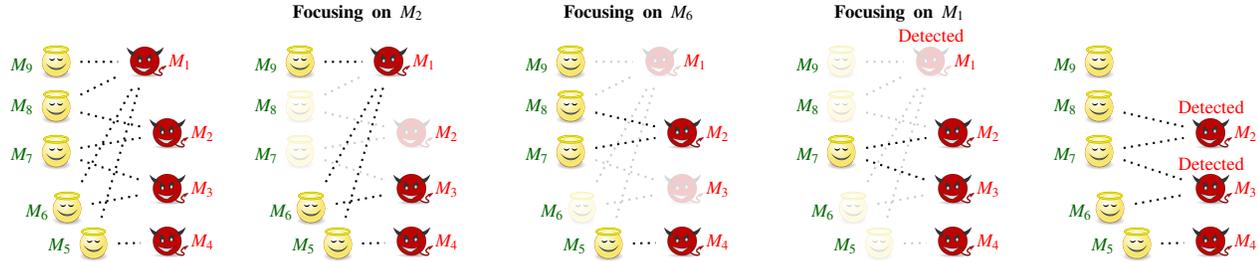

**Claim 1.** *Every node  $M_i$  that satisfies  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) > n_m - \mu_i$  is a malicious node.*

*Proof.* Assume to the contrary, that there exists a mix  $M_i$  such that  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) > n_m - \mu_i$  but  $M_i$  is an honest mix. Since there are  $n_m$  malicious mixes in  $\bar{\mathcal{M}}$ , and  $\mu_i$  of them are not neighbors of  $M_i$ , then the maximum number of malicious mixes that can be also neighbors of  $M_i$  is  $n_m - \mu_i$ , since  $M_i$  is honest. But if  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) > n_m - \mu_i$ , then at least one of the neighbors of  $M_i$  is also honest, which contradicts the assumption that honest links never fail. Therefore, if  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) > n_m - \mu_i$  then  $M_i$  must be a malicious mix.  $\square$

For example, see Figure 4b which depicts the graph  $\bar{\mathcal{G}}_1$ . By observing  $\bar{\mathcal{G}}_1$ , we know that at least one of the mixes  $M_2, M_3$  are malicious (since they share an edge), therefore,  $\mu_i \geq 1$  since we successfully identified a malicious mix which is not in  $\{M_1 \cup N(M_1)\}$ . Alternatively, the same argument can be made regarding  $M_2$  and  $M_4$  *instead* of the pair  $M_2$  and  $M_3$ . Since after removing  $M_2, M_4$  from  $\bar{\mathcal{G}}_1$  there are no edges left in  $\bar{\mathcal{G}}_1$ , then  $\mu_i = 1$ .

Algorithm 2 presents the *Community Detection* algorithm, which leverages Claim 1 to detect malicious mixes. An illustration of the operation of this algorithm is demonstrated in Figure 5.

Notice that the algorithm only examines nodes with a degree larger than 1 (line 3). The reason is that if  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) = 0$  then  $M_i$  did not perform an active attack yet, thus it cannot be detected, and if  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) = 1$  then  $M_i$  cannot be classified based on its neighbors. Therefore, an execution of the

- (a)  $\forall M_i : \text{Deg}_{\overline{\mathcal{G}}}(M_i) < \text{thresh}$ , simple malicious mix filtering does not detect malicious mixes.
- (b) When we observe  $\overline{\mathcal{G}}_2$ , i.e.,  $\overline{\mathcal{G}}$  after the removal of  $M_2$  and  $N(M_2)$ , two scenarios are possible. In the first scenario,  $\mu_2 = 3$  (e.g., if  $M_1$  and  $M_9$  are removed first), thus  $\text{Deg}_{\overline{\mathcal{G}}}(M_2) = 2 > 1 = n_m - \mu_2$ , and therefore  $M_2$  is detected as malicious. In the second scenario,  $\mu_2 = 2$  (e.g., if  $M_1$  and  $M_6$  are removed first), thus  $\text{Deg}_{\overline{\mathcal{G}}}(M_2) = 2 \leq 2 = n_m - \mu_2$ , and therefore  $M_2$  is *not* detected as malicious (yet). A similar situation occurs with  $M_3$  when observing  $\overline{\mathcal{G}}_3$ .
- (c) When we observe  $\overline{\mathcal{G}}_6$ , two malicious mixes can be identified, thus  $\mu_6 = 2$ . As a result, since  $\text{Deg}_{\overline{\mathcal{G}}}(M_6) = 2 \leq 2 = n_m - \mu_6$ ,  $M_6$  is not classified as malicious (nor should it be). Note that even if  $M_3$  was removed in (b), then  $\text{Deg}_{\overline{\mathcal{G}}}(M_6) = 1$  and therefore the algorithm cannot classify it based on its neighbors. The same explanations apply to the rest of the honest mixes.
- (d) When we observe  $\overline{\mathcal{G}}_1$ , only one malicious mix can be identified, thus  $\mu_1 = 1$ . As a result, since  $\text{Deg}_{\overline{\mathcal{G}}}(M_1) = 4$  is larger than  $n_m - \mu_1 = 3$ ,  $M_1$  is detected as malicious.
- (e) If  $M_2$  and  $M_3$  were not detected as malicious as explained in (b), then after the removal of  $M_1$  in (c) they will be detected, because the removal of  $M_1$  causes  $n_m = 4 \rightarrow n_m = 3$ . Since the algorithm runs in a loop, when the algorithm will re-check  $\overline{\mathcal{G}}_2$ , it will discover that  $\mu_2 = 2$  and thus  $\text{Deg}_{\overline{\mathcal{G}}}(M_2) = 2 > 1 = n_m - \mu_2$ , which results in removal of  $M_2$ . The same goes for  $M_3$ . After the removal of  $M_1, M_2$  and  $M_3$ , the algorithm cannot classify  $M_4$  as malicious based on its neighbors, since  $M_4$  only dropped one link. However, the algorithm has the option to *aggressively* remove both  $M_4, M_5$ .

Figure 5: A demonstration how Miranda's community detection can significantly improve the detection of malicious mixes using an example graph  $\overline{\mathcal{G}}$  and  $\text{thresh} = n_m + 1$ .

---

**Algorithm 2** *CommunityDetection*( $\overline{\mathcal{G}} = (\overline{\mathcal{V}}, \overline{\mathcal{E}})$ )

```

1:  $n'_m \leftarrow n_m$ 
2: while  $\overline{\mathcal{E}} \neq \emptyset$  do
3:   for each  $M_i \in \overline{\mathcal{V}}$  s.t.  $\text{Deg}_{\overline{\mathcal{G}}}(M_i) > 1$  do
4:     Construct  $\overline{\mathcal{G}}_i = (\overline{\mathcal{V}}_i, \overline{\mathcal{E}}_i)$  from  $\overline{\mathcal{G}}$ .
5:      $\mu_i \leftarrow 0$ 
6:     while  $\overline{\mathcal{E}}_i \neq \emptyset$  do
7:       Invoke VIRTUALPAIRREMOVAL( $\overline{\mathcal{G}}_i$ ).
8:        $\mu_i \leftarrow \mu_i + 1$ 
9:     if  $\text{Deg}_{\overline{\mathcal{G}}}(M_i) > n'_m - \mu_i$  then
10:       $M_i$  is malicious (remove from  $\overline{\mathcal{G}}, \overline{\mathcal{G}}, \mathcal{M}$ ).
11:       $n_m \leftarrow n_m - 1, n'_m \leftarrow n'_m - 1$ 
12:   if  $\overline{\mathcal{E}} \neq \emptyset$  then
13:     Invoke VIRTUALPAIRREMOVAL( $\overline{\mathcal{G}}$ ).
14:      $n'_m \leftarrow n'_m - 1$ 

```

---

*CommunityDetection* might not be able to detect all malicious mixes that exposed themselves, e.g., mixes with a degree that equals to 1. If desired, there is always the opportunity to execute the aggressive pair removal technique *after* the *CommunityDetection* algorithm to potentially remove more malicious mixes (with price of possible removal of an honest mix). Also, randomly picking a pair of mixes that share an edge in  $\overline{\mathcal{G}}$  might not always be the optimal strategy. In small graphs, the algorithm can exhaust all possible

removal variations, but this is a time-consuming option in large graphs. A more sophisticated picking strategy might yield better results; however, when we experimented with some possible strategies, we did not notice a significant improvement over the random picking strategy.

The techniques discussed in this section provide Miranda a significant advantage, since malicious mixes can be detected even if they do not pass *thresh*. Merely the threat of such techniques is significant in deterring active attacks. In Section 7.4 we analyze the security of the mechanisms discussed here and evaluate them empirically. In [34] we present alternative scheme for community detection based on random walks.

## 7 Analysis of Active Attacks

In this section, we analyze the impact of active attacks in the presence of Miranda. We first analyze Miranda against traditional and non-traditional active attacks, including attacks designed to abuse the protocol to increase the chances of clients choosing fully malicious cascades. We continue by examining the security of loop messages and conclude this section by evaluating how community detection strengthens Miranda.

## 7.1 Resisting Active Attacks

As discussed in Section 4, a malicious mix that drops a packet sent from a preceding mix or destined to a subsequent mix, loses at least one link; in some cases, the malicious mix gets completely excluded. Hence, the adversary quickly loses its attacking capabilities, before any significant impact is introduced. However, the adversary might try other approaches in order to link the communicating users or gain advantage in the network, as we now discuss.

A malicious first mix can refuse clients' packets; however, such attack is imprudent, since clients can migrate to other cascades. Furthermore, clients can force the malicious mix to relay their packets, using a witness. Similarly, it is ineffective for the last mix of a cascade to drop *all* packets it receives, since clients learn through isolation that the dropped loop packets successfully arrived at the last mix. Although clients cannot prove the mix maliciousness, they avoid future cascades containing the malicious mix, including fully malicious cascades.

Instead of directly dropping packets, adversaries can cause a packet to be dropped by delaying the packet. However, such attack is also detected.

**Claim 2.** *A malicious mix that delays a packet, is either expelled from the system or loses a link.*

*Argument.* When an honest mix receives a delayed packet, it drops it. However, the honest mix still sends a receipt back for that packet. If the malicious mix acknowledges the receipt, the malicious mix is exposed when the client performs the isolation process: the client can obtain a signed receipt proving that the malicious mix received the packet on time, and also the acknowledged receipt from the honest mix that dropped the delayed packet. The latter contains the round number when the packet was dropped, which proves the malicious mix delayed the packet and therefore should be excluded. Otherwise, if the malicious mix refuses to sign the receipt, the honest mix disconnects from the malicious mix.  $\square$

**Injecting malformed packets.** Notice how the honest mix that dropped the delayed message still sends back a receipt for it. The reason is that the dropping mix cannot be sure that the previous mix did delay the message. Instead, this can be the result of an adversary that crafts a packet with the same round number in two successive layers.

**Claim 3.** *An adversary cannot craft a loop message that causes a link loss between two honest mixes.*

*Argument.* Any loop message has to be well-formed in order for directory authorities to accept it. An adversary can craft a message with invalid round numbers in the packet's routing information, which would cause the honest mix to drop the packet. However, although the honest mix drops

the packet, it still sends back a receipt for that packet. Otherwise, the preceding mix, which has no way of knowing that the next layer is intentionally malformed, would disconnect from the subsequent mix. While the adversary can obtain a proof showing that a loop message was dropped, it cannot prove that the loop message was well-formed.  $\square$

**Aggressive active attacks.** In order to de-anonymize the network users, the adversary can choose a more aggressive approach and drop a significant number of packets. For example, in the  $(n - 1)$  attack [45] applied to the full network, the adversary tracks a target packet from Alice by blocking other packets from arriving to an honest mix, and instead injecting their own packets. Another example is the intersection attack [8], where the adversary tries disconnecting target clients. If the adversary cannot directly disconnect a client with a targeted attack, it can disconnect a client by dropping an entire batch of packets where one of them belongs to the client (the adversary simply does not know which). However, it is important to note, that if an adversary can engineer a scenario where a single target packet is injected and mixed with only messages that the adversary controls, *any* mix-based system is vulnerable. Nevertheless, we argue that Miranda inflicts serious penalty on the adversary who attempts to perform an aggressive dropping of packets.

**Claim 4.** *Miranda deters aggressive active attacks.*

*Argument.* Aggressive active attacks require the ability to drop many packets. In Miranda, a malicious mix that drops any packet from another mix without sending back a receipt, loses a link (see Section 4 and Figure 2c). Alternatively, if the malicious mix drops packets but does send receipts for these dropped packets, clients can prove that the malicious mix received their (loop) packets and did not forward them, which results in the exclusion of the malicious mix (see Figure 2b). A malicious entry mix may drop packets from clients, since losing a link to a client is not a serious 'penalty'; but in Miranda, clients then use a *witness mix* (see Section 4.4) – forcing the mix to either relay their packets, or - lose a link to a mix or risk discovery, as discussed above.

Miranda enforces a minimum number of  $\omega$  packets for mixing by the entry mix. This is designed to protect the *rare* cases where a client sends via an entry mix which is used only by few (or no) other clients, which could allow an eavesdropper attack; we now explain why this cannot be abused to facilitate an active attack (by the first mix).

Recall, that in this case, as in our entire analysis of corrupt-mix attacks, we assume that at least  $2\omega$  honest clients send packets to the (possibly corrupt) entry mix; and, as mentioned above, the mix cannot simply 'drop' these (since clients will use witness and then the corrupt mix will lose - at least - a link).

Instead, the corrupt mix could send to these clients, or most of them, the special 'under- $\omega$  receipt', claiming (incorrectly) that it didn't receive  $\omega$  messages during this round.

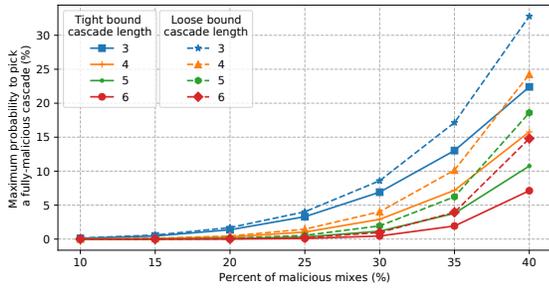

Figure 6: The maximum probability of picking a fully malicious cascade as a function of the cascade length and the power of the adversary.

However, senders *report* these (rare) under- $\omega$  receipts to the directories, who would quickly detect that this mix is corrupt.  $\square$

## 7.2 Fully Malicious Cascades Attacks

If the packets are relayed via a *fully malicious cascade*, an adversary can trivially track them. Consequently, adversaries would like to divert as much traffic as possible to the fully malicious cascades. Attackers can try to maximize their chances by: (1) increasing the probability that fully malicious cascades are included in the set  $\mathcal{C}$  produced by the directory authorities during the inter-epoch process, and/or (2) increasing the probability that clients pick a fully malicious cascade from  $\mathcal{C}$  during an epoch.

Because cascades are chosen uniformly over all valid cascades, the only way the adversary can influence the cascades generation process is by excluding semi-honest cascades. However, they can only exclude cascades by dropping links they are a part of, therefore, the adversary cannot exclude any honest links or honest mixes<sup>6</sup>, meaning they cannot exclude any fully honest cascades. However, adversaries are able to disconnect semi-honest cascades by disconnecting semi-honest links and thereby increase the probability of picking a fully malicious cascade. Interestingly, we found that such an attack only slightly increases the chance of selecting a fully malicious cascade – while significantly increasing the chance of selecting a fully honest cascade (see Claim 5). Further, this strategy makes it easier to detect and eliminate sets of connected adversarial domains (see section 6).

**Claim 5.** Let  $C_{Adv}$  denote a set of fully malicious cascades. The maximum probability to pick a fully malicious cascade during cascades generation process, after the semi-honest

<sup>6</sup>Even if all adversarial mixes disconnect from an honest mix, it is still not enough for exclusion, since  $thresh > n_m$ .

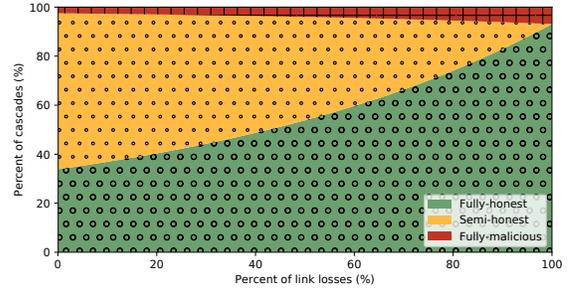

Figure 7: The probability of picking particular classes of cascades after each link loss. The parameters of the simulated mix network are  $l = 3$ ,  $n = 100$  and  $n_m = 30$ .

*cascades were excluded by the adversary is*

$$\Pr(c \in C_{Adv}) \leq \left( \frac{n_m}{n_h - l + 1} \right)^l.$$

*Argument.* See [34].

Figure 6 and Figure 7 present the probability of picking a fully malicious cascade depending on the number of mixes colluding with the adversary and the percentage of lost links.

Once  $n_c$  cascades are generated, the adversary could try to bias the probability of clients choosing a fully malicious cascade. To do so, the adversary can sabotage semi-honest cascades [9] through dropping messages, and in an extreme case, exclude them all. We illustrate in Figure 8 the attack cost, expressed as the number of links the adversary must affect in order to achieve a certain probability of success in shifting clients to a fully malicious cascade. Note, that the larger the number of cascades  $n_c$ , the more expensive the attack, and the lower the probability of success.

## 7.3 Security of Loop Messages

Since loop messages are generated and processed in the same way as genuine messages, the binary pattern does not leak any information. However, adversaries can still seek ways to predict when loop messages are sent; for example, by observing the timing pattern and the rate of sent messages.

**Detecting loop messages.** Adversaries can try to guess whether a particular message is a loop message or not. A successful guess allows the adversary to drop non-loop messages without being detected, while still sending receipts for them to the previous mix. We formulate the following claim:

**Claim 6.** Assume that an adversary that does not control the last mix in the cascade, drops a packet. The probability of this message being a loop message sent by a non-malicious client is at least  $\alpha$ .

*Argument.* It suffices to consider packets sent by non-malicious clients. When a non-last mix receives such pack-

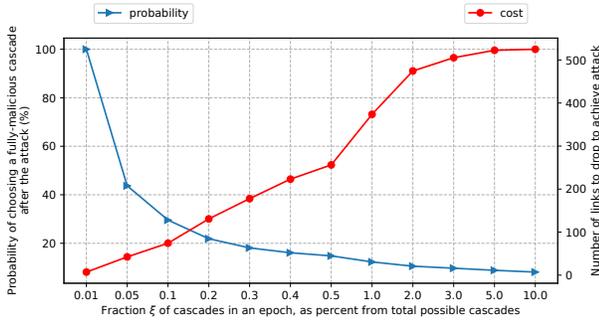

Figure 8: The costs (red, right axis) and success probability (blue, left axis) of performing DoS [9] attacks based on the fraction of cascades active in every epoch. Cost is measured in links the adversary must sacrifice; as Figure 9 shows, even the minimal ‘cost’ essentially implies detection of *all* active corrupt mixes. Furthermore, using just 1% of the possible cascades suffices to reduce success probability to about 10% or less.

ets, it does not know the destination. Furthermore, as described in section 4.3, loop packets are sent by non-malicious clients according to the rate defined by  $\alpha$  of genuine traffic and are bitwise indistinguishable from genuine packets. Hence, even if the mix would know the identity of the sender, e.g., by being the first mix, the packet can still be a loop message with probability at least  $\alpha$ .  $\square$

Note that a malicious non-last mix that drops a loop message, yet sends a receipt for it and remains connected to the next mix, would be proven malicious and excluded from the network. On the other hand, if such mix does not send a receipt, then it loses a link.

**Malicious last mix.** Claim 6 does not address the last mix. There are two reasons for that: first, in contrast to mixes, clients do not send receipts back to mixes. Therefore, a last mix cannot prove it actually delivered the packets. Secondly, the last mix may, in fact, identify non-loop messages in some situations. For example, if a client did not send packets in round  $r$ , then all the packets it is about to receive in round  $r+x$  (where  $x$  is the number of rounds it takes to complete a loop) are genuine traffic sent by other clients. Therefore, these messages can be dropped without detection.

However, dropping of messages by the last mix can also be done against the *ideal mix* (see Section 2.4), e.g., by a man-in-the-middle attacker. In fact, similar correlation attacks can be performed even without dropping packets, if clients have specific sending patterns. Therefore, mitigating this attack is beyond Miranda goals, and should be handled by the applications adopting Miranda<sup>7</sup>.

<sup>7</sup>For example, [24, 44] use fixed sending rate (thus, foiling the attack). A concerned client can simply make sure to send additional loop packets in every round where no genuine traffic is relayed.

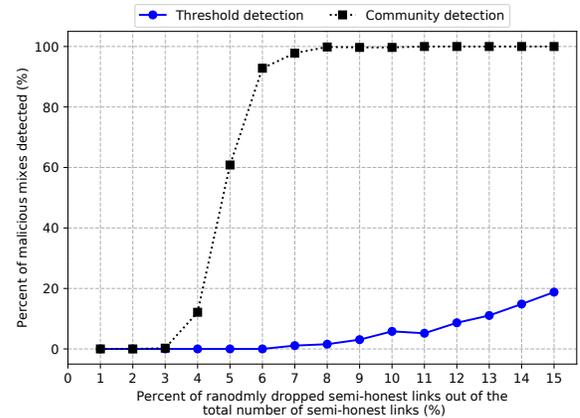

Figure 9: The effect of using community detection against malicious mixes.

## 7.4 Evaluation of Community Detection

The discussion in Section 6 presented several community detection techniques to leverage Miranda’s reported links information into a detection tool that removes malicious mixes from the system. We now argue that the contribution of these mechanisms is both important and secure.

### 7.4.1 Empirical Results

We implemented the *Threshold Detection* and *Community Detection* algorithms described in Section 6, and evaluated them as follows. We generated a complete graph of  $n = 100$  mixes where  $n_m = 33$  of them are malicious. We modeled a random adversary by randomly dropping a fraction of the semi-honest links, making sure that any mix does not drop more than or equal to  $thresh = n_m + 1$  links.

Figure 9 demonstrates the effectiveness of the algorithms. The *Threshold Detection* algorithm starts to become effective when roughly 10% of the semi-honest links are reported and improves as the number of reports increases. In comparison, the *Community Detection* algorithm presents significantly better results, starting when 4% of the semi-honest links are dropped and after 8% the algorithm is able to expose all possible malicious mixes. Considering that the *Community Detection* algorithm can only operate on malicious mixes that dropped more than one link, these results show that the algorithm effectively mitigates the non-strategic adversary. In [34], we discuss and compare another possible community detection algorithm, which potentially yields even better results.

### 7.4.2 Security Analysis

In essence, both the *Threshold Detection* algorithm and the *Community Detection* algorithm do the same thing: they both remove malicious mixes from the system. Therefore,

the only way for a strategic adversary to abuse these algorithms is to strategically drop links in a way that causes these algorithms to wrongfully remove honest mixes from the system, due to misclassification of honest mixes as malicious. We now argue that the *ThresholdDetection* and *CommunityDetection* algorithms are secured against such attack.

**Claim 7.** *An honest mix  $M_i \in \bar{\mathcal{G}}$  never satisfies  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) \geq \text{thresh}$ .*

*Proof.* Assume to the contrary that there exists an honest mix  $M_i \in \bar{\mathcal{G}}$  that satisfies  $\text{Deg}(M_i) \geq \text{thresh}$ . However, if this is the case, then  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) \geq \text{thresh}$ , which implies  $\text{Deg}_{\bar{\mathcal{G}}}(M_i) \leq n - \text{thresh} \leq n_h - 1$ , which means that at least one honest mix disconnected from  $M_i$ , contradicting the assumption that honest links never fail.  $\square$

**Claim 8.** *The *ThresholdDetection* algorithm never removes honest mixes.*

*Proof.* According to the implementation of *Threshold Detection*, the algorithm only removes mix  $M_i \in \bar{\mathcal{G}}$  that satisfies  $\text{Deg}(M_i) \geq \text{thresh}$ . However, following Claim 7, this cannot happen for honest mixes.  $\square$

**Claim 9.** *The *CommunityDetection* algorithm never removes honest mixes.*

*Proof.* According to the implementation of *Community Detection*, the algorithm only removes mix  $M_i \in \bar{\mathcal{G}}$  that satisfies  $\text{Deg}(M_i) > n_m - \mu_i$ , which according to Claim 1 never happens for honest mixes.  $\square$

## 8 Related Work

In this section, we place our system in the context of existing approaches and compare Miranda with related works. First, we focus on works that present a similar design to Miranda. Next, we discuss how Miranda improves upon previous mix network designs. Finally, we briefly outline other techniques used to support reliable mixing.

**Receipts.** The idea of using digitally signed receipts to improve the reliability of the mix network was already used in many designs. In Chaum’s original mix network design [12] each participant obtains a signed receipt for packets they submit to the entry mix. Each mix signs the output batch as a whole, therefore the absence of a single packet can be detected. The detection that a particular mix failed to correctly process a packet relies on the fact that the neighbouring mixes can compare their signed inputs and outputs. Additionally, [12] uses the untraceable return addresses to provide end-to-end receipts for the sender.

Receipts were also used in reputation-based proposals. In [20], receipts are used to verify a mix failure and rank

their reputation in order to identify the reliable mixes and use them for building cascades. The proposed design uses a set of trusted global witnesses to prove the misbehavior of a mix. If a mix fails to provide a receipt for any packet, the previous mix enlists the witnesses, which try to send the packet and obtain a receipt. Witnesses are the key part of the design and have to be engaged in every verification of a failure claim, which leads to a trust and performance bottleneck. In comparison, Miranda does not depend on the witnesses, and a single one is just used to enhance the design. Moreover, in [20] a failure is attributed to a single mix in a cascade, which allows the adversary to easily obtain high reputation and misuse it to de-anonymize clients. Miranda rather than focusing on a single mix, looks at the link between the mixes.

In the extended reputation system proposed in [22] the reputation score is quantified by decrementing the reputation of all nodes in the failed cascade and incrementing of all nodes in the successful one. In order to detect misbehaviors of malicious nodes, the nodes send *test messages* and verify later via a snapshot from the last mix, whether it was successfully delivered. Since the test messages are indistinguishable, dishonest mixes risk being caught if they drop any message. However, the penalty for dropping is very strong – if a single mix drops any message, the whole cascade is failed. Therefore, because a single mix’s behavior affects the reputation of all mixes in the cascade, the malicious nodes can intentionally fail a cascade to incriminate honest mixes. This design also proposed the *delivery receipts*, which the recipient returns to the last mix in the cascade in order to prove that the message exited the network correctly. If the last mix is not able to present the receipt, then the sender contacts a random node from the cascade, which then asks the last mix to pass the message and attempts to deliver the message.

**Trap messages and detecting active attacks.** The idea of using trap messages to test the reliability of the network was discussed in many works. The original DC-network paper [11] suggested using *trap* messages, which include a safety contestable bit, to detect message disruption. In contrast, the flash mixing [28] technique, which was later proved to be broken [38], introduces two dummy messages that are included in the input, and are later de-anonymized after all mixes have committed to their outputs. This allows the participants to verify whether the mix operation was performed correctly and detect tampering. However, both of those types of trap messages are limited to these particular designs.

The RGB-mix [18] mechanism uses heartbeat *loop* messages to detect the (n-1) attacks [45]. Each mix sends heartbeat messages back to itself, and if the (n-1) attack is detected the mix injects cover traffic to confuse the adversary. However, the key assumption of the proposed mechanism is limited only for anonymity among mix peers.

Mixmaster [39] and Mixminion [14] employed an infrastructure of *pingers* [43], special clients sending probe traffic

through the different paths in the mix network and recording publicly the observed reliability of delivery. The users of the network can use the obtained reliability statistics to choose which nodes to use.

Recent proposals for anonymous communication have also employed built-in reliability mechanisms. For example, the new Loopix [44] mix-network system uses *loop cover traffic* to detect (n-1) attacks, both for clients and mixes. However, this idea is limited to detecting only aggressive (n-1) attacks, but mix nodes systematically dropping single packets can operate undetected. Moreover, the authors do not also specify any after-steps or how to penalize misbehaving mixes.

The Atom [33] messaging system is an alternative design to a traditional mix networks and uses *trap* messages to detect misbehaving servers. The sender submits *trap* ciphertext with the ciphertext of a message, and later uses it to check whether the relaying server modified the message. However, the trap message does not detect which mix failed. Moreover, Atom does not describe any technique to exclude malicious servers, and a failed trap only protects against releasing the secret keys.

**Other approaches.** The literature on secure electronic elections has been preoccupied with reliable mixing to ensure the integrity of election results by using zero-knowledge proofs [3, 6, 29] of correct shuffling to verify that the mixing operation was performed correctly. However, those rely on computationally heavy primitives and require re-encryption mix networks, which significantly increase their performance cost and limits their applicability. On the other hand, the more ‘efficient’ proofs restrict the size of messages to a single group element that is too small for email or even instant messaging.

An alternative approach for verifying the correctness of the mixing operation were mix-nets with randomized partial checking (RPC) [30]. This cut-and-choose technique detects packet drops in both Chaumian and re-encryption mix-nets, however, it requires interactivity and considerable network bandwidth. Moreover, the mix nodes have to routinely disclose information about their input/output relations in order to provide evidence of correct operation, what was later proven to be flawed [32].

## 9 Limitations and Future Work

**Challenges for making Miranda practical.** The Miranda design includes several significant simplifying assumptions, mainly: (1) fixed set of mixes, (2) majority of benign mixes, (3) reliable communication and processing, and (4) synchronized clocks. Such assumptions are very limiting in terms of practical deployment; practical systems, e.g., Tor, cannot ‘assume away’ such issues. Future work should try to avoid these assumptions, while maintaining tight security analysis

and properties as done in Miranda, or identify any inherent trade-offs.

Avoiding the clock synchronization assumption seems easy - simply adopt a secure clock synchronization protocol. However, avoiding the other three assumptions ((1) to (3)) seems much more challenging.

First, consider assumptions (1) and (2), i.e., assuming a *fixed set of mixes with majority of benign mixes*. These assumptions are central to Miranda design; since the goal of Miranda is to provide a way to penalize active attackers. If the adversary can simply retire penalized malicious nodes and replace them with new nodes that have an untarnished reputation, then there is no real gain in even trying to penalize or expose the adversary, and it becomes hard to argue why we can even assume most mixes are benign. However, a practical mixnet must allow a dynamic set of mixes, for both scalability and churn - mixes joining and leaving over time.

Next, consider the third assumption: *reliable communication and processing*. In practice, communication and processing failures will definitely happen - in particular, as a result of intentional DoS attacks. We believe that future work may deal with this significant challenge by both *minimizing failures*, by designing robust underlying mechanisms such as highly-resilient transport layer; and *refined assumptions and analysis*, e.g., considering incentives and game-theory analysis, to ensure that the system is robust to ‘reasonable’ levels of failures.

These issues are significant challenges for future research, essential towards the implementation of Miranda in practical systems. For example, such research must develop a reasonable model to allow nodes to join (or re-join), without allowing the adversary to gain majority by adding many mixes, as in Sybil attacks, and to retain the impact of removing corrupt mixes.

**Extension to Continuous Mixnet.** Miranda is designed for a synchronous mixnet. Recent research in mix networks showed that continuous-time mixes, especially pool mixes, may allow anonymity for low latency communication [44]. Future work may investigate how to integrate Miranda with continuous mixnets such as Loopix [44]. Such integration would raise challenges, such as, how would a mix know when it should receive the response from the next mix, esp. without leaking information to an attacker.

## 10 Conclusion

In this work, we revisited the problem of protecting mix networks against active attacks. The analysis performed showed that active attacks can significantly increase the adversary’s chances to correctly de-anonymize users. Miranda achieves much better efficiency than previous designs, but at the same time quickly detects and mitigates active adversaries. Miranda employs previously studied techniques such as packet

receipts and loop traffic alongside novel techniques to ensure that each dropped packet penalizes the adversary. We take a new approach of focusing on problematic links between mixes, instead of mixes themselves. We also investigate how community detection enhances our mechanism effectively. The overall contribution of our work is an efficient and scalable detection and mitigation of active attacks. For additional details, including implementation details and efficiency, see [34].

## Acknowledgments

We are grateful to our shepherd, Roger Dingledine, and to the anonymous reviewers, for their helpful and constructive feedback. This work was partially supported by the IRIS Grant Ref: EP/R006865/1 and by an endowment from the Comcast corporation. The opinions expressed in the paper are those of the researchers themselves and not of the universities or sources of support.

## Abstract

Crowdsourcing enables application developers to benefit from large and diverse datasets at a low cost. Specifically, mobile crowdsourcing (MCS) leverages users' devices as sensors to perform geo-located data collection. The collection of geo-located data raises serious privacy concerns for users. Yet, despite the large research body on location privacy-preserving mechanisms (LPPMs), MCS developers implement little to no protection for data collection or publication. To understand this mismatch, we study the performance of existing LPPMs on publicly available data from two mobile crowdsourcing projects. Our results show that well-established defenses are either not applicable or offer little protection in the MCS setting. Additionally, they have a much stronger impact on applications' utility than foreseen in the literature. This is because existing LPPMs, designed with location-based services (LBSs) in mind, are optimized for utility functions based on users' locations, while MCS utility functions depend on the values (e.g., measurements) associated with those locations. We finally outline possible research avenues to facilitate the development of new location privacy solutions that fit the needs of MCS so that the increasing number of such applications do not jeopardize their users' privacy.

## 1 Introduction

Crowdsourcing is a participative online activity in which the undertaking of a task is outsourced to a group of individuals [29]. This new paradigm of distributing a fragmented task, is an efficient, scalable business model that allows the cheap (or often free) massive collection of data. Indicative of the growth of this data collection methods is the appearance of over 2,000 crowdsourcing platforms [1, 56] in the last years [83]. Furthermore, according to recent industrial reports [40], in the last decade, 85% of top global brands have already adopted crowdsourcing, and in 2018, 75% of the world's highest performing enterprises would use crowdsourcing. For instance, Google [2], Microsoft [3] and Mozilla [4] use crowdsourcing to build WiFi location databases.

A driving force of the crowdsourcing ecosystem growth is the widespread adoption of smart mobile devices, which enable users to collect geo-located data on their devices and share it with central servers to attain a particular objective. Mobile crowdsourcing applications (MCS) have millions of users around the world. For instance, OpenStreetMaps [5], a map generation project from contributed GPS points, reports 4.3 million users in 2018,<sup>1</sup> with 1 million active map editors contributing over 4 billion GPS points. Similarly, OpenSignal [6], a popular network-measuring application, reports over 20 million users.<sup>2</sup> Safecast [7], a citizen science project collecting environmental data, currently reports over 75 million measurements from approximately three thousand users. Many other applications are available [4, 6, 8–18].

MCS can bring great benefits for organizations and society. However, the collection and sharing of geo-located data raises serious privacy concerns, as demonstrated by scandals related to the publication of data by fitness applications [19, 20] or irresponsible data analysis by transportation companies [21]. Location data can be used to identify points of interest (POIs) [49, 52, 64], infer users preferences, or de-anonymize anonymous traces [89]. This risk increases when considering auxiliary publicly available information [30, 63, 70], and persists even when protections are put in place [77, 78].

Over the last decade, the research community has proposed a vast number of LPPMs to address these issues [76], some of which can provide strong differentially private guarantees [28, 34, 48] and even offer optimal utility [33, 73]. Even though it seems like the location privacy question is technically solved, the reality is that these LPPMs *solely focus on one use case*. They are generally geared towards LBSs in which users sporadically reveal their location in return for a service (e.g., to find nearby restaurants). In this context, utility is user-centric and hinges on the precision of the reported locations. In MCS applications, on the contrary, geo-located data is often shared continuously and over long periods and, while

<sup>1</sup><https://wiki.openstreetmap.org/wiki/Stats>

<sup>2</sup><https://opensignal.com/methodology#over-20-million-users-of-our-app>

the data utility is still correlated with the location precision, it is foremost tied to the values of the measurements reported at these locations (e.g., WiFi signal strength, or radiation level). Moreover, MCS utility cannot be captured with a user-centric approach as, by definition, MCS benefits from aggregating data collected by a large amount of users.

In this paper, we conduct the first in-depth evaluation of the effectiveness of LPPMs in the context of MCS. We use two representative applications, Safecast [7] and Radiocells [9], which make their contributors' data publicly available on their websites and which have very different utility functions. We propose two new privacy metrics based on statistical measures developed for binary classification and information retrieval to capture the privacy gain provided by the LPPMs with respect to the identification of areas and points of interest. We also consider new utility measures that, instead of relying on distance-based errors, quantify the accuracy of the aggregate values of data collectively generated.

The results of our experimental evaluation on real data contradict common beliefs regarding the privacy-utility trade-off offered by different LPPMs. First, location hiding methodologies, which in LBSs help concealing trajectories [60], do not bring any privacy benefits to MCS users. This is mainly because, in MCS, the volume of geo-located data is larger and contains points reported over long periods of time (more than a day). Second, differentially private mechanisms [28] offer good protection only for very strong parameters, and even when they are optimized for utility [33], they dramatically perturb the radiation measurements. For instance, in Safecast, we observed that it tremendously changed some areas' radiation levels, urging people to evacuate a place, and completely hindered the ability to localize radiation hotspots (location with elevated radiation). Finally, generalization techniques, usually dismissed in LBSs because of their poor utility, offer one of the best privacy-utility balance in MCS.

In summary, existing LPPMs are not well aligned with the needs of MCS applications. Therefore, new research is needed to approach the design of optimal LPPMs based on collective, value-based, utility metrics instead of user-centric, location-based utility.

**Our contributions** can be summarized as follows:

- ✓ We propose novel privacy and utility metrics suitable to evaluate the performance of LPPMs for MCS data publishing patterns.
- ✓ Using real data collected from two representative MCS applications, we show that existing LPPMs impose too high utility price and that many of them do not even provide good privacy guarantees in the context of MCS.
- ✓ We discuss technical and non-technical countermeasures to improve the privacy protection of MCS users.

## 2 Mobile Crowdsourcing Applications

In this section, we introduce the two crowdsourcing applications studied in detail in this paper.

### 2.1 Safecast

Safecast [7] is a volunteer-centered organization whose goal is to monitor the global radiation levels and detect abnormalities in near real time. Safecast crowdsources the collection of radiation data by providing users with devices that collect radiation measurements every five seconds.

**Safecast dataset.** This dataset contains 64.2 million measurements from 608 users, collected from 2011 to 2017. Radiation measurements contain the user's name, a unique user ID, the device's ID, latitude and longitude, a UTC timestamp, and the radiation value and units. No registration is required to access these data and Safecast's privacy policy<sup>3</sup> states that to enable flexibility "Anyone is free to use with no licensing restrictions". For our experiments we removed IDs corresponding to organizations, malformed entries, and converted all UTC times to local. After this process, the dataset has almost 56.7 million measurements from 540 users.

**Safecast utility.** The Safecast project uses the collected data to study different phenomena related to radiation. In this paper, we consider two of the main uses of the data.

First, we consider the interactive map to visualize radiation published on Safecast website. Safecast computes the visualized radiation levels from the crowdsourced measurements as follows. For a given region of interest, Safecast filters the measurements within the region and computes the average radiation at each location over the last 270 days. Second, they discretize the area to 2.25 million grid points (1500 discrete locations per axis). They create the displayed map using nearest-neighbor interpolation on the averaged radiation measurements associated to the points of the grid. The reported radiation is measured in counts per minute (cpm), expressing how many ionized particles are detected per minute by a monitoring instrument. This use case, which relies on averaging and interpolation, represents a setting in principle amenable to noise in the data.

Second, we consider the detection of *hotspots* – specific areas where radiation is above a pre-defined threshold. These hotspots indicate locations where radiation could be harmful for public safety. Once identified, Safecast might send experts to perform on-site examination to better understand the causes and consequences of such dangerous zones. Therefore, it is crucial that the localization of hotspots is accurate.

### 2.2 Radiocells

Radiocells [9] is a community project whose goal is to provide an open-source alternative to commercial, closed source, geo-

<sup>3</sup><https://blog.safecast.org/faq/licenses/>

location databases for cell towers and wifi base stations. They also aim to provide raw telecommunication infrastructure data for use in diverse scientific studies. Radiocells crowdsources the collection of measurements via a mobile application called ‘Radiobeacon’.<sup>4</sup> With this application, users continuously collect measurements as they perform daily activities. Users choose when to start and stop measuring, and when to upload the measurements to the Radiocells server. Furthermore, they can select a specific area where measurements will not be recorded, e.g., to protect their home locations. We do not study the impact of this defense in this paper, but previous work shows that it is rather fragile [57].

**Radiocells dataset.** The raw data uploaded to the server is publicly available for download. It is licensed under Creative Commons Attribution-ShareAlike 3.0 Unported and ODbL licences aimed at not restricting the use of the data.<sup>5</sup> Amongst other information, the measurements include: signal strength, cell (antenna) ID, location, timestamp, and smartphone model, software, OS version, and manufacturer. In an effort to preserve users’ privacy, this dataset does not contain usernames. However, the combination of the smartphone characteristics, the location, and the network provider is likely to represent a quasi-identifier. We downloaded data for 2013 to 2017, obtaining 25 million measurements. To separate users’ measurements, we grouped the measurements according to phone manufacturer, phone model, country and network operator. We obtained 998 potential unique users, of which we only kept those that had more than 100 measurements. We also removed users with spatial inconsistencies, i.e., we removed all users whose speed between two contiguous measurements was greater than 200 km/h. The dataset finally contains 568 users and about 4 million measurements.

**Radiocells utility.** Amongst other purposes, the Radiocells data can be used to geolocate antennas. Such information is useful to enable scientific studies about antennas distribution and signal quality in specific places. Contrary to Safecast, Radiocells does not provide documentation, nor provide code indicating how they produce their map of antennas. Thus, we use the location function described by OpenCellID [8], another crowdsourcing project with the same goal, which defines the location of an antenna as the average of the latitudes and longitudes of the measurements referring to this antenna.

### 3 Protecting Location Privacy in MCS

In this section, we describe the existing LPPMs we evaluate in our study. These LPPMs are designed for LBSs settings, which are different than MCS in two aspects. First, LBSs aim at fulfilling an individual need related to one user’s location (e.g., find nearby restaurants), while MCS aims at fulfilling a common objective through collaborative measurements. Sec-

ond, LBSs can often work with sparser geo-located data (just few points per geo-located query) than MCS, which requires continuous data collection and in a larger volume.

#### 3.1 Defenses

We consider three type of LPPMs [65, 81]: (i) spatial obfuscation, (ii) hiding, and (iii) generalization. We do not consider the use of dummy locations or synthetic data [32, 35]. Both approaches focus on producing plausible artificial locations, but to the best of our knowledge there is no proposal that provides the means to generate measurements (or other values) to be associated to these locations. In fact, we argue that generating fake measurements, even using prior information, is bound to pollute the real-time measurements that these applications aim at collecting.

**Spatial obfuscation.** The state of the art in spatial obfuscation, which perturbs reported locations with noise, is *geo-indistinguishability (GeoInd)* [28]. This mechanism adapts differential privacy to location data, providing privacy guarantees independent from the adversary’s prior information. This approach is widely used in the literature [22, 48, 62, 68, 75, 88]. Following the original definition in [28], we obfuscate locations by adding planar Laplacian noise. The magnitude of this noise is controlled by the parameter  $\epsilon = l/r$  which guarantees that the ratio between the probabilities of two points being the real location in an area of radius  $r$  is at most  $l$ .

**Release-GeoInd.** As with any differentially private mechanisms, in GeoInd the level of privacy decreases linearly with the number of reported locations. To address this limitation we implement a mechanism inspired by the predictive approach proposed in [34]. This defense reports a new noisy location if, and only if, the user has moved at least  $z$  meters away from his previous location. Otherwise, it repeats the last reported location. We call this approach “Release-GeoInd”.

**GeoInd-OR.** Remapping<sup>6</sup> obfuscated locations to popular places according to prior knowledge on users’ movements can offer optimal utility without reducing privacy [33, 73]. We complement GeoInd with the remapping approach in [33]. We refer to this approach as “GeoInd-OR”.

**Hiding.** This defense achieves privacy by suppressing some of the users’ locations [60, 61]. The released locations are *not* perturbed. We consider two hiding strategies: (i) a “Random” strategy in which users release a random subset of their points, and (ii) a “Release” strategy in which users only reveal a new point when they have traveled at least  $x$  meters away from the previously reported location.

**Generalization.** This defense reduces the precision with which locations are reported [31, 55]. We implement this approach by reducing the precision of the reported GPS coordinates [65]. We denote this defense as “Rounding”.

<sup>4</sup><https://f-droid.org/packages/org.openbmap/>

<sup>5</sup><https://radiocells.org/license>

<sup>6</sup>A remapping  $g$  is a function  $g : \mathbb{R}^2 \rightarrow \mathbb{R}^2$  that maps an output  $z \in \mathbb{R}^2$  to another output  $z' \in \mathbb{R}^2$  according to the probability density function  $g(z'|z)$ .

## 3.2 Measuring Privacy

Location privacy metrics in the literature are mostly based on a function of the distance between the real location of the user and the one inferred by the adversary [80, 81]. This function could measure the *correctness* of the adversary’s inference (e.g. using, Hamming or Euclidean distances [81]), or the *uncertainty* of the adversary regarding the user’s location (e.g., using entropy [73]). These metrics are very well suited for the case of LBSs, where users release one location per query, and the adversary tries to infer that location. However, they are hard to use in the MCS setting, where the adversary has access to locations released continuously over several days. In this case it is hard to establish between which points to compute a distance, or across which points to compute probability distributions for entropy-based metrics.

We also argue that the metrics above do not capture privacy in a manner understandable by users and developers of crowdsourcing applications. How much privacy is an error of 10 meters or 500 meters? It is clear that one is larger than the other, but not how much privacy they provide regarding the potential inference of sensitive information. Even more complicated is the case of entropy, whose units of measurement – bits, nats, or hartleys – are rarely known, let alone interpretable, by layman people.

**Privacy gain.** We propose to quantify privacy as the loss of adversarial inference power regarding two privacy dimensions understandable by users: geographical area and POIs. To quantify this loss, we use two well-established statistical measures: precision and recall. The former captures the increase in privacy when, after a defense, the adversary identifies many false candidate locations along with the user’s real whereabouts. Here, the adversary has low *precision* ( $\frac{TP}{TP+FP}$ , where *TP* and *FP* refer to *true positives* and *false positives*, respectively). The latter captures the increase when, after the defense, the adversary cannot correctly identify the original locations visited by the user. Here, the adversary has low *recall* ( $\frac{TP}{TP+FN}$ , where *FN* refers to *false negatives*).

**Spatial privacy gain.** Spatial privacy considers the geographical *area* in which the adversary infers the user can be. We define the true positives (*TP*) as the intersection of the areas where the user can be before and after applying the defense (i.e., the area inferred by the adversary that corresponds to the user’s real location). Similarly, we define the false positives (*FP*) to be the set difference of the area after the defense and the area before the defense (i.e., the area inferred by the adversary where the user was not present), and false negatives (*FN*) as the set difference of the area before the defense and the area inferred after the defense (i.e., the area where the user has been but that is missed by the adversary).

**POI privacy gain.** In reality though, the geographic area itself may not reflect users’ privacy [80]: if there is only one point of interest in a large area, privacy should be low; and in small areas with many POIs (e.g., a block in a city), privacy should

Table 1: Safecast (top) and Radiocells (bottom) measurements per region. Vulnerable users are those with at least one cluster.

| Region    | Users | Measurements | Average per user | Standard deviation | Vulnerable users |
|-----------|-------|--------------|------------------|--------------------|------------------|
| Tokyo     | 30    | 2,701,367    | 90,046           | 203,576            | 24 (80%)         |
| Fukushima | 104   | 7,765,773    | 74,671           | 260,671            | 65 (62%)         |
| World     | 540   | 56,655,768   | 105,504          | 70,954             | 349 (65%)        |
| World     | 568   | 3,710,547    | 6,532            | 17,312             | 91 (16%)         |

be large. We propose a complementary metric based on POIs. In this case, true positives (*TP*) are the POIs in the intersection of areas before and after the defense is applied. Similarly, false positives (*FP*) are POIs identified after the defense that were not present before, and false negatives (*FN*) are the POIs inferred initially that are missed after the defense.

## 3.3 Measuring Utility

Similarly to privacy, in LBSs, utility is measured as a function of distance between real and obfuscated locations of one user. This is unsuitable for MCS where location depends on the precision of the aggregate of multiple users’ geolocated measurements. We now introduce the utility metrics used in our evaluation.

**Distance-based.** We call distance-based metrics those associated to LPPMs in the context of LBSs. In our experiments, we use the per-location haversine distance<sup>7</sup> between original and obfuscated locations.

**Aggregate statistics.** Most MCS providers are interested in aggregate statistics computed over individuals’ contributions. This is the case for Safecast and Radiocells, where the radiation map, respectively the coordinates of the antennas, are derived from average measurements of MCS users. In our evaluation, we consider as MCS utility metrics the actual utility functions of the projects as described in Section 2.

## 4 Existing LPPMs Performance in MCS

### 4.1 Experimental setup

We experiment on all data available from Safecast and Radiocells. For Safecast, we additionally consider two regions in Japan with very different radiation profiles: Tokyo, where the radiation profile is quite uniform, and Fukushima, where the nuclear incident at the Daiichi power plant [23] in 2011 created areas with elevated radiation. Table 1 summarizes the statistics (number of users, total amount of measurements, and measurements per user) of the regions under study.

We evaluate the privacy gain and the utility loss of an LPPM as follows:

<sup>7</sup>Distance between two points on a sphere given their longitudes and latitudes.

*Step 1. Adversary’s inference.* Inspired by previous works, we use clustering to implement inference on the regions and the points of interest for all users. [36, 42, 46, 49, 59, 64, 69, 86]. Concretely, we use the density-based clustering algorithm (DBSCAN) [46]. Contrary to other clustering algorithms (such as K-Means), DBSCAN is robust to noise and outliers and does not require to specify the number of clusters a priori (see Appendix A.1). We keep the five clusters with the highest number of points, and we consider their total area as the geographical area input to the Spatial Gain metric. Once clusters are identified, we use the OSM API<sup>8</sup> to find the POIs in the clusters of the targeted user. We consider all points in the top five clusters as input for the POI Gain metric. Table 1 reports the percentage of users vulnerable to our attacks before the defenses are applied, i.e., the percentage of users for which we find at least one cluster. For Safecast-Tokyo, we only report statistics for the 30 users considered when using GeoInd-OR (see Section 4.3).

*Step 2. LPPM Application.* We apply the LPPM to all users’ data and repeat the actions in Step 1 to infer their regions and points of interest. Note that when Rounding to 2 or 3 decimals, obfuscated locations are separated by approximately 1,100 meters and 110 meters, respectively. Thus, our parametrization of DBSCAN is bound to not find any clusters. However, an adversary would know that given an obfuscated point, the actual location of the user is within a square of size 110, resp. 1,100 meters, centered in the reported location. Thus, for this case, instead of using DBSCAN clusters, we pick the squares of the respective sizes around the five most frequently reported obfuscated locations.

*Step 3. Privacy gain.* We compare the area (in square kilometers) of the clusters before and after the LPPM to compute the Spatial privacy gain, and the POIs inside the clusters for the POI privacy gain.

*Step 4. Utility loss.* In the case of aggregate statistics, the utility loss is application dependent. For Safecast, we consider the absolute difference in cpm per grid point between the radiation values on the application’s interactive map (see Section 2.1), before and after the LPPM. In Radiocells, we consider as utility loss the distance between the location of the antennas before and after the LPPM.

## 4.2 Validating the Inference Strategy

We now validate the suitability of DBSCAN as strategy for inferring areas and points of interest in the context of MCS. Specifically, we test its suitability to identify workplaces on data from Safecast and OpenStreetMaps. As both projects’ public data contain identifiable information about their users, we can validate the inferences against information available on other online platforms. We choose workplaces for ease of validation, but we note that it is just one of many inferences that could be done using location data [42]. Our results below

<sup>8</sup>[https://wiki.openstreetmap.org/wiki/Overpass\\_API](https://wiki.openstreetmap.org/wiki/Overpass_API)

Table 2: Safecast dataset statistics.

| Measurements | Users | Avg measurements | Avg days |
|--------------|-------|------------------|----------|
| <10k         | 213   | 3,331            | 5        |
| 10k-100k     | 230   | 38,341           | 20       |
| 100k-1M      | 87    | 270,387          | 105      |
| >1M          | 10    | 1,958,760        | 632      |

confirm that DBSCAN is a suitable choice as basis to compute areas and POIs to input in our privacy metrics.

**Ethical considerations.** For these experiments we do not collect any personal data other than that made publicly available by the MCS projects. We have limited our inferences to the minimum to validate the suitability of DBSCAN. We only report aggregated or anonymized data such that no individual’s data is exposed. We have notified the service providers about our findings, and we have shared our code with them so that they can make informed decisions regarding improvements of the privacy situation. Our code is open-source so that it can also be used by other crowdsourcing applications and improved by the research community [24]. This procedure has been approved by EPFL’s Human Research Ethics Committee (HREC).

**Safecast.** To evaluate the effectiveness of DBSCAN in different situations, we split the users in the dataset into four groups according to their amount of measurements they report. For each group, Table 2 shows the number of users, their average amount of measurements, and the average number of days in which they took at least one measurement. From each group we select as targets for inference the 10 users with the most measurements that provide their real names. Since in the group with >1M there are only 4 users with real names, we end up with 34 target users in total. This allows us to manually validate our inferences in reasonable time.

*Identifying workplaces.* We run DBSCAN on every users’ measurements during working hours (Monday to Friday from 9AM to 5PM). We configure DBSCAN to find clusters with at least 80 points separated by 60 meters and, if no clusters are found, we increase the distance by 30 meters (up to 120 meters maximum) and decrease the number of points by 15 (down to 35 points). These parameters have been chosen empirically to optimize the adversary’s success, see Appendix A.5. To keep the manual analysis feasible, we only consider the five clusters with the highest number of points.

We expect that the users’ workplace is one of the POIs within the inferred geographic area. In many cases, however, this area is large and contains many POIs. To ease manual validation, we use X-means clustering [74] to split these large clusters, and consider as POIs the centroids of the two largest subclusters. We end up with at most 10 POIs per user. We use the MapQuest API [25] to obtain these locations’ addresses and, if existing, the names of the businesses at those coordinates. We recall that in our LPPM evaluation below,

we consider all points in the clusters as input for the POI Gain metric. This represents a resourceful adversary that can afford checking manually all the points and filter out those corresponding to businesses. We note that considering more points could cause more false positives, but the semantics of locations often makes it easy to filter these out, e.g., lakes or parks can be usually discarded as workplaces.

Once we have candidate workplaces, we validate them using social networks such as Twitter or LinkedIn, or the users' personal webpages. We note that 9 of our target users did not have a publicly available profile or had too common names to find their correct information, thus we could not validate their inferred workplaces. Overall, we recover the workplace of 35% of the target users. This result is consistent across the groups: 40% of the users with less than 10k measurements, 20% of the users with 10k-100k measurements, 50% of the users with 100k-1M measurements, and 25% of the users with more than 1M measurements. We conclude that DBSCAN performs well for POI identification irrespectively of the amount of data shared by the users. Surprisingly, this means that privacy seems not correlated to the volume of data made available to the adversary. On the contrary, it seems to be highly dependent on the collection patterns of the users. We observe that people fall in one of two categories: (i) Those who travel to different places with the goal of obtaining measurements, whose work addresses cannot be inferred; and (ii) those who measure radiation during their daily activities, whose work place we can find. The Safecast co-founders, who are the top contributors in terms of data points, fall in the first category, explaining the lower inference power for users with more than 1M measurements.

Our results confirm recent findings in the literature regarding personal information inferences from location data [42, 45]. Yet, we want to stress that the threat may be worse for MCS, due to the volume of data exposed by participants. For reference, Safecast's lowest contributing group has on average 3k measurements per user (see Table 2) while in the Twitter analysis performed by Drakonakis et al. [42] only the top contributing users (less than 0.06%) have more than 3k geolocated tweets. Thus, even if the number of MCS users is not as large as social networks' users, we expect a significant fraction of them to be vulnerable to privacy attacks.

*Other POIs.* A deeper analysis of the times and semantics of the POIs identified by DBSCAN revealed further information about Safecast users. Among others, we could infer two users' membership to specific organizations: one member of the Scientology church who reported many points from the Church of Scientology Celebrity Centre in a major city; and a Masonic lodge member who regularly visited the lodge headquarters. We could verify this information online for both users. We also identified two work-related activities: a US-based scientist working on a project about radiation around a lake in the Southern part of the US, and a photographer working in a Japanese city. We validated these inferences using

Research Gate and the webpage of the artist, respectively. Finally, we could follow the education steps of a European PhD student. Her points of interest over time reveal the university where she obtained her master's degree, an exchange with another European university, and the university where she is completing her doctoral studies. We verified these facts on her CV available online.

**OpenStreetMaps.** Contrary to Safecast, OSM does not have an open API for accessing users' data. Yet, traces from users who have chosen to make their data available can be easily obtained from OSM's website.<sup>9</sup> To minimize the impact on OSM servers, and comply with their non-crawling policy, we manually downloaded data for 30 users with a large amount of contributions,<sup>10</sup> of which 17 used their actual names (or indicative nicknames). Although the majority of the points in the dataset were rather old (most of them at least 7-8 years old), we were able to verify previous workplaces for 3 of the 17 users (17%). We note that, for some users, we found out that they did not have a standard place of employment during data collection period (e.g., students). However, for *all* users, their POIs were within the area where they worked or lived. We used this fact to infer two of the users' short vacation trips which we manually verified with information publicly accessible from their social media accounts.

### 4.3 Privacy Gain

**Defenses implementation.** For the GeoInd defense, we set the privacy parameter  $l = \ln(1.6)$ , and use radius  $r \in \{50, 150, 300\}$  meters which yields  $\epsilon \in \{0.01, 0.003, 0.001\}$ . Remapping the locations for the LPPM GeoInd-OR requires computing the posterior probability for every candidate location. This operation is rather costly when the number of locations being considered grows. To keep a reasonable experimentation time, we only test GeoInd-OR for the Tokyo region in the Safecast dataset. We use 80% of the users to construct the prior probability distribution describing users' movements, and the remaining 20% to evaluate the effectiveness of the approach. We chose this 20% manually to keep a balanced testing set. It is composed of the top 10 users with many (more than 50k), moderate (between 10k and 50k), and few (less than 10k) measurements. Finally, for the Release-GeoInd mechanism, we use  $l = \ln(1.6)$ ,  $r = 50$  meters, and we select the distance between released locations to be  $z \in \{30, 60, 90\}$  meters. We provide details about the implementation of these LPPMs in Appendices A.2 and A.3.

We implement the Random mechanism tossing a biased coin every time a location is about to be reported. The bias is set so that users release on average 40%, 60% or 80% of their measurements. For the Release mechanism, we sort all the locations reported by a user in chronological order, and

<sup>9</sup><https://www.openstreetmap.org/traces>

<sup>10</sup><http://resultmaps.neis-one.org/ooc>

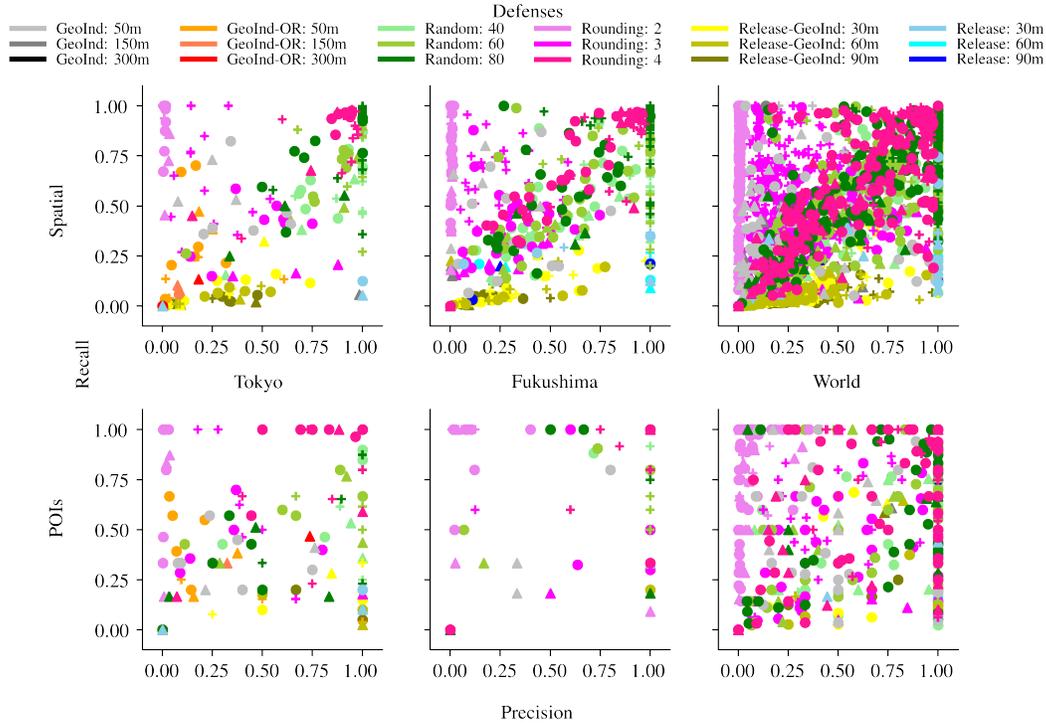

Figure 1: Safecast privacy gain: Spatial (top) and POIs (bottom). Amount of measurements per user + : <10k, ● : [10k,50k], ▲ : >50k. Each point on the graphs represents one user.

release a new location only if it is separated by (at least)  $x \in \{30, 60, 90\}$  meters from the previously reported one. If two locations are less than  $x$  meters apart but in different days, we release them both.

Last, we implement Rounding by rounding to 2, 3, or 4 decimals the latitude and longitude of the users' locations. Effectively, this reduces the location accuracy to roughly 1,100 meters, 110 meters and 11 meters, respectively.

### 4.3.1 Safecast

We first evaluate the privacy gain of the LPPMs in the Safecast dataset. Figure 1 shows the Spatial (top) and POI (bottom) gain for Tokyo, Fukushima, and the whole world. (Figure 12 in the appendix shows the results for each of the defenses separately for the whole world.) The x-axis represents precision, and the y-axis recall. Each point in the graph represents a user, and the markers' shape indicate the amount of measurements she contributes. The colors represent the LPPMs. To compute these graphs, we configure DBSCAN to find clusters with at least 75 points separated by at most 30 meters (roughly the size of a small building). As in [42], we also require that, for each cluster, users either stay more than 30 minutes, or visit it for at least two days. A first reason to fix these parameters is to evaluate the gain for all users under the same conditions. A second reason is that the loose parameters used in Section 4.2

can yield very sparse clusters with few points that are hard to break by removing or perturbing locations. Thus, the defenses would perform equally bad and we would gain little information about their properties. Tightening the parameters reduces the work inference success to 21% (some clusters are not found), which still represents a significant risk.

Defenses that provide large gains result in points close to the figure axes. Points near the y-axis indicate low precision, i.e., cases in which the adversary correctly identifies some (or even all) of the true locations but also inferred many other wrong locations. Points near the x-axis indicate low recall, i.e., cases in which the adversary correctly identifies some real locations, but misses many others. Unsurprisingly, we observe a high variance in the defenses' performance since it is highly dependent on the user behavior. However, it is possible to identify some trends.

We first discuss the Spatial privacy gain (Figure 1, top). For the least privacy-preserving parameter ( $r = 50m$ ), GeoInd significantly decreases the number of vulnerable users (grey points in the figure) from the values reported in Table 1. The reduction is 50% for Tokyo (from 24 vulnerable users to 12), 45% for Fukushima, and 45% for the whole world. When the mechanism is strengthened ( $r = 300m$ ), GeoInd adds so much noise (see Figure 10 in Appendix A.4 for reference) that no users are vulnerable after the defense. In summary, GeoInd seems to provide fairly good privacy gain in Tokyo

and Fukushima. Yet, when we look at the whole dataset, it becomes clear that the protection provided by GeoInd is highly dependent on the users' movement patterns.

The Release-GeoInd (yellow) mechanism works generally better than GeoInd. Even though more users are vulnerable (only between 4% and 13% of the users become not-vulnerable) and the adversary obtains reasonable precision, it yields very low recall. This is because in this method users keep reporting the same obfuscated location until they move. This repetition results in clusters being found on fake locations that often do not overlap with the original ones. This reduction becomes more significant as the defense is configured to provide more privacy (larger  $z$ ).

GeoInd-OR performs slightly better than vanilla GeoInd. This is because the remapping results in points being repeatedly mapped to popular places causing the generation of clusters around those not-real locations.

Similar to vanilla GeoInd, the Release mechanism (blue) significantly reduces the number of vulnerable users – by more than 50% even for the least conservative parameter. However, when precision is very high, i.e., when a cluster is found, it corresponds to a real location. The reason is that even though the user hides many points, if a location is visited regularly, the user will eventually report enough points around this location to make the cluster identifiable by the adversary.

The Random hiding mechanism (green) does not perform well. First, it reduces the number of vulnerable users less than other defenses (10% decrease in Tokyo, 27% in Fukushima, and only 5% when considering the whole world). From the vulnerable users only a handful obtain good protection. We could not find a clear pattern to predict which movement profiles would best benefit from this defense. For many users, especially those with a few points, removing points at random still yields high precision as the few measurements are very localized. Overall, we do not notice much influence of the fraction of hidden points on the privacy of the users.

Finally, the protection provided by Rounding (pink) depends on the rounding parameter. Keeping 4 decimals reduces accuracy by just 11 meters. Therefore, the adversary finds roughly the same clusters, i.e., for many users we observe high recall and precision after the defense (especially in Tokyo and Fukushima). On the contrary, rounding to 2 or 3 decimals significantly increases the size of inferred spatial areas, which leads to variable recall (depending on the users' movement patterns) and low precision.

Regarding the POI privacy gain (Figure 1, bottom), a first observation is that the amount of users vulnerable to the attack, i.e., points in the graph, is lower. This is because for many users the identified clusters do not contain any POI (according to the OSM API). Second, for the users who have POIs in their clusters, both recall and precision are higher than in the Spatial gain. This is because many of the large clusters that contribute to the low Spatial precision do not have POIs and thus do not contribute to the confusion of the adversary when

identifying particular POIs. Furthermore, the clusters that the adversary finds after the LPPMs may cover a smaller area than the original clusters, but still contain most of the users' initial POIs. This provides a higher POI recall than Spatial recall. Third, in this case we observe a significant difference between Tokyo and Fukushima. The reason is twofold. First, the Fukushima prefecture is much larger than the area of Tokyo we consider. Second, Fukushima is a rural area and thus contains fewer POIs than Tokyo where even small clusters have many places of interest.

These observations reinforce previous insights that solely considering the spatial dimension may provide a false perception of privacy [80]. Considering a POI-privacy measure is necessary for providing a comprehensive picture of the privacy threat users face in MCS applications. We note that this perception also depends on DBSCAN parameters, which define the size of the regions found, and consequently the number of POIs, increasing the manual effort of the adversary. We discuss this effect in Appendix A.5.

**Impact of the amount of measurements on privacy.** We present in Figure 2 the Spatial gain for the three best LPPMs (all parameters combined) split by the amount of measurements users contributed. We discard Rounding 4 as it does not provide any privacy. We see that all LPPMs provide low precision and recall regardless of the users' contribution volume. The exception is Rounding which, as explained above, by definition provides variable recall and low precision.

Counterintuitively, the LPPMs perform worse for users who contribute fewer points. This is because the attack constructs more, and larger (on average 10 times bigger), clusters for people who share many points than for those sharing fewer points. These clusters are split after the LPPMs are put in place, as some reported locations are moved away from their original clusters while other measurements, perturbed with noise, concentrate to new places forming wrong clusters. For Rounding, where every cluster created after the LPPM has roughly the same size, users with a few measurements have higher recall because their initial small clusters are often covered by the large regions resulting from the LPPM.

**Thwarting workplace inference.** Finally, we evaluate the effectiveness of the different LPPMs at hiding workplaces. Recall that, without protection, we can identify the workplace of 21% (7 out of 34) of the users. Five defenses, GeoInd, Release-GeoInd, Release, and Rounding 2, protect all users from inferences. Random hiding requires heavy sampling to be effective (hiding only 20% permits the identification of 6 workplaces, and hiding 40% still reveals 1). Finally, unsurprisingly, Rounding to 4 decimals does not protect against work inference, and Rounding with 3 decimals only hides one workplace out of 7.

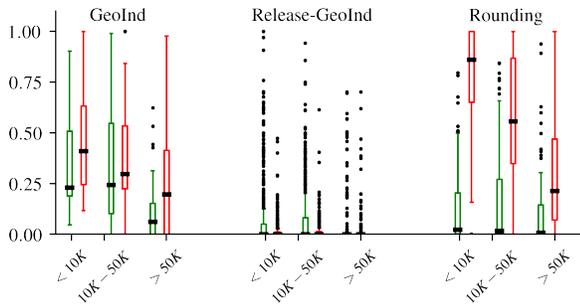

Figure 2: Precision (green) and recall (red), depending on the amount of measurements  $x$  per user for three selected defenses (all parameters combined).

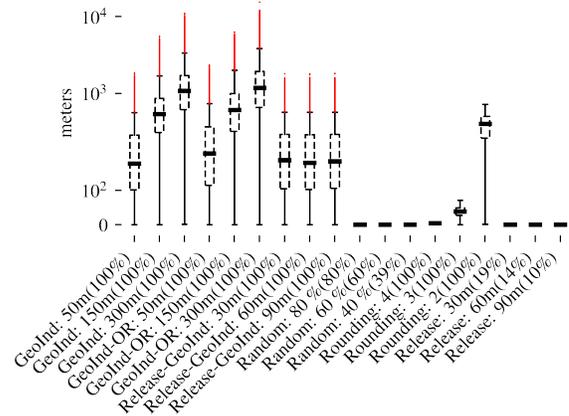

Figure 4: Measurement error in Tokyo using a distance-based metric. This can be interpreted either as privacy gain or utility loss.

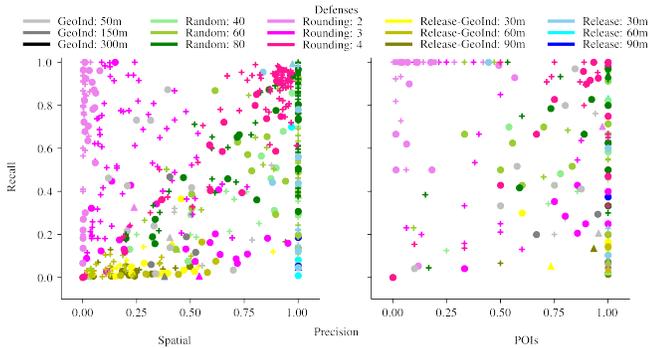

Figure 3: Spatial privacy gain (left part) and POI privacy gain (right part) in Radiocells. Amount of measurements per user + : <10k, ● : [10k,50k], ▲ : >50k. Each point on the graphs represents one user.

### 4.3.2 Radiocells

Users in Radiocells have on average fewer measurements than those in Safecast, and clustering requiring 75 points yields very few clusters. Hence, for this dataset we loosened the DBSCAN requirement to 25 points per cluster.

We see in Figure 3 that GeoInd-based mechanisms behave similarly to the Safecast case in terms of Spatial gain: GeoInd provides highly variable protection, and Release-GeoInd yields low recall while precision depends on the user behavior. Vanilla GeoInd decreases the number of vulnerable users by 14%, and Release-GeoInd by 2%. Given that only 16% of the users were initially vulnerable, this reduction is significant. For the hiding mechanisms, the Random and the Release mechanisms decrease the number of vulnerable users by 7% and 14%, respectively. For the vulnerable users, contrary to Safecast, these mechanisms consistently yield high precision, i.e., they offer poor privacy protection for Radiocell’s users movement profiles. Finally, the Rounding mechanisms with parameters 2 and 3 offer reasonable privacy. Regarding POIs, we observe similar behavior to the

Safecast dataset.

Overall, the results in Radiocells are consistent with our findings in the Safecast dataset, confirming the trends regarding the LPPMs behavior in the MCS setting.

## 4.4 Privacy-Utility Trade-Off

### 4.4.1 Safecast

**Distance-based metric vs Aggregate statistics for MCS.** We first evaluate the utility loss incurred by the LPPMs measured using the LBS-oriented distance-based metric described in Section 3.3. This utility metric is based on the distance between reported and real locations, but disregards the (radiation) values that Safecast cares about. Figure 4 displays the results for users in the Safecast-Tokyo dataset. The y-axis indicates the distance in meters, and the x-axis the LPPM and the percentage of points that are released. Random and Release LPPMs, which add no noise, are the best in terms of error; and GeoInd LPPMs offer the worst performance as they tend to spread locations — sometimes more than a kilometer away from the initial measurements (see Figure 10 in Appendix A.4).

Next we consider the utility loss for aggregated statistics, i.e., utility measured as the difference between radiation values to be plotted on the generated map. We plot per grid-point utility loss for Tokyo and Fukushima in Figures 5 and 6, respectively. We observe that the loss is similar in both regions, though in Fukushima the median loss is slightly higher and there are more, and larger (up to  $10^4$  radiation offset with respect to the original value), outliers than Tokyo. Because of the interpolation step, in this case all GeoInd variants offer roughly the same utility loss on average. Still, Hiding and Rounding strategies offer better performance, with small

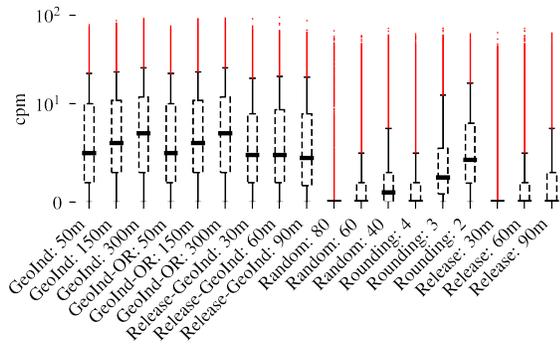

Figure 5: Absolute difference in Tokyo's radiation values with Safecast dataset.

median error for the least protective parameters.

If we compare the distance-based results (Figure 4) to the aggregated statistics utility loss (Figure 5), we observe significant differences. First, the interpolation step results in LPPMs based on GeoInd to fare much better in terms of aggregates than in terms of distance. Second, distance-based metrics underestimate the utility loss of hiding LPPMs (Random and Release). While it is true that the released points have no error in distance, hiding points comes at a cost not reflected in the metric. This is made evident by the aggregated metrics, which show that the more points are hidden, the larger is the utility loss. We note that relying on Markov mobility models such as in [51, 81] could help interpolate the hidden locations. Yet, this would not help recover the (radiation) values attached to them and the utility loss would remain. For the generalization mechanisms, distance-based metrics consistently report larger median loss, but have less variance and less outliers.

In summary, distance-based metrics provide a very different perception of the LPPM performance than considering utility functions computed on the geo-located values, overestimating the performance of some methods (e.g., hiding strategies) and underestimating others (e.g., GeoInd-based LPPMs). We conclude that traditional LBS-oriented metrics are inadequate for measuring utility in MCS scenarios.

**Semantic interpretation.** The absolute difference in cpm of measurements before and after the defense gives a rough idea about the utility loss, but it is difficult to interpret. Is it significant? What is the effect of outliers? Does reporting the values after the defense have any implication on the danger for human health? To answer these questions, we study how the variance introduced by the defenses can change the interpretation of the risk at a given location. To this end, we rely on the cpm safety scale [26] provided with one of the top-seller Geiger counters (radiation measurement devices) on the market. This scale contains five categories:

- Category 1: 0-50 cpm. Normal radiation background.
- Category 2: 51-99 cpm. Medium level.

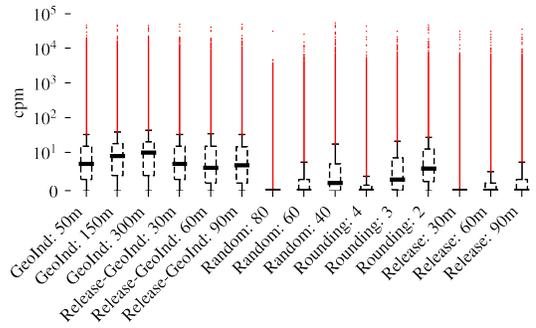

Figure 6: Absolute difference in Fukushima's radiation values with the Safecast dataset.

Table 3: Danger category changes after applying Geo-Ind ( $r = 300$  meters) in Fukushima.

| Geo-Ind: 300m | 1     | 2     | 3     | 4      | 5      | Number of points |
|---------------|-------|-------|-------|--------|--------|------------------|
| Original      |       |       |       |        |        |                  |
| 1             | 79.7% | 19.3% | 1%    | 0.003% | 0.001% | 1,354,110        |
| 2             | 41.5% | 49.5% | 9%    | 0.023% | 0.01%  | 650,486          |
| 3             | 8.7%  | 35.9% | 52.2% | 2.3%   | 0.9%   | 229,848          |
| 4             | 2.5%  | 3.3%  | 49.3% | 29.8%  | 15.1%  | 10,489           |
| 5             | 3.9%  | 1.7%  | 34.7% | 29.3%  | 30.4%  | 5,067            |

- Category 3: >100 cpm. High level.
- Category 4: >1000 cpm. Very high level, leave area.
- Category 5: >2000 cpm. Extremely high level, immediate evacuation.

We select the prefecture of Fukushima and two defenses that produce a good level of privacy: GeoInd 300m and Rounding 2. For each of the 2.25 million grid-points on Safecast's radiation map for Fukushima, we compute their radiation category according to the safety scale before and after each defense. For GeoInd 300m, which is of probabilistic nature, we repeat the procedure 10 times and report the average. We present the results in Tables 3 and 4. We observe that the majority of the points either stay in their original category or move to a nearby. However, we observe some extreme category jumps from the first category (safe radiation levels) to the fourth and fifth (high danger). For instance, GeoInd causes 53 places to be marked as dangerous instead of safe. Even more alarming, 283 locations that should be marked as extremely dangerous are marked as safe or slightly elevated (categories 1 and 2). On the contrary, the Rounding mechanism limits the number of extreme changes. For instance, there is a category jump from 5 to 1 and 2 only for 45 grid-points.

**Why optimal remapping does not work for MCS.** Even though GeoInd-OR was designed to increase utility while preserving privacy, we observe that, in the MCS case, utility roughly stays the same (Figure 5), and privacy slightly increases, both in decreasing the number of vulnerable users and in increasing the spatial gain. The reason for this mismatch is that this mechanism was designed in the context of

Table 4: Danger category changes after applying the Rounding mechanism (2 decimals) in Fukushima.

| Rounding: 2 | 1     | 2     | 3     | 4      | 5      | Number of points |
|-------------|-------|-------|-------|--------|--------|------------------|
| Original    |       |       |       |        |        |                  |
| 1           | 89.3% | 10.3% | 0.3%  | -      | 0.001% | 1,354,110        |
| 2           | 30.2% | 64%   | 5.8%  | 0.003% | -      | 650,486          |
| 3           | 0.7%  | 22.6% | 74.8% | 1.6%   | 0.3%   | 229,847          |
| 4           | 0.2%  | 0.01% | 43.3% | 39.6%  | 16.9%  | 10,490           |
| 5           | 0.9%  | -     | 9.3%  | 42.1%  | 47.6%  | 5,067            |

Figure 7: Prior probability of visiting locations in Tokyo (white - low probability, black - high probability).

LBSs, where remapping locations to places where the user is likely to be is bound to provide good utility on average. However, in Safecast, the utility does not depend on the locations themselves, but on the associated measurements. Remapping the location, however, concentrates measurements in these popular locations, effectively polluting the measurements. We illustrate this effect in Figure 7, which represents the prior probability of users' locations over all locations in Tokyo (low in white, high in black). In the low probability areas, most locations have the same probability, thus remapping has a randomizing effect. However, when there is a location with high probability, all locations are remapped to this popular location. We note that, while significantly hurting utility, this effect creates artificial clusters that reduce the adversary's precision and recall, thus increasing privacy.

**The case of high precision measurements.** Safecast also uses the crowdsourced measurements to monitor radiation hotspots that could be dangerous for public health. For this case, location precision is highly important, both to understand the dangers it can cause and to keep low costs if experts have to be sent to study the origin of the abnormality.

We study the impact of LPPMs on hotspot localization by looking for locations with more than 100 cpm radiation after averaging the measurements over the last 270 days but *before interpolating the data*. This is to avoid that interpolation modifies the position of the hotspots, or even eliminates them. We show the results of detection when using the raw measure-

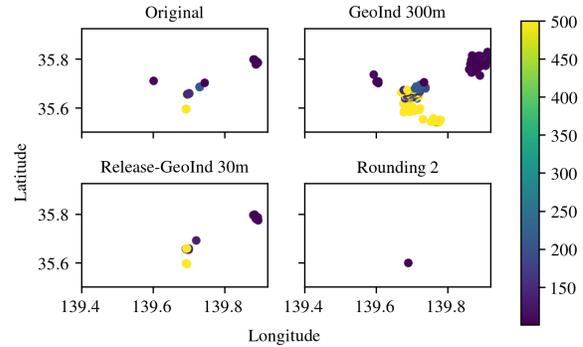

Figure 8: Safecast: Hotspot detection for areas with at least 100 cpm. Comparison of various defenses vs the original hotspots.

ments (top left), and after the application of Release-GeoInd 30m (bottom left), GeoInd 300m (top right), and Rounding 2 (bottom right) in Figure 8. We see that noise-based mechanisms spread the measurements and, as the noise increases, create additional hotspots. Thus, these mechanisms are useless for hotspot detection: the results cannot be properly interpreted. Imagine a hotspot in a place known to present high radiation, thus being already closely monitored by the authorities. Finding such hotspot is not alarming. However, after spreading, the finding of hotspots conveys a much different message, especially when they appear in zones that had low radiation in the past.

Generalization such as Rounding 2, which provides a good privacy-utility tradeoff for aggregated statistics, also performs poorly. In this case, the defense causes hotspots to disappear, potentially causing a dangerous situation if a high radiation zone is marked as safe. We also carry out experiments with hiding mechanisms and find that, similarly to Rounding, they miss some of the original hotspots.

**Safecast takeaways.** Considering only the privacy loss, GeoInd variants (except GeoInd 50m) and Rounding to 2 decimals seem to offer the best performance, while Random sampling and Release's protection is generally bad in terms of precision, and also too dependent on users' movement profiles. However, an analysis of the utility impact indicates that *none of the existent LPPMs is well suited* for the Safecast setting. The semantic interpretation results indicate that even if two defenses produce similar average results, the outliers they create can convey opposite messages. Furthermore, even a slight addition of noise or generalization can hinder the project's ability to correctly locate abnormal events. These limitations effectively prevent Safecast from deploying them to protect their users' privacy.<sup>11</sup>

<sup>11</sup>This statement was verified in communication with Safecast.

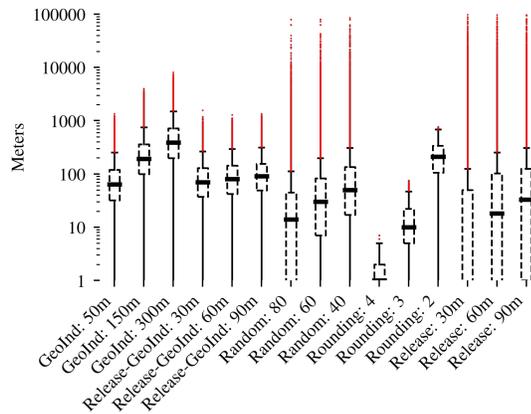

Figure 9: Radiocells: Utility loss (distance to tower location).

#### 4.4.2 Radiocells

Radiocells’ utility function is rather different than the one for Safecast. Instead of averaging measurements associated to a location, Radiocells averages all reported coordinates associated to an antenna to derive its position. We show the related utility loss for different LPPMs in Figure 9.

All GeoInd variants induce high utility loss, with medians between 80 and 400 meters, and with outliers beyond 2 kilometers. Surprisingly, in this use case hiding mechanisms (Release and Random) have many outliers. After manual inspection, we found out that several users had inconsistent measurements. For instance, a user was swapping her measurements’ longitudes and latitudes in a random pattern. Other outliers are caused by providers moving their antennas IDs creating mixed measurements for a given ID. Furthermore, hiding defenses also influence the number of antennas located. In our dataset, we detect from 10.2% up to 18.6% fewer antennas when the Release defense is used, and the Random mechanism eliminates from 2.6% up to 13.7% of them.

The best mechanism in the Radiocells dataset is Release GeoInd which offers on average lower utility loss than other LPPMs and provides acceptable privacy. However, some antennas might be moved over a kilometer away. The next best alternative is Rounding 2 that has a higher median utility loss but no outliers. However, as the goal of the project is to *accurately* detect antennas in order to give individuals the ability to geolocate themselves offline or to enable scientific studies, a median error of 100 meters (Release GeoInd) or 200 meters (Rounding 2) is considered too large and precludes Radiocells from deploying them.

## 5 What’s Next?

In this section, we elaborate on technical and non-technical steps to enhance privacy at smaller utility cost in the context of MCS applications.

## 5.1 Towards Effective Defenses

We first discuss possible strategies to improve the trade-off between users’ privacy and MCS utility.

An unexplored approach is the use of advanced cryptographic protocols to compute the values of interest for MCS without revealing the users’ individual values to the providers [41]. For instance, users could use multi-party computation to collaboratively compute aggregates and only report the result to the provider. However, cryptographic approaches require high computational power on the users’ side and increase the bandwidth needs to perform the joint computation. Furthermore, this would limit the availability of raw measurements for analysis other than those predefined by the cryptographic protocols, which is at odds with the principles of open data and open science defended by most of the MCS platforms.

In our evaluation, we only considered spatial generalization. Another avenue to explore would be to also generalize the time dimension. On its own time obfuscation cannot hide patterns revealed by repeated visits. However, combined with full de-identification and hiding of users could reduce the inference power of the adversary. For instance, the MCS service provider could release a batch of measurements once a day or once a week without linking these to any user identifier. These techniques would be cheaper than the use of cryptography, but require trust on the service provider to properly apply sanitization and protect the raw data.

A third research path is the co-design of defenses and aggregation algorithms. In this paper, we have considered that the output of the LPPMs is directly input to the utility functions currently used by MCS providers. However, it would be possible that the providers adapt their data processing to account for noise, using statistical methods or machine learning, as done in fields that rely on noisy sensors [79] or train in different settings from which they are deployed [43, 72, 85].

Finally, MCS could provide users with dedicated local software (e.g., building on our evaluation method) to alert them regarding the privacy dangers of publishing raw location data. Such a system would allow them to selectively hide some of their measurements, reducing the confidence of inference attacks. We note that, when building such a tool, one would like to consider attacks beyond the POI-based inferences considered in this paper. For instance, it has been shown that co-locations can unveil social links [38, 44]. We run a preliminary evaluation to learn whether our MCS setting is also prone to such an attack. We identified 50 unique pairs of users with real names and at least one co-location (similar latitude, longitude, and time) in the Safecast dataset. We could validate 16 of these pairs as real friendships using information available on online social networks, i.e., yielding a 32% correct inference rate. Note that many of the other pairs could not be verified because either users were not part of any social network or they did not publicly reveal their social links. More advanced methods, such as measuring the amount of time

two users are co-located or the number of different locations where two users jointly report their locations [30,38,87] could further improve these results. Therefore, new defenses need to also obfuscate co-locations [71].

## 5.2 Privacy Considerations for Developers

In our study, we identified a number of issues related to the collection and sharing of data that, even though cannot fully prevent inference, could make inference attacks detectable and could render potential attackers accountable.

A first consideration to make is the type of policy under which MCS publish the collected data. While making large datasets available to everyone for unrestricted use is admirable, and certainly of high value for the academic community, it can have serious implications for the altruistic contributors. To reduce this risk, developers could add clauses to the policies that not only mandate that use of the data is properly acknowledged, but also that it is well documented, implying that researchers or other individuals have to disclose how they have processed the data, and for which purpose.

Second, both Safecast and Radiocells datasets are available for download without the need for authentication. This hinders traceability of who has the data, and thus enables stealthy attacks where nor the users neither the applications are aware of the danger. Like in other projects that make data available for research and other purposes (e.g., the Drebin project<sup>12</sup>), these sites could require simple registration to maintain a log of who has had access to the datasets. Together with the previous requirement, which would include documentation of sharing, it should help mitigate the risks.

Third, these applications typically do not perform any control on who are the contributors. This poses a particular problem when it comes to children. In many jurisdictions, children's data are subject to particular legislation [37,47], and in particular require the parents' consent to be collected and processed. The lack of control upon collection implies that the datasets could contain children's geo-located data collected illegally. Adding control would solve this problem and also support the previous two points.

Finally, the datasets we studied contain data from users from all over the world. These users, therefore, are subject to different legislations that regulate how their data can be processed. While this may not be a problem for corporations or criminals that want to exploit the datasets, it creates a hurdle for researchers who have to obtain approval from their institution for data processing. This problem arised during our discussions with our institution's Ethical Review Committee, and almost caused us to stop the project. In other words, lack of proper documentation may limit the free use of the data for science, effectively hindering one of the main goals of these applications. Better documentation as to the origin of data and its use possibilities would greatly facilitate the process.

## 6 Related Work

We have covered the related work on LPPMs in Section 3.1 and the previous work on privacy quantification in Section 3.2. We complete this review of the literature with previous research on human mobility and its privacy implications.

Similar to [36,49,58,59,64,66,67,69,86], our POIs extraction attack is based on machine learning. Gambs and Killijian [52] also rely on POIs inference to build mobility Markov chains and de-anonymize traces. Gonzalez et al. [54] and Song et al. [82] study anonymized mobile phone data. Their results indicate that human trajectories have a high degree of temporal and spatial regularity, and that an individual's location data history is a unique identifier. De Montjoye et al. [39] investigate how the uniqueness of mobility traces decays depending on their resolution. They show that uniqueness cannot be avoided by lowering the resolution of a dataset. While these works aim at understanding the uniqueness of individuals or de-anonymize them, we focused on inferences that rely on labeled traces.

Similar to us, Gambs et al. [50] develop a platform for evaluating various sanitization methods and attacks on geo-located data. They focused on evaluating LBSs, while we evaluate the effectiveness of defenses on MCS applications. We also use different privacy metrics, and utility functions, tailored to the MCS scenario. Finally, Drakonakis et al. [42] explore the privacy loss stemming from by public location metadata. They propose a tool to infer users' regions of interest and, by experimenting with data gathered from Twitter, they illustrate the accuracy of their tool in pinpointing users' sensitive locations. Furthermore, they highlight how the spatial data provide additional context on the information shared by the user. We use similar techniques to prove that these inferences are also possible in MCS. For further information about the security and privacy landscape of location data we refer the reader to the surveys in [53,65,76,84].

## 7 Conclusion

Mobile crowdsourcing is an increasingly popular way to collect geo-located data from millions of contributors. We present the first study on privacy implications of MCS applications. We study the applicability of well-established location privacy defenses created for LBSs. We show that neither the location privacy and utility metrics typically found in the literature nor the existing privacy-preserving mechanisms are well-suited for the MCS case. On the one hand, given the persistent patterns stemming from continuous collection, these solutions provide less privacy than in the case of LBSs where locations are revealed once. Second, the existing mechanisms are optimized to provide utility regarding the location of the users, but MCS applications rely on measurements associated to these locations, or on some function of the locations. Therefore, state-of-the-art defenses have a detrimental impact on

the MCS utility.

In conclusion, we identify an underexplored space in the location privacy literature, that is of practical relevance for many new applications. We have outlined promising lines to improve the situation. We hope that our findings spawn new research that soon enables the deployment of privacy-preserving crowdsourcing applications.

## A Appendix

### A.1 Density Based Clustering (DBSCAN)

The algorithm receives as input all locations (also referred to as points) reported by a user, the minimum required amount of points per cluster, and the maximum allowed distance between the cluster’s points. It outputs a label for every point, indicating to which cluster it belongs, or if it has been labeled as noise.

DBSCAN starts by randomly selecting a point  $c$ . Then, it finds all points  $p$  that are in distance  $\epsilon$  from this point. Then, from the points  $p$  reachable from the first point, it tries to find more points  $q$  where  $q$  are reachable directly from  $p$  but not from  $c$ . If at the end of this procedure the minimum points have not been reached, it moves to another random point and starts all over again. In order to use our locations which are in latitudes and longitude, we converted the distance  $\epsilon$  to radians first. Moreover, we used a ball tree data structure to speed up the neighbors queries.

### A.2 Geo-Indistinguishability

The noise is drawn by first transforming the location to polar coordinates. Then, the angle is drawn randomly between 0 and  $2\pi$  while the distance is drawn from

$$C^{-1}(\rho) = -\frac{1}{\epsilon} \left( W^{-1} \left( \frac{\rho - 1}{e} \right) + 1 \right)$$

with  $W^{-1}$  denoting the  $-1$  branch of the Lambert  $W$  function. Finally, the generated distance and angle are added to the original location.

### A.3 Optimal Remapping

For the optimal remapping technique we follow these steps; For performance reasons, we first round each location to 3 digits, in order to merge nearby locations together. Then, we calculate the probability of each coordinate. Afterwards, we convert all coordinates to a Cartesian system using their distance from the center of the Earth. A useful tutorial on this can be found in [27]. Using the Cartesian coordinates we build a KD-Tree for efficient nearest neighbor calculations. Then, for every location where GeoInd has been applied, we query all nearest neighbors in a region  $r'$ . This  $r'$  is set to be as the 99% percentile of the distribution that generated the

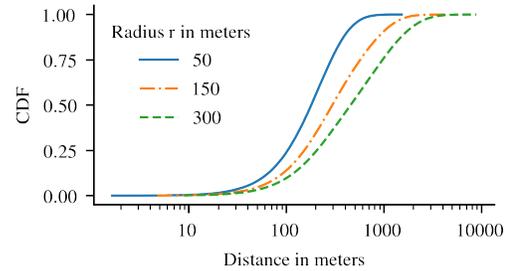

Figure 10: GeoInd noise magnitude for different radius ( $l = \ln(1.6)$ ).

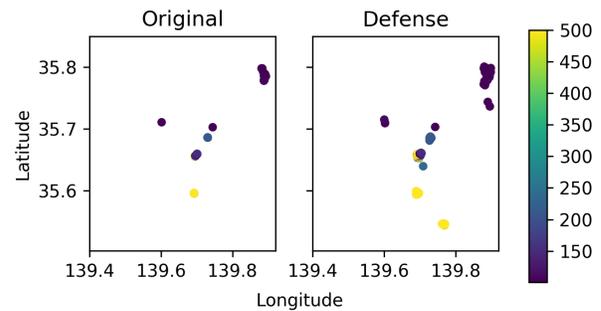

Figure 11: Safecast: Hotspot detection for areas with at least 100 cpm. The presented defense is GeoInd with 50m parameter.

parameter  $r$  used in GeoInd. In other words, the user has 99% chance of being remapped somewhere within this distance. For all neighboring points, we compute the posterior and then, we calculate the geometric median of those coordinates using the iterative Weiszfeld’s algorithm. The geometric median minimizes the average Euclidean distance and hence, returning us the new, optimal (in terms of utility as privacy should remain the same) location.

### A.4 Defenses evaluation

We include three more figures to complement the defense evaluation:

- Figure 10 portrays the CDF of the noise added by GeoInd. This noise is added on all GeoInd variants (Optimal Remapping and Release-GeoInd) and it is controlled by either the radius ( $r$ ) or the privacy parameter ( $l$ ).
- Figure 11 illustrates the hotspot detection results when GeoInd 50m is used. Even a slight addition of noise spreads the locations, not allowing Safecast to accurately detect elevated radiation regions.
- In Figure 12 we present the privacy gain results for each of the defense mechanisms for the whole Safecast dataset.

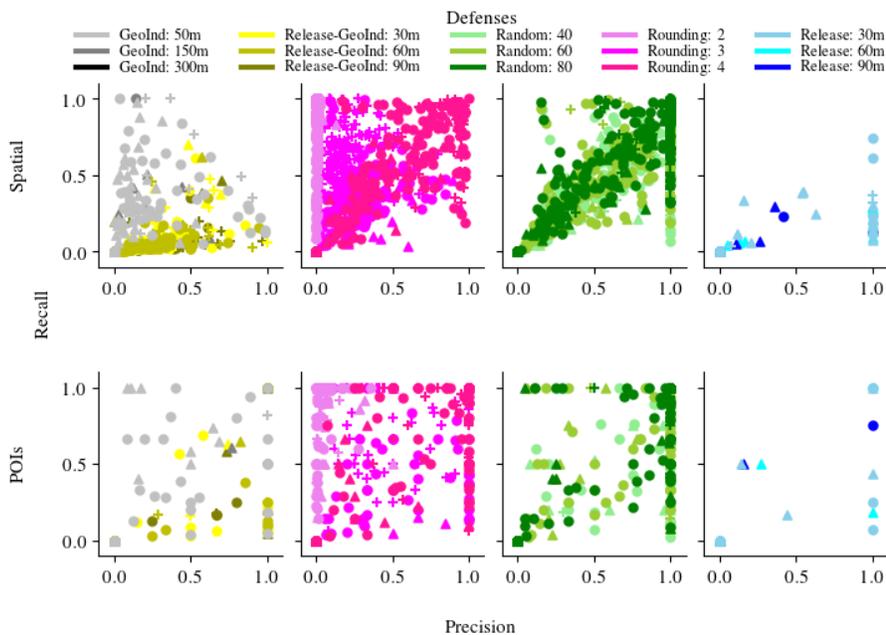

Figure 12: Safecast: Privacy gain for each of the defense mechanism (whole dataset).

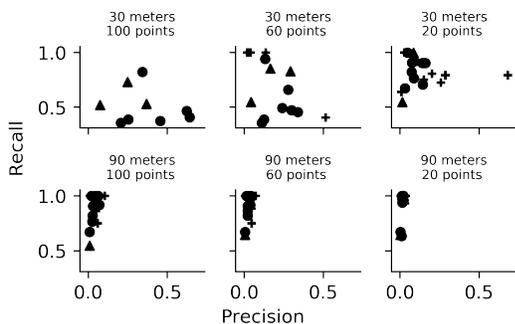

Figure 13: Precision and recall vs. clustering parameters for GeoInd ( $r = 50m$ ) in Tokyo.

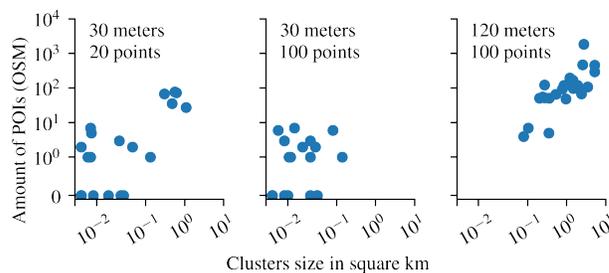

Figure 14: Clusters' size and amount of POIs per cluster vs. clustering parameters with GeoInd ( $r = 50m$ ) in Tokyo.

## A.5 Experimental results

**Adjusting the clustering parameters.** We now study the influence of the DBSCAN clustering parameters on our results. We show the difference in precision and recall for GeoInd ( $r=50$  meters) when we vary both the maximum distance and the minimum number of point per cluster in Figure 13. As we increase the maximum distance between points and decrease the minimum required points per cluster, the results concen-

trate on the upper left corner of the diagram. This is because as the parameters become 'looser', the resulting clusters grow in size increasing recall (more likelihood of covering all users' original clusters) but reducing precision due to many false positives. Furthermore, increasing the cluster size increases the adversary's cost, as the clusters contain a larger number of POIs (Figure 14) which requires more filtering and increases the probability of having false positives.

# Utility-Optimized Local Differential Privacy Mechanisms for Distribution Estimation \*

Takao Murakami  
*AIST*

Yusuke Kawamoto  
*AIST*

## Abstract

LDP (Local Differential Privacy) has been widely studied to estimate statistics of personal data (e.g., distribution underlying the data) while protecting users' privacy. Although LDP does not require a trusted third party, it regards all personal data equally sensitive, which causes excessive obfuscation hence the loss of utility. In this paper, we introduce the notion of *ULDP (Utility-optimized LDP)*, which provides a privacy guarantee equivalent to LDP only for sensitive data. We first consider the setting where all users use the same obfuscation mechanism, and propose two mechanisms providing ULDP: *utility-optimized randomized response* and *utility-optimized RAPPOR*. We then consider the setting where the distinction between sensitive and non-sensitive data can be different from user to user. For this setting, we propose a *personalized ULDP mechanism with semantic tags* to estimate the distribution of personal data with high utility while keeping secret what is sensitive for each user. We show theoretically and experimentally that our mechanisms provide much higher utility than the existing LDP mechanisms when there are a lot of non-sensitive data. We also show that when most of the data are non-sensitive, our mechanisms even provide almost the same utility as non-private mechanisms in the low privacy regime.

## 1 Introduction

DP (Differential Privacy) [21, 22] is becoming a gold standard for data privacy; it enables big data analysis while protecting users' privacy against adversaries with arbitrary background knowledge. According to the underlying architecture, DP can be categorized into the one in the *centralized model* and the one in the *local model* [22]. In the centralized model, a "trusted" database administrator, who can access to all users' personal data, obfuscates the data (e.g., by adding noise, generalization) before providing them to a (possibly malicious) data analyst. Although DP was extensively studied for the

centralized model at the beginning, the original personal data in this model can be leaked from the database by illegal access or internal fraud. This issue is critical in recent years, because the number of data breach incidents is increasing [15].

The local model does not require a "trusted" administrator, and therefore does not suffer from the data leakage issue explained above. In this model, each user obfuscates her personal data by herself, and sends the obfuscated data to a data collector (or data analyst). Based on the obfuscated data, the data collector can estimate some statistics (e.g., histogram, heavy hitters [45]) of the personal data. DP in the local model, which is called *LDP (Local Differential Privacy)* [19], has recently attracted much attention in the academic field [5, 12, 24, 29, 30, 39, 43, 45, 46, 50, 56], and has also been adopted by industry [16, 23, 49].

However, LDP mechanisms regard all personal data as equally sensitive, and leave a lot of room for increasing data utility. For example, consider questionnaires such as: "Have you ever cheated in an exam?" and "Were you with a prostitute in the last month?" [11]. Obviously, "Yes" is a sensitive response to these questionnaires, whereas "No" is not sensitive. A RR (Randomized Response) method proposed by Mangat [37] utilizes this fact. Specifically, it reports "Yes" or "No" as follows: if the true answer is "Yes", always report "Yes"; otherwise, report "Yes" and "No" with probability  $p$  and  $1 - p$ , respectively. Since the reported answer "Yes" may come from both the true answers "Yes" and "No", the confidentiality of the user reporting "Yes" is not violated. Moreover, since the reported answer "No" is always come from the true answer "No", the data collector can estimate a distribution of true answers with higher accuracy than Warner's RR [52], which simply flips "Yes" and "No" with probability  $p$ . However, Mangat's RR does not provide LDP, since LDP regards both "Yes" and "No" as equally sensitive.

There are a lot of "non-sensitive" data for other types of data. For example, locations such as hospitals and home can be sensitive, whereas visited sightseeing places, restaurants, and coffee shops are non-sensitive for many users. Divorced people may want to keep their divorce secret, while the oth-

\*This study was supported by JSPS KAKENHI JP19H04113, JP17K12667, and by Inria under the project LOGIS.

ers may not care about their marital status. The distinction between sensitive and non-sensitive data can also be different from user to user (e.g., home address is different from user to user; some people might want to keep secret even the sight-seeing places). To explain more about this issue, we briefly review related work on LDP and variants of DP.

**Related work.** Since Dwork [21] introduced DP, a number of its variants have been studied to provide different types of privacy guarantees; e.g., LDP [19],  $d$ -privacy [8], Pufferfish privacy [32], dependent DP [36], Bayesian DP [53], mutual-information DP [14], Rényi DP [38], and distribution privacy [31]. In particular, LDP [19] has been widely studied in the literature. For example, Erlingsson *et al.* [23] proposed the RAPPOR as an obfuscation mechanism providing LDP, and implemented it in Google Chrome browser. Kairouz *et al.* [29] showed that under the  $l_1$  and  $l_2$  losses, the randomized response (generalized to multiple alphabets) and RAPPOR are order optimal among all LDP mechanisms in the low and high privacy regimes, respectively. Wang *et al.* [51] generalized the RAPPOR and a random projection-based method [6], and found parameters that minimize the variance of the estimate.

Some studies also attempted to address the non-uniformity of privacy requirements among records (rows) or among items (columns) in the centralized DP: Personalized DP [28], Heterogeneous DP [3], and One-sided DP [17]. However, obfuscation mechanisms that address the non-uniformity among input values in the “local” DP have not been studied, to our knowledge. In this paper, we show that data utility can be significantly increased by designing such local mechanisms.

**Our contributions.** The goal of this paper is to design obfuscation mechanisms in the local model that achieve high data utility while providing DP for sensitive data. To achieve this, we introduce the notion of *ULDP (Utility-optimized LDP)*, which provides a privacy guarantee equivalent to LDP only for sensitive data, and obfuscation mechanisms providing ULDP. As a task for the data collector, we consider *discrete distribution estimation* [2, 23, 24, 27, 29, 39, 46, 56], where personal data take discrete values. Our contributions are as follows:

- We first consider the setting in which all users use the same obfuscation mechanism, and propose two ULDP mechanisms: *utility-optimized RR* and *utility-optimized RAPPOR*. We prove that when there are a lot of non-sensitive data, our mechanisms provide much higher utility than two state-of-the-art LDP mechanisms: the RR (for multiple alphabets) [29, 30] and RAPPOR [23]. We also prove that when most of the data are non-sensitive, our mechanisms even provide almost the same utility as a non-private mechanism that does not obfuscate the personal data in the low privacy regime where the privacy budget is  $\epsilon = \ln |\mathcal{X}|$  for a set  $\mathcal{X}$  of personal data.
- We then consider the setting in which the distinction between sensitive and non-sensitive data can be different

from user to user, and propose a *PUM (Personalized ULDP Mechanism) with semantic tags*. The PUM keeps secret what is sensitive for each user, while enabling the data collector to estimate a distribution using some background knowledge about the distribution conditioned on each tag (e.g., geographic distributions of homes). We also theoretically analyze the data utility of the PUM.

- We finally show that our mechanisms are very promising in terms of utility using two large-scale datasets.

The proofs of all statements in the paper are given in the extended version of the paper [40].

**Cautions and limitations.** Although ULDP is meant to protect sensitive data, there are some cautions and limitations.

First, we assume that each user sends a single datum and that each user’s personal data is independent (see Section 2.1). This is reasonable for a variety of personal data (e.g., locations, age, sex, marital status), where each user’s data is irrelevant to most others’ one. However, for some types of personal data (e.g., flu status [48]), each user can be highly influenced by others. There might also be a correlation between sensitive data and non-sensitive data when a user sends multiple data (on a related note, non-sensitive attributes may lead to re-identification of a record [41]). A possible solution to these problems would be to incorporate ULDP with *Pufferfish privacy* [32, 48], which is used to protect correlated data. We leave this as future work (see Section 7 for discussions on the case of multiple data per user and the correlation issue).

We focus on a scenario in which it is easy for users to decide what is sensitive (e.g., cheating experience, location of home). However, there is also a scenario in which users do not know what is sensitive. For the latter scenario, we cannot use ULDP but can simply apply LDP.

Apart from the sensitive/non-sensitive data issue, there are scenarios in which ULDP does not cover. For example, ULDP does not protect users who have a sensitivity about “information disclosure” itself (i.e., those who will not disclose any information). We assume that users have consented to information disclosure. To collect as much data as possible, we can provide an incentive for the information disclosure; e.g., provide a reward or point-of-interest (POI) information nearby a reported location. We also assume that the data collector obtains a consensus from users before providing reported data to third parties. Note that these cautions are common to LDP.

There might also be a risk of discrimination; e.g., the data collector might discriminate against all users that provide a yes-answer, and have no qualms about small false positives. False positives decrease with increase in  $\epsilon$ . We note that LDP also suffer from this attack; the false positive probability is the same for both ULDP and LDP with the same  $\epsilon$ .

In summary, ULDP provides a privacy guarantee equivalent to LDP for sensitive data under the assumption of the data independence. We consider our work as a building-block of broader DP approaches or the basis for further development.

## 2 Preliminaries

### 2.1 Notations

Let  $\mathbb{R}_{\geq 0}$  be the set of non-negative real numbers. Let  $n$  be the number of users,  $[n] = \{1, 2, \dots, n\}$ ,  $\mathcal{X}$  (resp.  $\mathcal{Y}$ ) be a finite set of personal (resp. obfuscated) data. We assume continuous data are discretized into bins in advance (e.g., a location map is divided into some regions). We use the superscript “ $(i)$ ” to represent the  $i$ -th user. Let  $X^{(i)}$  (resp.  $Y^{(i)}$ ) be a random variable representing personal (resp. obfuscated) data of the  $i$ -th user. The  $i$ -th user obfuscates her personal data  $X^{(i)}$  via her obfuscation mechanism  $\mathbf{Q}^{(i)}$ , which maps  $x \in \mathcal{X}$  to  $y \in \mathcal{Y}$  with probability  $\mathbf{Q}^{(i)}(y|x)$ , and sends the obfuscated data  $Y^{(i)}$  to a data collector. Here we assume that each user sends a single datum. We discuss the case of multiple data in Section 7.

We divide personal data into two types: *sensitive data* and *non-sensitive data*. Let  $\mathcal{X}_S \subseteq \mathcal{X}$  be a set of sensitive data common to all users, and  $\mathcal{X}_N = \mathcal{X} \setminus \mathcal{X}_S$  be the remaining personal data. Examples of such “common” sensitive data  $x \in \mathcal{X}_S$  are the regions including public sensitive locations (e.g., hospitals) and obviously sensitive responses to questionnaires described in Section 1<sup>1</sup>.

Furthermore, let  $\mathcal{X}_S^{(i)} \subseteq \mathcal{X}_N$  ( $i \in [n]$ ) be a set of sensitive data specific to the  $i$ -th user (here we do not include  $\mathcal{X}_S$  into  $\mathcal{X}_S^{(i)}$  because  $\mathcal{X}_S$  is protected for all users in our mechanisms).  $\mathcal{X}_S^{(i)}$  is a set of personal data that is possibly non-sensitive for many users but sensitive for the  $i$ -th user. Examples of such “user-specific” sensitive data  $x \in \mathcal{X}_S^{(i)}$  are the regions including private locations such as their home and workplace. (Note that the majority of working population can be uniquely identified from their home/workplace location pairs [25].)

In Sections 3 and 4, we consider the case where all users divide  $\mathcal{X}$  into the same sets of sensitive data and of non-sensitive data, i.e.,  $\mathcal{X}_S^{(1)} = \dots = \mathcal{X}_S^{(n)} = \mathcal{X}_S$ , and use the same obfuscation mechanism  $\mathbf{Q}$  (i.e.,  $\mathbf{Q} = \mathbf{Q}^{(1)} = \dots = \mathbf{Q}^{(n)}$ ). In Section 5, we consider a general setting that can deal with the user-specific sensitive data  $\mathcal{X}_S^{(i)}$  and user-specific mechanisms  $\mathbf{Q}^{(i)}$ . We call the former case a *common-mechanism scenario* and the latter a *personalized-mechanism scenario*.

We assume that each user’s personal data  $X^{(i)}$  is independently and identically distributed (i.i.d.) with a probability distribution  $\mathbf{p}$ , which generates  $x \in \mathcal{X}$  with probability  $\mathbf{p}(x)$ . Let  $\mathbf{X} = (X^{(1)}, \dots, X^{(n)})$  and  $\mathbf{Y} = (Y^{(1)}, \dots, Y^{(n)})$  be tuples of all personal data and all obfuscated data, respectively. The data collector estimates  $\mathbf{p}$  from  $\mathbf{Y}$  by a method described in Section 2.5. We denote by  $\hat{\mathbf{p}}$  the estimate of  $\mathbf{p}$ . We further denote by  $\mathcal{C}$  the probability simplex; i.e.,  $\mathcal{C} = \{\mathbf{p} | \sum_{x \in \mathcal{X}} \mathbf{p}(x) = 1, \mathbf{p}(x) \geq 0 \text{ for any } x \in \mathcal{X}\}$ .

<sup>1</sup>Note that these data might be sensitive for many/most users but not for all in practice (e.g., some people might not care about their cheating experience). However, we can regard these data as sensitive for all users (i.e., be on the safe side) by allowing a small loss of data utility.

### 2.2 Privacy Measures

LDP (Local Differential Privacy) [19] is defined as follows:

**Definition 1 ( $\epsilon$ -LDP).** Let  $\epsilon \in \mathbb{R}_{\geq 0}$ . An obfuscation mechanism  $\mathbf{Q}$  from  $\mathcal{X}$  to  $\mathcal{Y}$  provides  $\epsilon$ -LDP if for any  $x, x' \in \mathcal{X}$  and any  $y \in \mathcal{Y}$ ,

$$\mathbf{Q}(y|x) \leq e^\epsilon \mathbf{Q}(y|x'). \quad (1)$$

LDP guarantees that an adversary who has observed  $y$  cannot determine, for any pair of  $x$  and  $x'$ , whether it is come from  $x$  or  $x'$  with a certain degree of confidence. As the privacy budget  $\epsilon$  approaches to 0, all of the data in  $\mathcal{X}$  become almost equally likely. Thus, a user’s privacy is strongly protected when  $\epsilon$  is small.

### 2.3 Utility Measures

In this paper, we use the  $l_1$  loss (i.e., absolute error) and the  $l_2$  loss (i.e., squared error) as utility measures. Let  $l_1$  (resp.  $l_2^2$ ) be the  $l_1$  (resp.  $l_2$ ) loss function, which maps the estimate  $\hat{\mathbf{p}}$  and the true distribution  $\mathbf{p}$  to the loss; i.e.,  $l_1(\hat{\mathbf{p}}, \mathbf{p}) = \sum_{x \in \mathcal{X}} |\hat{\mathbf{p}}(x) - \mathbf{p}(x)|$ ,  $l_2^2(\hat{\mathbf{p}}, \mathbf{p}) = \sum_{x \in \mathcal{X}} (\hat{\mathbf{p}}(x) - \mathbf{p}(x))^2$ . It should be noted that  $\mathbf{X}$  is generated from  $\mathbf{p}$  and  $\mathbf{Y}$  is generated from  $\mathbf{X}$  using  $\mathbf{Q}^{(1)}, \dots, \mathbf{Q}^{(n)}$ . Since  $\hat{\mathbf{p}}$  is computed from  $\mathbf{Y}$ , both the  $l_1$  and  $l_2$  losses depend on  $\mathbf{Y}$ .

In our theoretical analysis in Sections 4 and 5, we take the expectation of the  $l_1$  loss over all possible realizations of  $\mathbf{Y}$ . In our experiments in Section 6, we replace the expectation of the  $l_1$  loss with the sample mean over multiple realizations of  $\mathbf{Y}$  and divide it by 2 to evaluate the TV (Total Variation). In Appendix C, we also show that the  $l_2$  loss has similar results to the ones in Sections 4 and 6 by evaluating the expectation of the  $l_2$  loss and the MSE (Mean Squared Error), respectively.

### 2.4 Obfuscation Mechanisms

We describe the RR (Randomized Response) [29, 30] and a generalized version of the RAPPOR [51] as follows.

**Randomized response.** The RR for  $|\mathcal{X}|$ -ary alphabets was studied in [29, 30]. Its output range is identical to the input domain; i.e.,  $\mathcal{X} = \mathcal{Y}$ .

Formally, given  $\epsilon \in \mathbb{R}_{\geq 0}$ , the  $\epsilon$ -RR is an obfuscation mechanism that maps  $x$  to  $y$  with the probability:

$$\mathbf{Q}_{RR}(y|x) = \begin{cases} \frac{e^\epsilon}{|\mathcal{X}| + e^\epsilon - 1} & (\text{if } y = x) \\ \frac{1}{|\mathcal{X}| + e^\epsilon - 1} & (\text{otherwise}). \end{cases} \quad (2)$$

It is easy to check by (1) and (2) that  $\mathbf{Q}_{RR}$  provides  $\epsilon$ -LDP.

**Generalized RAPPOR.** The RAPPOR (Randomized Aggregatable Privacy-Preserving Ordinal Response) [23] is an obfuscation mechanism implemented in Google Chrome browser. Wang *et al.* [51] extended its simplest configuration called the basic one-time RAPPOR by generalizing two

probabilities in perturbation. Here we call it the *generalized RAPPOR* and describe its algorithm in detail.

The generalized RAPPOR is an obfuscation mechanism with the input alphabet  $\mathcal{X} = \{x_1, x_2, \dots, x_{|\mathcal{X}|}\}$  and the output alphabet  $\mathcal{Y} = \{0, 1\}^{|\mathcal{X}|}$ . It first deterministically maps  $x_i \in \mathcal{X}$  to  $e_i \in \{0, 1\}^{|\mathcal{X}|}$ , where  $e_i$  is the  $i$ -th standard basis vector. It then probabilistically flips each bit of  $e_i$  to obtain obfuscated data  $y = (y_1, y_2, \dots, y_{|\mathcal{X}|}) \in \{0, 1\}^{|\mathcal{X}|}$ , where  $y_i \in \{0, 1\}$  is the  $i$ -th element of  $y$ . Wang *et al.* [51] compute  $\epsilon$  from two parameters  $\theta \in [0, 1]$  (representing the probability of keeping 1 unchanged) and  $\psi \in [0, 1]$  (representing the probability of flipping 0 into 1). In this paper, we compute  $\psi$  from two parameters  $\theta$  and  $\epsilon$ .

Specifically, given  $\theta \in [0, 1]$  and  $\epsilon \in \mathbb{R}_{\geq 0}$ , the  $(\theta, \epsilon)$ -generalized RAPPOR maps  $x_i$  to  $y$  with the probability:

$$\mathbf{Q}_{RAP}(y|x_i) = \prod_{1 \leq j \leq |\mathcal{X}|} \Pr(y_j|x_i),$$

where  $\Pr(y_j|x_i) = \theta$  if  $i = j$  and  $y_j = 1$ , and  $\Pr(y_j|x_i) = 1 - \theta$  if  $i = j$  and  $y_j = 0$ , and  $\Pr(y_j|x_i) = \psi = \frac{\theta}{(1-\theta)e^\epsilon + \theta}$  if  $i \neq j$  and  $y_j = 1$ , and  $\Pr(y_j|x_i) = 1 - \psi$  otherwise. The basic one-time RAPPOR [23] is a special case of the generalized RAPPOR where  $\theta = \frac{e^{\epsilon/2}}{e^{\epsilon/2} + 1}$ .  $\mathbf{Q}_{RAP}$  also provides  $\epsilon$ -LDP.

## 2.5 Distribution Estimation Methods

Here we explain the empirical estimation method [2, 27, 29] and the EM reconstruction method [1, 2]. Both of them assume that the data collector knows the obfuscation mechanism  $\mathbf{Q}$  used to generate  $\mathbf{Y}$  from  $\mathbf{X}$ .

**Empirical estimation method.** The empirical estimation method [2, 27, 29] computes an empirical estimate  $\hat{\mathbf{p}}$  of  $\mathbf{p}$  using an empirical distribution  $\hat{\mathbf{m}}$  of the obfuscated data  $\mathbf{Y}$ . Note that  $\hat{\mathbf{p}}$ ,  $\hat{\mathbf{m}}$ , and  $\mathbf{Q}$  can be represented as an  $|\mathcal{X}|$ -dimensional vector,  $|\mathcal{Y}|$ -dimensional vector, and  $|\mathcal{X}| \times |\mathcal{Y}|$  matrix, respectively. They have the following equation:

$$\hat{\mathbf{p}}\mathbf{Q} = \hat{\mathbf{m}}. \quad (3)$$

The empirical estimation method computes  $\hat{\mathbf{p}}$  by solving (3).

Let  $\mathbf{m}$  be the true distribution of obfuscated data; i.e.,  $\mathbf{m} = \mathbf{p}\mathbf{Q}$ . As the number of users  $n$  increases, the empirical distribution  $\hat{\mathbf{m}}$  converges to  $\mathbf{m}$ . Therefore, the empirical estimate  $\hat{\mathbf{p}}$  also converges to  $\mathbf{p}$ . However, when the number of users  $n$  is small, many elements in  $\hat{\mathbf{p}}$  can be negative. To address this issue, the studies in [23, 51] kept only estimates above a significance threshold determined via Bonferroni correction, and discarded the remaining estimates.

**EM reconstruction method.** The EM (Expectation-Maximization) reconstruction method [1, 2] (also called the iterative Bayesian technique [2]) regards  $\mathbf{X}$  as a hidden variable and estimates  $\mathbf{p}$  from  $\mathbf{Y}$  using the EM algorithm [26] (for details of the algorithm, see [1, 2]). Let  $\hat{\mathbf{p}}_{EM}$  be an estimate of  $\mathbf{p}$  by the EM reconstruction method. The feature of this

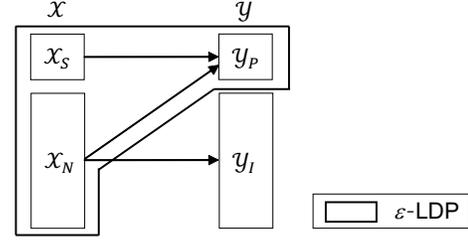

Figure 1: Overview of ULDP. It has no transitions from  $\mathcal{X}_S$  to  $\mathcal{Y}_I$ , and every output in  $\mathcal{Y}_I$  reveals the corresponding input in  $\mathcal{X}_N$ . It also provides  $\epsilon$ -LDP for  $\mathcal{Y}_P$ .

algorithm is that  $\hat{\mathbf{p}}_{EM}$  is equal to the maximum likelihood estimate in the probability simplex  $C$  (see [1] for the proof). Since this property holds irrespective of the number of users  $n$ , the elements in  $\hat{\mathbf{p}}_{EM}$  are always non-negative.

In this paper, our theoretical analysis uses the empirical estimation method for simplicity, while our experiments use the empirical estimation method, the one with the significance threshold, and the EM reconstruction method.

## 3 Utility-Optimized LDP (ULDP)

In this section, we focus on the common-mechanism scenario (outlined in Section 2.1) and introduce ULDP (Utility-optimized Local Differential Privacy), which provides a privacy guarantee equivalent to  $\epsilon$ -LDP only for sensitive data. Section 3.1 provides the definition of ULDP. Section 3.2 shows some theoretical properties of ULDP.

### 3.1 Definition

Figure 1 shows an overview of ULDP. An obfuscation mechanism providing ULDP, which we call the utility-optimized mechanism, divides obfuscated data into *protected data* and *invertible data*. Let  $\mathcal{Y}_P$  be a set of protected data, and  $\mathcal{Y}_I = \mathcal{Y} \setminus \mathcal{Y}_P$  be a set of invertible data.

The feature of the utility-optimized mechanism is that it maps sensitive data  $x \in \mathcal{X}_S$  to only protected data  $y \in \mathcal{Y}_P$ . In other words, it restricts the output set, given the input  $x \in \mathcal{X}_S$ , to  $\mathcal{Y}_P$ . Then it provides  $\epsilon$ -LDP for  $\mathcal{Y}_P$ ; i.e.,  $\mathbf{Q}(y|x) \leq e^\epsilon \mathbf{Q}(y|x')$  for any  $x, x' \in \mathcal{X}$  and any  $y \in \mathcal{Y}_P$ . By this property, a privacy guarantee equivalent to  $\epsilon$ -LDP is provided for any sensitive data  $x \in \mathcal{X}_S$ , since the output set corresponding to  $\mathcal{X}_S$  is restricted to  $\mathcal{Y}_P$ . In addition, every output in  $\mathcal{Y}_I$  reveals the corresponding input in  $\mathcal{X}_N$  (as in Mangat's randomized response [37]) to optimize the estimation accuracy.

We now formally define ULDP and the utility-optimized mechanism:

**Definition 2** ( $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP). Given  $\mathcal{X}_S \subseteq \mathcal{X}$ ,  $\mathcal{Y}_P \subseteq \mathcal{Y}$ , and  $\epsilon \in \mathbb{R}_{\geq 0}$ , an obfuscation mechanism  $\mathbf{Q}$  from  $\mathcal{X}$  to  $\mathcal{Y}$  provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP if it satisfies the following properties:

1. For any  $y \in \mathcal{Y}_I$ , there exists an  $x \in \mathcal{X}_N$  such that

$$\mathbf{Q}(y|x) > 0 \text{ and } \mathbf{Q}(y|x') = 0 \text{ for any } x' \neq x. \quad (4)$$

2. For any  $x, x' \in \mathcal{X}$  and any  $y \in \mathcal{Y}_P$ ,

$$\mathbf{Q}(y|x) \leq e^\epsilon \mathbf{Q}(y|x'). \quad (5)$$

We refer to an obfuscation mechanism  $\mathbf{Q}$  providing  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP as the  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -utility-optimized mechanism.

**Example.** For an intuitive understanding of Definition 2, we show that Mangat’s randomized response [37] provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP. As described in Section 1, this mechanism considers binary alphabets (i.e.,  $\mathcal{X} = \mathcal{Y} = \{0, 1\}$ ), and regards the value 1 as sensitive (i.e.,  $\mathcal{X}_S = \mathcal{Y}_P = \{1\}$ ). If the input value is 1, it always reports 1 as output. Otherwise, it reports 1 and 0 with probability  $p$  and  $1 - p$ , respectively. Obviously, this mechanism does not provide  $\epsilon$ -LDP for any  $\epsilon \in [0, \infty)$ . However, it provides  $(\mathcal{X}_S, \mathcal{Y}_P, \ln \frac{1}{p})$ -ULDP.

$(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP provides a privacy guarantee equivalent to  $\epsilon$ -LDP for any sensitive data  $x \in \mathcal{X}_S$ , as explained above. On the other hand, no privacy guarantees are provided for non-sensitive data  $x \in \mathcal{X}_N$  because every output in  $\mathcal{Y}_I$  reveals the corresponding input in  $\mathcal{X}_N$ . However, it does not matter since non-sensitive data need not be protected. Protecting only minimum necessary data is the key to achieving locally private distribution estimation with high data utility.

We can apply any  $\epsilon$ -LDP mechanism to the sensitive data in  $\mathcal{X}_S$  to provide  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP as a whole. In Sections 4.1 and 4.2, we propose a utility-optimized RR (Randomized Response) and utility-optimized RAPPOR, which apply the  $\epsilon$ -RR and  $\epsilon$ -RAPPOR, respectively, to the sensitive data  $\mathcal{X}_S$ .

In Appendix B, we also consider OSLDP (One-sided LDP), a local model version of OSDP introduced in a preprint [17], and explain the reason for using ULDP in this paper.

It might be better to generalize ULDP so that different levels of  $\epsilon$  can be assigned to different sensitive data. We leave introducing such granularity as future work.

**Remark.** It should also be noted that the data collector needs to know  $\mathbf{Q}$  to estimate  $\mathbf{p}$  from  $\mathbf{Y}$  (as described in Section 2.5), and that the  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -utility-optimized mechanism  $\mathbf{Q}$  itself includes the information on *what is sensitive for users* (i.e., the data collector learns whether each  $x \in \mathcal{X}$  belongs to  $\mathcal{X}_S$  or not by checking the values of  $\mathbf{Q}(y|x)$  for all  $y \in \mathcal{Y}$ ). This does not matter in the common-mechanism scenario, since the set  $\mathcal{X}_S$  of sensitive data is common to all users (e.g., public hospitals). However, in the personalized-mechanism scenario, the  $(\mathcal{X}_S \cup \mathcal{X}_S^{(i)}, \mathcal{Y}_P, \epsilon)$ -utility-optimized mechanism  $\mathbf{Q}^{(i)}$ , which expands the set  $\mathcal{X}_S$  of personal data to  $\mathcal{X}_S \cup \mathcal{X}_S^{(i)}$ , includes the information on *what is sensitive for the  $i$ -th user*. Therefore, the data collector learns whether each  $x \in \mathcal{X}_N$  belongs to  $\mathcal{X}_S^{(i)}$  or not by checking the values of  $\mathbf{Q}^{(i)}(y|x)$  for all  $y \in \mathcal{Y}$ , despite the fact that the  $i$ -th user wants to hide her user-specific

sensitive data  $\mathcal{X}_S^{(i)}$  (e.g., home, workplace). We address this issue in Section 5.

## 3.2 Basic Properties of ULDP

Previous work showed some basic properties of differential privacy (or its variant), such as compositionality [22] and immunity to post-processing [22]. We briefly explain theoretical properties of ULDP including the ones above.

**Sequential composition.** ULDP is preserved under adaptive sequential composition when the composed obfuscation mechanism maps sensitive data to pairs of protected data. Specifically, consider two mechanisms  $\mathbf{Q}_0$  from  $\mathcal{X}$  to  $\mathcal{Y}_0$  and  $\mathbf{Q}_1$  from  $\mathcal{X}$  to  $\mathcal{Y}_1$  such that  $\mathbf{Q}_0$  (resp.  $\mathbf{Q}_1$ ) maps sensitive data  $x \in \mathcal{X}_S$  to protected data  $y_0 \in \mathcal{Y}_{0P}$  (resp.  $y_1 \in \mathcal{Y}_{1P}$ ). Then the sequential composition of  $\mathbf{Q}_0$  and  $\mathbf{Q}_1$  maps sensitive data  $x \in \mathcal{X}_S$  to pairs  $(y_0, y_1)$  of protected data ranging over:

$$(\mathcal{Y}_0 \times \mathcal{Y}_1)_P = \{(y_0, y_1) \in \mathcal{Y}_0 \times \mathcal{Y}_1 \mid y_0 \in \mathcal{Y}_{0P} \text{ and } y_1 \in \mathcal{Y}_{1P}\}.$$

Then we obtain the following compositionality.

**Proposition 1 (Sequential composition).** *Let  $\epsilon_0, \epsilon_1 \geq 0$ . If  $\mathbf{Q}_0$  provides  $(\mathcal{X}_S, \mathcal{Y}_{0P}, \epsilon_0)$ -ULDP and  $\mathbf{Q}_1(y_0)$  provides  $(\mathcal{X}_S, \mathcal{Y}_{1P}, \epsilon_1)$ -ULDP for each  $y_0 \in \mathcal{Y}_0$ , then the sequential composition of  $\mathbf{Q}_0$  and  $\mathbf{Q}_1$  provides  $(\mathcal{X}_S, (\mathcal{Y}_0 \times \mathcal{Y}_1)_P, \epsilon_0 + \epsilon_1)$ -ULDP.*

For example, if we apply an obfuscation mechanism providing  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP for  $t$  times, then we obtain  $(\mathcal{X}_S, (\mathcal{Y}_P)^t, \epsilon t)$ -ULDP in total (this is derived by repeatedly using Proposition 1).

**Post-processing.** ULDP is immune to the post-processing by a randomized algorithm that *preserves data types*: protected data or invertible data. Specifically, if a mechanism  $\mathbf{Q}_0$  provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP and a randomized algorithm  $\mathbf{Q}_1$  maps protected data over  $\mathcal{Y}_P$  (resp. invertible data) to protected data over  $\mathcal{Z}_P$  (resp. invertible data), then the composite function  $\mathbf{Q}_1 \circ \mathbf{Q}_0$  provides  $(\mathcal{X}_S, \mathcal{Z}_P, \epsilon)$ -ULDP.

Note that  $\mathbf{Q}_1$  needs to preserve data types for utility; i.e., to make all  $y \in \mathcal{Y}_I$  invertible (as in Definition 2) after post-processing. The DP guarantee for  $y \in \mathcal{Y}_P$  is preserved by any post-processing algorithm. See Appendix A.1 for details.

**Compatibility with LDP.** Assume that data collectors A and B adopt a mechanism providing ULDP and a mechanism providing LDP, respectively. In this case, all protected data in the data collector A can be combined with all obfuscated data in the data collector B (i.e., data integration) to perform data analysis under LDP. See Appendix A.2 for details.

**Lower bounds on the  $l_1$  and  $l_2$  losses.** We present lower bounds on the  $l_1$  and  $l_2$  losses of any ULDP mechanism by using the fact that ULDP provides (5) for any  $x, x' \in \mathcal{X}_S$  and any  $y \in \mathcal{Y}_P$ . Specifically, Duchi *et al.* [20] showed that for  $\epsilon \in [0, 1]$ , the lower bounds on the  $l_1$  and  $l_2$  losses (minimax rates) of any  $\epsilon$ -LDP mechanism can be expressed as  $\Theta(\frac{|x|}{\sqrt{n\epsilon^2}})$

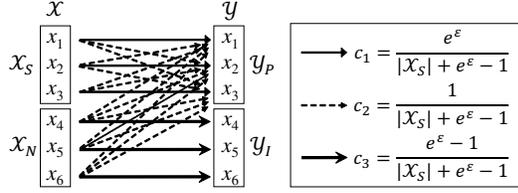

Figure 2: Utility-optimized RR in the case where  $X_S = \mathcal{Y}_P = \{x_1, x_2, x_3\}$  and  $X_N = \mathcal{Y}_I = \{x_4, x_5, x_6\}$ .

and  $\Theta(\frac{|X|}{ne^2})$ , respectively. By directly applying these bounds to  $X_S$  and  $\mathcal{Y}_P$ , the lower bounds on the  $l_1$  and  $l_2$  losses of any  $(X_S, \mathcal{Y}_P, \epsilon)$ -ULDP mechanisms for  $\epsilon \in [0, 1]$  can be expressed as  $\Theta(\frac{|X_S|}{\sqrt{ne^2}})$  and  $\Theta(\frac{|X_S|}{ne^2})$ , respectively. In Section 4.3, we show that our utility-optimized RAPPOR achieves these lower bounds when  $\epsilon$  is close to 0 (i.e., high privacy regime).

## 4 Utility-Optimized Mechanisms

In this section, we focus on the common-mechanism scenario and propose the *utility-optimized RR (Randomized Response)* and *utility-optimized RAPPOR* (Sections 4.1 and 4.2). We then analyze the data utility of these mechanisms (Section 4.3).

### 4.1 Utility-Optimized Randomized Response

We propose the utility-optimized RR, which is a generalization of Mangat's randomized response [37] to  $|X|$ -ary alphabets with  $|X_S|$  sensitive symbols. As with the RR, the output range of the utility-optimized RR is identical to the input domain; i.e.,  $X = \mathcal{Y}$ . In addition, we divide the output set in the same way as the input set; i.e.,  $X_S = \mathcal{Y}_P$ ,  $X_N = \mathcal{Y}_I$ .

Figure 2 shows the utility-optimized RR with  $X_S = \mathcal{Y}_P = \{x_1, x_2, x_3\}$  and  $X_N = \mathcal{Y}_I = \{x_4, x_5, x_6\}$ . The utility-optimized RR applies the  $\epsilon$ -RR to  $X_S$ . It maps  $x \in X_N$  to  $y \in \mathcal{Y}_P (= X_S)$  with the probability  $\mathbf{Q}(y|x)$  so that (5) is satisfied, and maps  $x \in X_N$  to itself with the remaining probability. Formally, we define the utility-optimized RR (uRR) as follows:

**Definition 3** ( $(X_S, \epsilon)$ -utility-optimized RR). *Let  $X_S \subseteq X$  and  $\epsilon \in \mathbb{R}_{\geq 0}$ . Let  $c_1 = \frac{e^\epsilon}{|X_S| + e^\epsilon - 1}$ ,  $c_2 = \frac{1}{|X_S| + e^\epsilon - 1}$ , and  $c_3 = 1 - |X_S|c_2 = \frac{e^\epsilon - 1}{|X_S| + e^\epsilon - 1}$ . Then the  $(X_S, \epsilon)$ -utility-optimized RR (uRR) is an obfuscation mechanism that maps  $x \in X$  to  $y \in \mathcal{Y} (= X)$  with the probability  $\mathbf{Q}_{uRR}(y|x)$  defined as follows:*

$$\mathbf{Q}_{uRR}(y|x) = \begin{cases} c_1 & (\text{if } x \in X_S, y = x) \\ c_2 & (\text{if } x \in X_S, y \in X_S \setminus \{x\}) \\ c_2 & (\text{if } x \in X_N, y \in X_S) \\ c_3 & (\text{if } x \in X_N, y = x) \\ 0 & (\text{otherwise}). \end{cases} \quad (6)$$

**Proposition 2.** *The  $(X_S, \epsilon)$ -uRR provides  $(X_S, X_S, \epsilon)$ -ULDP.*

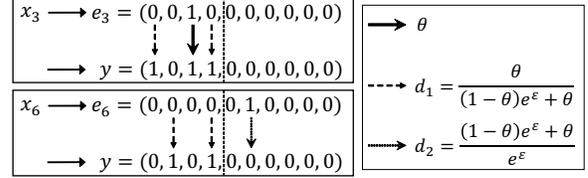

Figure 3: Utility-optimized RAPPOR in the case where  $X_S = \{x_1, \dots, x_4\}$  and  $X_N = \{x_5, \dots, x_{10}\}$ .

### 4.2 Utility-Optimized RAPPOR

Next, we propose the utility-optimized RAPPOR with the input alphabet  $X = \{x_1, x_2, \dots, x_{|X|}\}$  and the output alphabet  $\mathcal{Y} = \{0, 1\}^{|X|}$ . Without loss of generality, we assume that  $x_1, \dots, x_{|X_S|}$  are sensitive and  $x_{|X_S|+1}, \dots, x_{|X|}$  are non-sensitive; i.e.,  $X_S = \{x_1, \dots, x_{|X_S|}\}$ ,  $X_N = \{x_{|X_S|+1}, \dots, x_{|X|}\}$ .

Figure 3 shows the utility-optimized RAPPOR with  $X_S = \{x_1, \dots, x_4\}$  and  $X_N = \{x_5, \dots, x_{10}\}$ . The utility-optimized RAPPOR first deterministically maps  $x_i \in X$  to the  $i$ -th standard basis vector  $e_i$ . It should be noted that if  $x_i$  is sensitive data (i.e.,  $x_i \in X_S$ ), then the last  $|X_N|$  elements in  $e_i$  are always zero (as shown in the upper-left panel of Figure 3). Based on this fact, the utility-optimized RAPPOR regards obfuscated data  $y = (y_1, y_2, \dots, y_{|X|}) \in \{0, 1\}^{|X|}$  such that  $y_{|X_S|+1} = \dots = y_{|X|} = 0$  as protected data; i.e.,

$$\mathcal{Y}_P = \{(y_1, \dots, y_{|X_S|}, 0, \dots, 0) | y_1, \dots, y_{|X_S|} \in \{0, 1\}\}. \quad (7)$$

Then it applies the  $(\theta, \epsilon)$ -generalized RAPPOR to  $X_S$ , and maps  $x \in X_N$  to  $y \in \mathcal{Y}_P$  (as shown in the lower-left panel of Figure 3) with the probability  $\mathbf{Q}(y|x)$  so that (5) is satisfied. We formally define the utility-optimized RAPPOR (uRAP):

**Definition 4** ( $(X_S, \theta, \epsilon)$ -utility-optimized RAPPOR). *Let  $X_S \subseteq X$ ,  $\theta \in [0, 1]$ , and  $\epsilon \in \mathbb{R}_{\geq 0}$ . Let  $d_1 = \frac{\theta}{(1-\theta)e^\epsilon + \theta}$ ,  $d_2 = \frac{(1-\theta)e^\epsilon + \theta}{e^\epsilon}$ . Then the  $(X_S, \theta, \epsilon)$ -utility-optimized RAPPOR (uRAP) is an obfuscation mechanism that maps  $x_i \in X$  to  $y \in \mathcal{Y} = \{0, 1\}^{|X|}$  with the probability  $\mathbf{Q}_{uRAP}(y|x)$  given by:*

$$\mathbf{Q}_{uRAP}(y|x_i) = \prod_{1 \leq j \leq |X|} \Pr(y_j|x_i), \quad (8)$$

where  $\Pr(y_j|x_i)$  is written as follows:

(i) if  $1 \leq j \leq |X_S|$ :

$$\Pr(y_j|x_i) = \begin{cases} 1 - \theta & (\text{if } i = j, y_j = 0) \\ \theta & (\text{if } i = j, y_j = 1) \\ 1 - d_1 & (\text{if } i \neq j, y_j = 0) \\ d_1 & (\text{if } i \neq j, y_j = 1). \end{cases} \quad (9)$$

(ii) if  $|X_S| + 1 \leq j \leq |X|$ :

$$\Pr(y_j|x_i) = \begin{cases} d_2 & (\text{if } i = j, y_j = 0) \\ 1 - d_2 & (\text{if } i = j, y_j = 1) \\ 1 & (\text{if } i \neq j, y_j = 0) \\ 0 & (\text{if } i \neq j, y_j = 1). \end{cases} \quad (10)$$

**Proposition 3.** *The  $(\mathcal{X}_S, \theta, \varepsilon)$ -uRAP provides  $(\mathcal{X}_S, \mathcal{Y}_P, \varepsilon)$ -ULDP, where  $\mathcal{Y}_P$  is given by (7).*

Although we used the generalized RAPPOR in  $\mathcal{X}_S$  and  $\mathcal{Y}_P$  in Definition 4, hereinafter we set  $\theta = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1}$  in the same way as the original RAPPOR [23]. There are two reasons for this. First, it achieves “order” optimal data utility among all  $(\mathcal{X}_S, \mathcal{Y}_P, \varepsilon)$ -ULDP mechanisms in the high privacy regime, as shown in Section 4.3. Second, it maps  $x_i \in \mathcal{X}_N$  to  $y \in \mathcal{Y}_I$  with probability  $1 - d_2 = 1 - e^{-\varepsilon/2}$ , which is close to 1 when  $\varepsilon$  is large (i.e., low privacy regime). Wang *et al.* [51] showed that the generalized RAPPOR with parameter  $\theta = \frac{1}{2}$  minimizes the variance of the estimate. However, our uRAP with parameter  $\theta = \frac{1}{2}$  maps  $x_i \in \mathcal{X}_N$  to  $y \in \mathcal{Y}_I$  with probability  $1 - d_2 = \frac{e^\varepsilon - 1}{2e^\varepsilon}$  which is less than  $1 - e^{-\varepsilon/2}$  for any  $\varepsilon > 0$  and is less than  $\frac{1}{2}$  even when  $\varepsilon$  goes to infinity. Thus, our uRAP with  $\theta = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1}$  maps  $x_i \in \mathcal{X}_N$  to  $y \in \mathcal{Y}_I$  with higher probability, and therefore achieves a smaller estimation error over all non-sensitive data. We also consider that an optimal  $\theta$  for our uRAP is different from the optimal  $\theta (= \frac{1}{2})$  for the generalized RAPPOR. We leave finding the optimal  $\theta$  for our uRAP (with respect to the estimation error over all personal data) as future work.

We refer to the  $(\mathcal{X}_S, \theta, \varepsilon)$ -uRAP with  $\theta = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2}+1}$  in shorthand as the  $(\mathcal{X}_S, \varepsilon)$ -uRAP.

### 4.3 Utility Analysis

We evaluate the  $l_1$  loss of the uRR and uRAP when the empirical estimation method is used for distribution estimation<sup>2</sup>. In particular, we evaluate the  $l_1$  loss when  $\varepsilon$  is close to 0 (i.e., high privacy regime) and  $\varepsilon = \ln|\mathcal{X}|$  (i.e., low privacy regime). Note that ULDP provides a natural interpretation of the latter value of  $\varepsilon$ . Specifically, it follows from (5) that if  $\varepsilon = \ln|\mathcal{X}|$ , then for any  $x \in \mathcal{X}$ , the likelihood that the input data is  $x$  is almost equal to the sum of the likelihood that the input data is  $x' \neq x$ . This is consistent with the fact that the  $\varepsilon$ -RR with parameter  $\varepsilon = \ln|\mathcal{X}|$  sends true data (i.e.,  $y = x$  in (2)) with probability about 0.5 and false data (i.e.,  $y \neq x$ ) with probability about 0.5, and hence provides plausible deniability [29].

**uRR in the general case.** We begin with the uRR:

**Proposition 4** ( $l_1$  loss of the uRR). *Let  $\varepsilon \in \mathbb{R}_{\geq 0}$ ,  $u = |\mathcal{X}_S| + e^\varepsilon - 1$ ,  $u' = e^\varepsilon - 1$ , and  $v = \frac{u}{u}$ . Then the expected  $l_1$  loss of*

<sup>2</sup>We note that we use the empirical estimation method in the same way as [29], and that it might be possible that other mechanisms have better utility with a different estimation method. However, we emphasize that even with the empirical estimation method, the uRAP achieves the lower bounds on the  $l_1$  and  $l_2$  losses of any ULDP mechanisms when  $\varepsilon \approx 0$ , and the uRR and uRAP achieve almost the same utility as a non-private mechanism when  $\varepsilon = \ln|\mathcal{X}|$  and most of the data are non-sensitive.

the  $(\mathcal{X}_S, \varepsilon)$ -uRR mechanism is given by:

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p})] \approx \sqrt{\frac{2}{n\pi}} \left( \sum_{x \in \mathcal{X}_S} \sqrt{(\mathbf{p}(x) + 1/u')(v - \mathbf{p}(x) - 1/u')} + \sum_{x \in \mathcal{X}_N} \sqrt{\mathbf{p}(x)(v - \mathbf{p}(x))} \right), \quad (11)$$

where  $f(n) \approx g(n)$  represents  $\lim_{n \rightarrow \infty} f(n)/g(n) = 1$ .

Let  $\mathbf{p}_{U_N}$  be the uniform distribution over  $\mathcal{X}_N$ ; i.e., for any  $x \in \mathcal{X}_S$ ,  $\mathbf{p}_{U_N}(x) = 0$ , and for any  $x \in \mathcal{X}_N$ ,  $\mathbf{p}_{U_N}(x) = \frac{1}{|\mathcal{X}_N|}$ . Symmetrically, let  $\mathbf{p}_{U_S}$  be the uniform distribution over  $\mathcal{X}_S$ .

For  $0 < \varepsilon < \ln(|\mathcal{X}_N| + 1)$ , the  $l_1$  loss is maximized by  $\mathbf{p}_{U_N}$ :

**Proposition 5.** *For any  $0 < \varepsilon < \ln(|\mathcal{X}_N| + 1)$  and  $|\mathcal{X}_S| \leq |\mathcal{X}_N|$ , (11) is maximized by  $\mathbf{p}_{U_N}$ :*

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p})] \lesssim \mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] = \sqrt{\frac{2}{n\pi}} \left( \frac{|\mathcal{X}_S| \sqrt{|\mathcal{X}_S| + e^\varepsilon - 2}}{e^\varepsilon - 1} + \sqrt{\frac{|\mathcal{X}_S| |\mathcal{X}_N|}{e^\varepsilon - 1} + |\mathcal{X}_N| - 1} \right), \quad (12)$$

where  $f(n) \lesssim g(n)$  represents  $\lim_{n \rightarrow \infty} f(n)/g(n) \leq 1$ .

For  $\varepsilon \geq \ln(|\mathcal{X}_N| + 1)$ , the  $l_1$  loss is maximized by a mixture distribution of  $\mathbf{p}_{U_N}$  and  $\mathbf{p}_{U_S}$ :

**Proposition 6.** *Let  $\mathbf{p}^*$  be a distribution over  $\mathcal{X}$  defined by:*

$$\mathbf{p}^*(x) = \begin{cases} \frac{1 - |\mathcal{X}_N|/(e^\varepsilon - 1)}{|\mathcal{X}_S| + |\mathcal{X}_N|} & (\text{if } x \in \mathcal{X}_S) \\ \frac{1 + |\mathcal{X}_S|/(e^\varepsilon - 1)}{|\mathcal{X}_S| + |\mathcal{X}_N|} & (\text{otherwise}) \end{cases} \quad (13)$$

Then for any  $\varepsilon \geq \ln(|\mathcal{X}_N| + 1)$ , (11) is maximized by  $\mathbf{p}^*$ :

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p})] \lesssim \mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}^*)] = \sqrt{\frac{2(|\mathcal{X}| - 1)}{n\pi}} \cdot \frac{|\mathcal{X}_S| + e^\varepsilon - 1}{e^\varepsilon - 1}, \quad (14)$$

where  $f(n) \lesssim g(n)$  represents  $\lim_{n \rightarrow \infty} f(n)/g(n) \leq 1$ .

Next, we instantiate the  $l_1$  loss in the high and low privacy regimes based on these propositions.

**uRR in the high privacy regime.** When  $\varepsilon$  is close to 0, we have  $e^\varepsilon - 1 \approx \varepsilon$ . Thus, the right-hand side of (12) in Proposition 5 can be simplified as follows:

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \sqrt{\frac{2}{n\pi}} \cdot \frac{|\mathcal{X}_S| \sqrt{|\mathcal{X}_S| - 1}}{\varepsilon}. \quad (15)$$

It was shown in [29] that the expected  $l_1$  loss of the  $\varepsilon$ -RR is at most  $\sqrt{\frac{2}{n\pi}} \frac{|\mathcal{X}| \sqrt{|\mathcal{X}| - 1}}{\varepsilon}$  when  $\varepsilon \approx 0$ . The right-hand side of (15) is much smaller than this when  $|\mathcal{X}_S| \ll |\mathcal{X}|$ . Although both of them are “upper-bounds” of the expected  $l_1$  losses, we show that the total variation of the  $(\mathcal{X}_S, \varepsilon)$ -uRR is also much smaller than that of the  $\varepsilon$ -RR when  $|\mathcal{X}_S| \ll |\mathcal{X}|$  in Section 6.

**uRR in the low privacy regime.** When  $\varepsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|$ , the right-hand side of (14) in Proposition 6 can be simplified by using  $|\mathcal{X}_S|/|\mathcal{X}| \approx 0$ :

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}^*)] \approx \sqrt{\frac{2(|\mathcal{X}| - 1)}{n\pi}}.$$

It should be noted that the expected  $l_1$  loss of the non-private mechanism, which does not obfuscate the personal data at all, is at most  $\sqrt{\frac{2(|\mathcal{X}|-1)}{n\pi}}$  [29]. Thus, when  $\varepsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|$ , the  $(\mathcal{X}_S, \varepsilon)$ -uRR achieves almost the same data utility as the non-private mechanism, whereas the expected  $l_1$  loss of the  $\varepsilon$ -RR is twice larger than that of the non-private mechanism [29].

**uRAP in the general case.** We then analyze the uRAP:

**Proposition 7** ( $l_1$  loss of the uRAP). *Let  $\varepsilon \in \mathbb{R}_{>0}$ ,  $u' = e^{\varepsilon/2} - 1$ , and  $v_N = \frac{e^{\varepsilon/2}}{e^{\varepsilon/2} - 1}$ . The expected  $l_1$ -loss of the  $(\mathcal{X}_S, \varepsilon)$ -uRAP mechanism is:*

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p})] \approx \sqrt{\frac{2}{n\pi}} \left( \sum_{j=1}^{|\mathcal{X}_S|} \sqrt{(\mathbf{p}(x_j) + 1/u')(v_N - \mathbf{p}(x_j))} + \sum_{j=|\mathcal{X}_S|+1}^{|\mathcal{X}|} \sqrt{\mathbf{p}(x_j)(v_N - \mathbf{p}(x_j))} \right), \quad (16)$$

where  $f(n) \approx g(n)$  represents  $\lim_{n \rightarrow \infty} f(n)/g(n) = 1$ .

When  $0 < \varepsilon < 2\ln(\frac{|\mathcal{X}_N|}{2} + 1)$ , the  $l_1$  loss is maximized by the uniform distribution  $\mathbf{p}_{U_N}$  over  $\mathcal{X}_N$ :

**Proposition 8.** *For any  $0 < \varepsilon < 2\ln(\frac{|\mathcal{X}_N|}{2} + 1)$  and  $|\mathcal{X}_S| \leq |\mathcal{X}_N|$ , (16) is maximized when  $\mathbf{p} = \mathbf{p}_{U_N}$ :*

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p})] \lesssim \mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] = \sqrt{\frac{2}{n\pi}} \left( \frac{e^{\varepsilon/4} |\mathcal{X}_S|}{e^{\varepsilon/2} - 1} + \sqrt{\frac{e^{\varepsilon/2} |\mathcal{X}_N|}{e^{\varepsilon/2} - 1} - 1} \right), \quad (17)$$

where  $f(n) \lesssim g(n)$  represents  $\lim_{n \rightarrow \infty} f(n)/g(n) \leq 1$ .

Note that this proposition covers a wide range of  $\varepsilon$ . For example, when  $|\mathcal{X}_S| \leq |\mathcal{X}_N|$ , it covers both the high privacy regime ( $\varepsilon \approx 0$ ) and low privacy regime ( $\varepsilon = \ln|\mathcal{X}|$ ), since  $\ln|\mathcal{X}| < 2\ln(\frac{|\mathcal{X}_N|}{2} + 1)$ . Below we instantiate the  $l_1$  loss in the high and low privacy regimes based on this proposition.

**uRAP in the high privacy regime.** If  $\varepsilon$  is close to 0, we have  $e^{\varepsilon/2} - 1 \approx \varepsilon/2$ . Thus, the right-hand side of (17) in Proposition 8 can be simplified as follows:

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \sqrt{\frac{2}{n\pi}} \cdot \frac{2|\mathcal{X}_S|}{\varepsilon}. \quad (18)$$

It is shown in [29] that the expected  $l_1$  loss of the  $\varepsilon$ -RAPPOR is at most  $\sqrt{\frac{2}{n\pi}} \cdot \frac{2|\mathcal{X}|}{\varepsilon}$  when  $\varepsilon \approx 0$ . Thus, by (18), the expected  $l_1$  loss of the  $(\mathcal{X}_S, \varepsilon)$ -uRAP is much smaller than that of the  $\varepsilon$ -RAPPOR when  $|\mathcal{X}_S| \ll |\mathcal{X}|$ .

Moreover, by (18), the expected  $l_1$  loss of the  $(\mathcal{X}_S, \varepsilon)$ -uRAP in the worst case is expressed as  $\Theta(\frac{|\mathcal{X}_S|}{\sqrt{ne^2}})$  in the high privacy regime. As described in Section 3.2, this is “order” optimal among all  $(\mathcal{X}_S, \mathcal{F}_P, \varepsilon)$ -ULDP mechanisms (in Appendix C.1, we also show that the expected  $l_2$  of the  $(\mathcal{X}_S, \varepsilon)$ -uRAP is expressed as  $\Theta(\frac{|\mathcal{X}_S|}{ne^2})$ ).

**uRAP in the low privacy regime.** If  $\varepsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|^{\frac{3}{4}}$ , the right-hand side of (17) can be simplified, using  $|\mathcal{X}_S|/|\mathcal{X}|^{\frac{3}{4}} \approx 0$ , as follows:

$$\mathbb{E}[l_1(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \sqrt{\frac{2(|\mathcal{X}|-1)}{n\pi}}.$$

Thus, when  $\varepsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|^{\frac{3}{4}}$ , the  $(\mathcal{X}_S, \varepsilon)$ -uRAP also achieves almost the same data utility as the non-private mechanism, whereas the expected  $l_1$  loss of the  $\varepsilon$ -RAPPOR is  $\sqrt{|\mathcal{X}|}$  times larger than that of the non-private mechanism [29].

**Summary.** In summary, the uRR and uRAP provide much higher utility than the RR and RAPPOR when  $|\mathcal{X}_S| \ll |\mathcal{X}|$ . Moreover, when  $\varepsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|$  (resp.  $|\mathcal{X}_S| \ll |\mathcal{X}|^{\frac{3}{4}}$ ), the uRR (resp. uRAP) achieves almost the same utility as a non-private mechanism.

## 5 Personalized ULDP Mechanisms

We now consider the personalized-mechanism scenario (outlined in Section 2.1), and propose a *PUM (Personalized ULDP Mechanism)* to keep secret what is sensitive for each user while enabling the data collector to estimate a distribution.

Sections 5.1 describes the PUM. Section 5.2 explains its privacy properties. Section 5.3 proposes a method to estimate the distribution  $\mathbf{p}$  from  $\mathbf{Y}$  obfuscated using the PUM. Section 5.4 analyzes the data utility of the PUM.

### 5.1 PUM with $\kappa$ Semantic Tags

Figure 4 shows the overview of the PUM  $\mathbf{Q}^{(i)}$  for the  $i$ -th user ( $i = 1, 2, \dots, n$ ). It first deterministically maps personal data  $x \in \mathcal{X}$  to *intermediate data* using a *pre-processor*  $f_{pre}^{(i)}$ , and then maps the intermediate data to obfuscated data  $y \in \mathcal{Y}$  using a utility-optimized mechanism  $\mathbf{Q}_{cmn}$  common to all users. The pre-processor  $f_{pre}^{(i)}$  maps user-specific sensitive data  $x \in \mathcal{X}_S^{(i)}$  to one of  $\kappa$  bots:  $\perp_1, \perp_2, \dots$ , or  $\perp_\kappa$ . The  $\kappa$  bots represent user-specific sensitive data, and each of them is associated with a *semantic tag* such as “home” or “workplace”. The  $\kappa$  semantic tags are the same for all users, and are useful when the data collector has some background knowledge about  $\mathbf{p}$  conditioned on each tag. For example, a distribution of POIs tagged as “home” or “workplace” can be easily obtained via the Fousquare venue API [54]. Although this is not a user distribution but a “POI distribution”, it can be used to roughly approximate the distribution of users tagged as “home” or “workplace”, as shown in Section 6. We define a set  $\mathcal{Z}$  of intermediate data by  $\mathcal{Z} = \mathcal{X} \cup \{\perp_1, \dots, \perp_\kappa\}$ , and a set  $\mathcal{Z}_S$  of sensitive intermediate data by  $\mathcal{Z}_S = \mathcal{X}_S \cup \{\perp_1, \dots, \perp_\kappa\}$ .

Formally, the PUM  $\mathbf{Q}^{(i)}$  first maps personal data  $x \in \mathcal{X}$  to intermediate data  $z \in \mathcal{Z}$  using a pre-processor  $f_{pre}^{(i)}: \mathcal{X} \rightarrow \mathcal{Z}$  specific to each user. The pre-processor  $f_{pre}^{(i)}$  maps sensitive

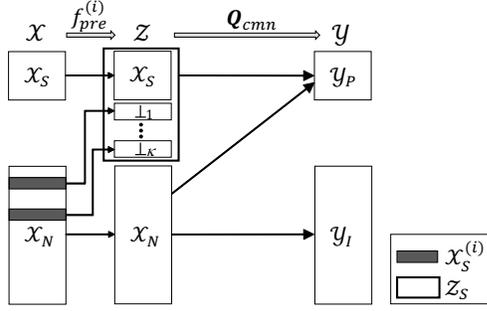

Figure 4: Overview of the PUM  $\mathbf{Q}^{(i)}$  ( $= \mathbf{Q}_{cmn} \circ f_{pre}^{(i)}$ ).

data  $x \in \mathcal{X}_S^{(i)}$  associated with the  $k$ -th tag ( $1 \leq k \leq \kappa$ ) to the corresponding bot  $\perp_k$ , and maps other data to themselves. Let  $\mathcal{X}_{S,k}^{(i)}$  be a set of the  $i$ -th user’s sensitive data associated with the  $k$ -th tag (e.g., set of regions including her primary home and second home). Then,  $\mathcal{X}_S^{(i)}$  is expressed as  $\mathcal{X}_S^{(i)} = \bigcup_{1 \leq k \leq \kappa} \mathcal{X}_{S,k}^{(i)}$ , and  $f_{pre}^{(i)}$  is given by:

$$f_{pre}^{(i)}(x) = \begin{cases} \perp_k & (\text{if } x \in \mathcal{X}_{S,k}^{(i)}) \\ x & (\text{otherwise}). \end{cases} \quad (19)$$

After mapping personal data  $x \in \mathcal{X}$  to intermediate data  $z \in \mathcal{Z}$ , the  $(\mathcal{Z}_S, \mathcal{Y}_P, \epsilon)$ -utility-optimized mechanism  $\mathbf{Q}_{cmn}$  maps  $z$  to obfuscated data  $y \in \mathcal{Y}$ . Examples of  $\mathbf{Q}_{cmn}$  include the  $(\mathcal{Z}_S, \epsilon)$ -uRR (in Definition 3) and  $(\mathcal{Z}_S, \epsilon)$ -uRAP (in Definition 4). As a whole, the PUM  $\mathbf{Q}^{(i)}$  can be expressed as:  $\mathbf{Q}^{(i)} = \mathbf{Q}_{cmn} \circ f_{pre}^{(i)}$ . The  $i$ -th user stores  $f_{pre}^{(i)}$  and  $\mathbf{Q}_{cmn}$  in a device that obfuscates her personal data (e.g., mobile phone, personal computer). Note that if  $f_{pre}^{(i)}$  is leaked,  $x \in \mathcal{X}_N$  corresponding to each bot (e.g., home, workplace) is leaked. Thus, the user keeps  $f_{pre}^{(i)}$  secret. To strongly prevent the leakage of  $f_{pre}^{(i)}$ , the user may deal with  $f_{pre}^{(i)}$  using a tamper-resistant hardware/software. On the other hand, the utility-optimized mechanism  $\mathbf{Q}_{cmn}$ , which is common to all users, is available to the data collector.

The feature of the proposed PUM  $\mathbf{Q}^{(i)}$  is two-fold: (i) the secrecy of the pre-processor  $f_{pre}^{(i)}$  and (ii) the  $\kappa$  semantic tags. By the first feature, the  $i$ -th user can keep  $\mathcal{X}_S^{(i)}$  (i.e., what is sensitive for her) secret, as shown in Section 5.2. The second feature enables the data collector to estimate a distribution  $\mathbf{p}$  with high accuracy. Specifically, she estimates  $\mathbf{p}$  from obfuscated data  $\mathbf{Y}$  using  $\mathbf{Q}_{cmn}$  and some background knowledge about  $\mathbf{p}$  conditioned on each tag, as shown in Section 5.3.

In practice, it may happen that a user has her specific sensitive data  $x \in \mathcal{X}_S^{(i)}$  that is not associated with any semantic tags. For example, if we prepare only tags named “home” and “workplace”, then sightseeing places, restaurants, and any other places are not associated with these tags. One way to deal with such data is to create another bot associated with a tag named “others” (e.g., if  $\perp_1$  and  $\perp_2$  are associated with

“home” and “workplace”, respectively, we create  $\perp_3$  associated with “others”), and map  $x$  to this bot. It would be difficult for the data collector to obtain background knowledge about  $\mathbf{p}$  conditioned on such a tag. In Section 5.3, we will explain how to estimate  $\mathbf{p}$  in this case.

## 5.2 Privacy Properties

We analyze the privacy properties of the PUM  $\mathbf{Q}^{(i)}$ . First, we show that it provides ULDP.

**Proposition 9.** *The PUM  $\mathbf{Q}^{(i)}$  ( $= \mathbf{Q}_{cmn} \circ f_{pre}^{(i)}$ ) provides  $(\mathcal{X}_S \cup \mathcal{X}_S^{(i)}, \mathcal{Y}_P, \epsilon)$ -ULDP.*

We also show that our PUM provides DP in that an adversary who has observed  $y \in \mathcal{Y}_P$  cannot determine, for any  $i, j \in [n]$ , whether it is obfuscated using  $\mathbf{Q}^{(i)}$  or  $\mathbf{Q}^{(j)}$ , which means that  $y \in \mathcal{Y}_P$  reveals almost no information about  $\mathcal{X}_S^{(i)}$ :

**Proposition 10.** *For any  $i, j \in [n]$ , any  $x \in \mathcal{X}$ , and any  $y \in \mathcal{Y}_P$ ,*

$$\mathbf{Q}^{(i)}(y|x) \leq e^\epsilon \mathbf{Q}^{(j)}(y|x).$$

We then analyze the secrecy of  $\mathcal{X}_S^{(i)}$ . The data collector, who knows the common-mechanism  $\mathbf{Q}_{cmn}$ , cannot obtain any information about  $\mathcal{X}_S^{(i)}$  from  $\mathbf{Q}_{cmn}$  and  $y \in \mathcal{Y}_P$ . Specifically, the data collector knows, for each  $z \in \mathcal{Z}$ , whether  $z \in \mathcal{Z}_S$  or not by viewing  $\mathbf{Q}_{cmn}$ . However, she cannot obtain any information about  $\mathcal{X}_S^{(i)}$  from  $\mathcal{Z}_S$ , because she does not know the mapping between  $\mathcal{X}_S^{(i)}$  and  $\{\perp_1, \dots, \perp_\kappa\}$  (i.e.,  $f_{pre}^{(i)}$ ). In addition, Propositions 9 and 10 guarantee that  $y \in \mathcal{Y}_P$  reveals almost no information about both input data and  $\mathcal{X}_S^{(i)}$ .

For example, assume that the  $i$ -th user obfuscates her home  $x \in \mathcal{X}_S \cup \mathcal{X}_S^{(i)}$  using the PUM  $\mathbf{Q}^{(i)}$ , and sends  $y \in \mathcal{Y}_P$  to the data collector. The data collector cannot infer either  $x \in \mathcal{X}_S \cup \mathcal{X}_S^{(i)}$  or  $z \in \mathcal{Z}_S$  from  $y \in \mathcal{Y}_P$ , since both  $\mathbf{Q}_{cmn}$  and  $\mathbf{Q}^{(i)}$  provide ULDP. This means that the data collector cannot infer *the fact that she was at home* from  $y$ . Furthermore, the data collector cannot infer *where her home is*, since  $\mathcal{X}_S^{(i)}$  cannot be inferred from  $\mathbf{Q}_{cmn}$  and  $y \in \mathcal{Y}_P$  as explained above.

We need to take a little care when the  $i$ -th user obfuscates non-sensitive data  $x \in \mathcal{X}_N \setminus \mathcal{X}_S^{(i)}$  using  $\mathbf{Q}^{(i)}$  and sends  $y \in \mathcal{Y}_I$  to the data collector. In this case, the data collector learns  $x$  from  $y$ , and therefore learns that  $x$  is not sensitive (i.e.,  $x \notin \mathcal{X}_S^{(i)}$ ). Thus, the data collector, who knows that the user wants to hide her home, would reduce the number of possible candidates for her home from  $\mathcal{X}$  to  $\mathcal{X} \setminus \{x\}$ . However, if  $|\mathcal{X}|$  is large (e.g.,  $|\mathcal{X}| = 625$  in our experiments using location data), the number  $|\mathcal{X}| - 1$  of candidates is still large. Since the data collector cannot further reduce the number of candidates using  $\mathbf{Q}_{cmn}$ , her home is still kept strongly secret. In Section 7, we also explain that the secrecy of  $\mathcal{X}_S^{(i)}$  is achieved under reasonable assumptions even when she sends multiple data.

### 5.3 Distribution Estimation

We now explain how to estimate a distribution  $\mathbf{p}$  from data  $\mathbf{Y}$  obfuscated using the PUM. Let  $\mathbf{r}^{(i)}$  be a distribution of intermediate data for the  $i$ -th user:

$$\mathbf{r}^{(i)}(z) = \begin{cases} \sum_{x \in \mathcal{X}_{S,k}^{(i)}} \mathbf{p}(x) & (\text{if } z = \perp_k \text{ for some } k = 1, \dots, \kappa) \\ 0 & (\text{if } z \in \mathcal{X}_S^{(i)}) \\ \mathbf{p}(z) & (\text{otherwise}). \end{cases}$$

and  $\mathbf{r}$  be the average of  $\mathbf{r}^{(i)}$  over  $n$  users; i.e.,  $\mathbf{r}(z) = \frac{1}{n} \sum_{i=1}^n \mathbf{r}^{(i)}(z)$  for any  $z \in \mathcal{Z}$ . Note that  $\sum_{x \in \mathcal{X}} \mathbf{p}(x) = 1$  and  $\sum_{z \in \mathcal{Z}} \mathbf{r}(z) = 1$ . Furthermore, let  $\pi_k$  be a distribution of personal data  $x \in \mathcal{X}$  conditioned on  $\perp_k$  defined by:

$$\pi_k(x) = \frac{\sum_{i=1}^n \mathbf{p}_k^{(i)}(x)}{\sum_{x' \in \mathcal{X}} \sum_{i=1}^n \mathbf{p}_k^{(i)}(x')}, \quad (20)$$

$$\mathbf{p}_k^{(i)}(x) = \begin{cases} \mathbf{p}(x) & (\text{if } \text{pre}^{(i)}(x) = \perp_k) \\ 0 & (\text{otherwise}). \end{cases}$$

$\pi_k(x)$  in (20) is a normalized sum of the probability  $\mathbf{p}(x)$  of personal data  $x$  whose corresponding intermediate data is  $\perp_k$ . Note that although  $x \in \mathcal{X}$  is deterministically mapped to  $z \in \mathcal{Z}$  for each user, we can consider the probability distribution  $\pi_k$  for  $n$  users. For example, if  $\perp_k$  is tagged as “home”, then  $\pi_k$  is a distribution of users at home.

We propose a method to estimate a distribution  $\mathbf{p}$  from obfuscated data  $\mathbf{Y}$  using some background knowledge about  $\pi_k$  as an estimate  $\hat{\pi}_k$  of  $\pi_k$  (we explain the case where we have no background knowledge later). Our estimation method first estimates a distribution  $\mathbf{r}$  of intermediate data from obfuscated data  $\mathbf{Y}$  using  $\mathbf{Q}_{cmn}$ . This can be performed in the same way as the common-mechanism scenario. Let  $\hat{\mathbf{r}}$  be the estimate of  $\mathbf{r}$ .

After computing  $\hat{\mathbf{r}}$ , our method estimates  $\mathbf{p}$  using the estimate  $\hat{\pi}_k$  (i.e., background knowledge about  $\pi_k$ ) as follows:

$$\hat{\mathbf{p}}(x) = \hat{\mathbf{r}}(x) + \sum_{k=1}^{\kappa} \hat{\mathbf{r}}(\perp_k) \hat{\pi}_k(x), \quad \forall x \in \mathcal{X}. \quad (21)$$

Note that  $\hat{\mathbf{p}}$  in (21) can be regarded as an empirical estimate of  $\mathbf{p}$ . Moreover, if both  $\hat{\mathbf{r}}$  and  $\hat{\pi}_k$  are in the probability simplex  $\mathcal{C}$ , then  $\hat{\mathbf{p}}$  in (21) is always in  $\mathcal{C}$ .

If we do not have estimates  $\hat{\pi}_k$  for some bots (like the one tagged as “others” in Section 5.1), then we set  $\hat{\pi}_k(x)$  in proportion to  $\hat{\mathbf{r}}(x)$  over  $x \in \mathcal{X}_N$  (i.e.,  $\hat{\pi}_k(x) = \frac{\hat{\mathbf{r}}(x)}{\sum_{x' \in \mathcal{X}_N} \hat{\mathbf{r}}(x')}$ ) for such bots. When we do not have any background knowledge  $\hat{\pi}_1, \dots, \hat{\pi}_\kappa$  for all bots, it amounts to simply discarding the estimates  $\hat{\mathbf{r}}(\perp_1), \dots, \hat{\mathbf{r}}(\perp_\kappa)$  for  $\kappa$  bots and normalizing  $\hat{\mathbf{r}}(x)$  over  $x \in \mathcal{X}_N$  so that the sum is one.

### 5.4 Utility Analysis

We now theoretically analyze the data utility of our PUM. Recall that  $\hat{\mathbf{p}}$ ,  $\hat{\mathbf{r}}$ , and  $\hat{\pi}_k$  are the estimate of the distribution

of personal data, intermediate data, and personal data conditioned on  $\perp_k$ , respectively. In the following, we show that the  $l_1$  loss of  $\hat{\mathbf{p}}$  can be upper-bounded as follows:

**Theorem 1** ( $l_1$  loss of the PUM).

$$l_1(\hat{\mathbf{p}}, \mathbf{p}) \leq l_1(\hat{\mathbf{r}}, \mathbf{r}) + \sum_{k=1}^{\kappa} \hat{\mathbf{r}}(\perp_k) l_1(\hat{\pi}_k, \pi_k). \quad (22)$$

This means the upper-bound on the  $l_1$  loss of  $\hat{\mathbf{p}}$  can be decomposed into the  $l_1$  loss of  $\hat{\mathbf{r}}$  and of  $\hat{\pi}_k$  weighted by  $\hat{\mathbf{r}}(\perp_k)$ .

The first term in (22) is the  $l_1$  loss of  $\hat{\mathbf{r}}$ , which depends on  $\mathbf{Q}_{cmn}$ . For example, if we use the uRR or uRAP as  $\mathbf{Q}_{cmn}$ , the expectation of  $l_1(\hat{\mathbf{r}}, \mathbf{r})$  is given by Propositions 4 and 7, respectively. In Section 6, we show they are very small.

The second term in (22) is the summation of the  $l_1$  loss of  $\hat{\pi}_k$  weighted by  $\hat{\mathbf{r}}(\perp_k)$ . If we accurately estimate  $\pi_k$ , the second term is very small. In other words, if we have enough background knowledge about  $\pi_k$ , we can accurately estimate  $\mathbf{p}$  in the personalized-mechanism scenario.

It should be noted that when the probability  $\hat{\mathbf{r}}(\perp_k)$  is small, the second term in (22) is small *even if we have no background knowledge about  $\pi_k$* . For example, when only a small number of users map  $x \in \mathcal{X}_S^{(i)}$  to a tag named “others”, they hardly affect the accuracy of  $\hat{\mathbf{p}}$ . Moreover, the second term in (22) is upper-bounded by  $2 \sum_{k=1}^{\kappa} \hat{\mathbf{r}}(\perp_k)$ , since the  $l_1$  loss is at most 2. Thus, after computing  $\hat{\mathbf{r}}$ , the data collector can easily compute the worst-case value of the second term in (22) to know the effect of the estimation error of  $\hat{\pi}_k$  on the accuracy of  $\hat{\mathbf{p}}$ .

Last but not least, the second term in (22) does not depend on  $\epsilon$  (while the first term depends on  $\epsilon$ ). Thus, the effect of the second term is relatively small when  $\epsilon$  is small (i.e., high privacy regime), as shown in Section 6.

**Remark.** Note that different privacy preferences might skew the distribution  $\pi_k$ . For example, doctors might not consider hospitals as sensitive as compared to patients. Consequently, the distribution  $\pi_k$  conditioned on “hospital” might be a distribution of patients (not doctors) in hospitals. This kind of systematic bias can increase the estimation error of  $\hat{\pi}_k$ . Theorem 1 and the above discussions are also valid in this case.

## 6 Experimental Evaluation

### 6.1 Experimental Set-up

We conducted experiments using two large-scale datasets:

**Foursquare dataset.** The Foursquare dataset (global-scale check-in dataset) [54] is one of the largest location datasets among publicly available datasets (e.g., see [10], [44], [55], [57]); it contains 33278683 check-ins all over the world, each of which is associated with a POI ID and venue category (e.g., restaurant, shop, hotel, hospital, home, workplace).

We used 359054 check-ins in Manhattan, assuming that each check-in is from a different user. Then we divided Manhattan into  $25 \times 25$  regions at regular intervals and used them

as input alphabets; i.e.,  $|\mathcal{X}| = 625$ . The size of each region is about 400m (horizontal)  $\times$  450m (vertical). We assumed a region that includes a hospital visited by at least ten users as a sensitive region common to all users. The number of such regions was  $|\mathcal{X}_S| = 15$ . In addition, we assumed a region in  $\mathcal{X}_N$  that includes a user’s home or workplace as her user-specific sensitive region. The number of users at home and workplace was 5040 and 19532, respectively.

**US Census dataset.** The US Census (1990) dataset [35] was collected as part of the 1990 U.S. census. It contains responses from 2458285 people (each person provides one response), each of which contains 68 attributes.

We used the responses from all people, and used age, income, marital status, and sex as attributes. Each attribute has 8, 5, 5, and 2 categories, respectively. (See [35] for details about the value of each category ID.) We regarded a tuple of the category IDs as a total category ID, and used it as an input alphabet; i.e.,  $|\mathcal{X}| = 400 (= 8 \times 5 \times 5 \times 2)$ . We considered the fact that “divorce” and “unemployment” might be sensitive for many users [34], and regarded such categories as sensitive for all users (to be on the safe side, as described in Section 2.1). Note that people might be students until their twenties and might retire in their fifties or sixties. Children of age twelve and under cannot get married. We excluded such categories from sensitive ones. The number of sensitive categories was  $|\mathcal{X}_S| = 76$ .

We used a frequency distribution of all people as a true distribution  $\mathbf{p}$ , and randomly chose a half of all people as users who provide their obfuscated data; i.e.,  $n = 179527$  and 1229143 in the Foursquare and US Census datasets, respectively. Here we did not use all people, because we would like to evaluate the non-private mechanism that does not obfuscate the personal data; i.e., the non-private mechanism has an estimation error in our experiments due to the random sampling from the population.

As utility, we evaluated the TV (Total Variation) by computing the sample mean over a hundred realizations of  $\mathbf{Y}$ .

## 6.2 Experimental Results

**Common-mechanism scenario.** We first focused on the common-mechanism scenario, and evaluated the RR, RAPPOR, uRR, and uRAP. As distribution estimation methods, we used empirical estimation, empirical estimation with the significance threshold, and EM reconstruction (denoted by “emp”, “emp+thr”, and “EM”, respectively). In “emp+thr”, we set the significance level  $\alpha$  to be  $\alpha = 0.05$ , and uniformly assigned the remaining probability to each of the estimates below the significance threshold in the same way as [51].

Figure 5 shows the results in the case where  $\epsilon$  is changed from 0.1 to 10. “no privacy” represents the non-private mechanism. It can be seen that our mechanisms outperform the existing mechanisms by one or two orders of magnitude. Our mechanisms are effective especially in the Foursquare

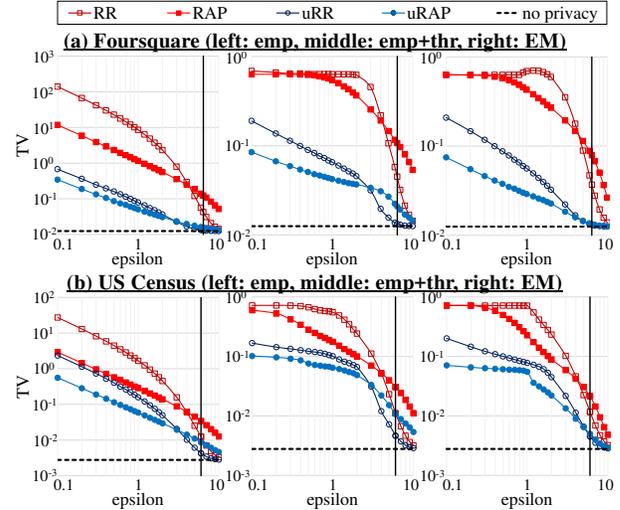

Figure 5:  $\epsilon$  vs. TV (common-mechanism). A bold line parallel to the y-axis represents  $\epsilon = \ln |\mathcal{X}|$ .

dataset, since the proportion of sensitive regions is very small ( $15/625 = 0.024$ ). Moreover, the uRR provides almost the same performance as the non-private mechanism when  $\epsilon = \ln |\mathcal{X}|$ , as described in Section 4.3. It can also be seen that “emp+thr” and “EM” significantly outperform “emp”, since the estimates in “emp+thr” and “EM” are always non-negative. Although “EM” outperforms “emp+thr” for the RAPPOR and uRAP when  $\epsilon$  was large, the two estimation methods provide very close performance as a whole.

We then evaluated the relationship between the number of sensitive regions/categories and the TV. To this end, we randomly chose  $\mathcal{X}_S$  from  $\mathcal{X}$ , and increased  $|\mathcal{X}_S|$  from 1 to  $|\mathcal{X}|$  (only in this experiment). We attempted one hundred cases for randomly choosing  $\mathcal{X}_S$  from  $\mathcal{X}$ , and evaluated the TV by computing the sample mean over one hundred cases.

Figure 6 shows the results for  $\epsilon = 0.1$  (high privacy regime) or  $\ln |\mathcal{X}|$  (low privacy regime). Here we omit the performance of “emp+thr”, since it is very close to that of “EM” in the same way as in Figure 5. The uRAP and uRR provide the best performance when  $\epsilon = 0.1$  and  $\ln |\mathcal{X}|$ , respectively. In addition, the uRR provides the performance close to the non-private mechanism when  $\epsilon = \ln |\mathcal{X}|$  and the number  $|\mathcal{X}_S|$  of sensitive regions/categories is less than 100. The performance of the uRAP is also close to that of the non-private mechanism when  $|\mathcal{X}_S|$  is less than 20 (note that  $|\mathcal{X}|^{\frac{3}{4}} = 125$  and 89 in the Foursquare and US Census datasets, respectively). However, it rapidly increases with increase in  $|\mathcal{X}_S|$ . Overall, our theoretical results in Section 4.3 hold for the two real datasets.

We also evaluated the performance when the number of attributes was increased from 4 to 9 in the US Census dataset. We added, one by one, five attributes as to whether or not a user has served in the military during five periods (“Sept80”, “May75880”, “Vietnam”, “Feb55”, and “Korean” in [18]; we added them in this order). We assumed that these attributes

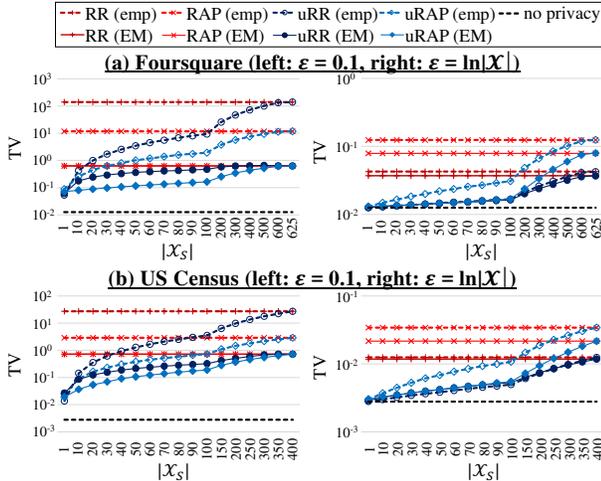

Figure 6:  $|X_S|$  vs. TV when  $\epsilon = 0.1$  or  $\ln|X|$ .

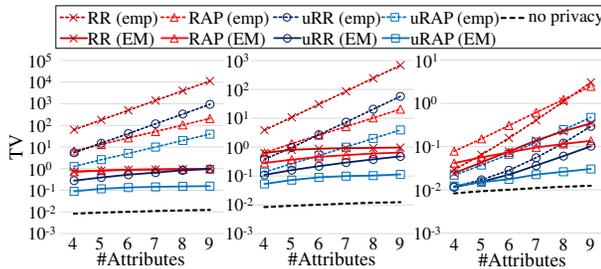

Figure 7: Number of attributes vs. TV (US Census dataset; left:  $\epsilon = 0.1$ , middle:  $\epsilon = 1.0$ , right:  $\epsilon = 6.0$ ).

are non-sensitive. Since each of the five attributes had two categories (1: yes, 0: no),  $|X|$  (resp.  $|X_S|$ ) was changed from 400 to 12800 (resp. from 76 to 2432). We randomly chose  $n = 240000$  people as users who provide obfuscated data, and evaluated the TV by computing the sample mean over ten realizations of  $\mathbf{Y}$  (only in this experiment).

Figure 7 shows the results in the case where  $\epsilon = 0.1, 1.0$ , or  $6.0$  ( $=\ln 400$ ). Here we omit the performance of “emp+thr” in the same way as Figure 6. Although the TV increases with an increase in the number of attributes, overall our utility-optimized mechanisms remain effective, compared to the existing mechanisms. One exception is the case where  $\epsilon = 0.1$  and the number of attributes is 9; the TV of the RR (EM), RAPPOR (EM), and uRR (EM) is almost 1. Note that when we use the EM reconstruction method, the worst value of the TV is 1. Thus, as with the RR and RAPPOR, the uRR fails to estimate a distribution in this case. On the other hand, the TV of the uRAP (EM) is much smaller than 1 even in this case, which is consistent with the fact that the uRAP is order optimal in the high privacy regime. Overall, the uRAP is robust to the increase of the attributes at the same value of  $\epsilon$  (note that for large  $|X|$ ,  $\epsilon = 1.0$  or  $6.0$  is a medium privacy regime where  $0 \ll \epsilon \ll \ln|X|$ ).

We also measured the running time (i.e., time to estimate  $\mathbf{p}$  from  $\mathbf{Y}$ ) of “EM” (which sets the estimate by “emp+thr” as

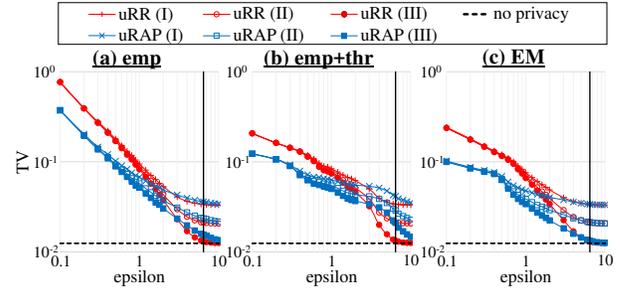

Figure 8:  $\epsilon$  vs. TV (personalized-mechanism) ((I): w/o knowledge, (II): POI distribution, (III): true distribution).

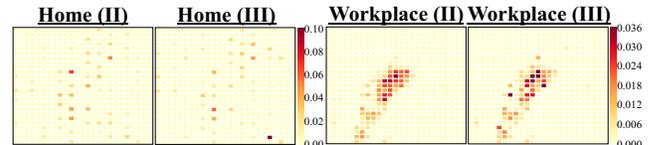

Figure 9: Visualization of the distributions ((II): POI distribution, (III): true distribution).

an initial value of  $\hat{\mathbf{p}}$ ) on an Intel Xeon CPU E5-2620 v3 (2.40 GHz, 6 cores, 12 logical processors) with 32 GB RAM. We found that the running time increases roughly linearly with the number of attributes. For example, when  $\epsilon = 6.0$  and the number of attributes is 9, the running time of “EM” required 3121, 1258, 5225, and 1073 seconds for “RR”, “uRR”, “RAP”, and “uRAP”, respectively. We also measured the running time of “emp” and “emp+thr”, and found that they required less than one second even when the number of attributes is 9. Thus, if “EM” requires too much time for a large number of attributes, “emp+thr” would be a good alternative to “EM”.

**Personalized-mechanism scenario.** We then focused on the personalized-mechanism scenario, and evaluated our utility-optimized mechanisms using the Foursquare dataset. We used the PUM with  $\kappa = 2$  semantic tags (described in Section 5.1), which maps “home” and “workplace” to bots  $\perp_1$  and  $\perp_2$ , respectively. As the background knowledge about the bot distribution  $\pi_k$  ( $1 \leq k \leq 2$ ), we considered three cases: (I) we do not have any background knowledge; (II) we use a distribution of POIs tagged as “home” (resp. “workplace”), which is computed from the POI data in [54], as an estimate of the bot probability  $\hat{\pi}_1$  (resp.  $\hat{\pi}_2$ ); (III) we use the true distributions (i.e.,  $\hat{\pi}_k = \pi_k$ ). Regarding (II), we emphasize again that it is not a user distribution but a “POI distribution”, and can be easily obtained via the Foursquare venue API [54].

Figure 8 shows the results. We also show the POI and true distributions in Figure 9. It can be seen that the performance of (II) lies in between that of (I) and (III), which shows that the estimate  $\hat{\pi}_k$  of the bot distribution affects utility. However, when  $\epsilon$  is smaller than 1, all of (I), (II), and (III) provide almost the same performance, since the effect of the estimation error of  $\hat{\pi}_k$  does not depend on  $\epsilon$ , as described in Section 5.4.

We also computed the  $l_1$  loss  $l_1(\hat{\mathbf{p}}, \mathbf{p})$  and the first and second terms in the right-hand side of (22) to investigate

Table 1:  $l_1$  loss  $l_1(\hat{\mathbf{p}}, \mathbf{p})$  and the first and second terms in the right-hand side of (22) in the case where  $\epsilon = \ln |\mathcal{X}|$  and the EM reconstruction method is used.

| Method     | $l_1(\hat{\mathbf{p}}, \mathbf{p})$ | first term            | second term           |
|------------|-------------------------------------|-----------------------|-----------------------|
| uRR (I)    | $6.73 \times 10^{-2}$               | $2.70 \times 10^{-2}$ | $7.34 \times 10^{-2}$ |
| uRR (II)   | $4.24 \times 10^{-2}$               | $2.70 \times 10^{-2}$ | $2.96 \times 10^{-2}$ |
| uRR (III)  | $2.62 \times 10^{-2}$               | $2.70 \times 10^{-2}$ | 0                     |
| uRAP (I)   | $6.77 \times 10^{-2}$               | $2.76 \times 10^{-2}$ | $7.35 \times 10^{-2}$ |
| uRAP (II)  | $4.28 \times 10^{-2}$               | $2.76 \times 10^{-2}$ | $2.96 \times 10^{-2}$ |
| uRAP (III) | $2.67 \times 10^{-2}$               | $2.76 \times 10^{-2}$ | 0                     |

whether Theorem 1 holds. Table 1 shows the results (we averaged the values over one hundred realizations of  $\mathbf{Y}$ ). It can be seen that  $l_1(\hat{\mathbf{p}}, \mathbf{p})$  is smaller than the summation of the first and second terms in all of the methods, which shows that Theorem 1 holds in our experiments.

From these experimental results, we conclude that our proposed methods are very effective in both the common-mechanism and personalized-mechanism scenarios. In Appendix C.2, we show the MSE has similar results to the TV.

## 7 Discussions

**On the case of multiple data per user.** We have so far assumed that each user sends only a single datum. Now we discuss the case where each user sends multiple data based on the compositionality of ULDP described in Section 3.2. Specifically, when a user sends  $t$  ( $> 1$ ) data, we obtain  $(\mathcal{X}_S, (\mathcal{Y}_P)^t, \epsilon)$ -ULDP in total by obfuscating each data using the  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon/t)$ -utility-optimized mechanism. Note, however, that the amount of noise added to each data increases with increase in  $t$ . Consequently, for  $\epsilon \in [0, t]$ , the lower bound on the  $l_1$  (resp.  $l_2$ ) loss (described in Section 3.2) can be expressed as  $\Theta(\frac{\sqrt{t}|\mathcal{X}_S|}{\sqrt{n\epsilon^2}})$  (resp.  $\Theta(\frac{t|\mathcal{X}_S|}{n\epsilon^2})$ ), which increases with increase in  $t$ . Thus,  $t$  cannot be large for distribution estimation in practice. This is also common to all LDP mechanisms.

Next we discuss the secrecy of  $\mathcal{X}_S^{(i)}$ . Assume that the  $i$ -th user obfuscates  $t$  data using different seeds, and sends  $t_P$  protected data in  $\mathcal{Y}_P$  and  $t_I$  invertible data in  $\mathcal{Y}_I$ , where  $t = t_P + t_I > 1$  (she can also use the same seed for the same data to reduce  $t_I$  as in [23]). If all the  $t_I$  data in  $\mathcal{Y}_I$  are different from each other, the data collector learns  $t_I$  original data in  $\mathcal{X}_N$ . However,  $t_I$  ( $\leq t$ ) cannot be large in practice, as explained above. In addition, in many applications, a user’s personal data is highly non-uniform and sparse. In locations data, for example, a user often visits only a small number of regions in the whole map  $\mathcal{X}$ . Let  $\mathcal{T}^{(i)} \subseteq \mathcal{X}_N$  be a set of possible input values for the  $i$ -th user in  $\mathcal{X}_N$ . Then, even if  $t_I$  is large, the data collector cannot learn more than  $|\mathcal{T}^{(i)}|$  data in  $\mathcal{X}_N$ .

Moreover, the  $t_P$  data in  $\mathcal{Y}_P$  reveal almost no information about  $\mathcal{X}_S^{(i)}$ , since  $\mathbf{Q}^{(i)}$  provides  $(\mathcal{X}_S, (\mathcal{Y}_P)^t, \epsilon)$ -ULDP.  $\mathbf{Q}_{cmn}$

provides no information about  $\mathcal{X}_S^{(i)}$ , since  $f_{pre}^{(i)}$  is kept secret. Thus, the data collector, who knows that the user wants to hide her home, cannot reduce the number of candidates for her home from  $\max\{|\mathcal{X}| - t_I, |\mathcal{X}| - |\mathcal{T}^{(i)}|\}$  using the  $t_P$  data and  $\mathbf{Q}_{cmn}$ . If either  $t_I$  or  $|\mathcal{T}^{(i)}|$  is much smaller than  $|\mathcal{X}|$ , her home is kept strongly secret.

Note that  $\mathbf{p}$  can be estimated even if  $\mathcal{X}_S^{(i)}$  changes over time.  $\mathcal{X}_S^{(i)}$  is also kept strongly secret if  $t_I$  or  $|\mathcal{T}^{(i)}|$  is small.

**On the correlation between  $\mathcal{X}_S$  and  $\mathcal{X}_N$ .** It should also be noted that there might be a correlation between sensitive data  $\mathcal{X}_S$  and non-sensitive data  $\mathcal{X}_N$ . For example, if a user discloses a non-sensitive region close to a sensitive region including her home, the adversary might infer approximate information about the original location (e.g., the fact that the user lives in Paris). However, we emphasize that if the size of each region is large, the adversary cannot infer the exact location such as the exact home address. Similar approaches can be seen in a state-of-the-art location privacy measure called *geo-indistinguishability* [4, 7, 42, 47]. Andrés *et al.* [4] considered privacy protection within a radius of 200m from the original location, whereas the size of each region in our experiments was about 400m  $\times$  450m (as described in Section 6.1). We can protect the exact location by setting the size of each region to be large enough, or setting all regions close to a user’s sensitive location to be sensitive.

There might also be a correlation between two attributes (e.g., income and marital status) in the US Census dataset. However, we combined the four category IDs into a total category ID for each user as described in Section 6.1. Thus, there is only “one” category ID for each user. Assuming that each user’s data is independent, there is no correlation between data. Therefore, we conclude that the sensitive data are strongly protected in both the Foursquare and US Census datasets in our experiments.

It should be noted, however, that the number of total category IDs increases exponentially with the number of attributes. Thus, when there are many attributes as in Figure 7, the estimation accuracy might be increased by obfuscating each attribute independently (rather than obfuscating a total ID) while considering the correlation among attributes. We also need to consider a correlation among “users” for some types of personal data (e.g., flu status). For rigorously protecting such correlated data, we should incorporate Pufferfish privacy [32, 48] into ULDP, as described in Section 1.

## 8 Conclusion

In this paper, we introduced the notion of ULDP that guarantees privacy equivalent to LDP for only sensitive data. We proposed ULDP mechanisms in both the common and personalized mechanism scenarios. We evaluated the utility of our mechanisms theoretically and demonstrated the effectiveness of our mechanisms through experiments.

## A Properties of ULDP

In this section, we describe the properties of ULDP (the immunity to post-processing and the compatibility with LDP) in more details.

## A.1 Post-processing

We first define a class of post-processing randomized algorithms that preserve data types:

**Definition 5** (Preservation of data types). Let  $\mathcal{Z}_P$  and  $\mathcal{Z}_I$  be sets of protected data, and  $\mathcal{Y}_I$  and  $\mathcal{Z}_I$  be sets of invertible data. Given a randomized algorithm  $\mathbf{Q}_1$  from  $\mathcal{Y}_P \cup \mathcal{Y}_I$  to  $\mathcal{Z}_P \cup \mathcal{Z}_I$ , we say that  $\mathbf{Q}_1$  *preserves data types* if it satisfies:

- for any  $z \in \mathcal{Z}_P$  and any  $y \in \mathcal{Y}_I$ ,  $\mathbf{Q}_1(z|y) = 0$ , and
- for any  $z \in \mathcal{Z}_I$ , there exists a  $y \in \mathcal{Y}_I$  such that  $\mathbf{Q}_1(z|y) > 0$  and  $\mathbf{Q}_1(z|y') = 0$  for any  $y' \neq y$ .

Then we show that ULDP is immune to the post-processing by this class of randomized algorithms.

**Proposition 11** (Post-processing). Let  $\epsilon \geq 0$ . Let  $\mathcal{Z}_P$  and  $\mathcal{Z}_I$  be sets of protected and invertible data respectively, and  $\mathcal{Z} = \mathcal{Z}_P \cup \mathcal{Z}_I$ . Let  $\mathbf{Q}_1$  be a randomized algorithm from  $\mathcal{Y}$  to  $\mathcal{Z}$  that preserves data types. If an obfuscation mechanism  $\mathbf{Q}_0$  from  $\mathcal{X}$  to  $\mathcal{Y}$  provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP then the composite function  $\mathbf{Q}_1 \circ \mathbf{Q}_0$  provides  $(\mathcal{X}_S, \mathcal{Z}_P, \epsilon)$ -ULDP.

For example, ULDP is immune to data cleaning operations (e.g., transforming values, merging disparate values) [33] as long as they are represented as  $\mathbf{Q}_1$  explained above.

Note that  $\mathbf{Q}_1$  needs to preserve data types for utility (i.e., to make all  $y \in \mathcal{Y}_I$  invertible, as in Definition 2, after post-processing), and the DP guarantee for  $y \in \mathcal{Y}_P$  is preserved by any post-processing algorithm. Specifically, by (5), for any randomized post-processing algorithm  $\mathbf{Q}_1^*$ , any obfuscated data  $z \in \mathcal{Z}$  obtained from  $y \in \mathcal{Y}_P$  via  $\mathbf{Q}_1^*$ , and any  $x, x' \in \mathcal{X}$ , we have:  $\Pr(z|x) \leq e^\epsilon \Pr(z|x')$ .

## A.2 Compatibility with LDP

Assume that data collectors A and B adopt a mechanism  $\mathbf{Q}_A$  providing  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon_A)$ -ULDP and a mechanism  $\mathbf{Q}_B$  providing  $\epsilon_B$ -LDP, respectively. In this case, all protected data in the data collector A can be combined with all obfuscated data in the data collector B (i.e., data integration) to perform data analysis under LDP. More specifically, assume that Alice transforms her sensitive personal data in  $\mathcal{X}_S$  into  $y_A \in \mathcal{Y}_P$  (resp.  $y_B \in \mathcal{Y}$ ) using  $\mathbf{Q}_A$  (resp.  $\mathbf{Q}_B$ ), and sends  $y_A$  (resp.  $y_B$ ) to the data collector A (resp. B) to request two different services (e.g., location check-in for A and point-of-interest search for B). Then, the composition  $(\mathbf{Q}_A, \mathbf{Q}_B)$  in parallel has the following property:

**Proposition 12** (Compatibility with LDP). If  $\mathbf{Q}_A$  and  $\mathbf{Q}_B$  respectively provide  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon_A)$ -ULDP and  $\epsilon_B$ -LDP, then for any  $x, x' \in \mathcal{X}$ ,  $y_A \in \mathcal{Y}_P$ , and  $y_B \in \mathcal{Y}$ , we have:

$$(\mathbf{Q}_A, \mathbf{Q}_B)(y_A, y_B|x) \leq e^{\epsilon_A + \epsilon_B} (\mathbf{Q}_A, \mathbf{Q}_B)(y_A, y_B|x').$$

Proposition 12 implies that Alice's sensitive personal data in  $\mathcal{X}_S$  is protected by  $(\epsilon_A + \epsilon_B)$ -LDP after the data integration.

## B Relationship between LDP, ULDP and OSLDP

In this section, we introduce the notion of OSLDP (One-sided LDP), a local model version of OSDP (One-sided DP) proposed in a preprint [17]:

**Definition 6** ( $(\mathcal{X}_S, \epsilon)$ -OSLDP). Given  $\mathcal{X}_S \subseteq \mathcal{X}$  and  $\epsilon \in \mathbb{R}_{\geq 0}$ , an obfuscation mechanism  $\mathbf{Q}$  from  $\mathcal{X}$  to  $\mathcal{Y}$  provides  $(\mathcal{X}_S, \epsilon)$ -OSLDP if for any  $x \in \mathcal{X}_S$ , any  $x' \in \mathcal{X}$  and any  $y \in \mathcal{Y}$ , we have

$$\mathbf{Q}(y|x) \leq e^\epsilon \mathbf{Q}(y|x'). \quad (23)$$

OSLDP is a special case of OSDP [17] that takes as input personal data of a single user. Unlike ULDP, OSLDP allows the transition probability  $\mathbf{Q}(y|x')$  from non-sensitive data  $x' \in \mathcal{X}_N$  to be very large for any  $y \in \mathcal{Y}$ , and hence does not provide  $\epsilon$ -LDP for  $\mathcal{Y}$  (whereas ULDP provides  $\epsilon$ -LDP for  $\mathcal{Y}_P$ ). Thus, OSLDP can be regarded as a ‘‘relaxation’’ of ULDP. In fact, the following proposition holds:

**Proposition 13.** If an obfuscation mechanism  $\mathbf{Q}$  provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP, then it also provides  $(\mathcal{X}_S, \epsilon)$ -OSLDP.

It should be noted that if an obfuscation mechanism provides  $\epsilon$ -LDP, then it obviously provides  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP, where  $\mathcal{Y}_P = \mathcal{Y}$ . Therefore,  $(\mathcal{X}_S, \mathcal{Y}_P, \epsilon)$ -ULDP is a privacy measure that lies between  $\epsilon$ -LDP and  $(\mathcal{X}_S, \epsilon)$ -OSLDP.

We use ULDP instead of OSLDP for the following two reasons. The first reason is that ULDP is compatible with LDP, and makes it possible to perform data integration and data analysis under LDP (Proposition 12). OSLDP does not have this property in general, since it allows the transition probability  $\mathbf{Q}(y|x')$  from non-sensitive data  $x' \in \mathcal{X}_N$  to be very large for any  $y \in \mathcal{Y}$ , as explained above.

The second reason, which is more important, is that *the utility of OSLDP is not better than that of ULDP*. Intuitively, it can be explained as follows. First, although  $\mathcal{Y}_P$  is not explicitly defined in OSLDP, we can define  $\mathcal{Y}_P$  in OSLDP as the *image* of  $\mathcal{X}_S$ , and  $\mathcal{Y}_I$  as  $\mathcal{Y}_I = \mathcal{Y} \setminus \mathcal{Y}_P$ , analogously to ULDP. Then, OSLDP differs from ULDP in the following two points: (i) it allows the transition probability  $\mathbf{Q}(y|x')$  from  $x' \in \mathcal{X}_N$  to  $y \in \mathcal{Y}_P$  to be very large (i.e., (5) may not satisfied); (ii) it allows  $y \in \mathcal{Y}_I$  to be non-invertible. (i.e., (4) may not satisfied). Regarding (i), it is important to note that the transition probability from  $x' \in \mathcal{X}_N$  to  $\mathcal{Y}_I$  decreases with increase in the transition probability from  $x'$  to  $\mathcal{Y}_P$ . Thus, (i) and (ii) only allow us to mix non-sensitive data with sensitive data or other non-sensitive data, and reduce the amount of output data  $y \in \mathcal{Y}_I$  that can be inverted to  $x \in \mathcal{X}_N$ .

Then, each OSLDP mechanism can be decomposed into a ULDP mechanism and a randomized post-processing that mixes non-sensitive data with sensitive data or other non-sensitive data. Note that this post-processing does not preserve data types (in Definition 5), and hence OSLDP does not have a compatibility with LDP as explained above. In

addition, although the post-processing might improve privacy for non-sensitive data, we would like to protect sensitive data in this paper and ULDP is sufficient for this purpose; i.e., it guarantees  $\epsilon$ -LDP for sensitive data.

Since the information is generally lost (never gained) by mixing data via the randomized post-processing, the utility of OSLDP is not better than that of ULDP (this holds for the information-theoretic utility such as mutual information and  $f$ -divergences [30] because of the data processing inequality [9, 13]; we also show this for the expected  $l_1$  and  $l_2$  losses at the end of Appendix B). Thus, it suffices to consider ULDP for our goal of designing obfuscation mechanisms that achieve high utility while providing LDP for sensitive data (as described in Section 1).

We now formalize our claim as follows:

**Proposition 14.** *Let  $\mathcal{M}_O$  be the class of all mechanisms from  $\mathcal{X}$  to  $\mathcal{Y}$  providing  $(\mathcal{X}_S, \epsilon)$ -OSLDP. For any  $\mathbf{Q}_O \in \mathcal{M}_O$ , there exist two sets  $\mathcal{Z}$  and  $\mathcal{Z}_P$ , a  $(\mathcal{X}_S, \mathcal{Z}_P, \epsilon)$ -ULDP mechanism  $\mathbf{Q}_U$  from  $\mathcal{X}$  to  $\mathcal{Z}$ , and a randomized algorithm  $\mathbf{Q}_R$  from  $\mathcal{Z}$  to  $\mathcal{Y}$  such that:*

$$\mathbf{Q}_O = \mathbf{Q}_R \circ \mathbf{Q}_U. \quad (24)$$

From Proposition 14, we show that the expected  $l_1$  and  $l_2$  losses of OSLDP are not better than those of ULDP as follows. For any OSLDP mechanism  $\mathbf{Q}_O \in \mathcal{M}_O$  and any estimation method  $\lambda_O$  from data in  $\mathcal{Y}$ , we can construct a ULDP mechanism  $\mathbf{Q}_U$  in (24) and an estimation method  $\lambda_U$  that perturbs data in  $\mathcal{Z}$  via  $\mathbf{Q}_R$  and then estimates a distribution from data in  $\mathcal{Y}$  via  $\lambda_O$ .  $\mathbf{Q}_U$  and  $\lambda_U$  provide the same expected  $l_1$  and  $l_2$  losses as  $\mathbf{Q}_O$  and  $\lambda_O$ , and there might also exist ULDP mechanisms and estimation methods from data in  $\mathcal{Z}$  that provide smaller expected  $l_1$  and  $l_2$  losses. Thus, the expected  $l_1$  and  $l_2$  losses of OSLDP are not better than those of ULDP.

## C L2 loss of the utility-optimized Mechanisms

### C.1 Utility Analysis

**uRR in the general case.** We first present the  $l_2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRR.

**Proposition 15** ( $l_2$  loss of the uRR). *The expected  $l_2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRR mechanism is given by:*

$$\begin{aligned} \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] &= \frac{2(e^\epsilon - 1)(|\mathcal{X}_S| - \mathbf{p}(\mathcal{X}_S)) + |\mathcal{X}_S|(|\mathcal{X}_S| - 1)}{n(e^\epsilon - 1)^2} \\ &\quad + \frac{1}{n} \left(1 - \sum_{x \in \mathcal{X}} \mathbf{p}(x)^2\right). \end{aligned} \quad (25)$$

When  $0 < \epsilon < \ln(|\mathcal{X}_N| + 1)$ , the  $l_2$  loss is maximized by the uniform distribution  $\mathbf{p}_{U_N}$  over  $\mathcal{X}_N$ .

**Proposition 16.** *For any  $0 < \epsilon < \ln(|\mathcal{X}_N| + 1)$ , (25) is maximized by  $\mathbf{p}_{U_N}$ :*

$$\begin{aligned} \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] &\leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \\ &= \frac{|\mathcal{X}_S|(|\mathcal{X}_S| + 2e^\epsilon - 3)}{n(e^\epsilon - 1)^2} + \frac{1}{n} \left(1 - \frac{1}{|\mathcal{X}_N|}\right). \end{aligned} \quad (26)$$

When  $\epsilon \geq \ln(|\mathcal{X}_N| + 1)$ , the  $l_2$  loss is maximized by a mixture of the uniform distribution  $\mathbf{p}_{U_S}$  over  $\mathcal{X}_S$  and the uniform distribution  $\mathbf{p}_{U_N}$  over  $\mathcal{X}_N$ .

**Proposition 17.** *For any  $\epsilon \geq \ln(|\mathcal{X}_N| + 1)$ , (25) is maximized by  $\mathbf{p}^*$  in (13):*

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}^*)] = \frac{(|\mathcal{X}_S| + e^\epsilon - 1)^2}{n(e^\epsilon - 1)^2} \left(1 - \frac{1}{|\mathcal{X}|}\right).$$

**uRR in the high privacy regime.** Consider the high privacy regime where  $\epsilon \approx 0$ . In this case,  $e^\epsilon - 1 \approx \epsilon$ . By using this approximation, the right-hand side of (26) in Proposition 16 can be simplified as follows:

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \frac{|\mathcal{X}_S|(|\mathcal{X}_S| - 1)}{n\epsilon^2}.$$

It is shown in [29] that the expected  $l_2$  loss of the  $\epsilon$ -RR is at most  $\frac{|\mathcal{X}|(|\mathcal{X}| - 1)}{n\epsilon^2}$  when  $\epsilon \approx 0$ . Thus, the expected  $l_2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRR is much smaller than that of the  $\epsilon$ -RR when  $|\mathcal{X}_S| \ll |\mathcal{X}|$ .

**uRR in the low privacy regime.** Consider the low privacy regime where  $\epsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|$ . By Proposition 17, the expected  $l_2^2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRR is given by:

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}^*)] \approx \frac{1}{n}.$$

It should be noted that the expected  $l_2$  loss of the non-private mechanism is at most  $\frac{1}{n} \left(1 - \frac{1}{|\mathcal{X}|}\right)$  [29], and that  $\frac{1}{n} \left(1 - \frac{1}{|\mathcal{X}|}\right) \approx \frac{1}{n}$  when  $|\mathcal{X}| \gg 1$ . Thus, when  $\epsilon = \ln|\mathcal{X}|$  and  $|\mathcal{X}_S| \ll |\mathcal{X}|$ , the  $(\mathcal{X}_S, \epsilon)$ -uRR achieves almost the same data utility as the non-private mechanism, whereas the expected  $l_1$  loss of the  $\epsilon$ -RR is four times larger than that of the non-private mechanism [29].

**Utility-optimized RAPPOR in the general case.** We then present the  $l_2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRAP.

**Proposition 18** ( $l_2$  loss of the uRAP). *Then the expected  $l_2$ -loss of the  $(\mathcal{X}_S, \epsilon)$ -uRAP mechanism is given by:*

$$\begin{aligned} \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] &= \frac{1}{n} \left(1 + \frac{(|\mathcal{X}_S| + 1)e^{\epsilon/2} - 1}{(e^{\epsilon/2} - 1)^2} - \frac{1}{e^{\epsilon/2} - 1} \mathbf{p}(\mathcal{X}_S) - \sum_{j=1}^{|\mathcal{X}|} \mathbf{p}(x_j)^2\right). \end{aligned} \quad (27)$$

For any  $0 < \epsilon < 2 \ln\left(\frac{|\mathcal{X}_N|}{2} + 1\right)$ , the  $l_2$  loss is maximized by the uniform distribution  $\mathbf{p}_{U_N}$  over  $\mathcal{X}_N$ .

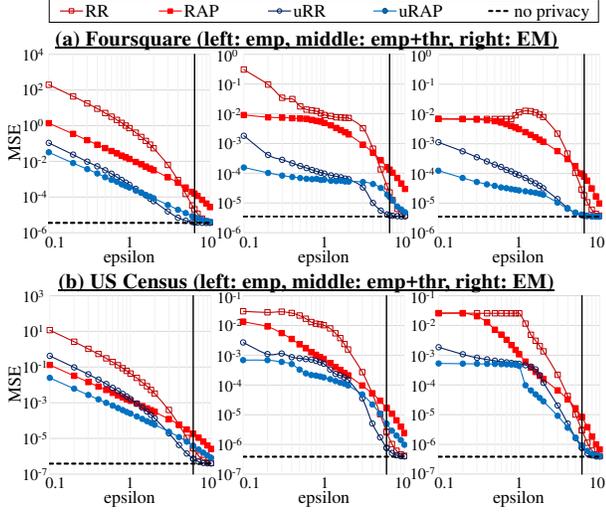

Figure 10:  $\epsilon$  vs. MSE (common-mechanism). A bold line parallel to the y-axis represents  $\epsilon = \ln |\mathcal{X}|$ .

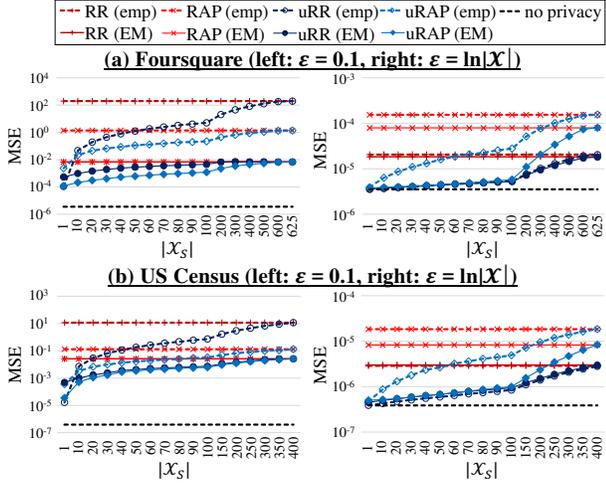

Figure 11:  $|\mathcal{X}_S|$  vs. MSE when  $\epsilon = 0.1$  or  $\ln |\mathcal{X}|$ .

**Proposition 19.** For any  $0 < \epsilon < 2 \ln(\frac{|\mathcal{X}_N|}{2} + 1)$ , the  $l_2$ -loss  $\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})]$  is maximized when  $\mathbf{p} = \mathbf{p}_{U_N}$ :

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] = \frac{1}{n} \left( 1 + \frac{(|\mathcal{X}_S|+1)e^{\epsilon/2}-1}{(e^{\epsilon/2}-1)^2} - \frac{1}{|\mathcal{X}_N|} \right). \quad (28)$$

**uRAP in the high privacy regime.** Consider the high privacy regime where  $\epsilon \approx 0$ . In this case,  $e^{\epsilon/2} - 1 \approx \epsilon/2$ . By using this approximation, the right-hand side of (28) in Proposition 19 can be simplified as:

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \frac{4|\mathcal{X}_S|}{n\epsilon^2}.$$

Thus, the expected  $l_2$  loss of the uRAP is at most  $\frac{4|\mathcal{X}_S|}{n\epsilon^2}$  in the high privacy regime. It is shown in [29] that the expected

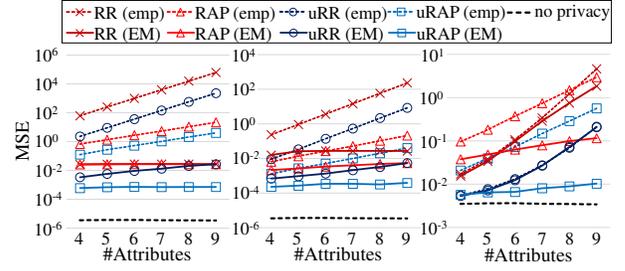

Figure 12: Number of attributes vs. MSE (US Census dataset; left:  $\epsilon = 0.1$ , middle:  $\epsilon = 1.0$ , right:  $\epsilon = 6.0$ ).

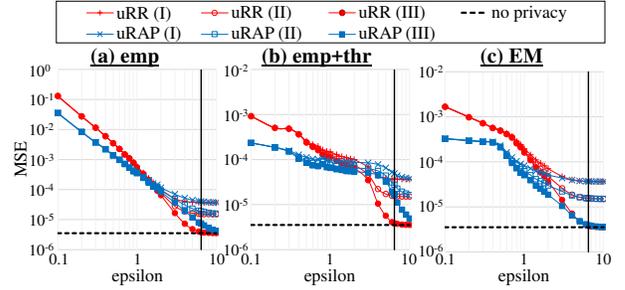

Figure 13:  $\epsilon$  vs. MSE (personalized-mechanism) (I): w/o knowledge, (II) POI distribution, (III) true distribution).

$l_2$  loss of the  $\epsilon$ -RAPPOR is at most  $\frac{4|\mathcal{X}|}{n\epsilon^2} (1 - \frac{1}{|\mathcal{X}|})$  when  $\epsilon \approx 0$ . Thus, the expected  $l_2$  loss of the  $(\mathcal{X}_S, \epsilon)$ -uRAP is much smaller than that of the  $\epsilon$ -RAPPOR when  $|\mathcal{X}_S| \ll |\mathcal{X}|$ .

Note that the expected  $l_2$  loss of the uRAP in the worst case can also be expressed as  $\Theta(\frac{|\mathcal{X}_S|}{n\epsilon^2})$  in this case. As described in Section 3.2, this is “order” optimal among all ULDP mechanisms.

**uRAP in the low privacy regime.** If  $\epsilon = \ln |\mathcal{X}|$  and  $|\mathcal{X}_S| \ll \sqrt{|\mathcal{X}|}$ , the right-hand side of (28) in Proposition 19 can be simplified as follows:

$$\mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p})] \leq \mathbb{E}[l_2^2(\hat{\mathbf{p}}, \mathbf{p}_{U_N})] \approx \frac{1}{n}. \quad (29)$$

Note that the expected  $l_2$  loss of the non-private mechanism is at most  $\frac{1}{n}(1 - \frac{1}{|\mathcal{X}|})$  [29], and that  $\frac{1}{n}(1 - \frac{1}{|\mathcal{X}|}) \approx \frac{1}{n}$  when  $|\mathcal{X}| \gg 1$ . Thus, when  $\epsilon = \ln |\mathcal{X}|$  and  $|\mathcal{X}_S| \ll \sqrt{|\mathcal{X}|}$ , the  $(\mathcal{X}_S, \epsilon)$ -uRAP achieves almost the same data utility as the non-private mechanism, whereas the expected  $l_2$  loss of the  $\epsilon$ -RAPPOR is  $\sqrt{|\mathcal{X}|}$  times larger than that of the non-private mechanism [29].

## C.2 Experimental Results of the MSE

Figures 10, 11, 12, and 13 show the results of the MSE corresponding to Figures 5, 6, 7, and 8, respectively. It can be seen that a tendency similar to the results of the TV is obtained for the results of the MSE, meaning that our proposed methods are effective in terms of both the  $l_1$  and  $l_2$  losses.

# Evaluating Differentially Private Machine Learning in Practice

Bargav Jayaraman and David Evans  
*Department of Computer Science*  
*University of Virginia*

## Abstract

Differential privacy is a strong notion for privacy that can be used to prove formal guarantees, in terms of a privacy budget,  $\epsilon$ , about how much information is leaked by a mechanism. When used in privacy-preserving machine learning, the goal is typically to limit what can be inferred from the model about individual training records. However, the calibration of the privacy budget is not well understood. Implementations of privacy-preserving machine learning often select large values of  $\epsilon$  in order to get acceptable utility of the model, with little understanding of the impact of such choices on meaningful privacy. Moreover, in scenarios where iterative learning procedures are used, relaxed definitions of differential privacy are often used which appear to reduce the needed privacy budget but present poorly understood trade-offs between privacy and utility. In this paper, we quantify the impact of these choices on privacy in experiments with logistic regression and neural network models. Our main finding is that there is no way to obtain privacy for free—relaxed definitions of differential privacy that reduce the amount of noise needed to improve utility also increase the measured privacy leakage. Current mechanisms for differentially private machine learning rarely offer acceptable utility-privacy trade-offs for complex learning tasks: settings that provide limited accuracy loss provide little effective privacy, and settings that provide strong privacy result in useless models.

## 1 Introduction

Differential privacy has become a de facto privacy standard, and nearly all works on privacy-preserving machine learning use some form of differential privacy. These works include designs for differentially private versions of prominent machine learning algorithms including empirical risk minimization [11, 12] and deep neural networks [1, 60].

While many methods for achieving differential privacy have been proposed, it is not well understood how to use these methods in practice. In particular, there is little concrete

guidance on how to choose an appropriate privacy budget  $\epsilon$ , and limited understanding of how variants of the differential privacy definition impact privacy in practice. As a result, privacy-preserving machine learning implementations tend to choose arbitrary values for  $\epsilon$  as needed to achieve acceptable model utility. For instance, the implementation of Shokri and Shmatikov [60] requires  $\epsilon$  proportional to the size of the target deep learning model, which could be in the order of few millions. Setting  $\epsilon$  to such arbitrarily large values severely undermines privacy, although there is no consensus on a hard threshold value for  $\epsilon$  above which formal guarantees differential privacy provides become meaningless in practice.

One proposed way to improve utility for a given privacy budget is to relax the definition of differential privacy. Several relaxed definitions of differential privacy have been proposed that are shown to provide better utility even for small  $\epsilon$  values [9, 18, 49]. How much privacy leakage these relaxations allow in adversarial scenarios, however, is not well understood. We shed light on this question by evaluating the relaxed differential privacy notions for different choices of  $\epsilon$  values and empirically measuring privacy leakage, including how many individual training records are exposed by membership inference attacks on different models.

**Contributions.** Our main contribution is the evaluation of differential privacy mechanisms for machine learning to understand the impact of different choices of  $\epsilon$  and different relaxations of differential privacy on both utility and privacy. We focus our evaluation on gradient perturbation mechanisms, which are applicable to a wide class of machine learning algorithms including empirical risk minimization (ERM) algorithms such as logistic regression and deep learning (Section 2.2). Our experiments cover three popular differential privacy relaxations: differential privacy with advanced composition, zero-concentrated differential privacy [9], and Rényi differential privacy [49] (described in Section 2.1). These variations allow for tighter analysis of cumulative privacy loss, thereby reducing the noise that must be added in the training process. We evaluate the concrete privacy loss of these variations using

membership inference attacks [61, 74] and attribute inference attacks [74] (Section 3). While the model utility increases with the privacy budget, increasing the privacy budget also increases the success rate of inference attacks. Hence, we aim to find the range of values of  $\epsilon$  which achieves a balance between utility and privacy, and also to evaluate the concrete privacy leakage in terms of the number of individual members of the training data at risk of exposure. We study both logistic regression and neural network models, on two multi-class classification data sets. Our key findings (Section 4) quantify the practical risks of using different differential privacy notions across a range of privacy budgets.

**Related work.** Orthogonal to our work, Ding et al. [13] and Hay et al. [26] evaluate the existing differential privacy implementations for the *correctness* of implementation. Whereas, we assume correct implementations and aim to evaluate the impact of the privacy budget and choice of differential privacy variant. While Carlini et al. [10] also explore the effectiveness of differential privacy against attacks, they do not explicitly answer what values of  $\epsilon$  should be used nor do they evaluate the privacy leakage of the relaxed definitions. Li et al. [42] raise concerns about relaxing the differential privacy notion in order to achieve better overall utility, but do not evaluate the leakage. We perform a thorough evaluation of the differential privacy variations and quantify their leakage for different privacy budgets. The work of Rahman et al. [58] is most closely related to our work. It evaluates differential privacy implementations against membership inference attacks, but does not evaluate the privacy leakage of relaxed variants of differential privacy. Ours is the first work to experimentally measure the excess privacy leakage due to the relaxed notions of differential privacy.

## 2 Differential Privacy for Machine Learning

Next, we review the definition of differential privacy and its relaxed variants. Section 2.2 surveys mechanisms for achieving differentially private machine learning. Section 2.3 summarizes applications of differential privacy to machine learning and surveys implementations' choices about privacy budgets.

### 2.1 Background on Differential Privacy

Differential privacy is a probabilistic privacy mechanism that provides an information-theoretic security guarantee. Dwork [16] gives the following definition:

**Definition 2.1** ( $(\epsilon, \delta)$ -Differential Privacy). Given two neighboring data sets  $D$  and  $D'$  differing by one record, a mechanism  $\mathcal{M}$  preserves  $(\epsilon, \delta)$ -differential privacy if

$$Pr[\mathcal{M}(D) \in S] \leq Pr[\mathcal{M}(D') \in S] \times e^\epsilon + \delta$$

where  $\epsilon$  is the privacy budget and  $\delta$  is the failure probability.

When  $\delta = 0$  we achieve a strictly stronger notion of  $\epsilon$ -differential privacy.

The quantity

$$\ln \frac{Pr[\mathcal{M}(D) \in S]}{Pr[\mathcal{M}(D') \in S]}$$

is called the *privacy loss*.

One way to achieve  $\epsilon$ -DP and  $(\epsilon, \delta)$ -DP is to add noise sampled from Laplace and Gaussian distributions respectively, where the noise is proportional to the *sensitivity* of the mechanism  $\mathcal{M}$ :

**Definition 2.2** (Sensitivity). For two neighboring data sets  $D$  and  $D'$  differing by one record, the sensitivity of  $\mathcal{M}$  is the maximum change in the output of  $\mathcal{M}$  over all possible inputs:

$$\Delta \mathcal{M} = \max_{D, D', \|D-D'\|_1=1} \|\mathcal{M}(D) - \mathcal{M}(D')\|$$

where  $\|\cdot\|$  is a norm of the vector. Throughout this paper we assume  $\ell_2$ -sensitivity which considers the upper bound on the  $\ell_2$ -norm of  $\mathcal{M}(D) - \mathcal{M}(D')$ .

**Composition.** Differential privacy satisfies a simple composition property: when two mechanisms with privacy budgets  $\epsilon_1$  and  $\epsilon_2$  are performed on the same data, together they consume a privacy budget of  $\epsilon_1 + \epsilon_2$ . Thus, composing multiple differentially private mechanisms leads to a linear increase in the privacy budget (or corresponding increases in noise to maintain a fixed  $\epsilon$  total privacy budget).

**Relaxed Definitions.** Dwork [17] showed that this linear composition bound on  $\epsilon$  can be reduced at the cost of *slightly* increasing the failure probability  $\delta$ . In essence, this relaxation considers the linear composition of *expected* privacy loss of mechanisms which can be converted to a cumulative privacy budget  $\epsilon$  with high probability bound. Dwork defines this as the *advanced composition theorem*, and proves that it applies to any differentially private mechanism.

Three commonly-used subsequent relaxed versions of differential privacy are Concentrated Differential Privacy [18], Zero Concentrated Differential Privacy [9], and Rényi Differential Privacy [49]. All of these achieve tighter analysis of cumulative privacy loss by taking advantage of the fact that the privacy loss random variable is strictly centered around an *expected* privacy loss. The cumulative privacy budget obtained from these analyses bounds the worst case privacy loss of the composition of mechanisms with all but  $\delta$  failure probability. This reduces the noise required and hence improves utility over multiple compositions. However, it is important to consider the actual impact these relaxations have on the privacy leakage, which is a main focus of this paper.

Dwork et al. [18] note that the privacy loss of a differentially private mechanism follows a sub-Gaussian distribution. In other words, the privacy loss is strictly distributed around the expected privacy loss and the spread is controlled by the variance of the sub-Gaussian distribution. Multiple compositions of differentially private mechanisms thus result in the

|                                                 | Advanced Comp.                                                                | Concentrated (CDP)                                                              | Zero-Concentrated (zCDP)                                          | Rényi (RDP)                                                     |

Table 1: Comparison of Different Variations of Differential Privacy

Advanced composition is an implicit property of DP and hence there is no conversion to and from DP.

<sup>†</sup>. Derived indirectly via zCDP. <sup>‡</sup>. When  $\log(1/\delta) \geq \epsilon^2 k$ .

aggregation of corresponding mean and variance values of the individual sub-Gaussian distributions. This can be converted to a cumulative privacy budget similar to the advanced composition theorem, which in turn reduces the noise that must be added to the individual mechanisms. The authors call this *concentrated differential privacy* [18]:

**Definition 2.3** (Concentrated Differential Privacy (CDP)). A randomized algorithm  $\mathcal{M}$  is  $(\mu, \tau)$ -concentrated differentially private if, for all pairs of adjacent data sets  $D$  and  $D'$ ,

$$\mathcal{D}_{subG}(\mathcal{M}(D) \parallel \mathcal{M}(D')) \leq (\mu, \tau)$$

where the sub-Gaussian divergence,  $\mathcal{D}_{subG}$ , is defined such that the expected privacy loss is bounded by  $\mu$  and after subtracting  $\mu$ , the resulting centered sub-Gaussian distribution has standard deviation  $\tau$ . Any  $\epsilon$ -DP algorithm satisfies  $(\epsilon \cdot (e^\epsilon - 1)/2, \epsilon)$ -CDP, however the converse is not true.

A variation on CDP, *zero-concentrated differential privacy* (zCDP) [9] uses Rényi divergence as a different method to show that the privacy loss random variable follows a sub-Gaussian distribution.

**Definition 2.4** (Zero-Concentrated Differential Privacy (zCDP)). A randomized mechanism  $\mathcal{M}$  is  $(\xi, \rho)$ -zero-concentrated differentially private if, for all neighbouring data sets  $D$  and  $D'$  and all  $\alpha \in (1, \infty)$ ,

$$\mathcal{D}_\alpha(\mathcal{M}(D) \parallel \mathcal{M}(D')) \leq \xi + \rho\alpha$$

where  $\mathcal{D}_\alpha(\mathcal{M}(D) \parallel \mathcal{M}(D'))$  is the  $\alpha$ -Rényi divergence between the distribution of  $\mathcal{M}(D)$  and the distribution of  $\mathcal{M}(D')$ .

$\mathcal{D}_\alpha$  also gives the  $\alpha$ -th moment of the privacy loss random variable. For example,  $\mathcal{D}_1$  gives the first order moment which is the mean or the expected privacy loss, and  $\mathcal{D}_2$  gives the second order moment or the variance of privacy loss. There is a direct relation between DP and zCDP. If  $\mathcal{M}$  satisfies  $\epsilon$ -DP, then it also satisfies  $(\frac{1}{2}\epsilon^2)$ -zCDP. Furthermore, if  $\mathcal{M}$  provides  $\rho$ -zCDP, it is  $(\rho + 2 \sqrt{\rho \log(1/\delta)}, \delta)$ -DP for any  $\delta > 0$ .

The Rényi divergence allows zCDP to be mapped back to DP, which is not the case for CDP. However, Bun and

Steinke [9] give a relationship between CDP and zCDP, which allows an indirect mapping from CDP to DP (Table 1).

The use of Rényi divergence as a metric to bound the privacy loss leads to the formulation of a more generic notion of Rényi differential privacy that is applicable to any individual moment of privacy loss random variable:

**Definition 2.5** (Rényi Differential Privacy (RDP) [49]). A randomized mechanism  $\mathcal{M}$  is said to have  $\epsilon$ -Rényi differential privacy of order  $\alpha$  (which can be abbreviated as  $(\alpha, \epsilon)$ -RDP), if for any adjacent data sets  $D, D'$  it holds that

$$\mathcal{D}_\alpha(\mathcal{M}(D) \parallel \mathcal{M}(D')) \leq \epsilon.$$

The main difference is that CDP and zCDP linearly bound *all* positive moments of privacy loss, whereas RDP bounds one moment at a time, which allows for a more accurate numerical analysis of privacy loss [49]. If  $\mathcal{M}$  is an  $(\alpha, \epsilon)$ -RDP mechanism, it also satisfies  $(\epsilon + \frac{\log 1/\delta}{\alpha - 1}, \delta)$ -DP for any  $0 < \delta < 1$ .

Table 1 compares the relaxed variations of differential privacy. For all the variations, the privacy budget grows sub-linearly with the number of compositions  $k$ .

**Moments Accountant.** Motivated by relaxations of differential privacy, Abadi et al. [1] propose the *moments accountant* (MA) mechanism for bounding the cumulative privacy loss of differentially private algorithms. The moments accountant keeps track of a bound on the moments of the privacy loss random variable during composition. Though the authors do not formalize this as a relaxed definition, their definition of the moments bound is analogous to the Rényi divergence [49]. Thus, the moments accountant can be considered as an instantiation of Rényi differential privacy. The moments accountant is widely used for differentially private deep learning due to its practical implementation in the TensorFlow Privacy library [2] (see Section 2.3 and Table 4).

## 2.2 Differential Privacy Methods for ML

This section summarizes methods for modifying machine learning algorithms to satisfy differential privacy. First, we

**Data:** Training data set  $(X, y)$   
**Result:** Model parameters  $\theta$   
 $\theta \leftarrow \text{Init}(0)$   
**#1. Add noise here: objective perturbation**  
 $J(\theta) = \frac{1}{n} \sum_{i=1}^n \ell(\theta, X_i, y_i) + \lambda R(\theta) + \beta$   
**for epoch in epochs do**  
  | **#2. Add noise here: gradient perturbation**  
  |  $\theta = \theta - \eta(\nabla J(\theta) + \beta)$   
**end**  
**#3. Add noise here: output perturbation**  
**return  $\theta + \beta$**

**Algorithm 1:** Privacy noise mechanisms.

review convex optimization problems, such as empirical risk minimization (ERM) algorithms, and show several methods for achieving differential privacy during the learning process. Next, we discuss methods that can be applied to non-convex optimization problems, including deep learning.

**ERM.** Given a training data set  $(X, y)$ , where  $X$  is a feature matrix and  $y$  is the vector of class labels, an ERM algorithm aims to reduce the convex objective function of the form,

$$J(\theta) = \frac{1}{n} \sum_{i=1}^n \ell(\theta, X_i, y_i) + \lambda R(\theta),$$

where  $\ell(\cdot)$  is a convex loss function (such as mean square error (MSE) or cross-entropy loss) that measures the training loss for a given  $\theta$ , and  $R(\cdot)$  is a regularization function. Commonly used regularization functions include  $\ell_1$  penalty, which makes the vector  $\theta$  sparse, and  $\ell_2$  penalty, which shrinks the values of  $\theta$  vector.

The goal of the algorithm is to find the optimal  $\theta^*$  that minimizes the objective function:  $\theta^* = \arg \min_{\theta} J(\theta)$ . While many first order [14, 37, 57, 76] and second order [40, 43] methods exist to solve this minimization problem, the most basic procedure is gradient descent where we iteratively calculate the gradient of  $J(\theta)$  with respect to  $\theta$  and update  $\theta$  with the gradient information. This process is repeated until  $J(\theta) \approx 0$  or some other termination condition is met.

There are three obvious candidates for where to add privacy-preserving noise during this training process, demarcated in Algorithm 1. First, we could add noise to the objective function  $J(\theta)$ , which gives us the *objective perturbation mechanism* (#1 in Algorithm 1). Second, we could add noise to the gradients at each iteration, which gives us the *gradient perturbation mechanism* (#2). Finally, we can add noise to  $\theta^*$  obtained after the training, which gives us the *output perturbation mechanism* (#3). While there are other methods of achieving differential privacy such as input perturbation [15], sample-aggregate framework [51], exponential mechanism [48] and teacher ensemble framework [52]. We focus our experimental analysis on gradient perturbation since it is applicable to all

machine learning algorithms in general and is widely used for deep learning with differential privacy.

The amount of noise that must be added depends on the sensitivity of the machine learning algorithm. For instance, consider logistic regression with  $\ell_2$  regularization penalty. The objective function is of the form:

$$J(\theta) = \frac{1}{n} \sum_{i=1}^n \log(1 + e^{-X_i^T \theta y_i}) + \frac{\lambda}{2} \|\theta\|_2^2$$

Assume that the training features are bounded,  $\|X_i\|_2 \leq 1$  and  $y_i \in \{-1, 1\}$ . Chaudhuri et al. [12] prove that for this setting, objective perturbation requires sampling noise in the scale of  $\frac{2}{n\epsilon}$ , and output perturbation requires sampling noise in the scale of  $\frac{2}{n\lambda\epsilon}$ . The gradient of the objective function is:

$$\nabla J(\theta) = \frac{1}{n} \sum_{i=1}^n \frac{-X_i y_i}{1 + e^{X_i^T \theta y_i}} + \lambda \theta$$

which has a sensitivity of  $\frac{2}{n}$ . Thus, gradient perturbation requires sampling noise in the scale of  $\frac{2}{n\epsilon}$  at each iteration.

**Deep learning.** Deep learning follows the same learning procedure as in Algorithm 1, but the objective function is non-convex. As a result, the sensitivity analysis methods of Chaudhuri et al. [12] do not hold as they require a strong convexity assumption. Hence, their output and objective perturbation methods are not applicable. An alternative approach is to replace the non-convex function with a convex polynomial function [55, 56], and then use the standard objective perturbation. This approach requires carefully designing convex polynomial functions that can approximate the non-convexity, which can still limit the model's learning capacity. Moreover, it would require a considerable change in the existing machine learning infrastructure.

A simpler and more popular approach is to add noise to the gradients. Application of gradient perturbation requires a bound on the gradient norm. Since the gradient norm can be unbounded in deep learning, gradient perturbation can be used after manually clipping the gradients at each iteration. As noted by Abadi et al. [1], norm clipping provides a sensitivity bound on the gradients which is required for generating noise in gradient perturbation.

## 2.3 Implementing Differential Privacy

This section surveys how differential privacy has been used in machine learning applications, with a particular focus on the compromises implementers have made to obtain satisfactory utility. While the effective privacy provided by differential privacy mechanisms depends crucially on the choice of privacy budget  $\epsilon$ , setting the  $\epsilon$  value is discretionary and higher privacy budgets provide better utility.

Some of the early data analytics works on frequent pattern mining [7, 41], decision trees [21], private record linkage [30]

|                        | Perturbation         | Data Set           | $n$     | $d$ | $\epsilon$ |

Table 2: Simple ERM Methods which achieve High Utility with Low Privacy Budget.

<sup>†</sup> While MNIST is normally a 10-class task, Song et al. [63] use this for ‘1 vs rest’ binary classification.

and recommender systems [47] were able to achieve both high utility and privacy with  $\epsilon$  settings close to 1. These methods rely on finding frequency counts as a sub-routine, and hence provide  $\epsilon$ -differential privacy by either perturbing the counts using Laplace noise or by releasing the top frequency counts using the exponential mechanism [48]. Machine learning, on the other hand, performs much more complex data analysis, and hence requires higher privacy budgets to maintain utility.

Next, we cover simple binary classification works that use small privacy budgets ( $\epsilon \leq 1$ ). Then we survey complex classification tasks which seem to require large privacy budgets. Finally, we summarize recent works that aim to perform complex tasks with low privacy budgets by using relaxed definitions of differential privacy.

**Binary classification.** The first practical implementation of a private machine learning algorithm was proposed by Chaudhuri and Monteleoni [11]. They provide a novel sensitivity analysis under strong convexity constraints, allowing them to use output and objective perturbation for binary logistic regression. Chaudhuri et al. [12] subsequently generalized this method for ERM algorithms. This sensitivity analysis method has since been used by many works for binary classification tasks under different learning settings (listed in Table 2). While these applications can be implemented with low privacy budgets ( $\epsilon \leq 1$ ), they only perform learning in restricted settings such as learning with low dimensional data, smooth objective functions and strong convexity assumptions, and are only applicable to simple binary classification tasks.

There has also been considerable progress in general-

izing privacy-preserving machine learning to more complex scenarios such as learning in high-dimensional settings [33, 34, 64], learning without strong convexity assumptions [65], or relaxing the assumptions on data and objective functions [62, 68, 77]. However, these advances are mainly of theoretical interest and only a few works provide implementations [33, 34].

**Complex learning tasks.** All of the above works are limited to convex learning problems with binary classification tasks. Adopting their approaches to more complex learning tasks requires higher privacy budgets (see Table 3). For instance, the online version of ERM as considered by Jain et al. [32] requires  $\epsilon$  as high as 10 to achieve acceptable utility. From the definition of differential privacy, we can see that  $\Pr[\mathcal{M}(D) \in S] \leq e^{10} \times \Pr[\mathcal{M}(D') \in S]$ . In other words, even if the model’s output probability is 0.0001 on a data set  $D'$  that doesn’t contain the target record, the model’s output probability can be as high as 0.9999 on a neighboring data set  $D$  that contains the record. This allows an adversary to infer the presence or absence of a target record from the training data with high confidence. Adopting these binary classification methods for multi-class classification tasks requires even higher  $\epsilon$  values. As noted by Wu et al. [70], it would require training a separate binary classifier for each class. Finally, high privacy budgets are required for non-convex learning algorithms, such as deep learning [60, 79]. Since the output and objective perturbation methods of Chaudhuri et al. [12] are not applicable to non-convex settings, implementations of differentially private deep learning rely on gradient pertur-

Table 4: Gradient Perturbation based Classification Methods using Relaxed Notion of Differential Privacy

bation in their iterative learning procedure. These methods do not scale to large numbers of training iterations due to the composition theorem of differential privacy which causes the privacy budget to accumulate across iterations. The only exceptions are the works of Phan et al. [55, 56] that replace the non-linear functions in deep learning with polynomial approximations and then apply objective perturbation. With this transformation, they achieve high model utility for  $\epsilon = 1$ , as shown in Table 3. However, we note that this polynomial approximation is a non-standard approach to deep learning which can limit the model’s learning capacity, and thereby diminish the model’s accuracy for complex tasks.

**Machine learning with relaxed DP definitions.** To avoid the stringent composition property of differential privacy, several proposed privacy-preserving deep learning methods adopt the relaxed privacy definitions introduced in Section 2.1. Table 4 lists works that use gradient perturbation with relaxed notions of differential to reduce the overall privacy budget during iterative learning. The utility benefit of using relaxation is evident from the fact that the privacy budget for deep learning algorithms is significantly less than the prior works of Shokri and Shmatikov [60] and Zhao et al. [79] which do not use any relaxation.

While these *relaxed* definitions of differential privacy make complex iterative learning feasible for reasonable  $\epsilon$  values, they might lead to more privacy leakage in practice. The main goal of our study is to evaluate the impact of implementation decisions regarding the privacy budget and relaxed definitions of differential privacy on the concrete privacy leakage that can be exploited by an attacker in practice. We do this by experimenting with various inference attacks, described in the next section.

### 3 Inference Attacks on Machine Learning

This section surveys the two types of inference attacks, *membership inference* (Section 3.1) and *attribute inference* (Section 3.2), and explains why they are useful metrics for evaluating privacy leakage. Section 3.3 briefly summarizes other relevant privacy attacks on machine learning.

#### 3.1 Membership Inference

The aim of a *membership inference* attack is to infer whether or not a given record is present in the training set. Membership inference attacks can uncover highly sensitive information from training data. An early membership inference attack showed that it is possible to identify individuals contributing DNA to studies that analyze a mixture of DNA from many individuals, using a statistical distance measure to determine if a known individual is in the mixture [27].

Membership inference attacks can either be completely black-box where an attacker only has query access to the

target model [61], or can assume that the attacker has full white-box access to the target model, along with some auxiliary information [74]. The first membership inference attack on machine learning was proposed by Shokri et al. [61]. They consider an attacker who can query the target model in a black-box way to obtain confidence scores for the queried input. The attacker tries to exploit the confidence score to determine whether the query input was present in the training data. Their attack method involves first training shadow models on a labelled data set, which can be generated either via black-box queries to the target model or through assumptions about the underlying distribution of training set. The attacker then trains an attack model using the shadow models to distinguish whether or not an input record is in the shadow training set. Finally, the attacker makes API calls to the target model to obtain confidence scores for each given input record and infers whether or not the input was part of the target model’s training set. The inference model distinguishes the target model’s predictions for inputs that are in its training set from those it did not train on. The key assumption is that the confidence score of the target model is higher for the training instances than it would be for arbitrary instances not present in the training set. This can be due to the generalization gap, which is prominent in models that overfit to training data.

A more targeted approach was proposed by Long et al. [44] where the shadow models are trained with and without a targeted input record  $t$ . At inference time, the attacker can check if the input record  $t$  was present in the training set of target model. This approach tests the membership of a specific record more accurately than Shokri et al.’s approach [61]. Recently, Salem et al. [59] proposed more generic membership inference attacks by relaxing the requirements of Shokri et al. [61]. In particular, requirements on the number of shadow models, knowledge of training data distribution and the target model architecture can be relaxed without substantially degrading the effectiveness of the attack.

Yeom et al. [74] recently proposed a more computationally efficient membership inference attack when the attacker has access to the target model and knows the average training loss of the model. To test the membership of an input record, the attacker evaluates the loss of the model on the input record and then classifies it as a member if the loss is smaller than the average training loss.

**Connection to Differential Privacy.** Differential privacy, by definition, aims to obfuscate the presence or absence of a record in the data set. On the other hand, membership inference attacks aim to identify the presence or absence of a record in the data set. Thus, intuitively these two notions counteract each other. Li et al. [42] point to this fact and provide a direct relationship between differential privacy and membership inference attacks. Backes et al. [4] studied membership inference attacks on microRNA studies and showed that differential privacy can reduce the success of membership

inference attacks, but at the cost of utility.

Yeom et al. [74] formally define a membership inference attack as an adversarial game where a data element is selected from the distribution, which is randomly either included in the training set or not. Then, an adversary with access to the trained model attempts to determine if that element was used in training. The *membership advantage* is defined as the difference between the adversary's true and false positive rates for this game. The authors prove that if the learning algorithm satisfies  $\epsilon$ -differential privacy, then the adversary's advantage is bounded by  $e^\epsilon - 1$ . Hence, it is natural to use membership inference attacks as a metric to evaluate the privacy leakage of differentially private algorithms.

### 3.2 Attribute Inference

The aim of an *attribute inference* attack (also called *model inversion*) is to learn hidden sensitive attributes of a test input given at least API access to the model and information about the non-sensitive attributes. Fredrikson et al. [20] formalize this attack in terms of maximizing the posterior probability estimate of the sensitive attribute. More concretely, for a test record  $x$  where the attacker knows the values of its non-sensitive attributes  $x_1, x_2, \dots, x_{d-1}$  and all the prior probabilities of the attributes, the attacker obtains the output of the model,  $f(x)$ , and attempts to recover the value of the sensitive attribute  $x_d$ . The attacker essentially searches for the value of  $x_d$  that maximizes the posterior probability  $P(x_d | x_1, x_2, \dots, x_{d-1}, f(x))$ . The success of this attack is based on the correlation between the sensitive attribute,  $x_d$ , and the model output,  $f(x)$ .

Yeom et al. [74] also propose an attribute inference attack using the same principle they use for their membership inference attack. The attacker evaluates the model's empirical loss on the input instance for different values of the sensitive attribute, and reports the value which has the maximum posterior probability of achieving the empirical loss. The authors define the *attribute advantage* similarly to their definition of membership advantage for membership inference.

Fredrikson et al. [20] demonstrated attribute inference attacks that could identify genetic markers based on warfarin dosage output by a model with just black-box access to model API.<sup>1</sup> With additional access to confidence scores of the model (noted as white-box information by Wu et al. [69]), more complex tasks have been performed, such as recovering faces from the training data [19].

**Connection to Differential Privacy.** Differential privacy is mainly tailored to obfuscate the presence or absence of a record in a data set, by limiting the effect of any single record on the output of differential private model trained on the data

<sup>1</sup>This application has stirred some controversy based on the warfarin dosage output by the model itself being sensitive information correlated to the sensitive genetic markers, hence the assumption on attacker's prior knowledge of warfarin dosage is somewhat unrealistic [46].

set. Logically this definition also extends to attributes or features of a record. In other words, by adding sufficient differential privacy noise, we should be able to limit the effect of a sensitive attribute on the model's output. This relationship between records and attributes is discussed by Yeom et al. [74]. Hence, we include these attacks in our experiments.

### 3.3 Other Attacks on Machine Learning

Apart from inference attacks, many other attacks have been proposed in the literature which try to infer specific information from the target model. The most relevant are memorization attacks, which try to exploit the ability of high capacity models to memorize certain sensitive patterns in the training data [10]. These attacks have been found to be thwarted by differential privacy mechanisms with very little noise ( $\epsilon = 10^9$ ) [10].

Other privacy attacks include model stealing, hyperparameter stealing, and property inference attacks. A model stealing attack aims to recover the model parameters via black-box access to the target model, either by adversarial learning [45] or by equation solving attacks [66]. Hyperparameter stealing attacks try to recover the underlying hyperparameters used during the model training, such as regularization coefficient [67] or model architecture [72]. These hyperparameters are intellectual property of commercial organizations that deploy machine learning models as a service, and hence these attacks are regarded as a threat to valuable intellectual property. A property inference attack tries to infer whether the training data set has a specific property, given a white-box access to the trained model. For instance, given access to a speech recognition model, an attacker can infer if the training data set contains speakers with a certain accent. Here the attacker can use the shadow training method of Shokri et al. [61] for distinguishing the presence and absence of a target property. These attacks have been performed on HMM and SVM models [3] and neural networks [22].

Though all these attacks may leak sensitive information about the target model or training data, the information leaked tends to be application-specific and is not clearly defined in a general way. For example, a property inference attack leaks some statistical property of the training data that is surprising to the model developer. Of course, the overall purpose of the model is to learn statistical properties from the training data. So, there is no general definition of a property inference attack without a prescriptive decision about which statistical properties of the training data should be captured by the model and which are sensitive to leak. In addition, the attacks mentioned in this section do not closely follow the threat model of differential privacy. Thus, we only consider inference attacks for our experimental evaluation.

In addition to these attacks, several poisoning and adversarial training attacks have been proposed [5, 50, 71, 73] which require an adversary that can actively interfere with the model

training process. We consider these out of scope for this paper, and assume a clean training process not under the control of the adversary.

## 4 Empirical Evaluation

To quantify the privacy leakage of the differentially private implementations for machine learning, we conduct experiments to measure how much an adversary can infer from a model. As motivated in Section 3, we measure privacy leakage using membership and attribute inference in our experiments. Note, however, that the conclusions we can draw from experiments like this are limited to showing a lower bound on the information leakage since they are measuring the effectiveness of a particular attack. Such experimental results cannot be used to make strong claims about what the best possible attack would be able to infer, especially in cases where an adversary has auxiliary information to help guide the attack. Evidence from our experiments, however, does provide clear evidence for when implemented privacy protections do not appear to provide sufficient privacy.

### 4.1 Experimental Setup

We evaluate the privacy leakage of two differentially private algorithms using gradient perturbation: logistic regression for empirical risk minimization (Section 4.2) and neural networks for non-convex learning (Section 4.3). For both, we consider the different relaxed notions of differential privacy and compare their privacy leakage. The variations that we implement are naïve composition (NC), advanced composition (AC), zero-concentrated differential privacy (zCDP) and Rényi differential privacy (RDP) (see Section 2.1 for details). We do not include CDP as it has the same composition property as zCDP (Table 1). For RDP, we use the RDP accountant (previously moments accountant) of TF Privacy framework [2].

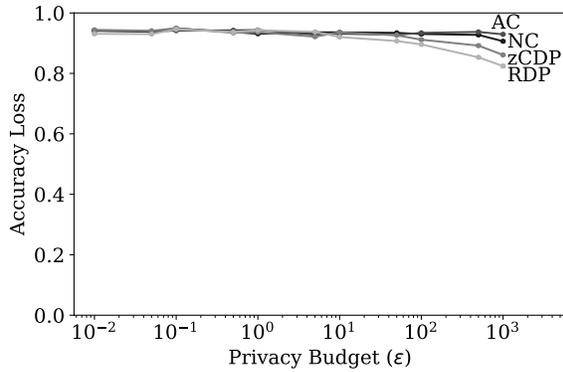

We evaluate the models on two main metrics: *accuracy loss*, the model’s accuracy loss on test set with respect to the non-private baseline, and *privacy leakage*, the attacker’s advantage as defined by Yeom et al. [74]. To evaluate out the inference attack, we provide the attacker with a set of 20,000 records consisting of 10,000 records from training set and 10,000 records from the test set. We call records in the training set *members*, and the other records *non-members*. These labels are not known to the attacker. The task of the attacker is to predict whether or not a given input record belongs to the training set (i.e., if it is a member). The privacy leakage metric is calculated by taking the difference between the true positive rate (TPR) and the false positive rate (FPR) of the inference attack. Thus the privacy leakage metric is always between 0 and 1, where the value of 0 indicates that there is no leakage. For example, if an attacker performs membership inference on a model and obtains a privacy leakage of 0.7 then it implies that for every 100 wrong membership predictions made by

the attacker, 170 ‘true’ members are revealed to the attacker. In other words, 170 training records are revealed to the attacker. To better understand the potential impact of leakage, we also conduct experiments to estimate the actual number of members who are at risk for disclosure in a membership inference attack.

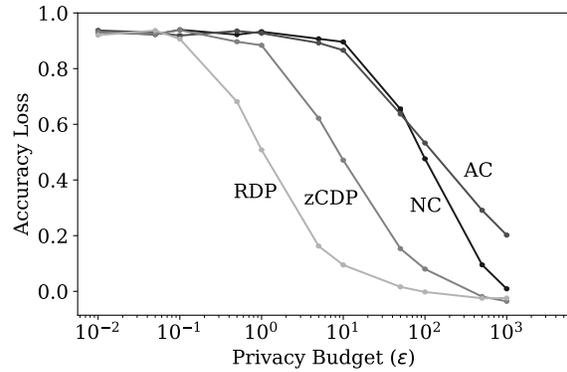

**Data sets.** We evaluate our models over two data sets for multi-class classification tasks: CIFAR-100 [38] and Purchase-100 [36]. CIFAR-100 consists of  $28 \times 28$  images of 100 real world objects, with 500 instances of each object class. We use PCA to reduce the dimensionality of records to 50. The Purchase-100 data set consists of 200,000 customer purchase records of size 100 each (corresponding to the 100 frequently-purchased items) where the records are grouped into 100 classes based on the customers’ purchase style. For both data sets, we use 10,000 randomly-selected instances for training and 10,000 randomly-selected non-training instances for the test set. The remaining records are used for training shadow models and inference model.

**Attacks.** For our experiments, we use the attack frameworks of Shokri et al. [61] and Yeom et al. [74] for membership inference and the method proposed by Yeom et al. [74] for attribute inference. In Shokri et al.’s framework [61], multiple shadow models are trained on data that is sampled from the same distribution as the private data set. These shadow models are used to train an inference model to identify whether an input record belongs to the private data set. The inference model is trained using a set of records used to train the shadow models, a set of records randomly selected from the distribution that are not part of the shadow model training, along with the confidence scores output by the shadow models for all of the input records. Using these inputs, the inference model learns to distinguish the training records from the non-training records. At the inference stage, the inference model takes an input record along with the confidence score of the target model on the input record, and outputs whether the input record belongs to the target model’s private training data set. The intuition is that if the target model overfits on its training set, its confidence score for a training record will be higher than its confidence score for an otherwise similar input that was not used in training. The inference model tries to exploit this property. In our instantiation of the attack framework, we use five shadow models which all have the same model architecture as the target model. Our inference model is a neural network with two hidden layers of size 64. This setting is consistent with the original work [61].

The attack framework of Yeom et al. [74] is simpler than Shokri et al.’s design. It assumes a white-box attacker with access to the target model’s expected training loss on the private data set, in addition to having access to the target model. For membership inference, the attacker simply observes the target model’s loss on the input record. The attacker classifies the record as a member if the loss is smaller than the target

(a) Batch gradient clipping

(b) Per-instance gradient clipping

Figure 1: Impact of clipping on accuracy loss of logistic regression (CIFAR-100).

model’s expected training loss, otherwise the record is classified as a non-member. The same principle is used for attribute inference. Given an input record, the attacker brute-forces all possible values for the unknown private attribute and observes the target model’s loss, outputting the value for which the loss is closest to the target’s expected training loss. Since there are no attributes in our data sets that are explicitly annotated as private, we randomly choose five attributes, and perform the attribute inference attack on each attribute independently, and report the averaged results.

**Hyperparameters.** For both data sets, we train logistic regression and neural network models with  $\ell_2$  regularization. First, we train a non-private model and perform a grid search over the regularization coefficient  $\lambda$  to find the value that minimizes the classification error on the test set. For CIFAR-100, we found optimal values to be  $\lambda = 10^{-5}$  for logistic regression and  $\lambda = 10^{-4}$  for neural network. For Purchase-100, we found optimal values to be  $\lambda = 10^{-5}$  for logistic regression and  $\lambda = 10^{-8}$  for neural network. Next, we fix this setting to train differentially private models using gradient perturbation. We vary  $\epsilon$  between 0.01 and 1000 while keeping  $\delta = 10^{-5}$ , and report the accuracy loss and privacy leakage. The choice of  $\delta = 10^{-5}$  satisfies the requirement that  $\delta$  should be smaller than the inverse of the training set size 10,000. We use the ADAM optimizer for training and fix the learning rate to 0.01 with a batch size of 200. Due to the random noise addition, all the experiments are repeated five times and the average results and standard errors are reported. We do not assume pre-trained model parameters, unlike the prior works of Abadi et al. [1] and Yu et al. [75].

**Clipping.** For gradient perturbation, clipping is required to bound the sensitivity of the gradients. We tried clipping at both the batch and per-instance level. Batch clipping is more computationally efficient and a standard practice in deep learning. On the other hand, per-instance clipping uses the privacy

budget more efficiently, resulting in more accurate models for a given privacy budget. We use the TensorFlow Privacy framework [2] which implements both batch and per-instance clipping. We fix the clipping threshold at  $C = 1$ .

Figure 1 compares the accuracy loss of logistic regression models trained over CIFAR-100 data set with both batch clipping and per-instance clipping. Per-instance clipping allows learning more accurate models for all values of  $\epsilon$  and amplifies the differences between the different mechanisms. For example, the model trained with RDP achieves accuracy close to the non-private model for  $\epsilon = 100$  when performing per-instance clipping. Whereas, the models do not learn anything useful when using batch clipping. Hence, for the rest of the paper we only report the results for per-instance clipping.

## 4.2 Logistic Regression Results

We train  $\ell_2$ -regularized logistic regression models on both the CIFAR-100 and Purchase-100 data sets.

**CIFAR-100.** The baseline model for non-private logistic regression achieves accuracy of 0.225 on training set and 0.155 on test set, which is competitive with the state-of-art neural network model [61] that achieves test accuracy close to 0.20 on CIFAR-100 after training on larger data set. Thus, there is a small generalization gap of 0.07, which the inference attacks try to exploit.

Figure 1(b) compares the accuracy loss for logistic regression models trained with different relaxed notions of differential privacy as we varying the privacy budget  $\epsilon$ . The accuracy loss is normalized with respect to the accuracy of non-private model to clearly depict the model utility. An accuracy loss value of 1 means that the model has 100% loss and hence has no utility, whereas the value of 0 means that the model achieves same accuracy as the non-private baseline. As depicted in the figure, naïve composition achieves accuracy

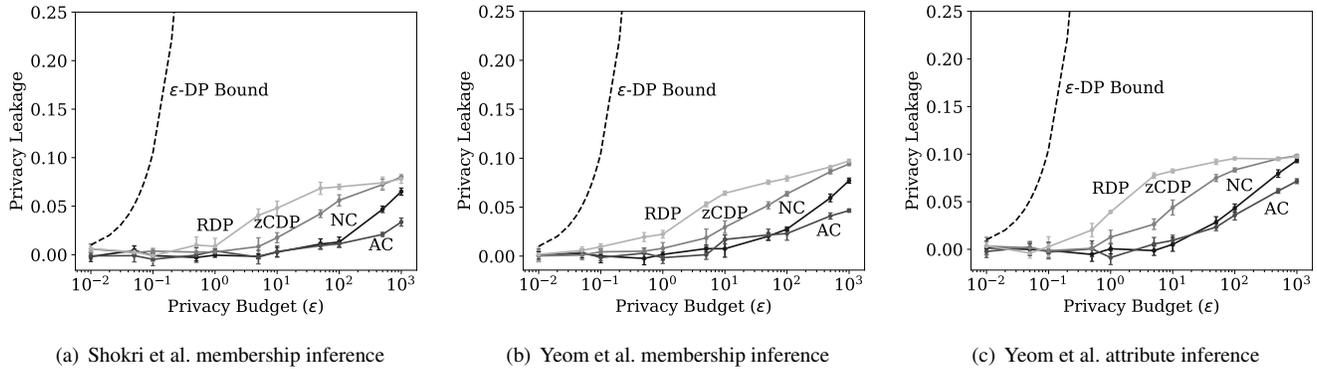

Figure 2: Inference attacks on logistic regression (CIFAR-100).

close to 0.01 for  $\epsilon \leq 10$  which is random guessing for 100-class classification. Naïve composition achieves accuracy loss close to 0 for  $\epsilon = 1000$ . Advanced composition adds more noise than naïve composition when privacy budget is greater than the number of training epochs ( $\epsilon \geq 100$ ). The relaxations zCDP and RDP achieve accuracy loss close to 0 at  $\epsilon = 500$  and  $\epsilon = 50$  respectively, which is order of magnitudes smaller than the naïve composition. This is expected since the relaxed definitions require less added noise.

Figures 2(a) and 2(b) show the privacy leakage due to membership inference attacks on logistic regression models. Figure 2(a) shows results for the black-box attacker of Shokri et al. [61], which has access to the target model’s confidence scores on the input record. Naïve composition achieves privacy leakage close to 0 for  $\epsilon \leq 10$ , and the leakage reaches  $0.065 \pm 0.004$  for  $\epsilon = 1000$ . The relaxed variants RDP and zCDP have average leakage close to  $0.080 \pm 0.004$  for  $\epsilon = 1000$ . As expected, the differential privacy variations have leakage in accordance with the amount of noise they add for a given  $\epsilon$ . The plots also show the theoretical upper bound on the privacy leakage for  $\epsilon$ -differential privacy, where the bound is  $e^\epsilon - 1$  (see Section 3.1).

Figure 2(b) shows results for the white-box attacker of Yeom et al. [61], which has access to the target model’s loss on the input record. As expected, zCDP and RDP relaxations leak the most. Naïve composition does not have any significant leakage for  $\epsilon \leq 10$ , but the leakage reaches  $0.077 \pm 0.003$  for  $\epsilon = 1000$ . The observed leakage of all the variations is in accordance with the noise magnitude required for different differential privacy guarantees.

Figure 2(c) depicts the privacy leakage due to the attribute inference attack. The privacy leakage of RDP is highest, closely followed by zCDP. Naïve composition has low privacy leakage for  $\epsilon \leq 10$  (attacker advantage of  $0.005 \pm 0.007$  at  $\epsilon = 10$ ), but it quickly increases to  $0.093 \pm 0.002$  for  $\epsilon = 1000$ . But for meaningful privacy budgets, there is no significant leakage ( $< 0.02$ ) for any of the methods. As expected, across all variations as privacy budgets increase both the attacker’s

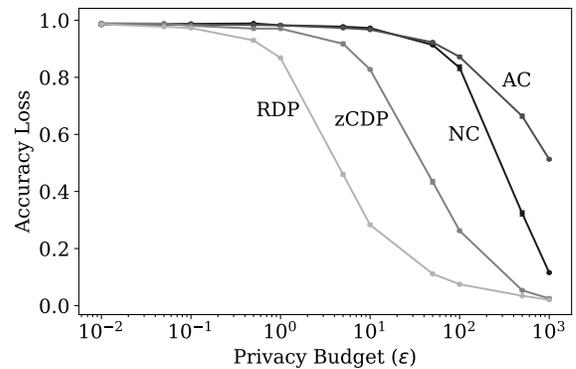

Figure 3: Accuracy loss of logistic regression (Purchase-100).

advantage (privacy leakage) and the model utility (accuracy) increase. For this example, there is no choice of  $\epsilon$  available that provides any effective privacy for a model that does better than random guessing.

To gain more understanding of the impact of privacy leakage, Table 5 shows the actual number of training set members exposed to the attacker for different differential privacy variations. We assume the attacker has some limited tolerance for falsely exposing a member (that is, a bound on the acceptable false positive rate), and sets the required threshold score for the inference model output as the level needed to achieve that false positive rate. Then, we count the number of members in the private training data set for whom the inference model output exceeds that confidence threshold. Table 5 reports the number of members exposed to an adversary who tolerates false positive rates of 1%, 2%, and 5%. As we increase the tolerance threshold, there is a gradual increase in membership leakage for all the methods, and the leakage of relaxed variants increases drastically. Naïve composition and advanced composition are resistant to attack for  $\epsilon \leq 10$ , whereas zCDP is resistant to attack for  $\epsilon \leq 1$ . RDP is resistant up to  $\epsilon = 0.05$ .

| $\epsilon$ | Naïve Composition |    |     |     | Advanced Composition |    |     |     | zCDP |    |     |     | RDP  |    |     |     |

| 1,000.0    | .01               | 65 | 138 | 413 | .20                  | 57 | 111 | 301 | .00  | 86 | 172 | 514 | .00  | 93 | 185 | 530 |

Table 5: Number of individuals (out of 10,000) exposed by Yeom et al. membership inference attack on logistic regression (CIFAR-100). The non-private ( $\epsilon = \infty$ ) model leaks 129, 240 and 704 members for 1%, 2% and 5% FPR respectively.

**Purchase-100.** The baseline model for non-private logistic regression achieves accuracy of 0.942 on the training set and 0.695 on test set. In comparison, Google ML platform’s black-box trained model achieves a test accuracy of 0.656 for Purchase-100 (see Shokri et al. [61] for details).

Figure 3 shows the accuracy loss of all differential privacy variants on Purchase-100 data set. Naïve composition and advanced composition have essentially no utility until  $\epsilon$  exceeds 100. At  $\epsilon = 1000$ , naïve composition achieves accuracy loss of  $0.116 \pm 0.003$ , the advanced composition achieves accuracy loss of  $0.513 \pm 0.003$  and the other variants achieve accuracy loss close to 0.02. RDP achieves the best utility across all  $\epsilon$  values. zCDP performs better than advanced composition and naïve composition.

Figure 4 compares the privacy leakage of the variants against the inference attacks. The leakage is in accordance to the noise each variant adds and it increases proportionally to the model utility. Hence, if a model has reasonable utility, it is bound to leak membership information. The white-box membership inference attack of Yeom et al. is relatively more effective than the black-box membership inference attack of Shokri et al. as shown in Figures 4(a) and 4(b). Table 6 shows the number of individual members exposed, with similar results to the findings for CIFAR-100.

### 4.3 Neural Networks

We train a neural network model consisting of two hidden layers and an output layer. The hidden layers have 256 neurons that use ReLU activation. The output layer is a softmax layer with 100 neurons, each corresponding to a class label. This architecture is similar to the one used by Shokri et al. [61].

**CIFAR-100.** The baseline non-private neural network model achieves accuracy of 1.000 on the training set and 0.168 on test set, which is competitive to the neural network model

of Shokri et al. [61]. Their model is trained on a training set of size 29,540 and achieves test accuracy of 0.20, whereas our model is trained on 10,000 training instances. There is a huge generalization gap of 0.832, which the inference attacks can exploit. Figure 5(a) compares the accuracy loss of neural network models trained with different relaxed notions of differential privacy with varying privacy budget  $\epsilon$ . The model trained with naïve composition does not learn anything useful until  $\epsilon = 100$  (accuracy loss of  $0.907 \pm 0.004$ ), at which point the advanced composition also has accuracy loss close to 0.935 and the other variants achieve accuracy loss close to 0.24. None of the variants approach zero accuracy loss, even for  $\epsilon = 1000$ . The relative performance is similar to that of logistic regression model discussed in Section 4.2.

Figures 6(a) and 6(b) shows the privacy leakage due to membership inference attacks on neural network models trained with different relaxed notions for both attacks. The privacy leakage for each variation of differential privacy accords with the amount of noise it adds to the model. The leakage is significant for relaxed variants at higher  $\epsilon$  values due to model overfitting. For  $\epsilon = 1000$ , with the Shokri et al. attack, naïve composition has leakage of 0.034 compared to 0.002 for advanced composition, 0.219 for zCDP, and 0.277 for RDP (above the region shown in the plot). For the white-box attacker of Yeom et al. [74], RDP leaks the most for  $\epsilon = 1000$  (membership advantage of 0.399) closely followed by zCDP. This is because these relaxed variations add considerably less noise in comparison to naïve composition. Naïve composition and advanced composition achieve strong privacy against membership inference attackers, but fail to learning anything useful. No option appears to provide both acceptable model utility and meaningful privacy.

Like we did for logistic regression, we report the actual number of training set members exposed to the attacker in Table 7. The impact of privacy leakage is far more severe for the non-private neural network model due to model overfitting—

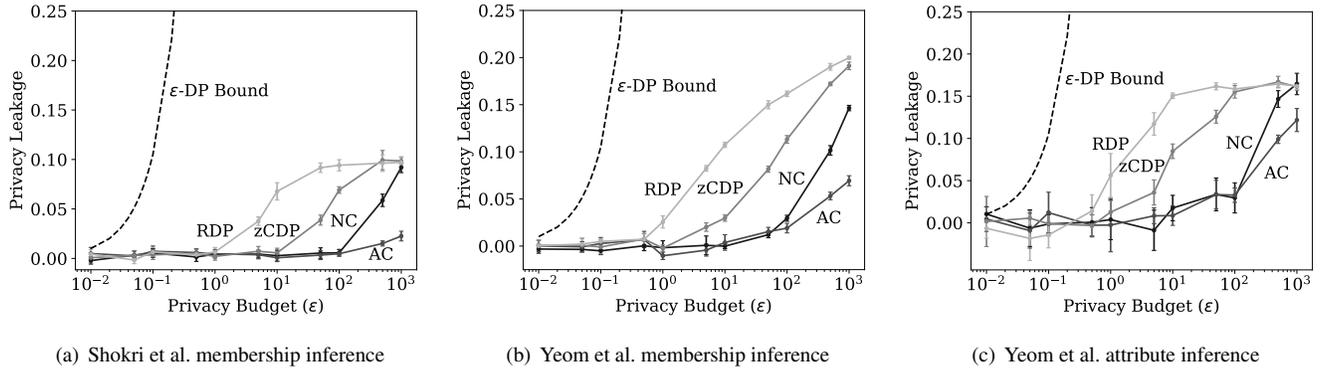

Figure 4: Inference attacks on logistic regression (Purchase-100).

Table 7: Number of members (out of 10,000) exposed by Yeom et al. membership inference attack on neural network (CIFAR-100). The non-private ( $\epsilon = \infty$ ) model leaks 0, 556 and 7349 members for 1%, 2% and 5% FPR respectively.

exposing over 73% of training set members at 5% false positive rate, compared to only 7% for the logistic regression model.<sup>2</sup> The privacy mechanisms provide substantial reduction in exposure, even with high  $\epsilon$  budgets, but the relaxed variants expose more members compared to naïve composition and advanced composition.

Figure 6(c) depicts the privacy leakage due to attribute inference attack on the neural network models. Naïve composition and advanced composition are both resistant to the attack for  $\epsilon \leq 100$ , but the relaxed variants reveal some privacy leakage for lower privacy budgets.

**Purchase-100.** The baseline non-private neural network model achieves accuracy of 0.982 on the training set and 0.605 on

<sup>2</sup>Curiously, this appears to be contradicted at 1% FPR where no members are revealed by non-private NN model but some are revealed by the privacy-preserving models. This is due to the number of extremely high-confidence incorrect outputs of the non-private model, meaning that there is no confidence threshold that does not include at least 1% false positives.

test set. In comparison, the neural network model of Shokri et al. [61] trained on a similar data set (but with 600 attributes instead of 100 as in our data set) achieves 0.670 test accuracy. Figure 5(b) compares the accuracy loss, and Figure 7 the privacy leakage, of neural network models trained with different variants of differential privacy. The trends for both accuracy and privacy are similar to those for the logistic regression models (Figure 3). The relaxed variants achieve model utility close to the non-private baseline for  $\epsilon = 1000$ , while naïve composition continues to suffer from high accuracy loss (0.372). Advanced composition has higher accuracy loss of 0.702 for  $\epsilon = 1000$  as it requires addition of more noise than naïve composition when  $\epsilon$  is greater than the number of training epochs. Figure 7 shows the privacy leakage comparison of the variants against the inference attacks. The results are consistent with those observed for CIFAR-100.

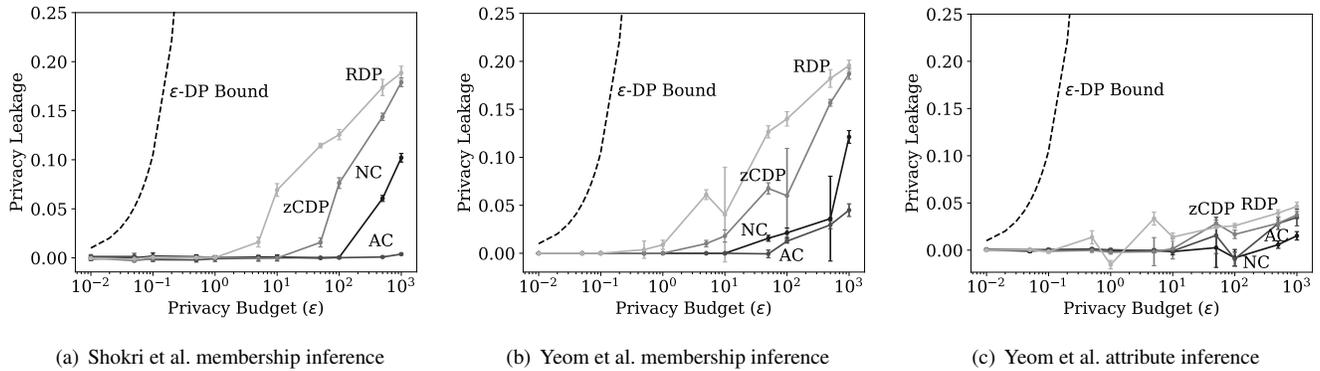

Figure 7: Inference attacks on neural network (Purchase-100).

## 4.4 Discussion

While the tighter cumulative noise bounds provided by relaxed variants of differential privacy improve model utility for a given privacy budget, the reduction in noise increases vulnerability to inference attacks. Thus, privacy does not come for free, and the relaxations of the differential privacy definition that result in lower noise requirements come with additional privacy risks. While these relaxed definitions still satisfy the  $(\epsilon, \delta)$ -differential privacy guarantees, the concrete value of these guarantees diminishes rapidly with high  $\epsilon$  values and non-zero  $\delta$ . Although the theoretical guarantees provided by differential privacy are very appealing, once  $\epsilon$  values exceed small values, the practical value of these guarantees is insignificant—in most of our inference attack figures, the theoretical bound given by  $\epsilon$ -DP falls off the graph before any measurable privacy leakage occurs (and at levels well before models provide acceptable utility). The value of these privacy mechanisms comes not from the theoretical guarantees, but from the impact of the mechanism on what realistic adversaries can infer.

We note that in our inference attack experiments, we use equal numbers of member and non-member records which provides 50-50 prior success probability to the attacker. Thus, even an  $\epsilon$ -DP implementation might leak even for small  $\epsilon$  values, though we did not observe any such leakage. Alternatively, a skewed prior probability may lead to smaller leakage even for large  $\epsilon$  values. Our goal in this work is to evaluate scenarios where risk of inference is high, so the use of 50-50 prior probability is justified. We also emphasize that our results show the privacy leakage due to two particular membership inference attacks. Attacks only get better, so future attacks may be able to infer more than is shown in our experiments.

## 5 Conclusion

Differential privacy has earned a well-deserved reputation providing principled and powerful mechanisms for ensuring

provable privacy. However, when it is implemented for challenging tasks such as machine learning, compromises must be made to preserve utility. It is essential that the privacy impact of those compromises is well understood when differential privacy is deployed to protect sensitive data. Our results are a step towards improving that understanding, and reveal that the commonly-used relaxations of differential privacy may provide unacceptable utility-privacy trade-offs. We hope our study will encourage more careful assessments of the practical privacy value of formal claims based on differential privacy, and lead to deeper understanding of the privacy impact of design decisions when deploying differential privacy, and eventually to solutions that provide desirable, and well understood, utility-privacy trade-offs.

## Availability

Open source code for reproducing all of our experiments is available at <https://github.com/bargavj/EvaluatingDPML>.

## Acknowledgments

The authors are deeply grateful to Úlfar Erlingsson for pointing out some key misunderstandings in an early version of this work and for convincing us of the importance of per-instance gradient clipping, and to Úlfar, Ilya Mironov, and Shuang Song for help validating and improving the work. We thank Vincent Bindschaedler for shepherding our paper. We thank Youssef Errami and Jonah Weissman for contributions to the experiments, and Ben Livshits for feedback on the work. Atallah Hezbor, Faysal Shezan, Tanmoy Sen, Max Naylor, Joshua Holtzman and Nan Yang helped systematize the related works. Finally, we thank Congzheng Song and Samuel Yeom for providing their implementation of inference attacks. This work was partially funded by grants from the National Science Foundation SaTC program (#1717950, #1915813) and support from Intel and Amazon.

# FUZZIFICATION: Anti-Fuzzing Techniques

Jinho Jung, Hong Hu, David Solodukhin, Daniel Pagan, Kyu Hyung Lee<sup>†</sup>, Taesoo Kim

## Abstract

Fuzzing is a software testing technique that quickly and automatically explores the input space of a program without knowing its internals. Therefore, developers commonly use fuzzing as part of test integration throughout the software development process. Unfortunately, it also means that such a blackbox and the automatic natures of fuzzing are appealing to adversaries who are looking for zero-day vulnerabilities.

To solve this problem, we propose a new *mitigation* approach, called FUZZIFICATION, that helps developers protect the released, binary-only software from attackers who are capable of applying state-of-the-art fuzzing techniques. Given a performance budget, this approach aims to hinder the fuzzing process from adversaries as much as possible. We propose three FUZZIFICATION techniques: 1) SpeedBump, which amplifies the slowdown in normal executions by hundreds of times to the fuzzed execution, 2) BranchTrap, interfering with feedback logic by hiding paths and polluting coverage maps, and 3) AntiHybrid, hindering taint-analysis and symbolic execution. Each technique is designed with best-effort, defensive measures that attempt to hinder adversaries from bypassing FUZZIFICATION.

Our evaluation on popular fuzzers and real-world applications shows that FUZZIFICATION effectively reduces the number of discovered paths by 70.3% and decreases the number of identified crashes by 93.0% from real-world binaries, and decreases the number of detected bugs by 67.5% from LAVA-M dataset while under user-specified overheads for common workloads. We discuss the robustness of FUZZIFICATION techniques against adversarial analysis techniques. We open-source our FUZZIFICATION system to foster future research.

## 1 Introduction

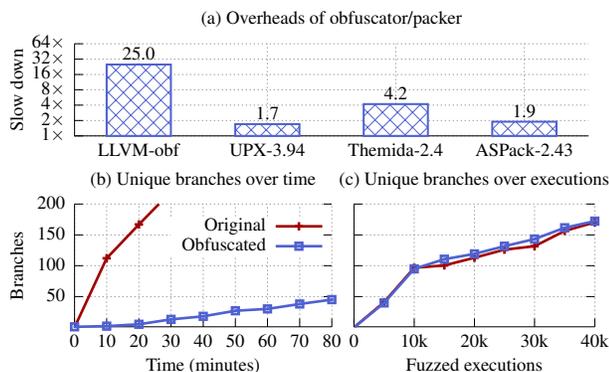

Fuzzing is a software testing technique that aims to find software bugs automatically. It keeps running the program with randomly generated inputs and waits for bug-exposing behaviors such as crashing or hanging. It has become a standard

practice to detect security problems in complex, modern software [40, 72, 37, 25, 23, 18, 9]. Recent research has built several efficient fuzzing tools [57, 52, 29, 34, 6, 64] and found a large number of security vulnerabilities [51, 72, 59, 26, 10].

Unfortunately, advanced fuzzing techniques can also be used by malicious attackers to find zero-day vulnerabilities. Recent studies [61, 58] confirm that attackers predominantly prefer fuzzing tools over others (*e.g.*, reverse engineering) in finding vulnerabilities. For example, a survey of information security experts [28] shows that fuzzing techniques discover 4.83 times more bugs than static analysis or manual detection. Therefore, developers might want to apply *anti-fuzzing* techniques on their products to hinder fuzzing attempts by attackers, similar in concept to using obfuscation techniques to cripple reverse engineering [12, 13].

In this paper, we propose a new direction of binary protection, called FUZZIFICATION, that hinders attackers from effectively finding bugs. Specifically, attackers may still be able to find bugs from the binary protected by FUZZIFICATION, but with significantly more effort (*e.g.*, CPU, memory, and time). Thus, developers or other trusted parties who get the original binary are able to detect program bugs and synthesize patches before attackers widely abuse them. An effective FUZZIFICATION technique should enable the following three features. First, it should be effective for hindering existing fuzzing tools, finding fewer bugs within a fixed time; second, the protected program should still run efficiently in normal usage; third, the protection code should not be easily identified or removed from the protected binary by straightforward analysis techniques.

No existing technique can achieve all three goals simultaneously. First, software obfuscation techniques, which impede static program analysis by randomizing binary representations, seem to be effective in thwarting fuzzing attempts [12, 13]. However, we find that it falls short of FUZZIFICATION in two ways. Obfuscation introduces unacceptable overhead to normal program executions. Figure 1(a) shows that obfuscation slows the execution by at least 1.7 times when using UPX [60] and up to 25.0 times when using

**Figure 1:** Impact of obfuscation techniques on fuzzing. (a) Obfuscation techniques introduce  $1.7\times$ - $25.0\times$  execution slow down. (b) and (c) fuzzing obfuscated binaries discovers fewer program paths over time, but gets a similar number of paths over executions.

LLVM-obfuscator [33]. Also, obfuscation cannot effectively hinder fuzzers in terms of path exploration. It can slow each fuzzed execution, as shown in Figure 1(b), but the path discovery per execution is almost identical to that of fuzzing the original binary, as shown in Figure 1(c). Therefore, obfuscation is not an ideal FUZZIFICATION technique. Second, software diversification changes the structure and interfaces of the target application to distribute diversified versions [35, 3, 53, 50]. For example, the technique of N-version software [3] is able to mitigate exploits because attackers often depend on clear knowledge of the program states. However, software diversification is powerless on hiding the original vulnerability from the attacker’s analysis; thus it is not a good approach for FUZZIFICATION.

In this paper, we propose three FUZZIFICATION techniques for developers to protect their programs from malicious fuzzing attempts: SpeedBump, BranchTrap, and AntiHybrid. The SpeedBump technique aims to slow program execution during fuzzing. It injects delays to *cold* paths, which normal executions rarely reach but that fuzzed executions frequently visit. The BranchTrap technique inserts a large number of input-sensitive jumps into the program so that any input drift will significantly change the execution path. This will induce coverage-based fuzzing tools to spend their efforts on injected bug-free paths instead of on the real ones. The AntiHybrid technique aims to thwart hybrid fuzzing approaches that incorporate traditional fuzzing methods with dynamic taint analysis and symbolic execution.

We develop defensive mechanisms to hinder attackers identifying or removing our techniques from protected binaries. For SpeedBump, instead of calling the `sleep` function, we inject randomly synthesized CPU-intensive operations to cold paths and create control-flow and data-flow dependencies between the injected code and the original code. We reuse existing binary code to realize BranchTrap to prevent an adversary from identifying the injected branches.

To evaluate our FUZZIFICATION techniques, we apply them on the LAVA-M dataset and nine real-world applications, including `libjpeg`, `libpng`, `libtiff`, `pcre2`, `readelf`, `objdump`, `nm`, `objcopy`, and `MuPDF`. These programs are extensively used to evaluate the effectiveness of fuzzing tools [19, 11, 48, 67]. Then, we use four popular fuzzers—AFL, Honggfuzz, VUzzer, and QSym—to fuzz the original programs and the protected ones for the same amount of time. On average, fuzzers detect 14.2 times more bugs from the original binaries and 3.0 times more bugs from the LAVA-M dataset than those from “fuzzified” ones. At the same time, our FUZZIFICATION techniques decrease the total number of discovered paths by 70.3%, and maintain user-specified overhead budget. This result shows that our FUZZIFICATION techniques successfully decelerate fuzzing performance on vulnerability discovery. We also perform an analysis to show that data-flow and control-flow analysis techniques cannot easily disarm our techniques.

In this paper, we make the following contributions:

- We first shed light on the new research direction of anti-fuzzing schemes, so-called, FUZZIFICATION.
- We develop three FUZZIFICATION techniques to slow each fuzzed execution, to hide path coverage, and to thwart dynamic taint-analysis and symbolic execution.
- We evaluate our techniques on popular fuzzers and common benchmarks. Our results show that the proposed techniques hinder these fuzzers, finding 93% fewer bugs from the real-world binaries and 67.5% fewer bugs from the LAVA-M dataset, and 70.3% less coverage while maintaining the user-specified overhead budget.

We will release the source code of our work at <https://github.com/sslabs-gatech/fuzzification>.

## 2 Background and Problem

### 2.1 Fuzzing Techniques

The goal of fuzzing is to automatically detect program bugs. For a given program, a fuzzer first creates a large number of inputs, either by random mutation or by format-based generation. Then, it runs the program with these inputs to see whether the execution exposes unexpected behaviors, such as a crash or an incorrect result. Compared to manual analysis or static analysis, fuzzing is able to execute the program orders of magnitude more times and thus can explore more program states to maximize the chance of finding bugs.

#### 2.1.1 Fuzzing with Fast Execution

A straightforward way to improve fuzzing efficiency is to make each execution faster. Current research highlights several fast execution techniques, including (1) customized system and hardware to accelerate fuzzed execution and (2) parallel fuzzing to amortize the absolute execution time in

large-scale. Among these techniques, AFL uses the fork server and persistent mode to avoid the heavy process creation and can accelerate fuzzing by a factor of two or more [68, 69]. AFL-PT, kAFL, and Honggfuzz utilize hardware features such as Intel Process Tracing (PT) and Branch Trace Store (BTS) to collect code coverage efficiently to guide fuzzing [65, 54, 23]. Recently, Xu *et al.* designed new operating system primitives, like efficient system calls, to speed up fuzzing on multi-core machines [64].

### 2.1.2 Fuzzing with Coverage-guidance

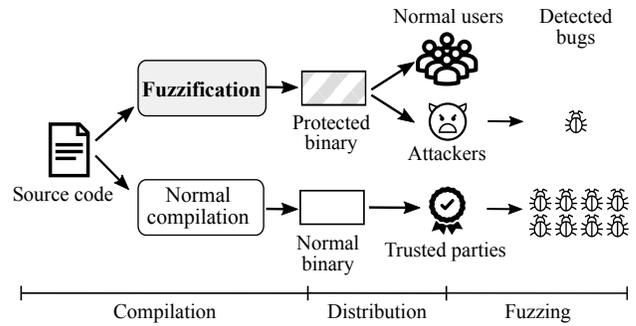

Coverage-guided fuzzing collects the code coverage for each fuzzed execution and prioritizes fuzzing the input that has triggered new coverage. This fuzzing strategy is based on two empirical observations: (1) a higher path coverage indicates a higher chance of exposing bugs; and (2) mutating inputs that ever trigger new paths is likely to trigger another new path. Most popular fuzzers take code coverage as guidance, like AFL, Honggfuzz, and LibFuzzer, but with different methods for coverage representation and coverage collection.

**Coverage representation.** Most fuzzers take basic blocks or branches to represent the code coverage. For example, Honggfuzz and VUzzer use basic block coverage, while AFL instead considers the branch coverage, which provides more information about the program states. Angora [11] combines branch coverage with the call stack to further improve coverage accuracy. However, the choice of representation is a trade-off between coverage accuracy and performance, as more fine-grained coverage introduces higher overhead to each execution and harms the fuzzing efficiency.

**Coverage collection.** If the source code is available, fuzzers can instrument the target program during compilation or assembly to record coverage at runtime, like in AFL-LLVM mode and LibFuzzer. Otherwise, fuzzers have to utilize either static or dynamic binary instrumentation to achieve a similar purpose, like in AFL-QEMU mode [70]. Also, several fuzzers leverage hardware features to collect the coverage [65, 54, 23]. Fuzzers usually maintain their own data structure to store coverage information. For example, AFL and Honggfuzz use a fixed-size array and VUzzer utilizes a *Set* data structure in Python to store their coverage. However, the size of the structure is also a trade-off between accuracy and performance: an overly small memory cannot capture every coverage change, while an overly large memory introduces significant overhead. For example, AFL’s performance drops 30% if the bitmap size is changed from 64KB to 1MB [19].

### 2.1.3 Fuzzing with Hybrid Approaches

Hybrid approaches are proposed to help solve the limitations of existing fuzzers. First, fuzzers do not distinguish input bytes with different types (*e.g.*, magic number, length specifier) and thus may waste time mutating less important bytes

**Figure 2:** Workflow of FUZZIFICATION protection. Developers create a protected binary with FUZZIFICATION techniques and release it to public. Meanwhile, they send the normally compiled binary to trusted parties. Attackers cannot find many bugs from the protected binary through fuzzing, while trusted parties can effectively find significantly more bugs and developers can patch them in time.

that cannot affect any control flow. In this case, taint analysis is used to help find which input bytes are used to determine branch conditions, like VUzzer [52]. By focusing on the mutation of these bytes, fuzzers can quickly find new execution paths. Second, fuzzers cannot easily resolve complicated conditions, such as comparison with magic value or checksum. Several works [57, 67] utilize symbolic execution to address this problem, which is good at solving complicated constraints but incurs high overhead.

## 2.2 FUZZIFICATION Problem

Program developers may want to completely control the bug-finding process, as any bug leakage can bring attacks and lead to financial loss [45]. They demand exposing bugs by themselves or by trusted parties, but not by malicious end-users. Anti-fuzzing techniques can help to achieve that by decelerating unexpected fuzzing attempts, especially from malicious attackers.

We show the workflow of FUZZIFICATION in Figure 2. Developers compile their code in two versions. One is compiled with FUZZIFICATION techniques to generate a protected binary, and the other is compiled normally to generate a normal binary. Then, developers distribute the protected binary to the public, including normal users and malicious attackers. Attackers fuzz the protected binary to find bugs. However, with the protection of FUZZIFICATION techniques, they cannot find as many bugs quickly. At the same time, developers distribute the normal binary to trusted parties. The trusted parties can launch fuzzing on the normal binary with the native speed and thus can find more bugs in a timely manner. Therefore, developers who receive bug reports from trusted parties can fix the bug before attackers widely abuse it.

| Anti-fuzz candidates  | Effective | Generic | Efficient | Robust |
|-----------------------|-----------|---------|-----------|--------|
| Pack & obfuscation    | ✓         | ✓       | ✗         | ✓      |
| Bug injection         | ✓         | ✓       | ✗         | ✗      |
| Fuzzer identification | ✓         | ✗       | ✓         | ✗      |
| Emulator bugs         | ✓         | ✗       | ✓         | ✓      |
| FUZZIFICATION         | ✓         | ✓       | ✓         | ✓      |

**Table 1:** Possible design choices and evaluation with our goals.

### 2.2.1 Threat Model

We consider motivated attackers who attempt to find software vulnerabilities through state-of-the-art fuzzing techniques, but with limited resources like computing power (at most similar resources as trusted parties). Adversaries have the binary protected by FUZZIFICATION and they have knowledge of our FUZZIFICATION techniques. They can use off-the-shelf binary analysis techniques to disarm FUZZIFICATION from the protected binary. Adversaries who have access to the unprotected binary or even to program source code (e.g., inside attackers, or through code leakage) are out of the scope of this study.

### 2.2.2 Design Goals and Choices

A FUZZIFICATION technique should achieve the following four goals simultaneously:

- **Effective:** It should effectively reduce the number of bugs found in the protected binary, compared to that found in the original binary.
- **Generic:** It tackles the fundamental principles of fuzzing and is generally applicable to most fuzzers.
- **Efficient:** It introduces minor overhead to the normal program execution.
- **Robust:** It is resistant to the adversarial analysis trying to remove it from the protected binary.

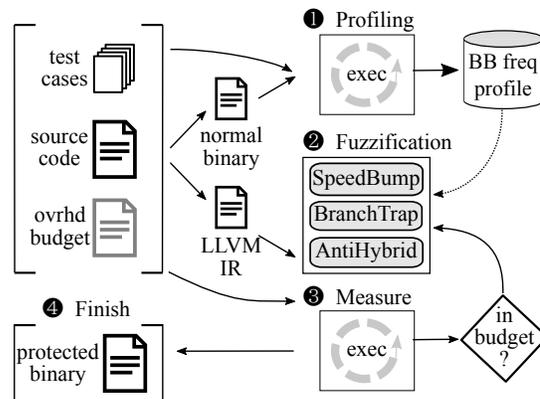

With these goals in mind, we examine four design choices for hindering malicious fuzzing, shown in Table 1. Unfortunately, no method can satisfy all goals.

**Packing/obfuscation.** Software packing and obfuscation are mature techniques against reverse engineering, both generic and robust. However, they usually introduce higher performance overhead to program executions, which not only hinders fuzzing, but also affects the use of normal users.

**Bug injection.** Injecting arbitrary code snippets that trigger non-exploitable crashes can cause additional bookkeeping overhead and affect end users in unexpected ways [31].

**Fuzzer identification.** Detecting the fuzzer process and changing the execution behavior accordingly can be bypassed easily (e.g., by changing fuzzer name). Also, we cannot enumerate all fuzzers or fuzzing techniques.

**Emulator bugs.** Triggering bugs in dynamic instrumentation tools [4, 14, 38] can interrupt fuzzing [42, 43]. However, it requires strong knowledge of the fuzzer, so it is not generic.

**Figure 3:** Overview of FUZZIFICATION process. It first runs the program with given test cases to get the execution frequency profile. With the profile, it instruments the program with three techniques. The protected binary is released if it satisfies the overhead budget.

## 2.3 Design Overview

We propose three FUZZIFICATION techniques – SpeedBump, BranchTrap, and AntiHybrid – to target each fuzzing technique discussed in §2.1. First, SpeedBump injects fine-grained delay primitives into cold paths that fuzzed executions frequently touch but normal executions rarely use (§3). Second, BranchTrap fabricates a number of input-sensitive branches to induce the coverage-based fuzzers to waste their efforts on fruitless paths (§4). Also, it intentionally saturates the code coverage storage with frequent path collisions so that the fuzzer cannot identify interesting inputs that trigger new paths. Third, AntiHybrid transforms explicit data-flows into implicit ones to prevent data-flow tracking through taint analysis, and inserts a large number of spurious symbols to trigger path explosion during the symbolic execution (§5).

Figure 3 shows an overview of our FUZZIFICATION system. It takes the program source code, a set of commonly used test cases, and an overhead budget as input and produces a binary protected by FUZZIFICATION techniques. Note that FUZZIFICATION relies on developers to determine the appropriate overhead budget, whatever they believe will create a balance between the functionality and security of their production. ① We compile the program to generate a normal binary and run it with the given normal test cases to collect basic block frequencies. The frequency information tells us which basic blocks are rarely used by normal executions. ② Based on the profile, we apply three FUZZIFICATION techniques to the program and generate a temporary protected binary. ③ We measure the overhead of the temporary binary with the given normal test cases again. If the overhead is over the budget, we go back to step ② to reduce the slow down to the program, such as using shorter delay and adding less instrumentation. If the overhead is far below the budget, we increase the overhead accordingly. Otherwise, ④ we generate the protected binary.

### 3 SpeedBump: Amplifying Delay in Fuzzing

We propose a technique called SpeedBump to slow the fuzzed execution while minimizing the effect to normal executions. Our observation is that the fuzzed execution frequently falls into paths such as error-handling (*e.g.*, wrong MAGIC bytes) that the normal executions rarely visit. We call them the *cold* paths. Injecting delays in cold paths will significantly slow fuzzed executions but will not affect regular executions that much. We first identify cold paths from normal executions with the given test cases and then inject crafted delays into least-executed code paths. Our tool automatically determines the number of code paths to inject delays and the length of each delay so that the protected binary has overhead under the user-defined budget during normal executions.

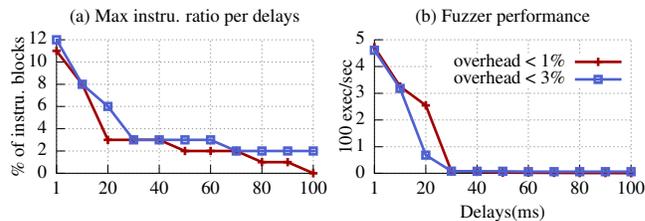

**Basic block frequency profiling.** FUZZIFICATION generates a basic block frequency profile to identify cold paths. The profiling process follows three steps. First, we instrument the target programs to count visited basic blocks during the execution and generate a binary for profiling. Second, with the user-provided test cases, we run this binary and collect the basic blocks visited by each input. Third, FUZZIFICATION analyzes the collected information to identify basic blocks that are rarely executed or never executed by valid inputs. These blocks are treated as cold paths in delay injection.

Our profiling does not require the given test cases to cover 100% of all legitimate paths, but just to trigger the commonly used functionalities. We believe this is a practical assumption, as experienced developers should have a set of test cases covering most of the functionalities (*e.g.*, regression test-suites). Optionally, if developers can provide a set of test cases that trigger uncommon features, our profiling results will be more accurate. For example, for applications parsing well-known file formats (*e.g.*, `readelf` parses ELF binaries), collecting valid/invalid dataset is straightforward.

**Configurable delay injection.** We perform the following two steps repeatedly to determine the set of code blocks to inject delays and the length of each delay:

- We start by injecting a 30ms delay to 3% of the least-executed basic blocks in the test executions. We find that this setting is close enough to the final evaluation result.
- We measure the overhead of the generated binary. If it does not exceed the user-defined overhead budget, we go to the previous step to inject more delay into more basic blocks. Otherwise, we use the delay in the previous round as the final result.

Our SpeedBump technique is especially useful for developers who generally have a good understanding of their applications, as well as the requirements for FUZZIFICATION. We provide five options that developers can use to finely tune SpeedBump's effect. Specifically, `MAX_OVERHEAD` defines the overhead budget. Developers can specify any value as long as they feel comfortable with the overhead. `DELAY_LENGTH` specifies the range of delays. We use 10ms to 300ms in the

**Figure 4:** Protecting `readelf` with different overhead budgets. While satisfying the overhead budget, (a) demonstrates the maximum ratio of instrumentation for each delay length, and (b) displays the execution speed of AFL-QEMU on protected binaries.

evaluation. `INCLUDE_INCORRECT` determines whether or not to inject delays to error-handling basic blocks (*i.e.*, locations that are *only* executed by invalid inputs), which is enabled by default. `INCLUDE_NON_EXEC` and `NON_EXEC_RATIO` specify whether to inject delays into how ever many basic blocks are never executed during test execution. This is useful when developers do not have a large set of test cases.

Figure 4 demonstrates the impact of different options on protecting the `readelf` binary with SpeedBump. We collect 1,948 ELF files on the Debian system as valid test cases and use 600 text and image files as invalid inputs. Figure 4(a) shows the maximum ratio of basic blocks that we can inject delay into while introducing overhead less than 1% and 3%. For a 1ms delay, we can instrument 11% of the least-executed basic blocks for a 1% overhead budget and 12% for 3% overhead. For a 120ms delay, we cannot inject any blocks for 1% overhead and can inject only 2% of the cold paths for 3% overhead. Figure 4(b) shows the actual performance of AFL-QEMU when it fuzzes SpeedBump-protected binaries. The ratio of injected blocks is determined as in Figure 4(a). The result shows that SpeedBump with a 30ms delay slows the fuzzer by more than 50 $\times$ . Therefore, we use 30ms and the corresponding 3% instrumentation as the starting point.

#### 3.1 Analysis-resistant Delay Primitives

As attackers may use program analysis to identify and remove simple delay primitives (*e.g.*, calling `sleep`), we design robust primitives that involve arithmetic operations and are connected with the original code base. Our primitives are based on CSmith [66], which can generate random and bug-free code snippets with refined options. For example, CSmith can generate a function that takes parameters, performs arithmetic operations, and returns a specific type of value. We modified CSmith to generate code that has data dependencies and code dependencies to the original code. Specifically, we pass a variable from the original code to the generated code as an argument, make a reference from the generated code to the original one, and use the return value to modify a global variable of the original code. Figure 5 shows an example of our delay primitives. It declares a local variable `PASS_VAR`

```

1 //Predefined global variables
2 int32_t GLOBAL_VAR1 = 1, GLOBAL_VAR2 = 2;
3 //Randomly generated code
4 int32_t * func(int32_t p6) {
5     int32_t *l0[1000];
6     GLOBAL_VAR1 = 0x4507L; // affect global var.
7     int32_t *l1 = &g8[1][0];
8     for (int i = 0; i < 1000; i++)
9         l0[i] = p6; // affect local var from argv.
10    (*g7) = func2(g6++);
11    (*g5) |= ~(1func3(**g4 = ~0UL));
12    return l1; // affect global var.
13 }
14 //Inject above function for delay
15 int32_t PASS_VAR = 20;
16 GLOBAL_VAR2 = func(PASS_VAR);

```

**Figure 5:** Example delay primitive. Function `func` updates global variables to build data-flow dependency with original program.

and modifies global variables `GLOBAL_VAR1` and `GLOBAL_VAR2`. In this way, we introduce data-flow dependency between the original code and the injected code (line 6, 9 and 12), and change the program state without affecting the original program. Although the code is randomly generated, it is tightly coupled with the original code via data-flow and control-flow dependencies. Therefore, it is non-trivial for common binary analysis techniques, like dead-code elimination, to distinguish it from the original code. We repeatedly run the modified CSmith to find appropriate code snippets that take a specific time (*e.g.*, 10ms) for delay injection.

**Safety of delay primitives.** We utilize the safety checks from CSmith and FUZZIFICATION to guarantee that the generated code is bug-free. First, we use CSmith’s default safety checks, which embed a collection of tests in the code, including integer, type, pointer, effect, array, initialization, and global variable. For example, CSmith conducts pointer analysis to detect any access to an out-of-scope stack variable or null pointer dereference, uses explicit initialization to prevent uninitialized usage, applies math wrapper to prevent unexpected integer overflow, and analyzes qualifiers to avoid any mismatch. Second, FUZZIFICATION also has a separate step to help detect bad side effects (*e.g.*, crashes) in delay primitives. Specifically, we run the code 10 times with fixed arguments and discard it if the execution shows any error. Finally, FUZZIFICATION embeds the generated primitives with the same fixed argument to avoid errors.

**Fuzzers aware of error-handling blocks.** Recent fuzzing proposals, like VUzzer [52] and T-Fuzz [48], identify error-handling basic blocks through profiling and exclude them from the code coverage calculation to avoid repetitive executions. This may affect the effectiveness of our SpeedBump technique, which uses a similar profiling step to identify cold paths. Fortunately, the cold paths from SpeedBump include not only error-handling basic blocks, but also rarely executed functional blocks. Further, we use similar methods to identify error-handling blocks from the cold paths and provide developers the option to choose not to instrument these blocks. Thus, our FUZZIFICATION will focus on instrumenting rarely executed functional blocks to maximize its effectiveness.

## 4 BranchTrap: Blocking Coverage Feedback

Code coverage information is widely used by fuzzers to find and prioritize interesting inputs [72, 37, 23]. We can make these fuzzers *diligent fools* if we insert a large number of conditional branches whose conditions are sensitive to slight input changes. When the fuzzing process falls into these branch traps, coverage-based fuzzers will waste their resources to explore (a huge number of) worthless paths. Therefore, we propose the technique of BranchTrap to deceive coverage-based fuzzers by misleading or blocking the coverage feedback.

### 4.1 Fabricating Fake Paths on User Input

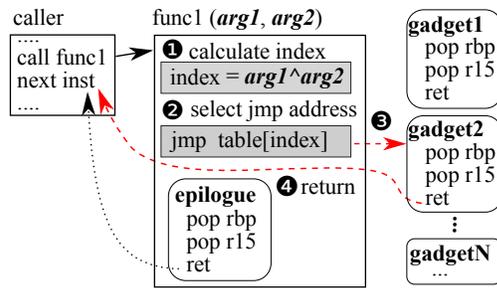

The first method of BranchTrap is to *fabricate* a large number of conditional branches and indirect jumps, and inject them into the original program. Each fabricated conditional branch relies on some input bytes to determine to take the branch or not, while indirect jumps calculate their targets based on user input. Thus, the program will take different execution paths even when the input slightly changes. Once a fuzzed execution triggers the fabricated branch, the fuzzer will set a higher priority to mutate that input, resulting in the detection of more fake paths. In this way, the fuzzer will keep wasting its resources (*i.e.*, CPU and memory) to inspect fruitless but bug-free fake paths.

To effectively induce the fuzzers focusing on fake branches, we consider the following four design aspects. First, BranchTrap should fabricate a sufficient number of fake paths to affect the fuzzing policy. Since the fuzzer generates various variants from one interesting input, fake paths should provide different coverage and be directly affected by the input so that the fuzzer will keep unearthing the trap. Second, the injected new paths introduce minimal overhead to regular executions. Third, the paths in BranchTrap should be deterministic regarding user input, which means that the same input should go through the same path. The reason is that some fuzzers can detect and ignore non-deterministic paths (*e.g.*, AFL ignores one input if two executions with it take different paths). Finally, BranchTrap cannot be easily identified or removed by adversaries.

A trivial implementation of BranchTrap is to inject a jump table and use some input bytes as the index to access the table (*i.e.*, different input values result in different jump targets). However, this approach can be easily nullified by simple adversarial analysis. We design and implement a robust BranchTrap with code-reuse techniques, similar in concept to the well-known return-oriented programming (ROP) [55].

#### 4.1.1 BranchTrap with CFG Distortion

To harden BranchTrap, we diversify the return addresses of each injected branch according to the user input. Our idea is inspired by ROP, which reuses existing code for malicious at-

**Figure 6:** BranchTrap by reusing the existing ROP gadgets in the original binary. Among functionally equivalent gadgets, BranchTrap picks the one based on function arguments.

tacks by chaining various small code snippets. Our approach can heavily distort the program control-flow and makes nullifying BranchTrap more challenging for adversaries. The implementation follows three steps. First, BranchTrap collects function epilogues from the program assembly (generated during program compilation). Second, function epilogues with the same instruction sequence are grouped into one jump table. Third, we rewrite the assembly so that the function will retrieve one of several equivalent epilogues from the corresponding jump table to realize the original function return, using some input bytes as the jump table index. As we replace the function epilogue with a functional equivalent, it guarantees the identical operations as the original program.

Figure 6 depicts the internal of the BranchTrap implementation at runtime. For one function, BranchTrap ① calculates the XORed value of all arguments. BranchTrap uses this value for indexing the jump table (*i.e.*, candidates for epilogue address). ② BranchTrap uses this value as the index to visit the jump table and obtains the concrete address of the epilogue. To avoid out-of-bounds array access, BranchTrap divides the XORed value by the length of the jump table and takes the remainder as the index. ③ After determining the target jump address, the control-flow is transferred to the gadget (*e.g.*, the same `pop rbp; pop r15; ret gadget`). ④ Finally, the execution returns to the original return address.

The ROP-based BranchTrap has three benefits:

- **Effective:** Control-flow is constantly and sensitively changed together with the user input mutation; thus FUZZIFICATION can introduce a sufficient number of unproductive paths and make coverage feedback less effective. Also, BranchTrap guarantees the same control-flow on the same input (*i.e.*, deterministic path) so that the fuzzer will not ignore these fake paths.
- **Low overhead:** BranchTrap introduces low overhead to normal user operations (*e.g.*, less than 1% overhead) due to its lightweight operations (Store argument; XOR; Resolve jump address; Jump to gadget).
- **Robust:** The ROP-based design significantly increases the complexity for an adversary to identify or patch the binary. We evaluate the robustness of BranchTrap against adversarial analysis in §6.4.

## 4.2 Saturating Fuzzing State

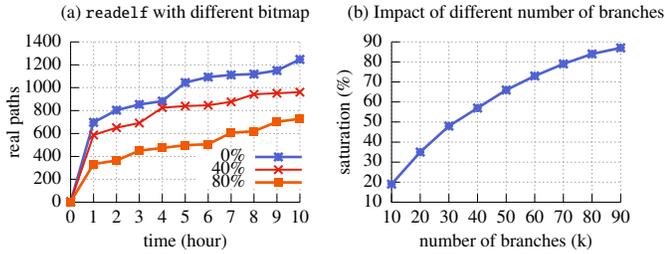

The second method of BranchTrap is to saturate the *fuzzing state*, which blocks the fuzzers from learning the progress in the code coverage. Different from the first method, which induces fuzzers focusing on fruitless inputs, our goal here is to prevent the fuzzers from finding real interesting ones. To achieve this, BranchTrap inserts a massive number of branches to the program, and exploits the coverage representation mechanism of each fuzzer to mask new findings. BranchTrap is able to introduce an extensive number (*e.g.*, 10K to 100K) of deterministic branches to some rarely visited basic blocks. Once the fuzzer reaches these basic blocks, its coverage table will quickly fill up. In this way, most of the newly discovered paths in the following executions will be treated as *visited*, and thus the fuzzer will discard the input that in fact explores interesting paths. For example, AFL maintains a fixed-size bitmap (*i.e.*, 64KB) to track edge coverage. By inserting a large number of distinct branches, we significantly increase the probability of bitmap collision and thus reduce the coverage inaccuracy.

Figure 7(a) demonstrates the impact of bitmap saturation on fuzzing `readElf`. Apparently, a more saturated bitmap leads to fewer path discoveries. Starting from an empty bitmap, AFL identifies over 1200 paths after 10 hours of fuzzing. For the 40% saturation rate, it only finds around 950 paths. If the initial bitmap is highly filled, such as 80% saturation, AFL detects only 700 paths with the same fuzzing effort.

**Fuzzers with collision mitigation.** Recent fuzzers, like CollAFL [19], propose to mitigate the coverage collision issue by assigning a unique identifier to each path coverage (*i.e.*, branch in case of CollAFL). However, we argue that these techniques will not effectively undermine the strength of our BranchTrap technique on saturating coverage storage for two reasons. First, current collision mitigation techniques require program source code to assign unique identifiers during the linking time optimization [19]. In our threat model, attackers cannot obtain the program source code or the original binary – they only have a copy of the protected binary, which makes it significantly more challenging to apply similar ID-assignment algorithms. Second, these fuzzers still have to adopt a fixed size storage of coverage because of the overhead of large storage. Therefore, if we can saturate 90% of the storage, CollAFL can only utilize the remaining 10% for ID-assignment; thus the fuzzing performance will be significantly affected.

## 4.3 Design Factors of BranchTrap

We provide developers an interface to configure ROP-based BranchTrap and coverage saturation for optimal protection. First, the number of generated fake paths of ROP-based BranchTrap is configurable. BranchTrap depends on the number of functions to make a distorted control-flow. Therefore, injected BranchTrap is effective when the original program

**Figure 7:** (a) AFL performance with different initial bitmap saturation. (b) Impact on bitmap with different number of branches.

contains plenty of functions. For binaries with fewer functions, we provide an option for developers to split existing basic blocks into multiple ones, each connected with conditional branches. Second, the size of the injected branches for saturating the coverage is also controllable. Figure 7(b) shows how the bitmap can be saturated in AFL by increasing the branch number. It clearly shows that more branches can fill up more bitmap entries. For example, 100K branches can fill up more than 90% of a bitmap entry. Injecting a massive number of branches into the program increases the output binary size. When we inject 100k branches, the size of the protected binary is 4.6MB larger than the original binary. To avoid high code size overhead, we inject a huge number of branches into only one or two of the most rarely executed basic blocks. As long as one fuzzed execution reaches such branches, the coverage storage will be filled and the following fuzzing will find fewer interesting inputs.

## 5 AntiHybrid: Thwarting Hybrid Fuzzers

A hybrid fuzzing method utilizes either symbolic execution or dynamic taint analysis to improve fuzzing efficiency. Symbolic (or concolic) execution is good at solving complicated branch conditions (e.g., magic number and checksum), and therefore can help fuzzers bypass these hard-to-mutate roadblocks. DTA (Dynamic Taint Analysis) helps find input bytes that are related to branch conditions. Recently, several hybrid fuzzing methods have been proposed and successfully discovered security-critical bugs. For example, Driller [57] adapted selective symbolic execution and proved its efficacy during the DARPA Cyber Grand Challenge (CGC). VUzzer [52] utilized dynamic taint analysis to identify path-critical input bytes for effective input mutation. QSym [67] suggested a fast concolic execution technique that can be scalable on real-world applications.

Nevertheless, hybrid approaches have well-known weaknesses. First, both symbolic execution and taint analysis consume a large amount of resources such as CPU and memory, limiting them to analyzing simple programs. Second, symbolic execution is limited by the path explosion problem. If complex operation is required for processing symbols, the symbolic execution engine has to exhaustively explore and evaluate all execution states; then, most of the symbolic ex-

```

1 char input[] = ...; /* user input */
2 int value = ...; /* user input */
3
4 // 1. using implicit data-flow to copy input to antistr
5 //   original code: if (!strcmp(input, "condition!")) { ... }
6 char antistr[strlen(input)];
7 for (int i = 0; i < strlen(input); i++){
8     int ch = 0, temp = 0, temp2 = 0;
9     for (int j = 0; j < 8; j++){
10        temp = input[i];
11        temp2 = temp & (1<<j);
12        if (temp2 != 0) ch |= 1<<j;
13    }
14    antistr[i] = ch;
15 }
16 if (!strcmp(antistr, "condition!")) { ... }
17
18 // 2. exploding path constraints
19 //   original code: if (value == 12345)
20 if (CRC_LOOP(value) == OUTPUT_CRC) { ... }

```

**Figure 8:** Example of AntiHybrid techniques. We use implicit data-flow (line 6-15) to copy strings to hinder dynamic taint analysis. We inject hash function around equal comparison (line 20) to cripple symbolic execution engine.

ecution engines fail to run to the end of the execution path. Third, DTA analysis has difficulty in tracking implicit data dependencies, such as covert channels, control channels, or timing-based channels. For example, to cover data dependency through a control channel, the DTA engine has to aggressively propagate the taint attribute to any variable after a conditional branch, making the analysis more expensive and the result less accurate.

**Introducing implicit data-flow dependencies.** We transform the explicit data-flows in the original program into implicit data-flows to hinder taint analysis. FUZZIFICATION first identifies branch conditions and interesting information sinks (e.g., strcmp) and then injects data-flow transformation code according to the variable type. Figure 8 shows an example application of AntiHybrid, where array input is used to decide branch condition and strcmp is an interesting sink function. Therefore, FUZZIFICATION uses implicit data-flows to copy the array (line 6-15) and replaces the original variable to the new one (line 16). Due to the transformed implicit data-flow, the DTA technique cannot identify the correct input bytes that affect the branch condition at line 16.

Implicit data-flow hinders data-flow analysis that tracks direct data propagation. However, it cannot prevent data dependency inference through differential analysis. For example, recent work, RedQueen [2], infers the potential relationship between input and branch conditions through pattern matching, and thus can bypass the implicit data-flow transformation. However, RedQueen requires the branch condition value to be explicitly shown in the input, which can be easily fooled through simple data modification (e.g., adding the same constant value to both operands of the comparison).

**Exploding path constraints.** To hinder hybrid fuzzers using symbolic execution, FUZZIFICATION injects multiple code chunks to intentionally trigger path explosions. Specifi-

| Project  | Version | Program   | Arg. | Seeds    | Overhead (Binary size) |               |             |               | Overhead (CPU) |            |            |      |

**Table 2:** Code size overhead and performance overhead of fuzzified binaries. GIT means Google Image Test-suite. We set performance overhead budget as 5%. For size overhead, we show the percentage and the increased size.

cally, we replace each comparison instruction by comparing the hash values of the original comparison operands. We adopt the hash function because symbolic execution cannot easily determine the original operand with the given hash value. As hash functions usually introduce non-negligible overhead to program execution, we utilize the lightweight cyclic redundancy checking (CRC) loop iteration to transform the branch condition to reduce performance overhead. Although theoretically CRC is not as strong as hash functions for hindering symbolic execution, it also introduces significant slow down. Figure 8 shows an example of the path explosion instrumentation. To be specific, FUZZIFICATION changes the original condition (`value == 12345`) to `(CRC_LOOP(value) == OUTPUT_CRC)` (at line 20). If symbolic execution decides to solve the constraint of the CRC, it will mostly return a timeout error due to the complicated mathematics. For example, QSym, a state-of-the-art fast symbolic execution engine, is armed with many heuristics to scale on real-world applications. When QSym first tries to solve the complicated constraint that we injected, it will fail due to the timeout or path explosion. Once injected codes are run by the fuzzer multiple times, QSym identifies the repetitive basic blocks (*i.e.*, injected hash function) and performs *basic block pruning*, which decides not to generate a further constraint from it to assign resources into a new constraint. After that, QSym will not explore the condition with the injected hash function; thus, the code in the branch can be explored rarely.

## 6 Evaluation

We evaluate our FUZZIFICATION techniques to understand their effectiveness on hindering fuzzers from exploring program code paths (§6.1) and detecting bugs (§6.2), their practicality of protecting real-world large programs (§6.3), and their robustness against adversarial analysis techniques (§6.4).

**Implementation.** Our FUZZIFICATION framework is implemented in a total of 6,559 lines of Python code and 758 lines of C++ code. We implement the SpeedBump technique as an

| Tasks    | Target     | AFL       | Honggfuzz | QSym      | VUzzer |
|----------|------------|-----------|-----------|-----------|--------|
| Coverage | 8 binaries | O,S,B,H,A | O,S,B,H,A | O,S,B,H,A | –      |
|          | MuPDF      | O,A       | O,A       | O,A       | –      |
| Crash    | 4 binaries | O,A       | O,A       | O,A       | –      |
|          | LAVA-M     | O,A       | O,A       | O,A       | O,A    |

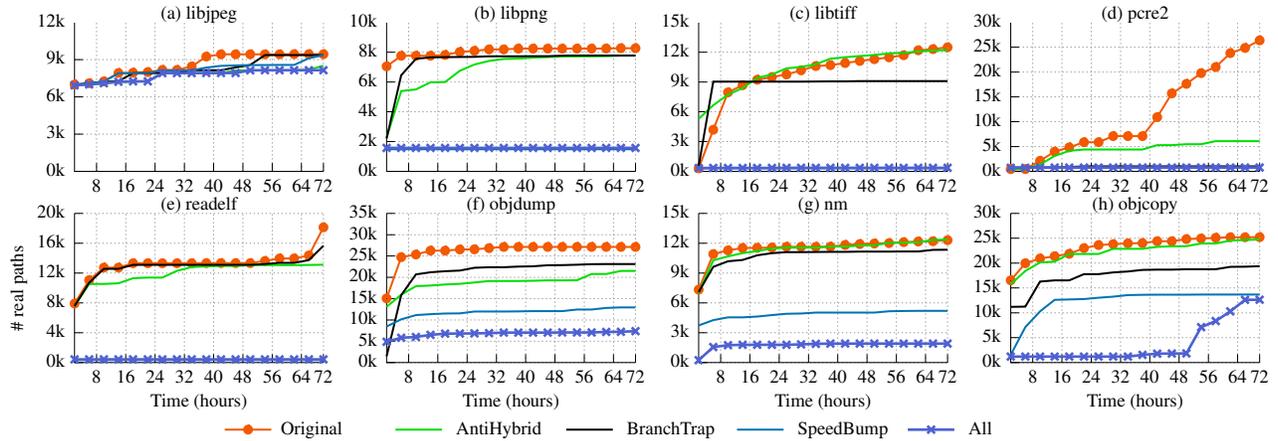

**Table 3:** Experiments summary. Protection options: **Original**, **SpeedBump**, **BranchTrap**, **AntiHybrid**, **All**. We use 4 binutils binaries, 4 binaries from Google OSS project and MuPDF to measure the code coverage. We use binutils binaries and LAVA-M programs to measure the number of unique crashes.

LLVM pass and use it to inject delays into cold blocks during the compilation. For the BranchTrap, we analyze the assembly code and modify it directly. For the AntiHybrid technique, we use an LLVM pass to introduce the path explosion and utilize a python script to automatically inject implicit data-flows. Currently, our system supports all three FUZZIFICATION techniques on 64bit applications, and is able to protect 32bit applications except for the ROP-based BranchTrap.

**Experimental setup.** We evaluate FUZZIFICATION against four state-of-the-art fuzzers that work on binaries, specifically, AFL in QEMU mode, Honggfuzz in Intel-PT mode, VUzzer 32<sup>1</sup>, and QSym with AFL-QEMU. We set up the evaluation on two machines, one with Intel Xeon CPU E7-8890 v4@2.20GHz, 192 processors and 504 GB of RAM, and another with Intel Xeon CPU E7-4820@2.00GHz, 32 processors and 128 GB of RAM.

To get reproducible results, we tried to eliminate the non-deterministic factors from fuzzers: we disable the address space layout randomization of the experiment machine and force the deterministic mode for AFL. However, we have to leave the randomness in Honggfuzz and VUzzer, as they do not support deterministic fuzzing. Second, we used the same set of test cases for basic block profiling in FUZZIFICATION, and fed the same seed inputs for different fuzzers. Third,

<sup>1</sup>We also tried to use VUzzer64 to fuzz different programs, but it did not find any crashes even for any original binary after three-day fuzzing. Since VUzzer64 is still experimental, we will try the stable version in the future.

**Figure 9:** Paths discovered by AFL-QEMU from real-world programs. Each program is compiled with five settings: original (no protection), SpeedBump, BranchTrap, AntiHybrid, and all protections. We fuzz them with AFL-QEMU for three days.

| Category   | Option            | Design Choice     |
|------------|-------------------|-------------------|
| SpeedBump  | max_overhead      | 2%                |
|            | delay_length      | 10ms to 300ms     |
|            | include_invalid   | True              |
|            | include_non_exec  | True (5%)         |
| BranchTrap | max_overhead      | 2%                |
|            | bitmap_saturation | 40% of 64k bitmap |
| AntiHybrid | max_overhead      | 1%                |
|            | include_non_exec  | True (5%)         |
| Overall    | max_overhead      | 5%                |

**Table 4:** Our configuration values for the evaluation.

we used identical FUZZIFICATION techniques and configurations when we conducted code instrumentation and binary rewriting for each target application. Last, we pre-generated FUZZIFICATION primitives (e.g., SpeedBump codes for 10ms to 300ms and BranchTrap codes with deterministic branches), and used the primitives for all protections. Note that developers should use different primitives for the actual releasing binary to avoid code pattern matching analysis.

**Target applications.** We select the LAVA-M data set [17] and nine real-world applications as the fuzzing targets, which are commonly used to evaluate the performance of fuzzers [11, 19, 64, 52]. The nine real-world programs include four applications from the Google fuzzer test-suite [24], four programs from the binutils [20] (shown in Table 2), and the PDF reader MuPDF. We perform two sets of experiments on these binaries, summarized in Table 3. First, we fuzz nine real-world programs with three fuzzers (all except VUzzer<sup>2</sup>) to measure the impact of FUZZIFICATION on finding code paths. Specifically, we compile eight real-world programs (all except MuPDF) with five different settings: original (no protection),

<sup>2</sup>Due to time limit, we only use VUzzer 32 to finding bugs from LAVA-M programs. We plan to do other evaluations in the future.

SpeedBump, BranchTrap, AntiHybrid, and a combination of three techniques (full protection). We compile MuPDF with two settings for simplicity: no protection and full protection. Second, we use three fuzzers to fuzz four binutils programs and all four fuzzers to fuzz LAVA-M programs to evaluate the impact of FUZZIFICATION on unique bug finding. All fuzzed programs in this step are compiled in two versions: with no protection and with full protection. We compiled the LAVA-M program to a 32bit version in order to be comparable with previous research. Table 4 shows the configuration of each technique used in our compilation. We changed the fuzzer’s timeout if the binaries cannot start with the default timeout (e.g., 1000 ms for AFL-QEMU).

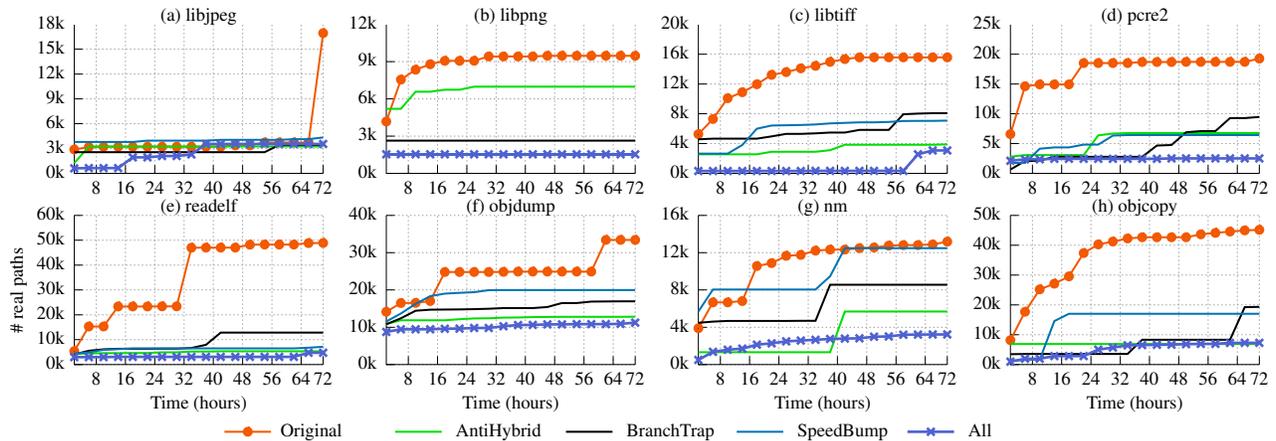

**Evaluation metric.** We use two metrics to measure the effectiveness of FUZZIFICATION: code coverage in terms of discovered *real paths*, and unique crashes. Real path is the execution path shown in the original program, excluding the fake ones introduced by BranchTrap. We further excluded the real paths triggered by seed inputs so that we can focus on the ones discovered by fuzzers. Unique crash is measured as the input that can make the program crash with a distinct real path. We filter out duplicate crashes that are defined in AFL [71] and are widely used by other fuzzers [11, 36].

## 6.1 Reducing Code Coverage

### 6.1.1 Impact on Normal Fuzzers

We measure the impact of FUZZIFICATION on reducing the number of real paths against AFL-QEMU and Honggfuzz-Intel-PT. Figure 9 shows the 72-hour fuzzing result from AFL-QEMU on different programs with five protection settings. The result of Honggfuzz-Intel-PT is similar and we leave it in Appendix A.

In summary, with all three techniques, FUZZIFICATION can reduce discovered real paths by 76% to AFL, and by

**Figure 10:** Paths discovered by QSym from real-world programs. Each program is compiled with the same five settings as in Figure 9. We fuzz these programs for three days, using QSym as the symbolic execution engine and AFL-QEMU as the native fuzzer.

67% to HonggFuzz, on average. For AFL, the reduction rate varies from 14% to 97% and FUZZIFICATION reduces over 90% of path discovery for `libtiff`, `pcre2` and `readelf`. For HonggFuzz, the reduction rate is between 38% to 90% and FUZZIFICATION only reduces more than 90% of paths for `pcre2`. As FUZZIFICATION automatically determines the details for each protection to satisfy the overhead budget, its effect varies for different programs.

Table 5 shows the effect of each technique on hindering path discovery. Among them, SpeedBump achieves the best protection against normal fuzzers, followed by BranchTrap and AntiHybrid. Interestingly, although AntiHybrid is developed to hinder hybrid approaches, it also helps reduce the discovered paths in normal fuzzers. We believe this is mainly caused by the slow down in fuzzed executions.

We measured the overhead by different FUZZIFICATION techniques, on program size and execution speed. The result is given in Table 2. In summary, FUZZIFICATION satisfies the user-specified overhead budget, but shows relatively high space overhead. On average, binaries armed with FUZZIFICATION are 62.1% larger than the original ones. The extra code mainly comes from the BranchTrap technique, which inserts massive branches to achieve bitmap saturation. Note that the extra code size is almost the same across different programs. Therefore, the size overhead is high for small programs, but is negligible for large applications. For example, the size overhead is less than 1% for LibreOffice applications, as we show in Table 7. Further, BranchTrap is configurable, and developers may inject a smaller number of fake branches to small programs to avoid large-size overhead.

**Analysis on less effective results.** FUZZIFICATION shows less effectiveness on protecting the `libjpeg` application. Specifically, it decreases the number of real paths on `libjpeg` by 13% to AFL and by 37% to HonggFuzz, whereas the average reduction is 76% and 67%, respectively. We analyzed

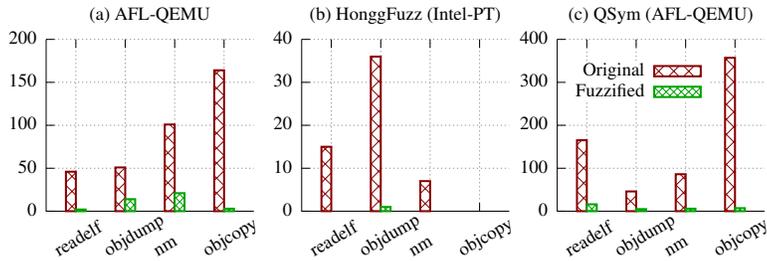

|                 | SpeedBump | BranchTrap | AntiHybrid | All  |
|-----------------|-----------|------------|------------|------|
| AFL-QEMU        | -66%      | -23%       | -18%       | -74% |
| HonggFuzz (PT)  | -44%      | -14%       | -7%        | -61% |
| QSym (AFL-QEMU) | -59%      | -58%       | -67%       | -80% |
| Average         | -56%      | -31%       | -30%       | -71% |

**Table 5:** Reduction of discovered paths by FUZZIFICATION techniques. Each value is an average of the fuzzing result from eight real-world programs, as shown in Figure 9 and Figure 10.

FUZZIFICATION on `libjpeg` and find that SpeedBump and BranchTrap cannot effectively protect `libjpeg`. Specifically, these two techniques only inject nine basic blocks within the user-specified overhead budget (2% for SpeedBump and 2% for BranchTrap), which is less than 0.1% of all basic blocks. To address this problem, developers may increase the overhead budget so that FUZZIFICATION can insert more roadblocks to protect the program.

### 6.1.2 Impact on Hybrid Fuzzers

We also evaluated FUZZIFICATION’s impact on code coverage against QSym, a hybrid fuzzer that utilizes symbolic execution to help fuzzing. Figure 10 shows the number of real paths discovered by QSym from the original and protected binaries. Overall, with all three techniques, FUZZIFICATION can reduce the path coverage by 80% to QSym on average, and shows consistent high effectiveness on all tested programs. Specifically, the reduction rate varies between 66% (`objdump`) to 90% (`readelf`). The result of `libjpeg` shows an interesting pattern: QSym finds a large number of real paths from the original binary in the last 8 hours, but it did not get the same result from any protected binary. Table 5 shows that AntiHybrid achieves the best effect (67% path reduction) against hybrid fuzzers, followed by SpeedBump (59%) and BranchTrap (58%).

**Figure 11:** Crashes found by different fuzzers from binutils programs. Each program is compiled as original (no protection) and fuzzified (three techniques) and is fuzzed for three days.

**Comparison with normal fuzzing result.** QSym uses efficient symbolic execution to help find new paths in fuzzing, and therefore it is able to discover 44% more real paths than AFL from original binaries. As we expect, AntiHybrid shows the most impact on QSym (67% reduction), and less effect on AFL (18%) and HonggFuzz (7%). With our FUZZIFICATION techniques, QSym shows less advantage over normal fuzzers, reduced from 44% to 12%.

## 6.2 Hindering Bug Finding

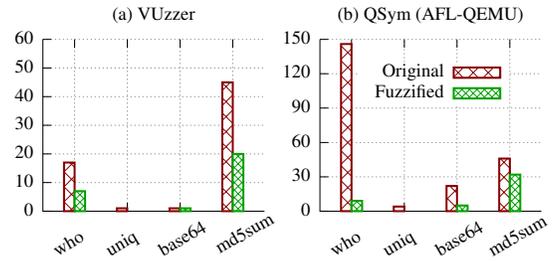

We measure the number of unique crashes that fuzzers find from the original and protected binaries. Our evaluation first fuzzes four binutils programs and LAVA-M applications with three fuzzers (all but VUzzer). Then we fuzz LAVA-M programs with VUzzer, where we compiled them into 32bit versions and excluded the protection of ROP-based BranchTrap, which is not implemented yet for 32bit programs.

### 6.2.1 Impact on Real-World Applications

Figure 11 shows the total number of unique crashes discovered by three fuzzers in 72 hours. Overall, FUZZIFICATION reduces the number of discovered crashes by 93%, specifically, by 88% to AFL, by 98% to HonggFuzz, and by 94% to QSym. If we assume a consistent crash-discovery rate along the fuzzing process, fuzzers have to take 40 times more effort to detect the same number of crashes from the protected binaries. As the crash-discovery rate usually reduces over time in real-world fuzzing, fuzzers will have to take much more effort. Therefore, FUZZIFICATION can effectively hinder fuzzers and makes them spend significantly more time discovering the same number of crash-inducing inputs.

### 6.2.2 Impact on LAVA-M Dataset

Compared with other tested binaries, LAVA-M programs are smaller in size and simpler in operation. If we inject a 1ms delay on 1% of rarely executed basic block on who binary, the program will suffer a slow down of more than 40 times. To apply FUZZIFICATION on the LAVA-M dataset, we

**Figure 12:** Bugs found by VUzzer and QSym from LAVA-M dataset. HonggFuzz discovers three bugs from the original uniq. AFL does not find any bug.

|                 | who             | uniq             | base64           | md5sum           | Average |
|-----------------|-----------------|------------------|------------------|------------------|---------|
| Overhead (Size) | 17.1%<br>(0.3M) | 220.6%<br>(0.3M) | 220.0%<br>(0.3M) | 210.7%<br>(0.3M) | 167.1%  |
| Overhead (CPU)  | 22.7%           | 13.2%            | 21.1%            | 6.5%             | 15.9%   |

**Table 6:** Overhead of FUZZIFICATION on LAVA-M binaries (all protections except ROP-based BranchTrap). The overhead is higher as LAVA-M binaries are relatively small (*e.g.*,  $\approx$  200KB).

allow higher overhead budget and apply more fine-grained FUZZIFICATION. Specifically, we used tiny delay primitives (*i.e.*, 10  $\mu$ s to 100  $\mu$ s), tuned the ratio of basic block instrumentation from 1% to 0.1%, reduced the number of applied AntiHybrid components, and injected smaller deterministic branches to reduce the code size overhead. Table 6 shows the run-time and space overhead of the generated LAVA-M programs with FUZZIFICATION techniques.

After fuzzing the protected binaries for 10 hours, AFL-QEMU does not find any crash. HonggFuzz detects three crashes from the original uniq binary and cannot find any crash from any protected binary. Figure 12 illustrates the fuzzing result of VUzzer and QSym. Overall, FUZZIFICATION can reduce 56% of discovered bugs to VUzzer and 78% of discovered bugs to QSym. Note that the fuzzing result on the original binaries is different from the ones reported in the original papers [67, 52] for several reasons: VUzzer and QSym cannot eliminate non-deterministic steps during fuzzing; we run the AFL part of each tool in QEMU mode; LAVA-M dataset is updated with several bug fixes<sup>3</sup>.

## 6.3 Anti-fuzzing on Realistic Applications

To understand the practicality of FUZZIFICATION on large and realistic applications, we choose six programs that have a graphical user interface (GUI) and depend on tens of libraries. As fuzzing large and GUI programs is a well-known challenging problem, our evaluation here focuses on measuring the overhead of FUZZIFICATION techniques and the functionality

<sup>3</sup><https://github.com/panda-re/lava/search?q=bugfix&type=Commits>

| Category       | Program    | Version | Overhead       |       |
|----------------|------------|---------|----------------|-------|
|                |            |         | Size           | CPU   |
| LibreOffice    | Writer     | 6.2     | < 1% (+1.3 MB) | 0.4%  |
|                | Calc       |         | < 1% (+1.3 MB) | 0.4%  |
|                | Impress    |         | < 1% (+1.3 MB) | 0.2%  |
| Music Player   | Clementine | 1.3     | 4.3% (+1.3 MB) | 0.5%  |
| PDF Reader     | MuPDF      | 1.13    | 4.1% (+1.3 MB) | 2.2%  |
| Image Viewer   | Nomacs     | 3.10    | 21% (+1.2 MB)  | 0.7%  |
| <b>Average</b> |            |         | 5.4%           | 0.73% |

**Table 7:** FUZZIFICATION on GUI applications. The CPU overhead is calculated on the application launching time. Due to the fixed code injection, code size overhead is negligible for these large applications.

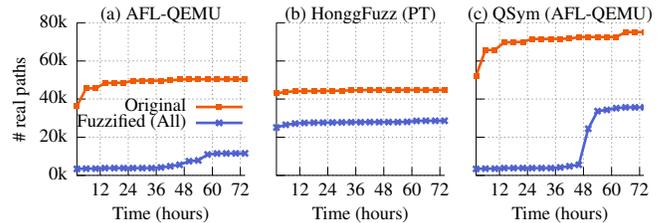

of protected programs. When applying the SpeedBump technique, we have to skip the basic block profiling step due to the lack of command-line interface (CLI) support (*e.g.*, `readelf` parses ELF file and displays results in command line); thus, we only insert slow down primitives into error-handling routines. For the BranchTrap technique, we choose to inject massive fake branches into basic blocks near the entry point. In this way, the program execution will always pass the injected component so that we can measure runtime overhead correctly. We apply the AntiHybrid technique directly.

For each protected application, we first manually run it with multiple inputs, including given test cases, and confirm that FUZZIFICATION does not affect the program’s original functionality. For example, MuPDF successfully displays, edits, saves, and prints all tested PDF documents. Second, we measure the code size and runtime overhead of the protected binaries for given test cases. As shown in Table 7, on average, FUZZIFICATION introduces 5.4% code size overhead and 0.73% runtime overhead. Note that the code size overhead is much smaller than that of previous programs (*i.e.*, 62.1% for eight relatively small programs Table 2 and over 100% size overhead for simple LAVA-M programs Table 6).

**Anti-fuzzing on MuPDF.** We also evaluated the effectiveness of FUZZIFICATION on protecting MuPDF against three fuzzers – AFL, HonggFuzz, and QSym– as MuPDF supports the CLI interface through the tool called “mutool.” We compiled the binary with the same parameter shown in Table 4 and performed basic block profiling using the CLI interface. After 72-hours of fuzzing, no fuzzer finds any bug from MuPDF. Therefore, we instead compare the number of real paths between the original binary and the protected one. As shown in Figure 13, FUZZIFICATION reduces the total paths by 55% on average, specifically, by 77% to AFL, by 36% to HonggFuzz, and 52% to QSym. Therefore, we believe it is more challenging for real-world fuzzers to find bugs from protected applications.

|                   | Pattern matching | Control analysis | Data analysis | Manual analysis |
|-------------------|------------------|------------------|---------------|-----------------|
| <b>SpeedBump</b>  | ✓                | ✓                | ✓             | -               |
| <b>BranchTrap</b> | ✓                | ✓                | ✓             | -               |
| <b>AntiHybrid</b> | -                | ✓                | ✓             | -               |

**Table 8:** Defense against adversarial analysis. ✓ indicates that the FUZZIFICATION technique is resistant to that adversarial analysis.

**Figure 13:** Paths discovered by different fuzzers from the original MuPDF and the one protected by three FUZZIFICATION techniques.

## 6.4 Evaluating Best-effort Countermeasures

We evaluate the robustness of FUZZIFICATION techniques against off-the-shelf program analysis techniques that adversaries may use to reverse our protections. However, the experiment results do not particularly indicate that FUZZIFICATION is robust against strong adversaries with incomparable computational resources.

Table 8 shows the analysis we covered and summarizes the evaluation result. First, attackers may search particular code patterns from the protected binary in order to identify injected protection code. To test anti-fuzzing against pattern matching, we examine a number of code snippets that are repeatedly used throughout the protected binaries. We found that the injected code by AntiHybrid crafts several observable patterns, like hash algorithms or data-flow reconstruction code, and thus could be detected by attackers. One possible solution to this problem is to use existing diversity techniques to eliminate the common patterns [35]. We confirm that no specific patterns can be found in SpeedBump and BranchTrap because we leverage CSmith [66] to randomly generate a new code snippet for each FUZZIFICATION process.

Second, control-flow analysis can identify unused code in a given binary automatically and thus automatically remove it (*i.e.*, dead code elimination). However, this technique cannot remove our FUZZIFICATION techniques, as all injected code is cross-referenced with the original code. Third, data-flow analysis is able to identify the data dependency. We run protected binaries inside the debugging tool, GDB, to inspect data dependencies between the injected code and the original code. We confirm that data dependencies always exist via global variables, arguments, and the return values of injected functions. Finally, we consider an adversary who is capable of conducting manual analysis for identifying the anti-fuzzing code with the knowledge of our techniques. It is worth noting that we do not consider strong adversaries who are capable

of analyzing the application logic for vulnerability discovery. Since FUZZIFICATION injected codes are supplemental to the original functions, we conclude that the manual analysis can eventually identify and nullify our techniques by evaluating the actual functionality of the code. However, since the injected code is functionally similar to normal arithmetic operations and has control- and data-dependencies on the original code, we believe that the manual analysis is time-consuming and error-prone, and thus we can deter the time for revealing real bugs.

## 7 Discussion and Future Work

In this section, we discuss the limitations of FUZZIFICATION and suggest provisional countermeasures against them.

**Complementing attack mitigation system.** The goal of anti-fuzzing is not to completely hide all vulnerabilities from adversaries. Instead, it introduces an expensive cost on the attackers' side when they try to fuzz the program to find bugs, and thus developers are able to detect bugs first and fix them in a timely manner. Therefore, we believe our anti-fuzzing technique is an important complement to the current attack mitigation ecosystem. Existing mitigation efforts either aim to avoid program bugs (*e.g.*, through type-safe language [32, 44]) or aim to prevent successful exploits, assuming attackers will find bugs anyway (*e.g.*, through control-flow integrity [1, 16, 30]). As none of these defenses can achieve 100% protection, our FUZZIFICATION techniques provide another level of defense that further enhances program security. However, we emphasize that FUZZIFICATION alone cannot provide the best security. Instead, we should keep working on all aspects of system security toward a completely secure computer system, including but not limited to secure development process, effective bug finding, and efficient runtime defense.

**Best-effort protection against adversarial analysis.** Although we examined existing generic analyses and believe they cannot completely disarm our FUZZIFICATION techniques, the defensive methods only provide a best-effort protection. First, if attackers have almost unlimited resources, such as when they launch APT (advanced persistent threat) attacks, no defense mechanism can survive the powerful adversarial analysis. For example, with extremely powerful binary-level control-flow analysis and data-flow analysis, attackers may finally identify the injected branches by BranchTrap and thus reverse it for an unprotected binary. However, it is hard to measure the amount of required resources to achieve this goal, and meanwhile, developers can choose more complicated branch logic to mitigate reversing. Second, we only examined currently existing techniques and cannot cover all possible analyses. It is possible that attackers who know the details of our FUZZIFICATION techniques propose a specific method to effectively bypass the protection, such as by

utilizing our implementation bugs. But in this case, the anti-fuzzing technique will also get updated quickly to block the specific attack once we know the reversing technique. Therefore, we believe the anti-fuzzing technique will get improved continuously along the back-and-forth attack and defense progress.

**Trade-off performance for security.** FUZZIFICATION improves software security at the cost of a slight overhead, including code size increase and execution slow down. A similar trade-off has been shown in many defense mechanisms and affects the deployment of defense mechanisms. For example, address space layout randomization (ASLR) has been widely adopted by modern operating systems due to small overhead, while memory safety solutions still have a long way to go to become practical. Fortunately, the protection by FUZZIFICATION is quite flexible, where we provide various configuration options for developers to decide the optimal trade-off between security and performance, and our tool will automatically determine the maximum protection under the overhead budget.

**Delay primitive on different H/W environments.** We adopt CSmith-generated code as our delay primitives using measured delay on one machine (*i.e.*, developer's machine). This configuration implies that those injected delays might not be able to bring the expected slow down to the fuzzed execution with more powerful hardware support. On the other hand, the delay primitives can cause higher overhead than expected for regular users with less powerful devices. To handle this, we plan to develop an additional variation that can dynamically adjust the delay primitives at runtime. Specifically, we measure the CPU performance by monitoring a few instructions and automatically adjusting a loop counter in the delay primitives to realize the accurate delay in different hardware environments. However, the code may expose static pattern such as time measurement system call or a special instruction like `rdtsc`; thus we note that this variation has inevitable trade-off between adaptability and robustness.

## 8 Related Work

**Fuzzing.** Since the first proposal by Barton Miller in 1990 [40], fuzzing has evolved into a standard method for automatic program testing and bug finding. Various fuzzing techniques and tools have been proposed [57, 52, 29, 21, 34], developed [72, 37, 25, 23, 18, 9], and used to find a large number of program bugs [51, 72, 59, 26, 10]. There are continuous efforts to help improve fuzzing efficiency by developing a more effective feedback loop [6], proposing new OS primitives [64], and utilizing clusters for large-scale fuzzing [22, 24, 39].

Recently, researchers have been using fuzzing as a general way to explore program paths with specialties, such as maximizing CPU usage [49], reaching a particular code location [5], and verifying the deep learning result empiri-

cally [47]. All these works result in a significant improvement to software security and reliability. In this paper, we focus on the opposite side of the double-edged sword, where attackers abuse fuzzing techniques to find zero-day vulnerabilities and thus launch a sophisticated cyber attack. We build effective methods to hinder attackers on bug finding using FUZZIFICATION, which can provide developers and trusted researchers time to defeat the adversarial fuzzing effort.

**Anti-fuzzing techniques.** A few studies briefly discuss the concept of anti-fuzzing [63, 27, 41, 31]. Among them, Göransson *et al.* evaluated two straightforward techniques, *i.e.*, crash masking to prevent fuzzers finding crashes and fuzzer detection to hide functionality when being fuzzed [27]. However, attackers can easily detect these methods and bypass them for effective fuzzing. Our system provides a fine-grained controllable method to slow the fuzzed execution and introduces effective ways to manipulate the feedback loop to fool fuzzers. We also consider defensive mechanisms to prevent attackers from removing our anti-fuzzing techniques.

Hu *et al.* proposed to hinder attacks by injecting provably (but not obviously) non-exploitable bugs to the program, called “Chaff Bugs” [31]. These bugs will confuse bug analysis tools and waste attackers’ effort on exploit generation. Both chaff bugs and FUZZIFICATION techniques work on close-source programs. Differently, our techniques hinder bug finding in the first place, eliminating the chance for an attacker to analyze bugs or construct exploits. Further, both techniques may affect normal-but-rare usage of the program. However, our methods, at most, introduce slow down to the execution, while improper chaff bugs lead to crashes, thus harming the usability.

**Anti-analysis techniques.** Anti-symbolic-execution and anti-taint-analysis are well-known topics. Sharif *et al.* [56] designed a conditional code obfuscation that encrypts a conditional branch with cryptographic operations. Wang *et al.* [62] proposed a method to harden the binary from symbolic execution by using linear operations instead of cryptographic functions. However, neither of them considered performance overhead as an evaluation metric. SymPro [7] presented symbolic profiling, a method to identify and diagnose bottlenecks of the application under symbolic execution. Cavallaro *et al.* [8] showed a comprehensive collection of evading techniques on dynamic-taint-analysis.

**Software obfuscation and diversity.** Software obfuscation transforms the program code into obscure formats that are difficult to analyze so as to prevent unexpected reverse engineering [12, 13]. Various tools have been developed to obfuscate binaries [15, 60, 33, 46]. However, obfuscation is not effective to impede unexpected fuzzing because it focuses on evading static analysis and the original program logic is still revealed at runtime. Software diversity instead provides different implementations of the same program for different execution environments, aiming to either limit at-

tacks on a specific version (usually a small set of all distributions), or significantly increase the effort to build generic exploits [35, 3, 53, 50]. Fuzzing one of many diversified versions could be less effective if the identified bug is specific to one version (which is likely caused by an implementation error of the diversity mechanism). However, for bugs stemming from a programming mistake, diversity cannot help hinder attackers finding them.

## 9 Conclusion

We propose a new attack mitigation system, called FUZZIFICATION, for developers to prevent adversarial fuzzing. We develop three principled ways to hinder fuzzing: injecting delays to slow fuzzed executions; inserting fabricated branches to confuse coverage feedback; transforming data-flows to prevent taint analysis and utilizing complicated constraints to cripple symbolic execution. We design robust anti-fuzzing primitives to hinder attackers from bypassing FUZZIFICATION. Our evaluation shows that FUZZIFICATION can reduce paths exploration by 70.3% and reduce bug discovery by 93.0% for real-world binaries, and reduce bug discovery by 67.5% for LAVA-M dataset.

## 10 Acknowledgment

We thank the anonymous reviewers, and our shepherd, Stephen McCamant, for their helpful feedback. *Ruhr-Universität Bochum*

## Abstract

A general defense strategy in computer security is to increase the cost of successful attacks in both computational resources as well as human time. In the area of binary security, this is commonly done by using obfuscation methods to hinder reverse engineering and the search for software vulnerabilities. However, recent trends in automated bug finding changed the *modus operandi*. Nowadays it is very common for bugs to be found by various fuzzing tools. Due to ever-increasing amounts of automation and research on better fuzzing strategies, large-scale, dragnet-style fuzzing of many hundreds of targets becomes viable. As we show, current obfuscation techniques are aimed at increasing the cost of human understanding and do little to slow down fuzzing.

In this paper, we introduce several techniques to protect a binary executable against an analysis with automated bug finding approaches that are based on fuzzing, symbolic/concolic execution, and taint-assisted fuzzing (commonly known as *hybrid fuzzing*). More specifically, we perform a systematic analysis of the fundamental assumptions of bug finding tools and develop general countermeasures for each assumption. Note that these techniques are not designed to target specific implementations of fuzzing tools, but address general assumptions that bug finding tools necessarily depend on. Our evaluation demonstrates that these techniques effectively impede fuzzing audits, while introducing a negligible performance overhead. Just as obfuscation techniques increase the amount of human labor needed to find a vulnerability, our techniques render automated fuzzing-based approaches futile.

## 1 Introduction

In recent years, fuzzing has proven a highly successful technique to uncover bugs in software in an automated way. Inspired by the large number of bugs found by fuzzers such as AFL [56], research recently focused heavily on improving the state-of-the-art in fuzzing techniques [10, 11, 22, 44, 54].

Previously, it was paramount to manually remove checksums and similar roadblocks from the fuzzing targets. Additionally, fuzzers typically required large, exhaustive seed corpora or a precise description of the input format in form of a grammar. In a push towards a greater degree of automation, research recently focused on avoiding these common roadblocks [14, 39, 44, 45, 48, 54]. This push toward automation greatly simplifies the usage of these tools. One can argue that, for the attacker, using a fuzzer is as easy as it is for the defender. In fact, recently the *Fuzzing Ex Machina* (FExM) [49] project managed to reduce the overhead of running fuzzers to a degree where they managed to fuzz the top 500 packages from the Arch Linux User Repository with no manual effort in seed selection or similar issues. This two day effort yielded crashes in 29 of the most popular packages of Arch Linux. It stands to reason that this kind of indiscriminate, dragnet-style searching for software bugs will become more prevalent in the future.

While the developers of a software system should typically thoroughly fuzz test every type of software, in practice they may want to maintain an asymmetric cost advantage. More specifically, it should be easier for the maintainers of a software project to fuzz their own software than for attackers. This can be achieved by adding mechanisms to the software such that the final binary executable is protected against fuzzing: the maintainers can then build an internal version that can be tested thoroughly, while an attacker can only access the protected binary which prohibits automated tests. In the past, similar asymmetric advantages in analysis and bug finding were introduced by obfuscation techniques. As we demonstrate, even very high levels of obfuscation will typically result only in a meager slowdown of current fuzzing techniques. This is due to the fact that obfuscation typically aims at protecting against program understanding and formal reasoning. On the other hand, fuzzers typically do not perform a significant amount of reasoning over the behaviour of the program. On the downside, these heavy obfuscation mechanisms will often incur a significant runtime overhead [19].

How software can be protected against fuzzing in an efficient and effective way is an open problem.

In this paper, we tackle this challenge and present several general methods to impede large scale, automated fuzzing audit of binary executables. We present several techniques that can be added during the compilation phase of a given software project such that the resulting binary executable withstands fuzzing and significantly hampers automated analysis. Our methods are based on a systematic analysis of 19 current bug finding tools with respect to their underlying assumptions. Note that we use the terms “fuzzer” and “bug finding tool” interchangeably to describe all kinds of tools that are analyzing programs to produce crashing inputs as opposed to static analysis tools and linters. We find that all of them rely on at least one of the following four basic assumptions: (i) coverage yields relevant feedback, (ii) crashes can be detected, (iii) many executions per second are achievable, and (iv) constraints are solvable with symbolic execution. Based on these insights, we develop fuzzing countermeasures and implement a lightweight protection scheme in the form of a configurable, auto-generated single C header file that developers can add to their application to impede fuzzers. For the evaluated programs, we had to change on average 29 lines of code, which took less than ten minutes. With these changes, attackers now need to spend a significant amount of time to manually remove these anti-fuzzing mechanisms from a protected binary executable (typically magnified by common obfuscation techniques on top), greatly increasing the cost of finding bugs as an attacker. Defenders, on the other hand, can still trivially fuzz the unmodified version of their software with no additional cost. Thus, only unwanted and unknown attackers are at a disadvantage.

We implemented a prototype of the proposed methods in a tool called ANTIFUZZ. We demonstrate in several experiments the effectiveness of our approach by showing that state-of-the-art fuzzers cannot find bugs in binary executables protected with ANTIFUZZ anymore. Moreover, we find that our approach introduces no observable, statistically significant performance overhead in the SPEC benchmark suite.

**Contributions** In summary, in this paper we make the following contributions:

- We present a survey of techniques employed by current fuzzers and systematically analyze the basic assumptions they make. We find that different fuzzing approaches rely on at least one of the fundamental assumptions which we identify.
- We demonstrate how small changes to a program nullify the main advantages of fuzzing by systematically violating the fundamental prerequisites. As a result, it becomes significantly harder (if not impossible with current approaches) to find bugs in a protected program without manual removal of our anti-fuzzing methods.

- We implemented our anti-fuzzing techniques in a tool called ANTIFUZZ that adds fuzzing countermeasures during the compilation phase. Our evaluation with several different programs shows that with a negligible performance overhead, ANTIFUZZ hardens a target binary executable such that none of the tested fuzzers are able to find any bugs.

To foster research on this topic, we release our implementation and the data sets used as part of the evaluation at <https://github.com/RUB-SysSec/antifuzz>.

## 2 Technical Background

Fuzzing (formerly known as random testing) has been around since at least 1981 [20]. In the beginning, fuzzers would simply try to execute programs with random inputs. While executing, the fuzzer observes the behavior of the program under test: if the program crashes, the fuzzer managed to find a bug and the input is stored for further evaluation. Even though this technique is surprisingly simple—particularly when compared to static program analysis techniques—with a sufficient number of executions per second it has been helpful at finding bugs in complex, real-world software in the past.

In recent years, the computer security community paid much more attention to improving the performance and scalability of fuzzing. For example, the OSS-FUZZ project has been fuzzing many highly-relevant pieces of software 24/7 since 2016 and exposed thousands of bugs [1]. FEXM automatized large parts of the setup and the authors were able to fuzz the top 500 packages from the Arch Linux User Repository [49]. To improve the usability of fuzzers in such scenarios, the biggest focus of the research community is to automatically overcome hard-to-fuzz code constructs that previous methods could not successfully solve with the goal of reaching deeper parts of the code. Particularly, common program analysis techniques were applied to the problem of fuzzing. For example, symbolic execution and its somewhat more scalable derivative concolic execution was used to overcome hard branches and trigger bugs that are only trigger-able by rare conditions [25–27, 31, 42, 48, 50, 54]. Other fuzzers use taint tracing to reduce the search space to mutations that actually influence interesting parts of the program [14, 23, 31, 42, 45]. A complementary line of work focused on improving the fuzzing process itself without falling back to (often costly) program analysis techniques. Many techniques propose improvements to the way AFL instruments the target [2, 22, 29, 47], or how inputs are scheduled and mutated [10, 11, 13, 46, 52]. Some methods go as far as removing hard parts from the target [44, 50]. Lastly, the effectiveness of machine learning models for efficient input generation was evaluated [9, 28, 32].

Generally speaking, existing methods for fuzzing can be categorized into the following three different categories based

on the techniques employed, which we explain in more detail in the following.

## 2.1 Blind Fuzzers

The oldest class of fuzzers are so-called *blind fuzzers*. Such fuzzers have to overcome the problem that random inputs will not exercise any interesting code within a given software. Two approaches were commonly applied: *mutational fuzzing* and *generational fuzzing*.

Mutational fuzzers require a good corpus of inputs to mutate. Generally, mutational fuzzers do not know which code regions depend on the input file and which inputs are necessary to reach more code regions. Instead, these fuzzers introduce some random mutations to the file and can only detect if the program has crashed or not. Mutational fuzzers need seed files that cover large parts of interesting code as they are unable to uncover new code effectively. In the past, these fuzzers were quite successful at uncovering bugs [33]. However, they typically need to perform a large number of executions per second to work properly. An example of mutational-only fuzzers are ZZUF [5] and RADAMSA [33].

The second approach is generational fuzzing: fuzzers which employ this technique need a formal specification to define the input format. Based on this specification, the fuzzer is able to produce many semi-valid inputs. This has the advantage that the fuzzer does not need to learn how to generate well-formed input files. However, manual human effort is necessary to create these definitions (e.g., a grammar that describes the input format). This task becomes hard for complex or unknown formats and the specification could still end up lacking certain features. The additional need for a formal specification makes this approach much less useful for large-scale bug hunting with little human interaction. An example of a generational fuzzer is PEACH [3].

In summary, the only thing a blind fuzzer is able to observe is whether its input led to a crash of the program or not. Therefore, these techniques have no indicator of their progress in exploring the programs state space and thus (especially in the case of mutational fuzzers), they are mostly limited to simple bugs even with non-empty and well-formed seed files.

## 2.2 Coverage-guided Fuzzers

To improve the performance of the mutational fuzzers, Zalewski introduced an efficient way to measure coverage-feedback of an application [56]. This led to a significant amount of research on coverage-guided fuzzers. These fuzzers typically use a feedback mechanism to receive information on how an input has affected the program under test. The key idea here is that this mechanism gives means by which to judge an input: Which (new) code regions were visited and how often? In contrast, a blind fuzzer introduces random mutations to the

input without knowing how those mutations affect the program. It effectively relies on pure chance for finding crashing inputs, while a coverage-guided fuzzer could mutate the same input file iteratively to increase the code coverage and thus get closer to new regions where a crash could happen. Examples of coverage-based fuzzers are AFL [56], HONGGFUZZ [4], ANGORA [14], T-FUZZ [44], KAFL [47], REDQUEEN [8] and VUZZER [45]. These fuzzers use multiple ways to obtain coverage feedback:

**Static Instrumentation:** One of the fastest methods for obtaining code coverage is static compile time coverage (widely used by tools such as AFL, ANGORA, LIBFUZZER, and HONGGFUZZ). In this case, the compiler adds special code at the start of each basic block that stores the coverage information. From a defender's point of view, this kind of instrumentation is not relevant, as we assume that the attackers do not have access to the source code.

**Dynamic Binary Instrumentation (DBI):** If only a binary executable is available, fuzzer typically use dynamic binary instrumentation (DBI) to obtain coverage information. This is done by adding the relevant code at runtime. Examples of this approach are VUZZER and STEELIX [39], which both use PIN-based [40] instrumentation, and AFL which has multiple forks using QEMU, PIN, DYNAMORIO, or DYNINST for DBI. Fuzzers like DRILLER [48] and T-FUZZ use AFL under the hood and typically rely on the QEMU-based instrumentation.

**Hardware Supported Tracing:** Modern CPUs support various forms of hardware tracing. For Intel processors, two technologies can be used: Last Branch Record and Intel-PT. HONGGFUZZ is able to utilize both techniques, while fuzzers like KAFL only support Intel-PT.

### 2.2.1 Using Coverage Information:

Different fuzzers tend to use the coverage feedback obtained in different ways. To illustrate these differences, we select two well-known coverage-guided fuzzers; namely AFL and VUZZER. We then describe how these fuzzers are using coverage information internally. It is worth noting that by choosing AFL, we are basically covering the way various other fuzzers such as T-FUZZ, ANGORA, KAFL, STEELIX, DRILLER, LIBFUZZER, WINAFL, AFLFAST [11], and COLLAFL [22] are using coverage information. All of these fuzzers (except ANGORA) use the same underlying technique for leveraging coverage information. In contrast to AFL, no other fuzzer followed the path of VUZZER in coverage information usage. However, due to the unique usage of coverage information in VUZZER, we describe it as well.

**AFL** A key factor behind the success of AFL is an efficient, approximate representation of the code coverage. To reduce the memory footprint, AFL maps each basic block transition (edge) to one index in a fixed size array referred to as the "bitmap". Upon encountering a basic block transi-

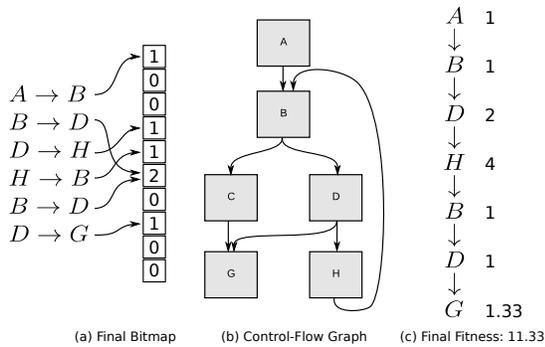

Figure 1: Using coverage information in AFL-like fuzzers versus Vuzzer in the same path of a given Control-Flow Graph (b).

tion, it increments the corresponding value in the bitmap as illustrated in Figure 1(a). The bitmap is typically limited to 64KiB, so it easily fits inside an L2 cache [55]. Although limiting the size of the bitmap allows very efficient updates, it also reduces its precision, since in some cases multiple edges share the same index in the bitmap. It is possible to increase the size of the bitmap, but at the cost of a significant decline in performance [22].

As mentioned earlier, ANGORA uses a very similar scheme with a slight difference: before updating the bitmap entry, ANGORA XORs the edge index with a hash of the call stack. This way, ANGORA can distinguish the same coverage in different contexts, while AFL can not. For example, in Listing 1, AFL cannot distinguish the coverage produced by lines 2 and 3 when called from line 10 from the coverage produced by the same lines (lines 2 and 3) in the second call. Therefore, AFL can use feedback to learn that the input should start with “fo”, however, it cannot use the same information to learn that the input should continue with “ba”. In contrast, ANGORA can identify the context (here “fo” and “ba”) of the code and thus distinguish between these two calls. It is worth to mention that this drastically increases the number of entries in the bitmap, and therefore ANGORA might need a bigger bitmap.

Listing 1: A sample code which illustrates the differences between AFL and ANGORA on distinguishing coverage information

```

1 bool cmp(char *a, char *b){
2     if (a[0]==b[0]){
3         if (a[1]==b[1]){
4             return true;
5         }
6     }
7     return false;
8 }
9 ...
10 if (cmp(input, "fo")){
11     if (cmp(input+2, "ba")){
12         ...
13     }
14 }

```

**Vuzzer** AFL does not discriminate among edges. Therefore, an input that covers one previously unseen edge is just as interesting as an input which covers hundreds of unseen edges. This is the fundamental difference between VUZZER

and AFL. Unlike AFL, VUZZER extracts the exact basic block coverage (instead of the bitmap) and enriches the feedback mechanism with additional data. For example, VUZZER uses a static disassembly to weight basic blocks according to how “deep” they are within a function (e.g., how many conditions have to be satisfied to reach this block). Higher scores are assigned to harder-to-reach blocks. To further improve the feedback mechanism, VUZZER excludes basic blocks that belong to error paths by measuring the coverage produced by random inputs. In the example shown in Figure 1(c), each basic block has a weight. As can be seen, basic block H has a much higher weight than basic block G because H is much less likely to be reached by a random walk across the control-flow graph (with back-edges removed). Finally, all the weights of all basic blocks in the path are added up to calculate a fitness value. VUZZER then uses an evolutionary algorithm to produce new mutations: inputs with a high fitness value produce more offspring. These newly created offspring are then used as the next generation.

## 2.3 Hybrid Fuzzers

While using coverage-based fuzzing already leads to interesting results on its own, there are code regions in a program which are hard to reach. This typically happens if only a very small percentage of the inputs satisfy some conditions. For example, a specific four-byte magic value that is checked by the program under the test makes it nearly impossible for coverage-based fuzzers to pass the check and therefore reach deeper code regions. To address this problem, various research suggest using a combination of program analysis techniques to assist the fuzzing process [44, 48, 54]. By using symbolic execution or taint analysis, a fuzzer is able to reason what inputs are necessary to cover new edges and basic blocks. Instead of only relying on random mutations and selection by information gathered through feedback mechanisms, these tools try to calculate and extract the correct input necessary for new code coverage. Examples of fuzzers which are using symbolic or concolic execution to assist the coverage-based fuzzer are DRILLER [48], QSYM [54], and T-FUZZ [44].

The archetypal hybrid fuzzer is DRILLER, which uses concolic execution to search for inputs that produce new coverage. It tries to provide a comprehensive analysis of the program’s behaviour. In contrast, QSYM [54] identified this behavior as a weakness since the fuzzer can validate that the input proposed by the symbolic or concolic execution generates new coverage very cheaply. Therefore, an unsound symbolic or concolic execution engine can produce a large number of false positive proposals, without reducing the overall performance of the fuzzer. Building upon this insight, QSYM discards all but the last constraint in the concrete execution trace as well as the symbolic values produced by basic blocks that were executed frequently. Finally, it is worth mentioning that in the case of T-FUZZ, symbolic execution is not used for

the fuzzing process itself. Instead, T-FUZZ patches hard constraints. Once T-FUZZ finds a crashing input for the patched program, it uses symbolic execution to calculate an input that actually crashes the unpatched target program.

### 3 Analysis of Fuzzing Assumptions

Based on the categories described in the previous section, we now analyze and identify fundamental assumptions that fuzzers use to find bugs. The first insight is that while many aspects of fuzzing have changed since 1981, two basic assumptions which were originally made still apply to most modern fuzzers: these two basic original assumptions are *crash detection* and *high execution throughput*. However, to achieve better performance in modern fuzzers, additional assumptions were made in the past years, as we discuss next.

To evade not only current but also future bug finding methods, we analyze under which *core assumptions* all (or at least most) of the current tools operate. By systematically breaking assumptions shared by most fuzzers, we can develop a more universal defense against automated audits. Using this systematic approach, we avoid targeting specific implementations and therefore will hamper all future fuzzing methods built upon the same general assumptions. We divide the current fuzzing assumptions into the following four groups:

**(A) Coverage Yields Relevant Feedback** Coverage-guided fuzzers typically assume that novel code coverage also strongly correlates with novel behavior. Therefore, every time a modern coverage-guided fuzzer generates an input which traverses through a new code region, it assumes that the program behaves differently from previous inputs. Based on the coverage, the fuzzer decides how much time to allocate for generating further mutations of this input. For example, most current fuzzers such as AFL, VUZZER, DRILLER, QSYM, KAFL, ANGORA, T-FUZZ, and LIBFUZZER use this assumption for coverage-guided fuzzing.

**(B) Crashes Can Be Detected** Triggering security-relevant bugs will typically lead to a program crash. Thus, most bug finding tools need the ability to tell a crashing input apart from a non-crashing input in an efficient and scalable way. As a result, they require some techniques to detect if an application has crashed. Nearly all random testing tools share this assumption since 1981 [20]. In addition to the coverage-guided fuzzers, this assumption is also shared by blind fuzzers such as PEACH, RADAMSA, and ZZUF.

**(C) Many Executions per Second** To efficiently generate input files with great coverage, the number of executions per second needs to be as high as possible. In our experience, depending on the application and fuzzer, a range from few hundreds up to a few thousands of executions per second are typical. Slow executions will drastically degrade the performance. All fuzzers mentioned in the previous assumptions

also fall into this class. Only pure symbolic execution tools such as KLEE do not fall into this category.

**(D) Constraints Are Solvable with Symbolic Execution** Hybrid fuzzers or tools based on symbolic execution such as DRILLER, KLEE, QSYM, and T-FUZZ need to be able to represent the program's behavior symbolically and solve the resulting formulas. Therefore, any symbolic or concolic execution-based tools only operate well when the semantics of the program under test are simple enough. This means that the internal representation of the state of the symbolic/concolic execution engine has to be small enough to store and the resulting constraints set has to be solvable by current solvers to avoid problems related to state explosion.

**Summary** We compiled a list of 19 different bug finding tools and systematically check which assumptions they rely on. An overview of the analyzed tools and their corresponding assumptions is shown in Table 1. It is worth mentioning that various tools in this table are based on AFL and thus share the same assumptions.

### 4 Impeding Fuzzing Audits

Based on the analysis results of the previous section, we now introduce techniques to break the identified assumptions of bug finding tools in a systematic and generic way. Moreover, we sketch how these techniques can be implemented; actual implementation details are provided in the next section.

**Attacker Model** Throughout this paper, we use the following attacker model. First, we assume that an attacker can only access the final protected binary executable and not the original source code of the software. She wants to find bugs in an automated way in the protected binary executable, while requiring only a minimum human intervention. Commonly there is the notion that source-based fuzzers significantly outperform binary-only fuzzers. Therefore, it is believed that defenders already have a significant cost advantage over attackers. However, recent advances in fuzzing have shown that this advantage is in decline. For example, recent binary-only fuzzing techniques paired with hardware acceleration technologies such as Intel PT have drastically reduced the performance gap between binary and source fuzzing. For example, Cisco Talos states that the overhead is only 5% to 15% [36] and similar numbers are reported for published Intel PT-based fuzzers such as KAFL [47]. Additionally, smart fuzzing techniques outperform source-based fuzzing even in binary-only targets [8, 54].

Although many relevant software projects are open source, a large part of all commercial software used in practice is not available in source code format (e.g., Windows, iOS and the vast majority of the embedded space). Nonetheless, some large software projects such as certain PDF viewer and hypervisors are not only well-tested by their developers, but also by whitehat attackers. This additional attention is an

Table 1: Bug finding tools and the assumptions they rely on.

important factor in their security model. Similarly, projects that have a history of helpful interactions with independent researchers should consider not to use ANTIFUZZ, to avoid scaring researchers away. As an alternative, projects with such a successful history of community integration can choose to release unprotected binaries to a set of trusted security researchers. On the other hand, the vast majority of software gets far less to no attention. These less well-known pieces of software are still used by many users and they might profit significantly from raising the bar against fuzzing (e.g., industrial controllers such as PLCs [6, 37] or other types of proprietary software).

Furthermore, in this paper, we consider the case that the attacker can use any state-of-the-art bug finding tool. However, we assume that she spends no time on manually reverse engineering the binary or building custom tooling. We are aware that in a more realistic scenario, the target application might be attacked by a human analyst. However, we assume that ANTIFUZZ is combined with other techniques that were developed to incur significant cost for human analyst during reverse engineering [16, 17, 21, 24, 41, 43, 53]. Therefore, to ensure that different concerns (defending against fuzzing *and* defending against analysis by a human) are separated, we explicitly exclude human analysts from our attacker model.

## 4.1 Attacking Coverage-guidance

As mentioned previously, the core assumption of coverage-guided fuzzers is that new coverage indicates new behavior in the program. To undermine this assumption, we modify the program which we want to defend against fuzzing by adding irrelevant code in such a way that its coverage information drowns out the actual signal. More specifically, by adding irrelevant code regions (which we call *fake code*), we deliber-

ately disturb the code coverage tracking mechanisms within fuzzers. Thereby, we weaken the fuzzer’s ability to use the feedback mechanism in any useful way and thus remove their advantage over blind fuzzers.

To introduce noise into the coverage information, we use two different techniques. The first technique aims at producing different “interesting” coverage for nearly all inputs. The rationale behind this is that according to the coverage-guide assumption, *any* new coverage means that the fuzzer found an input that causes new behavior. Therefore, if the program *always* displays new coverage (due to our fake code), the fuzzer cannot distinguish between legitimate new coverage and invalid fake coverage. As every single input seems to trigger new behavior, the fuzzer assumes that every input is interesting. Therefore, it spends a significant amount of time on generating mutations based on invalid input.

To implement this technique, we calculate the hash of the program input and based on this hash, we pick a small random subset of fake functions to call. Each fake function recursively calls the next fake function from a table of function pointers, in such a way that we introduce a large number of new edges in the protected program.

Since even a single bit flip in the input causes the hash to be completely different, nearly any input that the fuzzer generates displays new behavior. Fuzzers that are objective-driven and thus assign weights to more interesting code construct might find it easy to distinguish between this simple fake code and the actual application code. Since we cannot assume that future fuzzers will treat new coverage information in the same way as current fuzzers do, we introduce a second technique that aims at providing plausible-looking, semi-hard constraints. The second technique is designed to add fake code that looks like it belongs to the legitimate input handling

code of the original application. At the same time, this code should include a significant number of easy constraints as well as some very hard constraints. These hard constraints can draw the attention of different solving strategies, while the easy constraints allow us to add noise to the true coverage information. We create this fake code by creating random trees of nested conditions with conditions on the input ranging from simple to complicated.

**Evasion** Overall, the attack on the code-coverage assumption consists of a combination of these two techniques to fool the fuzzer into believing that most inputs lead to new code coverage and thus they are classified as “interesting”. This fills up the attention mechanism of the fuzzer (e.g., AFL’s bitmap or a queue) with random information which breaks the assumption that the feedback mechanism is helpful in determining which inputs will lead to interesting code.

## 4.2 Preventing Crash Detection

After applying our previous method, coverage-guided fuzzers are “blinded” and have few advantages left in comparison to blind fuzzers. To further reduce the ability of both coverage-guided and blind fuzzers to find bugs, we introduced two additional techniques that attack assumption B identified earlier.

There are multiple ways for a fuzzer to detect if a crash has happened. The three most common ways are (i) observing the exit status, (ii) catching the crashing signal by overwriting the signal handler, and (iii) using the operating system (OS) level debugging interfaces such as `ptrace`. To harden our protected program against fuzzers, we try to block these approaches by common anti-debugging measures as well as a custom signal handler that exits the application gracefully. After we install our custom signal handler, we intentionally trigger a `segfault` (*fake crash*) that our own signal handler recognizes and ignores. This way, if an outside entity is observing crashes that we try to mask, it will always observe a crash for each and every input. It is worth mentioning that by design, the fake crash is triggered at *every* program execution independent from the user input. Thus we do not introduce crashes based on user inputs.

**Evasion** We try to catch all crashes before they are reported to an outside entity. If the current application is under observation or analysis (i.e., where catching crashes is not allowed), the application is terminated. Typically, if it was deemed necessary to apply ANTIFUZZ to any application, there is likely no scenario where it would *also* be necessary to continue operating under the given conditions.

In all of these cases, no crashes will be detected even if they still occur, which breaks the assumption that a crashing input is detectable as such.

## 4.3 Delaying Execution

We found that fuzzing tools need many executions per second to operate efficiently. Our third countermeasure attacks this assumption, without reducing the overall performance of the protected program, as follows: we check whether the input is a well-formed input; if and only if we detect a malformed input, we enforce an artificial slowdown of the application. For most applications, this would not induce any slowdowns in real-world scenarios, where input files are typically well-formed. But at the same time, it would significantly reduce the execution speed for fuzzers, where most of the inputs will be incorrect. We believe that even if malformed input files occasionally happen in real scenarios, a slowdown of e.g., 250ms per invalid input is barely noticeable to the end user in most cases. In contrast, even such a small delay has drastic effects on fuzzing. Thus, only fuzzers are negatively affected by this technique.

Delaying the execution can happen through different means, the easiest way to cause a delay is using the `sleep()` function. However, to harden this technique against automated code analysis and patching tools, one can add a computationally-heavy task (e.g., encryption, hash calculation, or even cryptocurrency mining) to the protected program such that the resulting solution is necessary to continue the execution.

**Evasion** Most applications expect some kind of structure for their input files and have the ability to tell if the input adheres to this structure. Therefore, ANTIFUZZ does not need to rely on any formal specification; instead, our responses are triggered by existing error paths within the program. For the prototype implementation, we do not propose to detect error paths automatically, but instead insert them manually as a developer. If the input is malformed, we artificially slow down the execution speed of the program. This breaks the assumption that the application can be executed hundreds or thousands of times per second, thus severely limiting the chances of efficiently finding new code coverage.

## 4.4 Overloading Symbolic Execution Engines

To prevent program analysis techniques from extracting information to solve constraints and cover more code, we introduce two techniques. Both techniques are based on the idea that simple tasks can be rewritten in a way that it is a lot harder to reason about their behavior [51]. For example, we can replace an addition operation using an additive homomorphic encryption scheme. In the following, we introduce two practical techniques to achieve this goal.

First, we use hash comparisons. The idea is to replace all comparisons of input data to constants (e.g., magic bytes) with a comparison of their respective strong cryptographic hash values. While still practically equivalent (unless small collisions for current hashes are found), the resulting computation is significantly more complex. The resulting symbolic

expressions grow significantly, and the solvers fail to find a satisfying assignment for these equations; they become useless for finding correct inputs. However this technique has one weakness: If a seed file is provided that contains the correct value, a concolic execution engine might still be able to continue solving other branches.

As a second technique, we can encrypt and then decrypted the input with a block cipher. We later describe this technique in detail in Section 5.4.

**Evasion** By sending the input data through a strong block cipher and replacing direct comparisons of input data to magic bytes by hash operations, symbolic, concolic, and taint-based execution engines are significantly slowed down and hampered in their abilities to construct valid inputs. This breaks the assumption that constraints in the application are solvable. Even though the encryption/decryption combination is an identity transformation, it is very hard to prove automatically that the resulting output byte only depends on the corresponding input byte. Therefore, symbolic/concolic execution engines either carry very large expressions for each input byte, or they concretize every input byte, completely voiding the advantage they provide. Finally, common taint tracking engines will not be able to infer taint on the input, as the encryption thoroughly mixes the input bits.

## 5 Implementation Details

In this section, we provide an overview of the proof-of-concept implementation of our techniques in a tool called ANTI FUZZ. As explained above, the use case for ANTI FUZZ is a developer who has access to source code and wants to protect his application from attackers who use automatic bug finding tools to find bugs cost-effectively. Hence, an important objective was to keep the required modifications to the project at a minimum, so that ANTI FUZZ is easy to apply. The implementation consists of a Python script that automatically generates a single C header file that needs to be included in the target program. Furthermore, small changes need to be performed to instrument a given application. For our experiments, we analyzed the time it took us to apply ANTI FUZZ to LAVA-M (which consists of the four programs `base64`, `md5sum`, `uniq`, and `who`). As we were already familiar with the code base of these tools, we could more closely resemble a developer who has a good understanding of the structure of the code. It took us four to ten minutes to apply ANTI FUZZ to each application. The number of lines that needed to be added or changed depends on the number of constant comparisons that need to be replaced by hash comparisons. `base64` was an outlier with 79 changed lines, 64 of which were necessary due to a check against every possible character in the `base64` alphabet. The three remaining applications required 6 (`uniq`), 7 (`who`), and 23 (`md5sum`) changed lines, respectively.

In the following, we describe technical details of how ANTI FUZZ is implemented.

### 5.1 Attacking Coverage-guidance

To prevent coverage-guided fuzzing, it is necessary to generate random constraints, edges, and constant comparisons, as detailed in Section 4.1. The core idea here is to use every byte of the input file in a way that could lead to a new basic block, e.g., by making it depend on some constraints or by comparing it to randomly generated constants. Depending on the configurable number of constraints and the size of the input file, every byte could be part of *multiple* constraints and constant comparisons.

Implementation-wise, although it is possible to generate code for ANTI FUZZ dynamically at runtime, this might cause problems for fuzzers relying on static code instrumentation (i.e., they might not be able to “see” code introduced by ANTI FUZZ). Thus, our template engine, implemented in 300 lines of Python code, generates a C file containing all randomly chosen constraints and constants, and further provides the ability to set configuration values (e.g., number of fake basic blocks).

The random edge generation is implemented through a shuffled array (where the input file seeds the randomness) consisting of functions that call each other based on their position in the array (up to a certain configurable depth).

ANTI FUZZ provides a function called `antifuzz_init()` that needs to be called with the input filename, ideally before the file is being processed by the application. This change needs to be done manually by the developer when he wants to protect his software against fuzzing: the developer needs to add one line that calls this function. The function implements all the techniques against coverage-guided fuzzers mentioned earlier and sets up signal handlers to prevent crash detection, as detailed in the next section.

### 5.2 Preventing Crash Detection

When `antifuzz_init()` is called, ANTI FUZZ has to confirm that no crashes can be observed. As detailed in Section 4.2, it is necessary to overwrite the crash signal handlers, as well as prevent it from being observed with `ptrace`.

In the former case, ANTI FUZZ first checks whether overwriting signals is possible: we register a custom signal handler and deliberately crash the application. If the custom signal handler was called, it ignores the crash and resumes execution. If the application does not survive the crash, it means that overwriting signals is not possible and, for our purposes, the resulting crash is a desirable side-effect. If the application survives the crash, evidently, signal overwriting is possible.

ANTI FUZZ then installs custom signal handlers for all common crash signals and overwrites these with either a timeout or a graceful exit (depending on the configuration). This will

keep some fuzzers from covering any code because they do not survive the artificial crash at the beginning of the application. This behavior could also be replaced by an exit or by calling additional functions that lead to fake code coverage to keep up a facade of a working fuzzer.

In the case of `ptrace`, we use a well-known anti-debugging technique [34] to detect if we are being observed by `ptrace`: we check whether we can `ptrace` our own process. If we can `ptrace` our own process, it means that no other process is `ptracing` it. However, if we are unable to `ptrace` our own process, it implies that another process is `ptracing` it and therefore ANTI FUZZ terminates the application.

### 5.3 Delaying Execution

As detailed in Section 4.3, ANTI FUZZ needs to know when an input is malformed to slow down the application and hamper the performance of fuzzers. The main idea, implementation-wise, is to allow the developer to inform ANTI FUZZ whenever an input is malformed. Most applications already have some kind of error handling for malformed input, which either discards the input or terminates the application. Within this error handling function of the to-be-protected program, the developer needs to add a single call to `antifuzz_onerror()`.

Upon invocation of `antifuzz_onerror()`, ANTI FUZZ delays the execution for a configurable amount of time using either of the mechanisms mentioned in Section 4.3.

### 5.4 Overloading Symbolic Execution Engines

There are two main parts to our countermeasures against symbolic/concolic execution and taint analysis engines: replacing constant comparisons with comparisons of their respective cryptographic hashes, and putting the input through a cryptographic block cipher before usage.

The first part is implemented via the SHA-512 hash function. The developer needs to replace important (i.e., input-based) comparisons with the hash functions provided by ANTI FUZZ. Due to the nature of cryptographic hashes, two hash values can only be checked for equality, and not whether one is larger or smaller than the other.

To encrypt and decrypt the input buffer, we use the AES-256 encryption function in ECB mode. The key is generated from a hash of the input at runtime. We provide a function that provides the encryption-decryption routine. We can use this function on any kind of input stream. We provide `antifuzz_fread()` as a convenience to make it easier to integrate the common cases. Any call to `fread()` needs to be replaced with its ANTI FUZZ-equivalent call.

Figure 2 illustrates the implementation of all described techniques using ANTI FUZZ in a simple program. Figure 2.a shows an unprotected application which is checking an input value. If the input is valid, it might lead to a program crash caused by a bug. Otherwise, the program will print some error

and exit. Figure 2.b illustrates the same program which is now protected by ANTI FUZZ. Additional layers of fake edges and constraints are specifically targeting coverage-guided fuzzers. Further down the control-flow graph of the protected application, ANTI FUZZ added its input encryption/decryption routine. Next in the Figure 2.b, ANTI FUZZ installs its custom signal handler and then causes an intentional segmentation fault (fake crash). However, since ANTI FUZZ installed a custom signal handler, it receives the signal and checks whether it is the fake crash or not. If it is legitimate, it delays the execution and then exits gracefully. This step basically is the anti-crash detection implementation of ANTI FUZZ, which works together with an execution delay mechanism. Finally, in Figure 2.b, we harden the comparison against 1337 with a comparison of hashed values.

## 6 Evaluation

Our evaluation aims to answer the following five research questions (RQs):

- **RQ 1.** Are current obfuscation techniques efficient against automated bug-finding via fuzzing?
- **RQ 2.** Are the techniques we designed effective at disrupting the targeted fuzzing assumptions?
- **RQ 3.** Are the techniques effective at preventing fuzzers from finding bugs?
- **RQ 4.** Are the techniques effective at reducing the amount of code that is being tested?
- **RQ 5.** Do our techniques introduce any significant performance overhead?

To answer the first research question **RQ 1.**, we demonstrate that modifying a custom dummy application (which is illustrated in Listing 2) using the state-of-the-art obfuscation tool TIGRESS [15] does not yield a satisfying level of protection against current fuzzers.

Following the answer to **RQ 1.**, we test all our techniques individually on multiple fuzzers to demonstrate that they are effective if and only if the fuzzer employs the targeted assumptions. From this experiment, we can answer **RQ 2.** and conclude that our mitigations are working as intended. We use the same dummy application used in **RQ 1.** to evaluate eight fuzzers and bug-finding tools, namely: AFL 2.52b, VUZZER, HONGGFUZZ 1.6, DRILLER commit 66a3428, ZZUF 0.15, PEACH 3.1.124, and QSYM commit d4bf407. Besides the aforementioned fuzzers, we consider one purely symbolic execution based tool to complete the set of automatic bug finding techniques: KLEE 1.4.0.0 [12].

To answer **RQ 3.**, we test a subset of these fuzzers against the LAVA-M dataset to demonstrate that ANTI FUZZ is able to prevent bug finding in real-world applications.

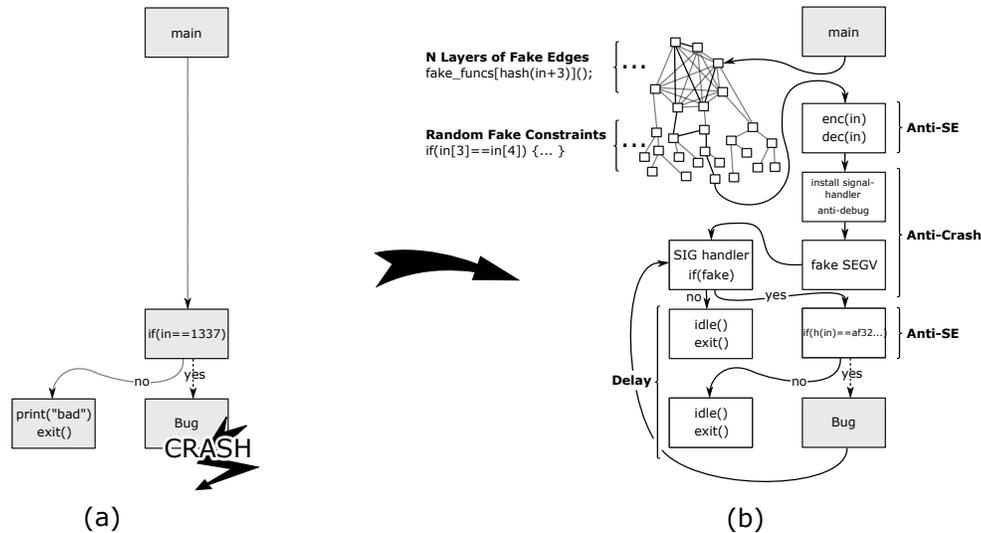

Figure 2: A simple program before (a) and after integration (b) with ANTI FUZZ.

To address **RQ 4.**, we evaluate ANTI FUZZ on binary executables from binutils to show the difference in test coverage in a protected and unprotected application. This experiment demonstrates that ANTI FUZZ does not simply hide bugs, but also drastically reduces the attack surface. It is worth mentioning that in all experiments mentioned above, the bug finding tools were able to find the bugs in a matter of minutes prior to enforcing ANTI FUZZ protection. After applying our techniques, there were *zero* bugs found by the tested tools within a period of 24 hours.

In the last step, we measure the overhead introduced by ANTI FUZZ using the SPEC CPU2006 benchmarking suite to answer **RQ 5.**

Note that, due to the configurable nature of ANTI FUZZ, we use the following configuration for all experiments:

- **Attacking Coverage-guidance:** Generates 10,000 fake functions with constraints, and 10,000 basic blocks for random edge generation.
- **Delaying Execution:** The signal handler introduces a slowdown in case of a crash to timeout the application (in addition to slowdowns due to malformed inputs). The duration of the sleep is set to 750ms.
- **Preventing Crash Detection:** We enabled all techniques mentioned in Section 5.2.
- **Overloading Symbolic Execution Engines:** Important comparisons for equivalence were replaced with SHA-512 hash comparisons and the input data was encrypted and decrypted via AES-256 in ECB mode.

If the fuzzer supported both binary instrumentation and compile-time instrumentation, we used the compile-time instrumentation. While in reality, a fuzzer would have to use

binary-only instrumentation mechanisms (given our attacker model), we chose to use compile-time instrumentation as it achieves better performance and is also more robust. Therefore, we erred on the side of caution by assuming that an attacker is more powerful than state-of-the-art tools.

## 6.1 ANTI FUZZ versus Software Obfuscation

One of the goals of software obfuscation is to prevent security researchers, who rely on traditional *manual* reverse engineering techniques, from finding bugs. In this section, we demonstrate that obfuscation on its own fails to thwart *automatic* bug finding tools.

Intuitively, blind fuzzers without feedback mechanisms are not hindered by obfuscation at all, because they neither have nor need any knowledge about the code. Feedback-driven fuzzers, however, *do* need access to edges and basic blocks to obtain coverage information they can use to guide the fuzzing process. Thus, obfuscating the control flow via common techniques such as control flow flattening or virtual machine based obfuscation [21] might impact coverage-guided fuzzers.

**Experiment** To demonstrate that obfuscation techniques alone do not protect an application from automatic bug finding tools, we obfuscated a dummy application (see Listing 2) with TIGRESS 2.2 [15] and let different fuzzers find the correct crashing input.

Listing 2: Dummy application that crashes if input is 'crsh'

```
int check(char* input, int size) {
    if(size == 4 && input[0] == 'c' && input[1] == 'r' &&
        input[2] == 's' && input[3] == 'h') {
        crash();
    }
}
```

For this experiment, we use AFL, HONGGFUZZ, KLEE and ZZUF which are representative of all three fuzzer categories. Note that VUZZER was excluded because (1) VUZZER is based on the IDA Pro disassembler, which is thwarted by obfuscation before the fuzzing process even begins, and (2) Tigress had trouble compiling non-64bit executables while VUZZER (at the time of the experiment) was not working on 64-bit binaries. Additionally, any fuzzer which is based on the aforementioned tools was excluded from the experiment. For example, QSYM and DRILLER use AFL with an additional symbolic execution engine. Therefore, if AFL is able to find the bug, we conclude that other tools that use AFL under the hood can also find the bug.

We configured TIGRESS by enabling as many of the obfuscation features as we could. The exact configuration is shown in Table 1 of Appendix A.

**Result** This experiment revealed that all fuzzers could find the crashing input despite all obfuscation techniques being enabled. This answers research question **RQ 1.**, current obfuscation techniques are not efficient against automated bug finding techniques. Even though changing the control-flow graph might have an impact on the feedback mechanism, the changes are static or random. In contrast, in ANTI FUZZ the additional information for the feedback mechanism is dependant on the input, which is a major difference between common obfuscation methods and our approach.

## 6.2 Finding Crashes in a Simple Dummy Application

To answer research question **RQ 2.**, we use the same dummy application from the previous experiment.

For this evaluation, we enable our anti-fuzzing techniques one at a time, rather than enabling all of them at once. This allows us to observe which fuzzer is vulnerable to each technique we introduced. We use this rather simple target for two reasons. (1) If a fuzzer is unable to find this very shallow bug, they will most likely also fail to find more complex crashes, and (2) the code is simple enough to be adjusted to different systems and fuzzers (e.g., DRILLER needs CGC binaries).

Any input that is not the crashing input is deemed to be malformed, i.e., ANTI FUZZ decides to slow down the application in that case. If countermeasures against program analysis techniques are activated, the data from the input file is first encrypted and then decrypted again. The comparisons against the individual bytes of “crsh” are done via hash comparisons (e.g., `hash("c") == hash(input[0])`). Signal tampering and anti-coverage techniques are all applied before the input file is opened. Since both PEACH and ZZUF are not able to overcome the four-byte constraints on their own, we provided ZZUF with the seed file where only the “c” character was missing. Similarly, PEACH was evaluated on an ELF64 parser

Table 2: Evaluation against the dummy application. ✓ means ANTI FUZZ was successful in preventing bug finding (no crash was found) and ✗ means that at least one crashing input was found. None means ANTI FUZZ was disabled, All means that all techniques against fuzzers (Coverage, Crash, Speed and Symbolic Execution) were turned on.

|           | None | Coverage | Crash | Speed | Symbolic Exec. | All            |
|-----------|------|----------|-------|-------|----------------|----------------|
| AFL       | ✗    | ✓        | ✓     | ✓     | ✗              | ✓              |

<sup>a</sup> Klee ran at least 24h and then crashed due to memory constraints.

(readelf). We modified the elf parser to include an additional one-byte check of a field in ELF64 that guards the crash.

Every possible combination of fuzzer and ANTI FUZZ configuration ran for a period of 24 hours. Moreover, in this experiment, the configuration with all fuzzing countermeasures enabled (“All”) ran for a total of 100 hours.

**Result** The results of this experiment are shown in Table 2. Without ANTI FUZZ, it only took a couple of seconds up to a few minutes for all eight fuzzers to find the crashing input. However, when ANTI FUZZ was fully activated, *no* fuzzer was able to do so even after 100 hours. Comparing this table to Table 1 shows that our techniques clearly address the fundamental assumptions that fuzzers use to find bugs.

All coverage-guided fuzzers were impeded by our anti-coverage feature. As expected, all fuzzers were unable to find crashes when we used our anti-crash detection technique. It is worth mentioning that DRILLER was not tested with this configuration because the CGC environment does not allow custom signal handlers. Surprisingly, KLEE was also unable to find the crash because of its incomplete handling of custom signals. Since delaying execution technique (speed) also relies on custom signals, the experiment with DRILLER was omitted and KLEE failed to find the bug. ZZUF was able to crash the target because there were only 256 different inputs to try.

As expected, KLEE was not able to find the correct input once countermeasures against symbolic execution were activated. Surprisingly, VUZZER is confused by this technique as well. A closer inspection suggests that this behavior was due to the fact that this technique is also highly effective at obfuscating taint information.

## 6.3 Finding Crashes in LAVA-M

The dummy application demonstrated our ability to thwart fuzzers for simple examples. To make sure that our techniques also hold up on more complex applications (and answer **RQ 3.**), we evaluate ANTI FUZZ with the LAVA-M dataset [18], which consists of four applications (base64, who, uniq and md5sum) where several bugs were artificially

Table 3: Statistical analysis of the code coverage on eight binaries from binutils. The effect size is given in percentage of the branches that could be covered after enabling ANTI FUZZ as compared to the coverage achieved on an unprotected program. Experiments where the two-tailed Mann-Whitney U test resulted in  $p < 0.05$  are displayed in bold.

inserted. All fuzzer configurations were allowed to run for 24 hours each. Due to DWORD comparisons that AFL has difficulty to solve, the AFL modification LAF-INTEL was used, which breaks comparisons (including string operations) down to single byte comparisons to allow for more nuanced edge generation during compilation. For blind fuzzers like ZZUF, solving four bytes is too hard, thus one constraint was reduced to a single bit-flip for this fuzzer alone.

**Results** Table 4 shows our result. The # sign denotes the number of unique crashes found (according to distinct LAVA-M fault IDs). Again we can see the same consistent result for all binaries: once ANTI FUZZ is turned on, it effectively prevents fuzzers from detecting bugs. The exceptional cases are similar to the ones we discussed in the previous section. In summary, these results demonstrate that our anti-fuzzing features are applicable to real-world binaries to prevent bug finding.

## 6.4 Reducing Code Coverage

As a next step, we want to answer **RQ 4**, by demonstrating that applying ANTI FUZZ results in far less coverage in coverage-based fuzzers. More specifically, we evaluated AFL, HONGGFUZZ, VUZZER, and QSYM against eight real-world binaries from the binutils collection (namely addr2line, ar, size, strings, objdump, readelf, nm-new, strip-new). Every fuzzer and every application was executed three times for 24 hours in the setting “None” (ANTI FUZZ is disabled) and then again in the setting “All” (all ANTI FUZZ features are enabled).

**Result** The results of this experiment are shown in Figure 3. For each of the eight binutils programs, we compare the performance of the four tested fuzzers (measured in the number of branches covered) without and with protection via ANTI FUZZ. It is apparent that ANTI FUZZ does indeed severely hinder fuzzers from extending code coverage. Note that in all cases, when ANTI FUZZ was activated, even after 24 hours the fuzzers could only reach coverage that would have been reached in the first few minutes without ANTI FUZZ.

We performed a statistical analysis on the resulting data, the results are shown in Table 3. All but three out of thirty experiments were statistically significant with  $p < 0.05$  according to a two-tailed Mann-Whitney U test. Two of the insignificant results are from VUZZER, which displayed rather low coverage scores even without ANTI FUZZ enabled. The other insignificant result is on ar, a target where most bug finding tools fail due to a multi-byte comparison. Additionally, we calculated the reduction of the amount of covered code that resulted from enabling ANTI FUZZ. Typically (in half of the experiments), less than 3% of the code that was tested on an unprotected target could be covered when ANTI FUZZ was enabled. The 95th percentile of coverage was less than 13% of the code that the fuzzers found when targeting an unprotected program. In the worst result, we achieved a reduction to 17%. Therefore, we conclude that ANTI FUZZ will typically reduce the test coverage achieved by 90% to 95%.

## 6.5 Performance Overhead

Lastly, to answer **RQ 5**, we measure the performance overhead caused by using ANTI FUZZ on complex programs. For this purpose, we use the SPEC CPU2006 version 1.1 INT benchmark. This experiment consists of all benchmarks that

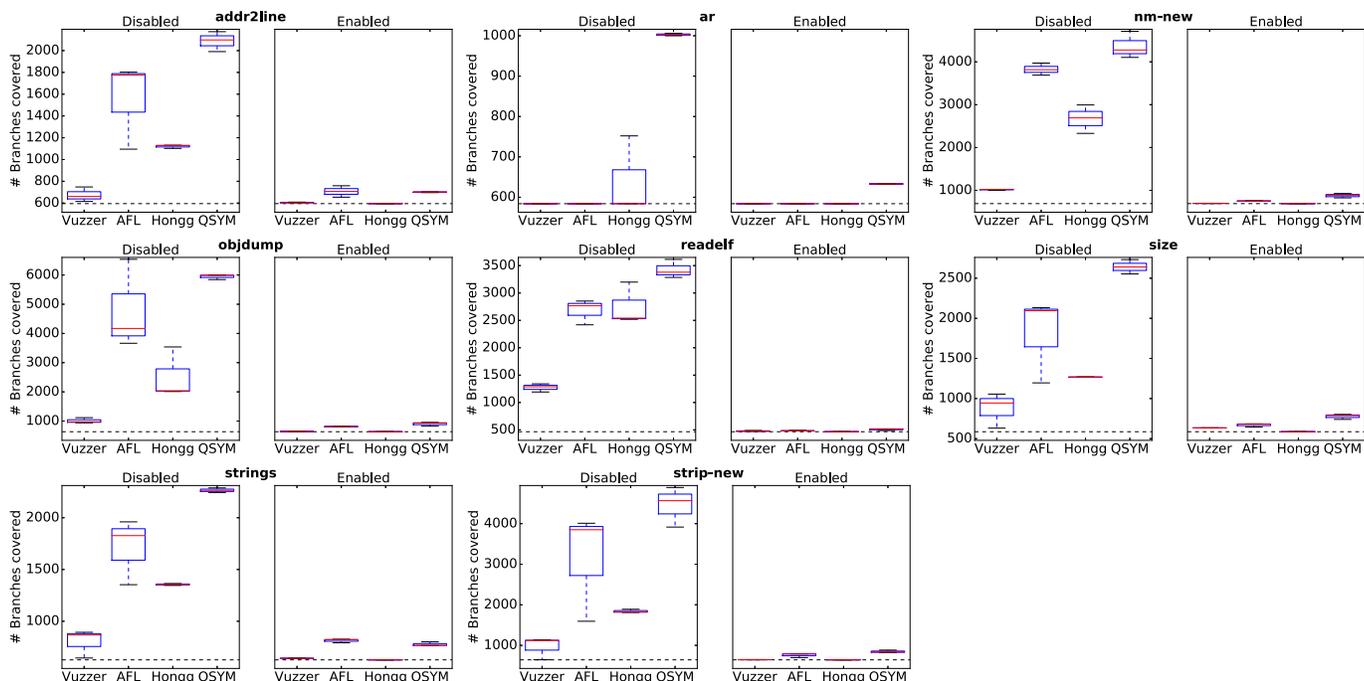

Figure 3: Evaluation of eight binutils binaries to show the branch coverage difference between unmodified binary ("Disabled") and binary with ANTI FUZZ ("Enabled"). The dashed line at the bottom is the baseline (i.e. the number of branches covered with the seed file).

take an input file (thus only 462.libquantum was excluded). The remaining benchmarks ran for three iterations each and were averaged over ten runs with the geometric mean.

**Result** The impact of ANTI FUZZ for each benchmark was insignificant enough to bear little to no observable overhead (see Table 5): most applications show small *negative* overheads (with the outlier being gcc with -3.80%), but the positive overheads also never reach 1%. The total average overhead is -0.42%. This is expected because `antifuzz_init()` is only called once when the input file is opened. Reading the file to memory and checking if the input data is well-formed usually happens only once in the beginning, thus it does not impact the computationally intensive main part of the benchmarks at all.

## 7 Limitations

In the following, we discuss limitations of both our proposed approach and implementation, and also consider threats to validity. For our current prototype implementation, a human analyst can likely remove the protection mechanisms added by ANTI FUZZ rather easily. However, according to our attacker model, we regard this threat out of scope in the context of this paper. Moreover, many other works have detailed techniques to prevent modification and human analysis using software obfuscation techniques [16, 17, 21, 24, 41, 43, 53]. For a more complete protection, we recommend to use a combination of

Table 5: SPEC CPU2006 INT benchmark.

| Benchmark            | Overhead      |
|----------------------|---------------|
| 400.perlbench        | 0.13%         |
| 401.bzip2            | 0.11%         |
| 403.gcc              | -3.80%        |
| 429.mcf              | -0.36%        |
| 445.gobmk            | 0.89%         |
| 456.hmmr             | 0.32%         |
| 458.sjeng            | 0.43%         |
| 464.h264ref          | -1.53%        |
| 471.omnetpp          | -0.8%         |
| 473.astar            | -1.06%        |
| 483.xalanbmk         | 0.17%         |
| <b>Total average</b> | <b>-0.42%</b> |

both ANTI FUZZ as well as traditional anti-analysis/-patching techniques.

The delay-inducing technique should not be applied to any kind of public-facing server software, as this would drastically weaken the server against Denial-of-Service attacks. Instead of sleeping or busy waiting, one should implement a similar approach based on rate limitation.

The number of functions added as fake code results in a fixed file size increase of approximately 25MB. While this is less relevant for large software binaries, it might pose significant code size overhead for small binaries. However, for modern machines we deem this to be a minor obstacle.

Furthermore, it is worth mentioning that one can avoid this increase in file size by using self-modifying code. We explicitly decided not to use self-modifying code since such techniques have the tendency of making exploitation easier by using memory pages with read/write/execute privileges and potentially raising alerts in anti-virus products.

Furthermore, ANTIFUZZ in its current form requires developer involvement which is not optimal from a usability perspective. However, most of the manual work in ANTIFUZZ can be automated. In particular, we require the developer to perform the following tasks: (a) find error paths, (b) replace constant comparisons, and (c) annotate functions which read user input or data. It is relatively easy to automate items (b) and (c) via a compiler pass. The reason that finding error paths is more challenging is that there are many different ways for handling errors. On the other hand, the responsible developer is well aware of the error handling code. Adding a single function call in the error handler is straightforward and does not significantly increase the complexity of the code base.

Additionally, it is worth mentioning that the benchmarking suite which we used was focused on CPU intensive tasks rather than I/O bound tasks. We assume that using our prototype AES implementation to encrypt and decrypt every input significantly increases the overhead on I/O bound tasks. Therefore, we recommend to replace AES by a much weaker and faster encryption algorithm, as our goal is not to be cryptographically secure, but to confuse SMT solvers.

Finally, it has to be considered that automatic program transformations for obfuscation can always be thwarted [7]. Therefore, tools like ANTIFUZZ can never completely guarantee that they can defeat a motivated human analyst. Based on this observation, the situation for anti-fuzzing mechanisms like ANTIFUZZ is similar to obfuscation mechanisms: given sufficient interest from the attackers and defenders, a prolonged arms race is to be expected. This also means that as time passes, continuing this arms race will become more and more expensive for both sides involved. However, similar to obfuscation, we expect only the implementation of tools like ANTIFUZZ to become more complicated. Similarly to modern obfuscation tools, usage of anti-fuzzing defenses will most likely remain cheap.

As we cannot evaluate against techniques not yet invented, some of our techniques could be attacked by smarter fuzzers. The junk code that was inserted could be detected based on statistical patterns or the way it interacts with the rest of the execution. To counter this, more complex and individualized junk code fragments could be used. For example, junk code can change global variables that are also used in the original code (e.g., in opaque predicates).

## 8 Related Work

Obfuscating software against program understanding has been exhaustively researched. Common techniques include inject-

ing junk code that is never executed [16, 53], often hidden behind conditional expressions that always evaluate to some fixed value [17]. The control flow can be further cloaked by creating many seemingly dissimilar paths that are picked randomly [43] to thwart dynamic analysis based approaches. Other common techniques include self-modifying code [41], which increases the difficulty of obtaining a useful disassembly and changes to the control-flow [21, 24]. Similarly, there has been some work that specifically target symbolic execution [51].

Recent research tried to address a very similar issue: To increase the cost of the attacker, Hu et al. [35] insert a large number of fake bugs into the target application. This approach has the advantage that it works against many different kinds of attack scenarios. However, they rely on the bugs being non-exploitable as otherwise the actual security of the application is reduced. For example, the authors state that they rely on the exact stack layout behavior of the chosen compiler. Any update to the compiler might render the previously "safe" bugs exploitable. Additionally, fuzzers generally tend to find many hundreds to thousands of crashes for each real bug uncovered. Adding some more crashes does not prevent the fuzzer from finding real bugs. The large number of crashes found might draw attention and common analysis techniques for bug triage (such as AFLs bug exploration mode) will greatly simplify weeding out the fake bugs.

In contrast, our approach is much more low key. Additionally, since in our approach no proper test coverage is achieved, no analysis of the produced fuzzing data will be able to uncover any bugs. An idea similar to our fake code insertions was also presented in a talk by Kang et al. [38]. However, they explicitly tried to prevent AFL in QEMU mode from finding a specific crashing path. In our scenario, the defenders do not know the specific crashing path, as otherwise, they would rather fix the bug. Additionally, as we demonstrated in our evaluation, our approach is effective across different fuzzers and does not attack a specific implementation.

Finally, a master thesis by Göransson and Edholm has introduced the idea of masking crashes and actively detecting if the program is being fuzzed, e.g., by detecting specific AFL environment variables [30]. Similarly to the work by Kang et al., the methods they devised are highly specific to the implementation of the only two fuzzers they considered: AFL and HONGGFUZZ. Additionally, to reduce the execution speed of fuzzers, they proposed to artificially decrease the overall performance of the program under test, whereas ANTIFUZZ only decreases the performance if the input is malformed.

## 9 Conclusion

In this paper, we categorized the general assumptions common to all current bug-finding tools. Based on this analysis, we developed techniques to systematically attack and break these assumptions (and thus a representative sample of contempo-

rary fuzzers). The evaluation demonstrated that obfuscation on its own fails to prevent fuzzing satisfyingly. In contrast, our techniques effectively prevent fuzzers from finding crashing inputs in simple programs, even if the crash was found in seconds in an unprotected application. Furthermore, we demonstrated that we get the same result for real-world applications, i.e., fuzzers are unable to detect any crashes or even achieve a significant amount of new code coverage. Our techniques also show no significant overhead when evaluated with the SPEC benchmark suite and can, therefore, be easily and efficiently integrated into projects with negligible impact to the performance.

In summary, we conclude that the techniques presented in this paper are well applicable to deter automated, dragnet-style hunting for bugs. In combination with common program obfuscation techniques, they will also hinder a targeted attack, as manual work is needed to reverse engineer and remove the anti-fuzzing measures before a more cost-efficient, automated fuzzing campaign can be started.

## Abstract

Mutation-based fuzzing is one of the most popular vulnerability discovery solutions. Its performance of generating interesting test cases highly depends on the mutation scheduling strategies. However, existing fuzzers usually follow a specific distribution to select mutation operators, which is inefficient in finding vulnerabilities on general programs. Thus, in this paper, we present a novel mutation scheduling scheme MOPT, which enables mutation-based fuzzers to discover vulnerabilities more efficiently. MOPT utilizes a customized Particle Swarm Optimization (PSO) algorithm to find the optimal selection probability distribution of operators with respect to fuzzing effectiveness, and provides a pacemaker fuzzing mode to accelerate the convergence speed of PSO. We applied MOPT to the state-of-the-art fuzzers AFL, AFLFast and VUzzer, and implemented MOPT-AFL, -AFLFast and -VUzzer respectively, and then evaluated them on 13 real world open-source programs. The results showed that, MOPT-AFL could find 170% more security vulnerabilities and 350% more crashes than AFL. MOPT-AFLFast and MOPT-VUzzer also outperform their counterparts. Furthermore, the extensive evaluation also showed that MOPT provides a good rationality, compatibility and steadiness, while introducing negligible costs.

## 1 Introduction

Mutation-based fuzzing is one of the most prevalent vulnerability discovery solutions. In general, it takes seed test cases and selects them in certain order, then mutates them in various ways, and tests target programs with the newly generated test cases. Many new solutions have been proposed in the past years, including the ones that improve the seed generation solution [1, 2, 3], the ones that improve the seed

selection strategy [4, 5, 6, 7, 8], the ones that improve the testing speed and code coverage [9, 10, 11, 12], and the ones that integrate other techniques with fuzzing [13, 14, 15].

However, less attention has been paid to how to mutate test cases to generate new effective ones. A large number of well-recognized fuzzers, e.g., AFL [16] and its descendants, libFuzzer [17], honggfuzz [18] and VUzzer [6], usually predefine a set of *mutation operators* to characterize where to mutate (e.g., which bytes) and how to mutate (e.g., add, delete or replace bytes). During fuzzing, they use certain *mutation schedulers* to select operators from this predefined set, in order to mutate test cases and generate new ones for fuzzing. Rather than directly yielding a mutation operator, the mutation scheduler yields a probability distribution of predefined operators, and the fuzzer will select operators following this distribution. For example, AFL uniformly selects mutation operators.

There are limited solutions focusing on improving the mutation scheduler. Previous works [7, 8] utilize reinforcement learning to dynamically select mutation operators in each round. However, they do not show significant performance improvements in vulnerability discovery [7, 8]. Thus, a better mutation scheduler is demanded. We figure out that, most previous works cannot achieve the optimal performance because they fail to take the following issues into consideration.

*Different operators' efficiency varies.* Different mutation operators have different efficiency in finding crashes and paths (as shown in Fig. 3). Thus, fuzzers that select mutation operators with the uniform distribution are likely to spend unnecessary computing power on inefficient operators and decrease the overall fuzzing efficiency.

*One operator's efficiency varies with target programs.* Each operator's efficiency is program-dependent, and it is unlikely or at least difficult to statically infer this dependency. Thus the optimal mutation scheduler has to make decisions per program, relying on each operator's runtime efficiency on the target program.

*One operator's efficiency varies over time.* A mutation operator that performs well on the current test cases may per-

Chenyang Lyu and Shouling Ji are the co-first authors. Shouling Ji and Chao Zhang are the co-corresponding authors.

form poorly on the following test cases in extreme cases. As aforementioned, the optimal mutation scheduler rely on operators' history efficiency to calculate the optimal probability distribution to select operators. Due to the dynamic characteristic of operator efficiency, this probability calculation process should converge fast.

*The scheduler incurs performance overhead.* Mutation schedulers have impacts on the execution speed of fuzzers. Since the execution speed is one of the key factors affecting fuzzers' efficiency, a better mutation scheduler should have fewer computations, to avoid slowing down fuzzers.

*Unbalanced data for machine learning.* During fuzzing, the numbers of positive and negative samples are not balanced, e.g., a mutation operator could only generate interesting test cases with a small probability, which may affect the effectiveness of gradient descent algorithms and other machine learning algorithms [7, 8].

In this paper, we consider mutation scheduling as an optimization problem and propose a novel mutation scheduling scheme MOPT, aiming at solving the aforementioned issues and improving the fuzzing performance. Inspired by the well-known optimization algorithm *Particle Swarm Optimization (PSO)* [19], MOPT dynamically evaluates the efficiency of candidate mutation operators, and adjusts their selection probability towards the optimum distribution.

MOPT models each mutation operator as a particle moving along the probability space  $[x_{min}, x_{max}]$ , where  $x_{min}$  and  $x_{max}$  are the pre-defined minimal and maximal probability, respectively. Guided by the local best probability and global best probability, each particle (i.e., operator) moves towards its optimal selection probability, which could yield more good-quality test cases. Accordingly, the target of MOPT is to find an optimal selection probability distribution of operators by aggregating the probabilities found by the particles, such that the aggregation yields more good-quality test cases. Similar to PSO, MOPT iteratively updates each particle's probability according to its local best probability and the global best probability. Then, it integrates the updated probabilities of all particles to obtain a new probability distribution. MOPT can quickly converge to the best solution of the probability distribution for selecting mutation operators and thus improves the fuzzing performance significantly.

MOPT is a generic scheme that can be applied to a wide range of mutation-based fuzzers. We have applied it to several state-of-the-art fuzzers, including AFL [16], AFLFast [5] and VUzzer [6], and implement MOPT-AFL, -AFLFast and -VUzzer, respectively. In AFL and its descendants, we further design a special pacemaker fuzzing mode, which could further accelerate the convergence speed of MOPT.

We evaluated these prototypes on 13 real world programs. In total, MOPT-AFL discovered 112 security vulnerabilities, including 97 previously unknown vulnerabilities (among which 66 are confirmed by CVE) and 15 known CVE vulnerabilities. Compared to AFL, MOPT-AFL found

170% more vulnerabilities, 350% more crashes and 100% more program paths. MOPT-AFLFast and MOPT-VUzzer also outperformed their counterparts on our dataset. We further demonstrated the rationality, steadiness and low costs of MOPT.

In summary, we have made the following contributions:

- We investigated the drawbacks of existing mutation schedulers, from which we conclude that mutation operators should be scheduled based on their history performance.

- We proposed a novel mutation scheduling scheme MOPT, which is able to choose better mutation operators and achieve better fuzzing efficiency. It can be generally applied to a broad range of existing mutation-based fuzzers.

- We applied MOPT to several state-of-the-art fuzzers, including AFL, AFLFast and VUzzer, and evaluated them on 13 real world programs. The results showed that MOPT could find much more vulnerabilities, crashes and program paths, with good steadiness, compatibility and low cost.

- MOPT-AFL discovers 97 previously unknown security vulnerabilities, and helps the vendors improve their products' security. It also finds 15 previously known vulnerabilities in these programs (of latest versions), indicating that security patching takes a long time in practice. We open source MOPT-AFL along with the employed data, seed sets, and results at <https://github.com/puppet-meteor/MOPT-AFL> to facilitate the research in this area. A technical report with more details can also be found there [20].

## 2 Background

### 2.1 Mutation-based Fuzzing

Mutation-based fuzzing [5, 6, 13, 14, 15, 16, 17, 18] is good at discovering vulnerabilities, without utilizing prior knowledge (e.g., test case specification) of target programs. Instead, it generates new test cases by mutating some well-formed seed test cases in certain ways.

The general workflow of mutation-based fuzzing is as follows. The fuzzer (1) maintains a queue of seed test cases, which can be updated at runtime; (2) selects some seeds from the queue in certain order; (3) mutates the seeds in various ways; (4) tests target programs with the newly generated test cases, and reports vulnerabilities or updates the seed queue if necessary; then (5) goes back to step (2).

In order to efficiently guide the mutation and fuzzing, some fuzzers will also instrument target programs to collect runtime information during testing, and use it to guide seeds updating and decide which seeds to select and how to mutate them. In this paper, we mainly focus on the mutation phase (i.e., step (3)).

### 2.2 Mutation Operators

Mutation-based fuzzers could mutate seeds in infinite number of ways. Considering the performance and usability,

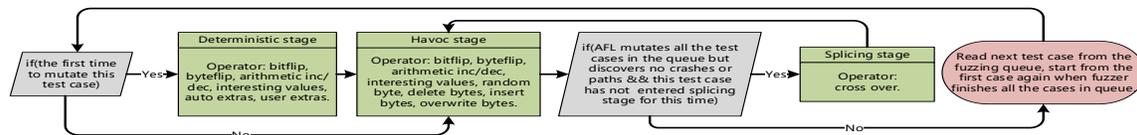

Figure 1: Three mutation scheduling schemes used in the three stages of AFL [16].

Table 1: Mutation operators defined by AFL [16].

| Type                      | Meaning                                                                                          | Operators                                        |
|---------------------------|--------------------------------------------------------------------------------------------------|--------------------------------------------------|
| <b>bitflip</b>            | Invert one or several consecutive bits in a test case, where the steppover is 1 bit.             | bitflip 1/1,<br>bitflip 2/1,<br>bitflip 4/1      |
| <b>byteflip</b>           | Invert one or several consecutive bytes in a test case, where the steppover is 8 bits.           | bitflip 8/8,<br>bitflip 16/8,<br>bitflip 32/8    |
| <b>arithmetic inc/dec</b> | Perform addition and subtraction operations on one byte or several consecutive bytes.            | arith 8/8,<br>arith 16/8,<br>arith 32/8          |
| <b>interesting values</b> | Replace bytes in the test cases with hard-coded interesting values.                              | interest 8/8,<br>interest 16/8,<br>interest 32/8 |
| <b>user extras</b>        | Overwrite or insert bytes in the test cases with user-provided tokens.                           | user (over),<br>user (insert)                    |
| <b>auto extras</b>        | Overwrite bytes in the test cases with tokens recognized by AFL during <b>bitflip</b> 1/1.       | auto extras (over)                               |
| <b>random bytes</b>       | Randomly select one byte of the test case and set the byte to a random value.                    | random byte                                      |
| <b>delete bytes</b>       | Randomly select several consecutive bytes and delete them.                                       | delete bytes                                     |
| <b>insert bytes</b>       | Randomly copy some bytes from a test case and insert them to another location in this test case. | insert bytes                                     |
| <b>overwrite bytes</b>    | Randomly overwrite several consecutive bytes in a test case.                                     | overwrite bytes                                  |
| <b>cross over</b>         | Splice two parts from two different test cases to form a new test case.                          | cross over                                       |

in practice these fuzzers, including AFL [16] and its descendants, libFuzzer [17], honggfuzz [18] and VUzzer [6], usually predefine a set of mutation operators, and choose some of them to mutate seeds at runtime. These mutation operators characterize where to mutate (e.g., which bytes) and how to mutate (e.g., add, delete or replace bytes).

For example, the well-recognized fuzzer AFL predefines 11 types of mutation operators, as shown in Table 1. In each type, there could be several concrete mutation operators. For instance, the `bitflip 2/1` operator flips 2 consecutive bits, where the steppover is 1 bit. Note that, different fuzzers could define different mutation operators.

### 2.3 Mutation Scheduling Schemes

At runtime, mutation-based fuzzers continuously select some predefined mutation operators to mutate seed test cases. *Different fuzzers have different schemes to select operators.* For example, AFL employs three different scheduling schemes used in three stages, as shown in Fig. 1.

1. **Deterministic stage scheduler.** AFL applies a deterministic scheduling scheme for seed test cases that are picked to mutate for the first time. This scheduler employs 6 deterministic types of mutation operators in order, and applies them on the seed test cases one by one. For instance, it will apply `bitflip 8/8` to flip each byte of the seed test cases.

2. **Havoc stage scheduler.** The major mutation scheduling scheme of AFL is used in the havoc stage. As shown in

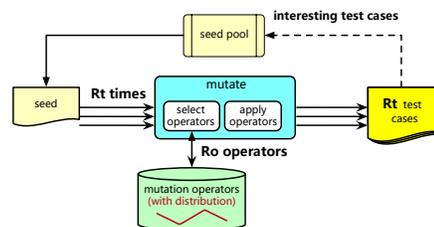

Figure 2: The general workflow of mutation-based fuzzing and mutation scheduling.

Fig. 2, AFL first decides the number, denoted as  $R_t$ , of new test cases to generate in this stage. Each time, AFL selects a series of  $R_o$  mutation operators following the uniform distribution, and applies them on the seed to generate one test case. The havoc stage ends after  $R_t$  new test cases have been generated.

3. **Splicing stage scheduler.** In some rare cases, AFL works through the aforementioned two stages for all seeds, but fails to discover any unique crash or path in one round. Then AFL will enter a special splicing stage. In this stage, AFL only employs one operator `cross over` to generate new test cases. These new test cases will be fed to the havoc stage scheduler, rather than the program being tested, to generate new test cases.

The mutation scheduler in the first stage is deterministic and slow, while the one in the last stage is rarely used. The scheduler in the havoc stage, as shown in Fig. 2, is more generic and has been widely adopted by many fuzzers. Therefore, in this paper we mainly focus on improving the scheduler used in the havoc stage, which thus can be implemented in most mutation-based fuzzers. More specifically, we aim at finding an optimal probability distribution, following which the scheduler could select better mutation operators and improve the fuzzing efficiency.

### 2.4 Mutation Efficiency

Different mutation operators work quite differently. An intuitive assumption is that, they have different efficiency on different target programs. Some are better than others at generating the test cases, denoted as *interesting test cases*, that can trigger new paths or crashes.

To verify our hypothesis, we conducted an experiment on AFL to evaluate each operator’s efficiency. To make the evaluation result deterministic, we only measured the interesting test cases produced by 12 mutation operators in the deterministic stage. The result is demonstrated in Fig. 3.

In the deterministic stage, the order of mutation operators and the times they are selected are fixed. Fig. 4 shows the

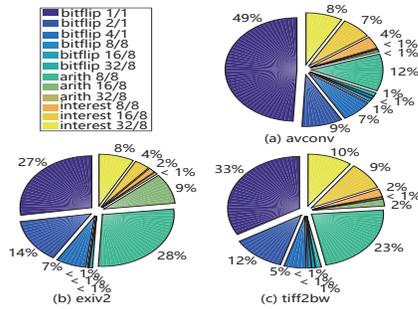

Figure 3: Percentages of interesting test cases produced by different operators in the deterministic stage of AFL.

order and the times that operators are selected by AFL during fuzzing *avconv*, indicating the time the fuzzer spent on.

- *Different mutation operators’ efficiencies on one target program are different.* For most programs, the operators *bitflip 1/1*, *bitflip 2/1* and *arith 8/8* could yield more interesting test cases than other operators. On the other hand, several other mutation operators, such as *bitflip 16/8*, *bitflip 32/8* and *arith 32/8*, could only produce less than 2% of interesting test cases.

- *Each operator’s efficiency varies with target programs.* An operator could yield good outputs on one program, but fail on another one. For example, *arith 8/8* performs well on *exiv2* and *tiff2bw*, but only finds 12% of the interesting test cases on *avconv*.

- *AFL spends most time on the deterministic stage.* We record the time each stage spends and the number of interesting test cases found by each stage in 24 hours, as shown in Fig. 5. We first analyze a special case. For *tiff2bw*, since AFL cannot find more interesting test cases, it finishes the deterministic stage of all the inputs in the fuzzing queue and skips the deterministic stage for a long time. Then, AFL spends most time on the havoc stage while finding nothing. For the other three cases, AFL spends more than 70% of the time on the deterministic stage. When fuzzing *avconv*, AFL even does not finish the deterministic stage of the first input in 24 hours. Another important observation is that the havoc stage is more efficient in finding interesting test cases compared to the deterministic stage. Moreover, since AFL spends too much time on the deterministic stage of one input, it cannot generate test cases from the later inputs in the fuzzing queue when fuzzing *avconv* and *pdfimages* given 24 hours. Note that since the splicing stage only uses *cross* over to mutate the test cases, it spends too little time to be shown in Fig. 5 compared to the other stages that will test the target program as mentioned in Section 2.3.

- *AFL spends much time on the inefficient mutation operators.* Fig. 3 shows that, the mutation operators *bitflip 1/1* and *bitflip 2/1* have found the most interesting test cases. But according to Fig. 4, they are only selected for a small number of times. On the other hand, inefficient operators like the ones of interesting values are selected too frequently but produce few interesting test cases, which

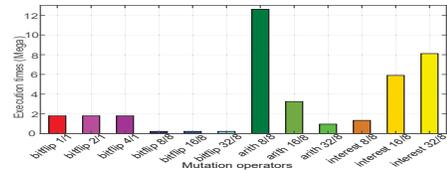

Figure 4: The times that mutation operators are selected when AFL fuzzes a target program *avconv*.

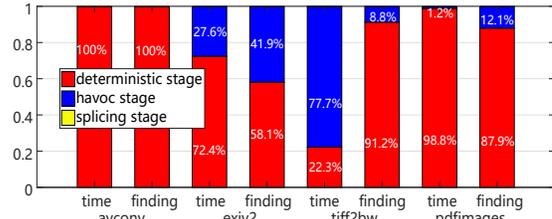

Figure 5: Percentages of time and interesting test cases used and found by the three stages in AFL, respectively.

decreases the fuzzing efficiency.

**Motivation.** Based on the analysis above, we observe that different mutation operators have different efficiencies. Hence, the mutation schedulers in existing fuzzers, which follow some pre-defined distributions, are not efficient. Ideally, more time should be spent on mutation operators that perform better at generating interesting test cases. Therefore, a better mutation scheduler is demanded.

### 3 Overview of MOPT

#### 3.1 Design Philosophy

The mutation scheduler aims at choosing the next optimal mutation operator, which could find more interesting test cases, for a given runtime context. We simplify this problem as finding an optimal probability distribution of mutation operators, following which the scheduler chooses next operators when testing a target program.

Finding an optimal probability distribution for all mutation operators is challenging. Instead, we could first let each operator explore its own optimal probability. Then, based on those optimal probabilities, we could obtain a global optimal probability distribution of mutation operators.

The *Particle Swarm Optimization (PSO)* algorithm can be leveraged to find the optimal distribution of the operators and we detail the modification of PSO in our setting as follows.

#### 3.2 Particle Swarm Optimization (PSO)

The PSO [19] algorithm is proposed by Eberhart and Kennedy, aiming at finding the optimal solution for a problem. It employs multiple particles to search the solution space iteratively, in which a position is a candidate solution.

As shown in Fig. 6, in each iteration, each particle is moved to a new position  $x_{now}$ , based on (1) its inertia (i.e.,

previous movement  $v_{now}$ ), (2) displacement to its local best position  $L_{best}$  that *this particle* has found so far, and (3) displacement to the global best position  $G_{best}$  that *all particles* have found so far. Specifically, the movement of a particle  $P$  is calculated as follows:

$$v_{now}(P) \leftarrow w \times v_{now}(P) + r \times (L_{best}(P) - x_{now}(P)) + r \times (G_{best} - x_{now}(P)). \quad (1)$$

$$x_{now}(P) \leftarrow x_{now}(P) + v_{now}(P). \quad (2)$$

where  $w$  is the inertia weight and  $r \in (0, 1)$  is a random displacement weight.

Hence, each particle moves towards  $L_{best}$  and  $G_{best}$ , and is likely to keep moving to better positions. By moving towards  $G_{best}$ , multiple particles could work synchronously and avoid plunging into the local optimum. As a result, the swarm will be led to the optimal solution. Moreover, PSO is easy to implement with low computational cost, making it a good fit for optimizing mutation scheduling.

### 3.3 Design Details

MOPT aims to find an optimal probability distribution. Rather than employing particles to explore candidate distributions directly, we propose a customized PSO algorithm to explore each operator's optimal probability first, and then construct the optimal probability distribution.

#### 3.3.1 Particles

MOPT employs a particle per operator, and tries to explore an optimal position for each operator in a predefined probability space  $[x_{min}, x_{max}]$ , where  $0 < x_{min} < x_{max} \leq 1$ .

The current position of a particle (i.e., operator) in the probability space, i.e.,  $x_{now}$ , represents the probability that this operator will be selected by the scheduler. Due to the nature of probabilities, the sum of all the particles' probabilities in one iteration should be normalized to 1.

#### 3.3.2 Local Best Position $L_{best}$

Similar to PSO, MOPT also appoints the best position that a particle has ever found as its local best position.

For a given particle, a position  $x_1$  is better than  $x_2$ , if and only if, its corresponding operator yields more interesting test cases (with a same amount of invocations) in the former position than the latter. Thus,  $L_{best}$  is the position of the particle where the corresponding operator yields the most interesting test cases (given the same amount of invocations).

To enable this comparison, for each particle (i.e., operator), we measure its **local efficiency**  $eff_{now}$ , i.e., the number of interesting test cases contributed by this operator divided by the number of invocations of this operator *during one iteration*. We denote the largest  $eff_{now}$  as  $eff_{best}$ . Thus,  $L_{best}$  is the position where the operator obtains  $eff_{best}$  in history.

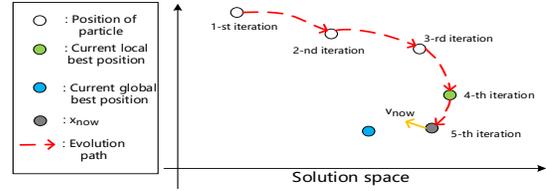

Figure 6: An example of illustrating the evolution of one particle at the 5-th iteration according to the PSO.

#### 3.3.3 Global Best Position $G_{best}$

PSO appoints the best position that all particles have ever found as the global best position. Note that, unlike the original PSO which moves particles in a unified solution space, MOPT moves particles in different probability spaces (with same shape and size). Hence, there is no sole global best position fit for all particles. Instead, different particles have different global best positions (in different spaces) here.

In PSO, global best positions depend on the relationship between different particles. Hereby we also evaluate each particle's efficiency from a global perspective, denoted as **global efficiency**  $global_{eff}$ , by evaluating multiple swarms of particles at a time.

More specifically, we measure the number of interesting test cases contributed by each operator till now in all swarms, and use it as the particle's global efficiency  $global_{eff}$ . Then we compute the distribution of all particles' global efficiency. For each operator (i.e., particle), its global best position  $G_{best}$  is defined as the proportion of its  $global_{eff}$  in this distribution. With this distribution, particles (i.e., operators) with higher efficiency can get higher probability to be selected.

#### 3.3.4 Multiple Swarms

Given the definitions of particles, local best positions and global best positions, we could follow the PSO algorithm to approach to an optimal solution (i.e., a specific probability distribution of mutation operators).

However, unlike the original PSO swarm that has multiple particles exploring the solution space, the swarm defined by MOPT actually only explores one candidate solution (i.e., probability distribution) in the solution space, and thus is likely to fall into local optimum. Thus, MOPT employs multiple swarms and applies the customized PSO algorithm to each swarm, as shown in Fig. 7, to avoid local optimum.

Synchronization is required between these swarms. MOPT simply takes the most efficient swarm as the best and uses its distribution to schedule mutation during fuzzing. Here, we define the **swarm's efficiency** (denoted as  $swarm_{eff}$ ) as the number of interesting test cases contributed by this swarm divided by the number of new test cases *during one iteration*.

**Overview:** In summary, MOPT employs multiple swarms and applies the customized PSO algorithm to each swarm. During fuzzing, the following three extra tasks are performed

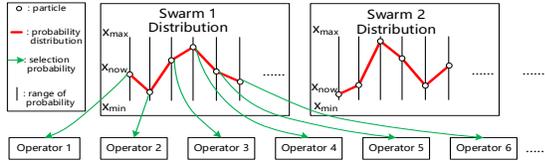

Figure 7: Illustration of the particle swarms of MOPT.

in each iteration of PSO.

- **T1:** *Locate local best positions for all particles in each swarm.* Within each swarm, each particle’s local efficiency  $eff_{now}$  in one iteration is evaluated during fuzzing. For each particle, the position with the highest efficiency  $eff_{best}$  in history is marked as its local best position  $L_{best}$ .

- **T2:** *Locate global best positions for all particles across swarms.* Each particle’s global efficiency  $global_{eff}$  is evaluated across swarms. The distribution of the particles’ global efficiency is then evaluated. The proportion of each particle’s  $global_{eff}$  in this distribution is used as its global best position  $G_{best}$ .

- **T3:** *Select the best swarm to guide fuzzing.* Each swarm’s efficiency  $swarm_{eff}$  in one iteration is evaluated. The swarm with the highest  $swarm_{eff}$  is chosen, and its probability distribution in the current iteration is applied for further fuzzing.

Then, at the end of each iteration, MOPT moves the particles in each swarm in a similar way as PSO. More specifically, for a particle  $P_j$  in a swarm  $S_i$ , we update its position as follows.

$$v_{now}[S_i][P_j] \leftarrow w \times v_{now}[S_i][P_j] + r \times (L_{best}[S_i][P_j] - x_{now}[S_i][P_j]) + r \times (G_{best}[P_j] - x_{now}[S_i][P_j]). \quad (3)$$

$$x_{now}[S_i][P_j] \leftarrow x_{now}[S_i][P_j] + v_{now}[S_i][P_j]. \quad (4)$$

where  $w$  is the inertia weight and  $r \in (0, 1)$  is a random displacement weight.

Further, we normalize these positions to meet some constraints. First, each particle’s position is adjusted to fit in the probability space  $[x_{min}, x_{max}]$ . Then for each swarm, all its particles’ positions (i.e., probabilities) will be normalized, such that the sum of these probabilities equals to 1.

After updating the positions of all particles in all swarms, the fuzzer could keep moving those particles into new positions, and enter a new iteration of PSO.

## 4 Implementation of MOPT

### 4.1 MOPT Main Framework

As shown in Fig. 8, MOPT consists of four core modules, i.e., the PSO initialization and updating modules, as well as the pilot fuzzing and core fuzzing modules.

The PSO initialization module is executed once and used for setting the initial parameters of the PSO algorithm. The

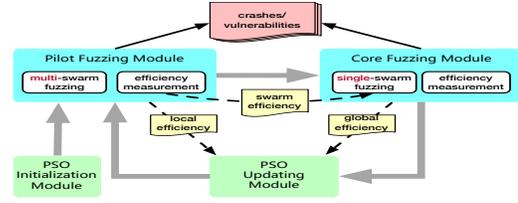

Figure 8: The workflow of MOPT.

other three modules form an iteration loop and work together to continuously fuzz target programs.

In each iteration of the loop, the PSO particles are updated once. In order to update particles’ positions with the PSO algorithm, we need to find each particle’s local best position and global best position in each iteration.

- The pilot fuzzing module employs multiple swarms, i.e., multiple probability distributions, to select mutation operators and fuzz. During fuzzing, the local efficiency of each particle in each swarm is measured. Hence, we could find the *local best position* of each particle in each swarm.

- Moreover, during the pilot fuzzing, each swarm’s efficiency is also evaluated. Then, the *most efficient swarm* is chosen, and the core fuzzing module will use the probability distribution explored by it to schedule mutation operators.

- After the core fuzzing module finishes, the total number of interesting test cases contributed by each operator till now can be evaluated. Hence, each particle’s global efficiency (i.e., *global best position*) could be evaluated.

With this iteration loop, the fuzzer could utilize the PSO to find an optimal probability distribution to select mutation operators, and gradually improve the fuzzing efficiency.

Note that, MOPT’s workflow is independent from the target fuzzer, as long as the fuzzer’s mutation scheduler uses a probability distribution to select operators. We do not need to change the behavior of the target fuzzer, except that evaluating the efficiency of the fuzzer in order to move PSO particles. The instrumentation to the target fuzzer is minimum and costs few performance overhead.

Hence, MOPT is a generic and practical mutation scheduling scheme, and can be applied to a variety of fuzzers.

#### 4.1.1 PSO Initialization Module

This module initializes parameters for the PSO algorithm. More specifically, MOPT (1) sets the initial location  $x_{now}$  of each particle in each swarm with a random value, and normalizes the sum of  $x_{now}$  of all the particles in one swarm to 1; (2) sets the displacement of particle movement  $v_{now}$  of each particle in each swarm to 0.1; (3) sets the initial local efficiency  $eff_{now}$  of each particle in each swarm to 0; (4) sets the initial local best position  $L_{best}$  of each particle in each swarm to 0.5; and (5) sets the initial global best position  $G_{best}$  of each particle across swarms to 0.5. Note that, the initialization module only executes once when the fuzzer starts running.

### 4.1.2 Pilot Fuzzing Module

This module employs multiple swarms to perform fuzzing, where each swarm explores a different probability distribution. This module evaluates each swarm in order, and stops testing a swarm after it has generated a configurable number (denoted as  $period_{pilot}$ ) of new test cases. The process of fuzzing with a specific swarm is as follows.

For each swarm, its probability distribution is used to schedule the selection of mutation operators and fuzz the target program. During fuzzing, the module will measure three measurements: (1) the number of interesting test cases contributed by a specific particle (i.e., operator), (2) the number of invocations of a specific particle, (3) the number of interesting test cases found by this swarm, by instrumenting target programs.

The local efficiency of each particle (in current swarm) is the first measurement divided by the second measurement. Hence, we could locate the *local best position* of each particle. The current *swarm's efficiency* is the third measurement divided by the test case count  $period_{pilot}$ . Therefore, we could find the most efficient swarm.

### 4.1.3 Core Fuzzing Module

This module will take the best swarm selected by the pilot fuzzing module, and use its probability distribution to perform fuzzing. It will stop after generating a configurable number (denoted as  $period_{core}$ ) of new test cases.

Once it stops, we could measure the number of interesting test cases contributed by each particle, regardless which swarm it belongs to, from the start of PSO initialization till now. Then we could calculate the distribution between particles, and locate each particle's *global best position*.

Note that, if we only use one swarm in the pilot module, then the core module could be merged with the pilot module.

### 4.1.4 PSO Updating Module

With the information provided by the pilot and core fuzzing modules, this module updates the particles in each swarm, following Equations 3 and 4.

After updating each particle, we will enter the next iteration of PSO updates. Hence, we could approach to an optimal swarm (i.e., probability distribution for operators), use it to guide the core fuzzing module, and help improve the fuzzing efficiency.

## 4.2 Pacemaker Fuzzing Mode

Although applying MOPT to mutation-based fuzzers is generic, we realize the performance of MOPT can be further optimized when applied to specific fuzzers such as AFL.

Based on extensive empirical analysis, we realize that AFL and its descendants spend much more time on the deterministic stage, than on the havoc and splicing stages that can discover many more unique crashes and paths. MOPT therefore provides an optimization to AFL-based fuzzers, denoted as *pacemaker fuzzing mode*, which selectively avoids the time-consuming deterministic stage.

Specifically, when MOPT finishes mutating one seed test case, if it has not discovered any new unique crash or path for a long time, i.e.,  $T$  that is set by users, it will selectively disable the deterministic stage for the following test cases. The pacemaker fuzzing mode has the following advantages.

- The deterministic stage spends too much time and would slow down the overall efficiency. On the other hand, MOPT only updates the probability distribution in the havoc stage, independent from the deterministic stage. Therefore, disabling the deterministic stage with *the pacemaker fuzzing mode* could accelerate the convergence speed of MOPT.

- In this mode, the fuzzer can skip the deterministic stage, without spending too much time on a sole test case. Instead, it will pick more seeds from the fuzzing queue for mutation, and thus has a better chance to find vulnerabilities faster.

- The deterministic stage may have good performance at the beginning of fuzzing, but becomes inefficient after a while. This mode selectively disables this stage only after the efficiency slows down, and thus benefits from this stage while avoiding wasting much time on it.

More specifically, MOPT provides two types of pacemaker fuzzing modes for AFL, based on whether the deterministic stage will be re-enabled or not: (1) MOPT-AFL-*tmp*, which will re-enable the deterministic stage again when the number of new interesting test cases exceeds a predefined threshold; (2) MOPT-AFL-*ever*, which will never re-enable the deterministic stage in the following fuzzing process.

## 5 Evaluation

### 5.1 Real World Datasets

We have evaluated MOPT on 13 open-source linux programs as shown in Table 2, each of which comes from dif-

ferent source files and has different functionality representing a broad range of programs. We choose these 13 programs mainly for the following reasons. First, many of the employed programs are also widely used in state-of-the-art fuzzing research [4, 5, 9, 10, 21]. Second, most programs employed in our experiments are real world programs from different vendors and have diverse functionalities and various code logic. Therefore, our datasets are representative and can all-sidedly measure the fuzzing performance of fuzzers to make our analysis more comprehensive. Third, all the employed programs are popular and useful open-source programs. Hence, evaluating the security of these programs are meaningful for the vendors and users of them.

## 5.2 Experiment Settings

The version of AFL used in our paper is 2.52b. We apply MOPT in the havoc stage of AFL and implement the prototypes of MOPT-AFL-tmp and MOPT-AFL-ever, where -tmp and -ever indicate the corresponding pacemaker fuzzing modes discussed in the previous section. The core functions of MOPT is implemented in C.

**Platform.** All the experiments run on a virtual machine configured with 1 CPU core of 2.40GHz E5-2640 V4, 4.5GB RAM and the OS of 64-bit Ubuntu 16.04 LTS.

**Initial seed sets.** Following the same seed collection and selection procedure as in previous works [3, 22, 23], we use randomly-selected files as the initial seed sets. In particular, for each objective program, we obtain 100 files with the corresponding input format as the initial seed set, e.g., we collect 100 mp3 files for mp3gain. The input format of each program is shown in Table 2. In particular, we first download the files with the corresponding input formats for each objective program from the music download websites, picture download websites, and so on (except for text files, where we obtain text files by randomly generating letters to fill them). Then, for the large files such as mp3 and PDF, we split them to make their sizes reasonable as seeds. Through this way,

we have a large corpus of files with the corresponding input formats for each objective program. Finally, we randomly select 100 files from the corpus. These 100 files will be the initial seed set of all the fuzzers when fuzzing one objective program.

**Evaluation metrics.** The main evaluation metric is the number of the unique crashes discovered by each fuzzer. Since coverage-based fuzzers such as *AFLFast* [5] and *VUzzer* [6] consider that exploring more unique paths leads to more unique crashes, the second evaluation metric is the number of unique paths discovered by each fuzzer.

## 5.3 Unique Crashes and Paths Discovery

We evaluate AFL, MOPT-AFL-tmp and MOPT-AFL-ever on the 13 programs in Table 2, with each experiment runs for 240 hours. The results are shown in Table 3, from which we can deduce the following conclusions.

- For exploring unique crashes, MOPT-AFL-tmp and MOPT-AFL-ever are significantly more efficient than AFL on all the programs. In total, MOPT-AFL-tmp and MOPT-AFL-ever discover 2,195 and 2,334 more unique crashes than AFL on the 13 programs. Thus, MOPT-AFL has much better performance than AFL in exploring unique crashes.
- For triggering unique paths, MOPT-AFL-tmp and MOPT-AFL-ever also significantly outperform AFL. In total, MOPT-AFL-tmp and MOPT-AFL-ever found 45,600 and 56,515 more unique paths than AFL on the 13 programs. As a result, the proposed MOPT can improve the coverage of AFL remarkably.
- When considering the pacemaker fuzzing mode, MOPT-AFL-tmp and MOPT-AFL-ever discover the most unique crashes on 8 and 6 programs, respectively, while MOPT-AFL-ever discovers more crashes in total. Since the main difference between the two fuzzers is whether using the deterministic stage later, it may be an interesting future work to figure out how to employ the deterministic stage properly.

Table 4: Vulnerabilities found by AFL, MOPT-AFL-tmp and MOPT-AFL-ever.

| Program       | AFL                     |     |                       |     | MOPT-AFL-tmp            |     |                       |     | MOPT-AFL-ever           |     |                       |     |

## 5.4 Vulnerability Discovery

To figure out the corresponding vulnerabilities of the crashes found in Section 5.3, we recompile the evaluated programs with *AddressSanitizer* [24] and reevaluate them with the discovered crash inputs. If the top three source code locations of the stack trace provided by *AddressSanitizer* are unique, we consider the corresponding crash input triggers a unique vulnerability of the objective program. This is a common way to find unique vulnerabilities in practice and has been used to calculate the stack hashing in [25]. Then, we check the vulnerability reports of the target program on the CVE website to see whether they correspond to some already existed CVEs. If not, we submit the vulnerability reports and the Proof of Concepts (PoCs) to the vendors and the CVE assignment team. The vulnerabilities discovered by AFL, MOPT-AFL-tmp and MOPT-AFL-ever are shown in Table 4, from which we have the following conclusions.

- Both MOPT-AFL-tmp and MOPT-AFL-ever discover more vulnerabilities than AFL by a wide margin. For instance, MOPT-AFL-tmp finds 45 more security CVEs than AFL; MOPT-AFL-ever finds 23 more unreported CVEs than AFL; Our fuzzers find 81 security CVEs with 66 new CVE IDs assigned on 11 programs. The results demonstrate that MOPT-AFL is very effective on exploring CVEs.

- Our fuzzers discover 15 previously known vulnerabilities published by CVE on the latest version of the objective programs. For instance, when fuzzing `pdfimages`, MOPT-AFL-tmp and MOPT-AFL-ever discover 3 and 2 existed vulnerabilities, respectively. The results demonstrate that security patching takes a long time in practice.

- AFL, MOPT-AFL-tmp and MOPT-AFL-ever discover 1, 2 and 2 unique vulnerabilities on `tiff2bw`, respectively. As for `sam2p`, MOPT-AFL-tmp and MOPT-AFL-ever discover 14 and 28 unique vulnerabilities, respectively. In comparison, AFL only finds 5 vulnerabilities. Since the vulnerabilities happened in the `tiff2bw` command-line program and the CVE assignment team thinks that `sam2p` is a UNIX command line program rather than a library, they cannot as-

sign CVE IDs for the vulnerabilities on `tiff2bw` and `sam2p`. On all the 13 programs, MOPT-AFL-tmp and MOPT-AFL-ever discover 112 unique vulnerabilities in total, and AFL discovers 33 vulnerabilities.

## 5.5 CVE Analysis

In this subsection, we analyze the CVEs discovered in Section 5.4 in detail and discuss the performance of different fuzzers. We also measure the severity of each CVE for each program by leveraging the Common Vulnerability Scoring System (CVSS) [26] and show the highest score in Table 5. We can learn the following conclusions.

- Both MOPT-AFL-tmp and MOPT-AFL-ever find more kinds of vulnerabilities than AFL, which means MOPT-AFL does not limit on discovering specific kinds of vulnerabilities. In other words, the MOPT scheme can guide the fuzzing tools to discover various vulnerabilities.

- We realize that MOPT-AFL-tmp discovers significantly more unique vulnerabilities than MOPT-AFL-ever on `pdfimages` and `w3m`. We analyze the reasons as follows. First of all, we would like to clarify the functionalities of these two objective programs. `pdfimages` is used to save images from the PDF files as the image files locally. `w3m` is a pager and/or text-based browser, which can handle tables, cookies, authentication, and almost everything except for JavaScript. We notice that PDF files have complex structures and so do the web data handled by `w3m`. Thus, there are many magic byte checks in `pdfimages` and `w3m` to handle the complex structures. Because it is hard to randomly generate a particular value, the operators in the deterministic stage, such as flipping the bits one by one (**bitflip**) and replacing the bytes with interesting values (**interesting values**), are better than the ones in the havoc stage to pass the magic byte checks and to test deeper execution paths. MOPT-AFL-tmp performs better than MOPT-AFL-ever on `pdfimages` and `w3m` since MOPT-AFL-tmp enables the deterministic stage later while MOPT-AFL-ever does not. However, since the deterministic stage performs multiple kinds of operators on each

Table 5: The types and IDs of CVE discovered by AFL, MOPT-AFL-tmp and MOPT-AFL-ever.

| Target        | Types                   | AFL                                                            | MOPT-AFL-tmp                                                                                                                                                                                                   | MOPT-AFL-ever                                                                                                  | Severity |

bit/byte of the test cases, it takes a lot of time to finish all the operations on each test case in the fuzzing queue, leading to the low efficiency. On the other hand, MOPT-AFL-tmp temporarily uses the deterministic stage on different test cases in the fuzzing queue to avoid this disadvantage.

- Interestingly, we can also see that although we fuzz the objective programs with the latest version, MOPT-AFL still discovers already existed CVEs. For instance, we reproduce the Proof of Concepts (PoCs) of CVE-2017-17723 of `exiv2`, which can cause the overflow and has 5.8 CVSS Score according to *CVE Details* [27]. It may be because the vendors do not patch the vulnerabilities before the release or they patch the vulnerabilities while MOPT-AFL still discovers other PoCs. Therefore, the servers using these programs may be attacked because of these vulnerabilities. In addition, most of the discovered vulnerabilities can crash the programs and allow remote attackers to launch denial of service attacks via a crafted file. Thus, a powerful fuzzer is needed to improve the security patching.

**Case study:** CVE-2018-18054 in `pdfimages`. An interesting vulnerability we found is a heap buffer overflow in `pdfimages`. Although the PDF files in the seed set do not contain pictures that use the CCITTFax encoding, a test case generated by MOPT-AFL-tmp still triggers the CCITTFax decoding process of `pdfimages`. Furthermore, even the PDF syntax of this test case is partially damaged, `pdfimages` continues to extract the pictures from it. Then, the test case triggers the function `GBool CCITTFaxStream::readRow()` in `Stream.cc` for multiple times and finally accesses the data that exceed the index of the array `refLine`, which leads to a

heap buffer overflow. This vulnerability shows the powerful mutation capability of MOPT-AFL-tmp, which not only generates a structure similar to an encoding algorithm but also triggers an array out of bounds.

## 5.6 More Analysis on Discovered Crashes

In this subsection, we give a close look on the growth of the number of unique crashes discovered by MOPT-AFL-ever, MOPT-AFL-tmp and AFL. The results are shown in Fig. 9, from which we have the following conclusions.

- Both MOPT-AFL-ever and MOPT-AFL-tmp are effective at finding unique crashes. On most programs, they take fewer than 100 hours to find more unique crashes than AFL does in 240 hours.

- We can learn from Fig. 9 (c) and (f) that within a relatively short time, AFL may discover more crashes than MOPT-AFL-ever and MOPT-AFL-tmp. The reasons are as follows. First, mutation-based fuzzing has randomness, and naturally such randomness may cause performance shaking within a short time. However, relatively stable performance will exhibit in a long time-scale as shown in the experiments. Second, the selection probability distribution of mutation operators in MOPT-AFL-ever and MOPT-AFL-tmp adopts random initialization, which may cause fuzzing randomness in the early fuzzing time. Thus, to reduce the performance instability of fuzzing, a relatively long time experiment is necessary, e.g., we run our experiments for 240 hours.

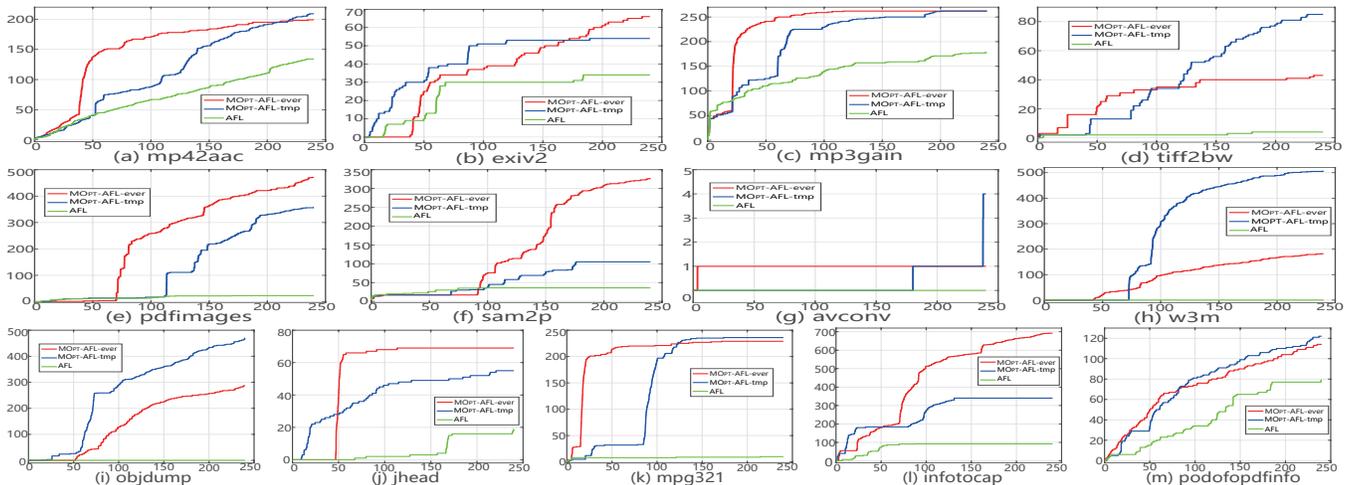

Figure 9: The number of unique crashes discovered by MOPT-AFL-ever, MOPT-AFL-tmp and AFL over 240 hours. X-axis: time (over 240 hours). Y-axis: the number of unique crashes.

## 5.7 Compatibility Analysis

In addition to AFL, we also generalize our analysis to several state-of-the-art mutation-based fuzzers, e.g., AFLFast [5] and VUzzer [6], and study the compatibility of MOPT.

AFLFast [5] is one of the coverage-based fuzzers. By using a power schedule to guide the fuzzer towards low frequency paths, AFLFast can detect more unique paths and explore the vulnerabilities much faster than AFL. To examine the compatibility of MOPT, we implement MOPT-AFLFast-tmp and MOPT-AFLFast-ever based on AFLFast.

VUzzer [6] is a fuzzer that focuses on exploring deeper paths. VUzzer can evaluate a test case with the triggered path and select the test cases with higher fitness scores to generate subsequent test cases. The mutation strategy of VUzzer is different from AFL. In each period, VUzzer generates a fixed number of mutated test cases, evaluates their fitness and only keeps *POPSIZE* test cases with the highest fitness scores to generate test cases in the next period, where *POPSIZE* is the population number of the parent test cases set by users. We regard the mutation operators as the high-efficiency operators that can generate the test cases with top- $(POPSIZE/3)$  fitness scores. Then, we combine MOPT with VUzzer and implement MOPT-VUzzer. Since VUzzer does not have a deterministic stage like AFL, we do not consider the pace-maker fuzzing mode here.

Now, we evaluate MOPT-AFLFast-tmp, MOPT-AFLFast-ever, and MOPT-VUzzer on mp42aac, exiv2, mp3gain, tiff2bw, pdfimages, sam2p and mpg321. Each experiment is lasted for 240 hours with the same settings as in Section 5.2. Specifically, we change the OS as the 32-bit Ubuntu 14.04 LTS for VUzzer and MOPT-VUzzer because of VUzzer’s implementation restriction. The results are shown in Table 6. We have the following conclusions.

- MOPT-AFLFast-tmp and MOPT-AFLFast-ever have much better performance than AFLFast in discovering unique crashes on all the programs. For instance, MOPT-

AFLFast-ever finds 327 more crashes than AFLFast on pdfimages. When combining MOPT with VUzzer, MOPT-VUzzer discovers more unique crashes than VUzzer on mp42aac, mp3gain, sam2p and mpg321. As a result, MOPT cannot only be combined with state-of-the-art fuzzers like AFLFast, but also be compatible with the different fuzzers like VUzzer to improve the fuzzing performance.

- MOPT-based fuzzers can explore more unique paths than their counterparts. For instance, MOPT-AFLFast-tmp discovers 2,156 more paths than AFLFast on mp42aac; MOPT-AFLFast-ever finds 14,777 more than AFLFast on pdfimages. MOPT-VUzzer has a better coverage performance than VUzzer on mp3gain. Overall, MOPT can help the mutation-based fuzzers discover more unique paths.

- MOPT-AFL has an outstanding performance in comparison to state-of-the-art fuzzers. MOPT-AFL outperforms AFLFast with a significant advantage on all the programs except mp42aac. For instance, MOPT-AFL-tmp and MOPT-AFL-tmp discover 85 and 43 more unique crashes than AFLFast on tiff2bw. Furthermore, MOPT-AFL-tmp and MOPT-AFL-ever find dozens of times more unique crashes than VUzzer on most programs.

## 5.8 Evaluation on LAVA-M

Recently, the LAVA-M dataset is proposed as one of the standard benchmarks to examine the performance of fuzzers [28]. It has 4 target programs, each of which contains the listed and unlisted bugs. The authors provide the test cases that can trigger the listed bugs. However, no test cases were provided for the unlisted bugs, making them more difficult to be found. For completeness, we test AFL, MOPT-AFL-ever, AFLFast, MOPT-AFLFast-ever, VUzzer and MOPT-VUzzer on LAVA-M with the same initial seed set and the same settings as in Section 5.7, for 5 hours. Furthermore, we run MOPT-AFL-ever with Angora [9] and QSYM [29] parallelly to construct MOPT-Angora and MOPT-QSYM,

Table 6: The compatibility of the MOPT scheme.

run AFL with them parallelly to construct AFL-Angora and AFL-QSYM, and evaluate them on the LAVA-M dataset under the same experiment settings. The results are shown in Table 7, from which we have the following conclusions.

- MOPT-based fuzzers significantly outperform their counterparts on LAVA-M. For instance, MOPT-AFL-ever finds 35 more listed bugs than AFL on base64. MOPT-VUzzer finds more listed bugs than VUzzer on all the four programs. Both MOPT-Angora and MOPT-QSYM find significantly more unique bugs on who compared to their counterparts. Thus, MOPT is effective in improving the performance of mutation-based fuzzers.

- The fuzzers, which use symbolic execution or similar techniques, perform significantly better than others on LAVA-M. MOPT again exhibits good compatibility and can be integrated with general mutation-based fuzzers. For instance, MOPT-Angora finds significantly more unique bugs than AFL-Angora, and MOPT improves the performance of AFL-QSYM in 3 cases. From Table 7, in addition to the compatibility, MOPT can find the unique bugs and paths which the symbolic execution fails to find.

## 6 Further Analysis

### 6.1 Steadiness Analysis

Following the guidance of [25] and to make our evaluation more comprehensive, we conduct three extra groups of evaluations in this subsection. In the following, we detail the seed selection process, the evaluation methodology, and the analysis of the results.

**Evaluation methodology and setup.** To provide statisti-

cal evidences of our improvements, we measure the performance of MOPT-AFL-ever, AFL, Angora [9] and VUzzer [6] on five programs including mp3gain, pdfimages, objdump, jhead and infotocap (the detail of each program is shown in Table 2). Each program is tested by each fuzzer for 24 hours, on a virtual machine configured with one CPU core of 2.40Ghz E5-2640 V4, 4.5GB RAM and the OS of 64-bit Ubuntu 16.04 LTS. To eliminate the effect of randomness, we run each testing for 30 times.

To investigate the influence of the initial seed set on the performance of MOPT, we consider using various initial seed sets in our experiments such as an empty seed, or the seeds with different coverage, which are widely used in previous works [1, 5, 9, 21].

In the first group of experiments, each program is fed with an empty seed, which is a text file containing a letter ‘a’. In the second and third groups of experiments, each program is fed with 20 and 200 well-formed seed inputs, respectively. In the third group, Angora is skipped since it reports errors to fuzz pdf images when given 200 seed PDF files.

To obtain the seed inputs, we first download more than necessary (e.g., 1,700) input files with correct formats from the Internet. For example, we download mp3 files from the music download websites. Then, we split the input files (of format PDF and mp3) into a reasonable size if they are too large. Further, we utilize AFL-cmin [16] to evaluate each input file’s coverage, and remove the inputs that have redundant coverage. In the remaining input files, we randomly select 20 (i.e., for the second group) or 200 (i.e., for the third group) seeds for the corresponding objective program.

**Evaluation metrics.** We measure the widely adopted metrics, i.e., *number of unique crashes* and *number of unique*

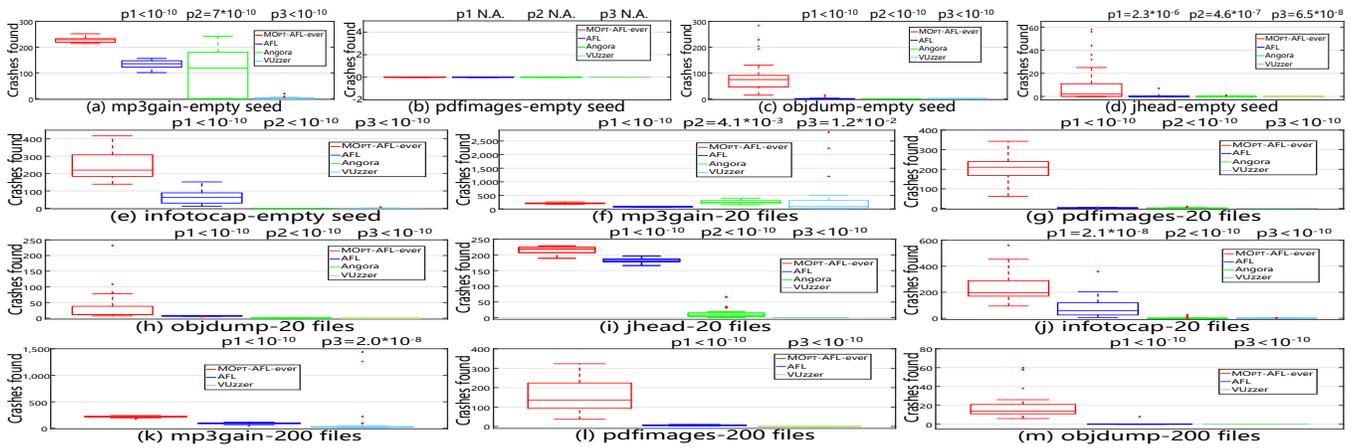

Figure 10: The boxplot generated by the number of unique crashes from 30 trials, which are found by AFL, MOPT-AFL-ever, Angora and VUzzer on five programs when fed with an empty seed, with 20 well-formed seed inputs and with 200 well-formed seed inputs. Y-axis: the number of unique crashes discovered in 24 hours.

bugs, to compare the performance of each fuzzer. To obtain the unique bugs, we recompile objective programs with the *AddressSanitizer* [24] instrumentation, and reevaluate the programs with the discovered crash inputs. If the top three source code locations of the stack trace provided by *AddressSanitizer* are unique, we consider the corresponding crash input triggers a unique bug of the objective program. This is a common way to find unique bugs in practice and has been used to calculate the stack hashing in [25].

Note that we do the statistical tests and use the  $p$  value [30] to measure the performance of the three fuzzers (suggested by [25]). In particular,  $p_1$  is the  $p$  value yielded from the difference between the performance of MOPT-AFL-ever and AFL,  $p_2$  is the  $p$  value yielded from the difference between the performance of MOPT-AFL-ever and Angora, and  $p_3$  is the  $p$  value generated from the difference between the performance of MOPT-AFL-ever and VUzzer.

We further validate the reliability of our  $p$  value analysis leveraging the Benjamini-Hochberg (BH) procedure [31]. For the details, please refer to the technical report [20].

**Results and analysis.** The number of unique crashes and unique bugs are shown in Fig. 10 and Fig. 11, respectively. From the results, we can learn the following facts.

- As shown in Fig. 10, among all the 13 evaluation settings, MOPT-AFL-ever discovers more unique crashes than the other fuzzers in 11 evaluations. In these 11 evaluations,  $p_1$ ,  $p_2$  and  $p_3$  are smaller than  $10^{-5}$ , meaning that the distribution of the number of unique crashes discovered by MOPT-AFL-ever and the other fuzzers is widely different, which demonstrates a significant statistical evidence for MOPT’s improvement. Therefore, according to the statistical results of 30 trials, MOPT-AFL-ever performs better than AFL, Angora and VUzzer in most cases.

- As for the number of discovered unique bugs, MOPT-AFL-ever still performs significantly better than AFL, Angora and VUzzer in most cases. For instance, the minimum number of unique bugs discovered by MOPT-AFL-

ever among the 30 runs is more than the maximum number of that discovered by other fuzzers when fuzzing *objdump* and *jhead* with 20 files as the initial seed set. Further, we find that both Angora and VUzzer discover more unique crashes but fewer unique bugs than MOPT-AFL-ever when fuzzing *mp3gain* with the 20 files. This indicates that their deduplication strategies do not work well in this evaluation.

- When using an empty seed as the initial seed set to fuzz *pdfimages*, all the fuzzers cannot discover any unique crash. The reason is that PDF files have complex structures. The test cases mutated from an empty seed are hard to generate such complex structures, which leads to the poor fuzzing performance. This reminds us the motivation of generation-based fuzzers and shows that: *although fuzzers like AFL may perform better with an empty seed, they cannot discover more crashes on the programs that require complex input formats when using an empty seed.*

## 6.2 Stepwise Analysis of MOPT Main Framework and Pacemaker Fuzzing Mode

To validate the effectiveness of MOPT main framework and the pacemaker fuzzing mode, we implement MOPT-AFL-off (that is based on MOPT-AFL-ever while disabling the pacemaker fuzzing mode) and AFL-ever (that is based on AFL and only implements the pacemaker fuzzing mode). We re-evaluate AFL, MOPT-AFL-off, AFL-ever and MOPT-AFL-ever on *pdfimages*, *w3m*, *objdump* and *infotocap* for 240 hours. The results are shown in Table 8.

*MOPT Main Framework (without Pacemaker Fuzzing Mode).* We can learn from Table 8 that MOPT-AFL-off discovers more crashes than AFL. For instance, on *w3m*, AFL cannot discover any crash in 240 hours, while MOPT-AFL-off discovers 74 unique crashes. Note that if without the pacemaker fuzzing mode, MOPT-AFL-off uses the *havoc* stage less frequently and iterates the selection distribution

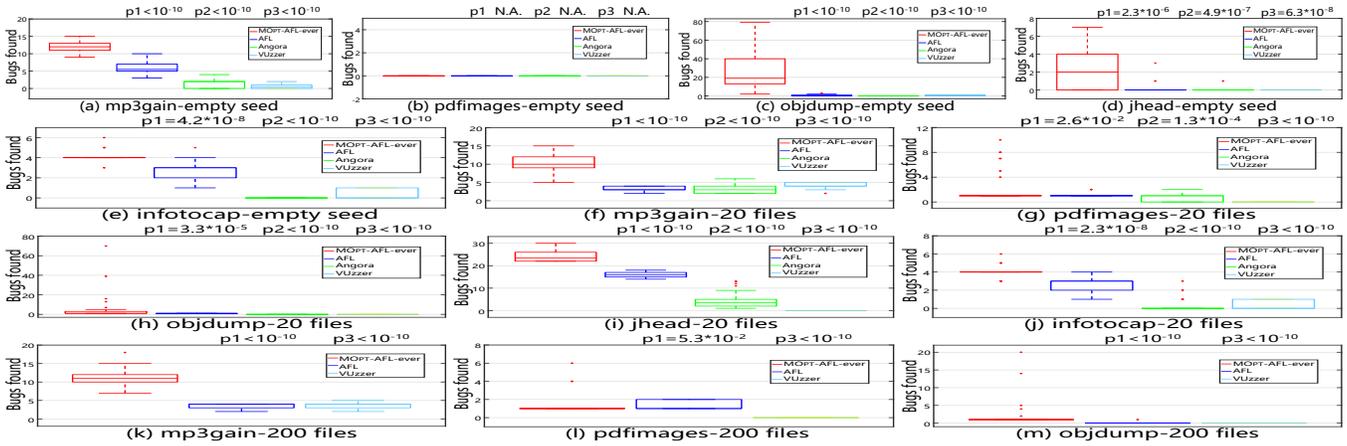

Figure 11: The boxplot generated by the number of unique bugs from 30 trials, which are found by AFL, MOPT-AFL-ever, Angora and VUzzer on five programs when fed with an empty seed, with 20 well-formed seed inputs and with 200 well-formed seed inputs. Y-axis: the number of unique bugs discovered in 24 hours.

Table 8: The results of AFL, MOPT-AFL-off, AFL-ever and MOPT-AFL-ever on 4 target programs.

more slowly, which limits the performance of the MOPT main framework. Comparing MOPT-AFL-ever with AFL-ever, we can learn that MOPT-AFL-ever has a better capability to explore unique crashes than AFL-ever. As for the coverage, MOPT-AFL-off discovers more unique paths than AFL, and the same situation applies for MOPT-AFL-ever and AFL-ever. As a conclusion, both two comparison groups demonstrate that the MOPT scheme without the pacemaker fuzzing mode can also improve the performance of AFL on exploring unique crashes and paths, but a better performance can be achieved if integrating the pacemaker fuzzing mode.

*Pacemaker Fuzzing Mode.* For discovering unique crashes, AFL-ever discovers 165 more unique crashes than AFL on objdump. Additionally, MOPT-AFL-ever finds 1,120 more unique crashes than MOPT-AFL-off on the 4 programs in total. As for the coverage, AFL-ever is better than AFL on w3m, objdump and infotocap. MOPT-AFL-ever finds nearly twice as many unique paths as MOPT-AFL-off on all the programs except w3m. As a conclusion, the experiments demonstrate that the pacemaker fuzzing mode can help fuzzers find much more unique crashes and paths.

In summary, *both the MOPT main framework and pacemaker fuzzing mode can improve the fuzzing performance significantly, while the combination of both parts would result in an even better performance (corresponding to MOPT-AFL-ever).* To further clarify this point, we use the number of unique crashes discovered by MOPT-AFL-ever as the baseline and observe the approximate fuzzing performance

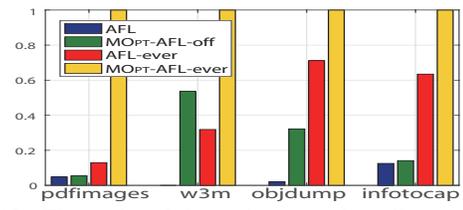

Figure 12: The ratio of the unique crashes discovered by 4 of each part. The results are shown in Fig. 12.

of each part. The results are shown in Fig. 12. From the results, the improvement of the pacemaker fuzzing mode is relatively limited for fuzzing; however, without the pacemaker fuzzing mode, MOPT cannot converge fast to the proper selection probability distribution, which on the other hand limits the fuzzing performance either. Nevertheless, *the performance can be significantly improved if we combine AFL with the complete MOPT scheme.*

### 6.3 Iteration Analysis of Selection Probability

To demonstrate the effectiveness of MOPT in obtaining the proper selection probability for the mutation operators, we record the probability of bitflip 1/1, arith 8/8 and interest 16/8 obtained by the particles in one swarm when using MOPT-AFL-ever to fuzz w3m and pdffimages. The results are shown in Fig. 13, from which we have the following observations.

- Different mutation operators have different proper selection probabilities on each program. Moreover, the proper

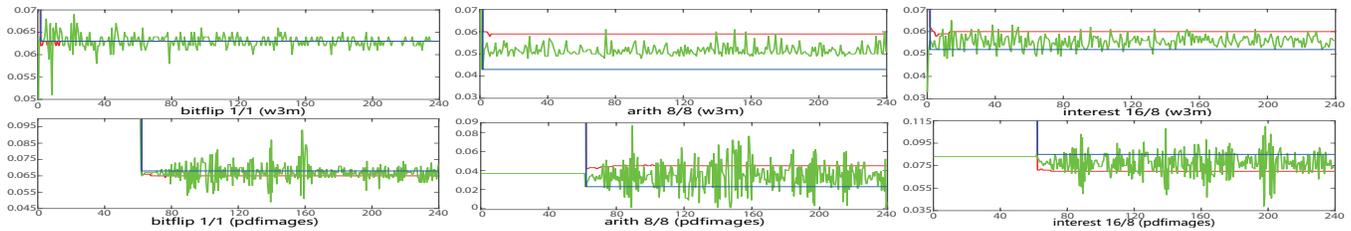

Figure 13: The probability when using MOPT-AFL-ever to fuzz `w3m` and `pdfimages`. X-axis: time (over 240 hours). Y-axis: the selection probability of the corresponding mutation operator. Green line:  $x_{now}$ . Red line:  $G_{best}$ . Blue line:  $L_{best}$ .

selection probability of one mutation operator varies with the objective programs. The results are consistent with our motivation that it is desired to dynamically determine the selection probability of operators during the fuzzing process.

- $G_{best}$  and  $L_{best}$  quickly converge to the proper values. For instance, it only takes an hour for  $G_{best}$  and  $L_{best}$  to converge to the proper values when fuzzing `w3m`. When the proper values of  $G_{best}$  and  $L_{best}$  are the same,  $x_{now}$  will converge to this value and oscillate around. Otherwise,  $x_{now}$  will oscillate between  $G_{best}$  and  $L_{best}$  to explore whether there is a better selection probability.

- We can learn from Fig. 13 that MOPT iterates slowly at first and iterates fast later on `pdfimages`. The reasons are that (1) the deterministic stage is effective at finding interesting test cases in the early fuzzing time; (2) the fuzzer spends a long time on the deterministic stage of one test case when fuzzing `pdfimages`. When the efficiency of the deterministic stage decreases, i.e., it cannot discover any new crash or path for a long time, MOPT-AFL-ever enters the pacemaker fuzzing mode and will not use the deterministic stage again. Then the selection probability converges quickly and MOPT iterates fast. The results demonstrate that the design of the pacemaker fuzzing mode is reasonable and meaningful, which exploits the deterministic stage at first and avoids repeating its high computation when it is inefficient.

## 6.4 Overhead Analysis

In order to compare the execution efficiency of each fuzzer in Section 5.3, we collect the total execution times of each fuzzer, which are the times a fuzzer uses the generated test cases to test an objective program, within 240 hours. The results are shown in Table 9, from which we learn the following conclusions.

Although MOPT fuzzers take partial computing power to improve the mutation scheduler, the execution efficiency of MOPT-AFL-tmp and MOPT-AFL-ever is still comparable with AFL on most programs. In many cases, although the MOPT-AFL fuzzers test the objective programs for fewer times, they find much more crashes and paths than AFL.

Interestingly, MOPT-AFL can execute the tests faster than AFL on several programs. Moreover, the MOPT-AFL yields a better average execution efficiency on the 13 programs. We analyze the reasons as follows. The execution speed of each

test case is different, and thus the test cases with slow execution speed will take more time consumption. When the fuzzing queue of AFL contains slow test cases, it will generate a number of test cases mutated from the slow test cases in the deterministic stage, which may also be executed slowly with a high probability and decrease AFL's execution efficiency. As for MOPT-AFL fuzzers, they will generate much fewer mutated cases from the slow test cases since they tend to disable the deterministic stage when it is not efficient. Therefore, MOPT-AFL fuzzers will spend much less time on the slow test cases, followed by yielding a high execution efficiency.

## 6.5 Long Term Parallel Experiments

We run the long term parallel experiments in order to verify the performance of MOPT-AFL in parallel for a long time. In each experiment, AFL, MOPT-AFL-tmp and MOPT-AFL-ever, are employed to fuzz `pdfimages` in parallel. Each experiment has three instances denoted by Fuzzer1, Fuzzer2 and Fuzzer3, with 20 carefully selected PDF files filtered from AFL-cmin [16] as the initial seed set. According to the parallel design of AFL and MOPT-AFL, the Fuzzer1 of AFL, MOPT-AFL-tmp and MOPT-AFL-ever will still perform the deterministic stage, while their Fuzzer2 and Fuzzer3 will disable it in the parallel experiments. Each experiment runs on a virtual machine configured with four CPU cores of 2.40Ghz E5-2640 V4, 4.5 GB RAM and the OS of 64-bit Ubuntu 16.04 LTS. The total CPU time of each experiment exceeds 70 days till the writing of this report and AFL, MOPT-AFL-tmp and MOPT-AFL-ever discover 1,778, 2,907 and 2,702 unique crashes, respectively.

The results are shown in Table 10, from which we can see that AFL's performance of discovering unique crashes is obviously inferior to MOPT-AFL's. Fuzzer1 of AFL enables the deterministic stage all the time and only discovers 11 unique crashes in more than 23 days, demonstrating the inefficiency of the deterministic stage. What's more, the performance of Fuzzer1 of MOPT-AFL-tmp is much better than that of MOPT-AFL-ever and AFL. We conjecture the reasons as follows. Since PDF files require the strict file format, there are many unique execution paths in `pdfimages` that contain strict magic byte checks. The operators, e.g., `bitflip 1/1`, in the deterministic stage are better at gen-

Table 9: The total execution times and executions per second of AFL, MOPT-AFL-tmp and MOPT-AFL-ever.

| Program      | AFL                   |                       | MOPT-AFL-tmp          |                       |          | MOPT-AFL-ever         |                       |          |

erating the correct magic bytes since fuzzers will flip every bit in the current test case to generate new test cases. In the later time, MOPT-AFL-tmp will enable the deterministic stage again while MOPT-AFL-ever will not. Thus MOPT-AFL-tmp is better at discovering unique paths containing magic byte checks than MOPT-AFL-ever. As for AFL, since it will go through the deterministic stage for all the test cases, it spends most time on this stage and discovers few unique crashes and paths. While MOPT-AFL-tmp will disable the deterministic stage when it cannot discover any interesting test case for a long time, after some time, it will re-enable the deterministic stage again and will perform the deterministic stage with the widely different test cases in the fuzzing queue. Therefore, MOPT-AFL-tmp can keep efficient fuzzing performance and can perform the deterministic stage on widely different test cases.

We can also observe from Table 10 that AFL's Fuzzer2 and Fuzzer3 find much more unique crashes than its Fuzzer1 without of the deterministic stage. The Fuzzer1 of MOPT-AFL-tmp and MOPT-AFL-ever finds much more crashes than AFL's Fuzzer1 and suppresses the performance of Fuzzer2 and Fuzzer3 in some way. Meantime, the Fuzzer2 and Fuzzer3 of both MOPT-AFL-tmp and MOPT-AFL-ever perform better than those of AFL. All these results demonstrate the improvement of the customized PSO algorithm.

## 7 Limitation and Discussion

In order to further analyze the compatibility of MOPT, we are eager to combine it with state-of-the-art fuzzers such as CollAFL [4] and Steelix [10] after they open-source their system code. By leveraging MOPT as an optimal strategy for selecting mutation operators, we believe the performance of these systems can be further enhanced.

In our evaluation, we consider 13 real world programs and several seed selection strategies, which are still a limited number of scenarios. In our evaluation, overall, MOPT-AFL discovers 31 vulnerabilities on tiff2bw and sam2p and 66 unreported CVEs on the other 11 programs. Further-

Table 10: The performance of three fuzzers in the long term parallel experiments when fuzzing pdf images.

|               | Fuzzer1        | Fuzzer2 | Fuzzer3 | Total  |
|---------------|----------------|---------|---------|--------|
| AFL           | Unique crashes | 11      | 871     | 896    |
|               | Unique paths   | 24,763  | 29,329  | 29,329 |
| MOPT-AFL-tmp  | Unique crashes | 834     | 1,031   | 1,042  |
|               | Unique paths   | 30,098  | 31,600  | 31,520 |
| MOPT-AFL-ever | Unique crashes | 723     | 974     | 1,005  |
|               | Unique paths   | 28,047  | 30,910  | 30,966 |

more, both MOPT-Angora and MOPT-QSYM perform better than previous methods on the benchmark dataset LAVA-M. Therefore, the proposed MOPT is promising to explore vulnerabilities for real world programs. Nevertheless, the performance advantage exhibited in our evaluation may not be applicable to all the possible programs and seeds. Our evaluation can be enhanced by further conducting more in-depth evaluation in large-scale. To make our evaluation more comprehensive, we are planning to perform a large-scale evaluation of MOPT using more real world programs and benchmarks in the future.

As a future work, it is interesting to investigate better mutation operators to further enhance the effectiveness of MOPT. Constructing a more comprehensive and representative benchmark dataset to systematically evaluate the performance of fuzzers is another interesting future work.

## 8 Related Work

In this section, we summarize the existing fuzzing mechanisms and the related seed selection strategies.

*Mutation-based fuzzing.* AFL is one of the most well-recognized fuzzers because of its high-efficiency and ease of use [16]. Multiple efficient fuzzers were developed based on AFL [4, 5]. To improve fuzzing performance, some combined the mutation-based fuzzing with other bug detection technologies [13, 14, 15, 32]. Another method to improve mutation-based fuzzers is coverage-based fuzzing [6, 10, 11]. Li et al. proposed a vulnerability-oriented fuzzer named *V-Fuzz* that pays more attention to potentially vulnerable components [33]. Yun et al. presented a fast concolic

execution engine named *QSYM* to help fuzzers explore more bugs and paths [29]. By solving the path constraints without symbolic execution, *Angora* presented by Chen et al. can significantly increase the branch coverage of programs [9].

MOPT presented in our paper is a scheme of improving the test case mutation process and generating high-quality mutated test cases. Taking the advantage of its compatibility, it can be combined with most of the aforementioned fuzzers.

Although in this paper we focus on using MOPT to improve mutation-based fuzzers, it can also be implemented in other kinds of fuzzers, such as generation-based fuzzers and kernel fuzzers, if they have the issues to select proper operators to generate test cases. MOPT can also be combined with most existing seed selection strategies since they can provide better initial seed sets for fuzzers. We briefly introduce the state-of-the-art related works in these area as follows.

*Generation-based fuzzing.* Generation-based fuzzers focus on the programs that require the test cases with specific input formats [34, 35]. Recently, Wang et al. presented a novel data-driven seed generation approach named *Skyfire* to generate interesting test cases for XML and XSL [1]. Godefroid et al. presented a RNN-based machine learning technique to automatically generate a grammar for the test cases with complex input formats [36].

*Other fuzzing strategies.* Several works presented effective kernel fuzzers [37, 38]. Xu et al. [12] implemented three new operating primitives to benefit large-scale fuzzing and cloud-based fuzzing services. You et al. presented *SemFuzz* to learn from vulnerability-related texts and automatically generate Proof-of-Concept (PoC) exploits [39]. Petsios et al. proposed *SlowFuzz* to trigger algorithmic complexity vulnerabilities [22]. Klees et al. performed extensive experiments and proposed several guidelines to improve the experimental evaluations for fuzzing [25]. Some works proposed state-of-the-art directed greybox fuzzers to rapidly reach the target program locations [21, 40]. Recently, several works [7], [8] employ the reinforcement learning algorithms as the mutation schedulers and propose their fuzzing frameworks, respectively. However, the performance improvement of these methods is limited based on their experimental results.

*Seed selection strategies.* Several works focused on how to select a better seed set [2, 3]. Nichols et al. showed that using the generated files of GAN to reinitialize AFL can find more unique paths of *ethkey* [41]. Lyu et al. presented *SmartSeed* to leverage machine learning algorithms to generate high-quality seed files for different input formats [42].

## 9 Conclusion

We first studied the issues of existing mutation-based fuzzers which employ the uniform distribution for selecting mutation operators. To overcome these issues, we presented a mutation scheduling scheme, named MOPT, based on Particle Swarm Optimization (PSO). By using MOPT to

search the optimal selection distribution for mutation operators and leveraging the pacemaker fuzzing mode to further accelerate the convergence speed of searching, MOPT can efficiently and effectively determine the proper distribution for selecting mutation operators. Our evaluation on 13 real-world applications demonstrated that MOPT-based fuzzers can significantly outperform the state-of-the-art fuzzers such as AFL, AFLFast and VUzzer in most cases. We also conducted systematic analysis to demonstrate the rationality, compatibility, low cost characteristic and steadiness of MOPT. Our fuzzers found 81 security CVEs on 11 real world programs, of which 66 are the newly reported CVEs. Overall, MOPT can serve as a key enabler for mutation-based fuzzers in discovering software vulnerabilities, crashes and program paths.

## Abstract

Fuzzing is widely used for vulnerability detection. There are various kinds of fuzzers with different fuzzing strategies, and most of them perform well on their targets. However, in industrial practice, it is found that the performance of those well-designed fuzzing strategies is challenged by the complexity and diversity of real-world applications. In this paper, we systematically study an ensemble fuzzing approach. First, we define the diversity of base fuzzers in three heuristics: diversity of coverage information granularity, diversity of input generation strategy and diversity of seed selection and mutation strategy. Based on those heuristics, we choose several of the most recent base fuzzers that are as diverse as possible, and propose a globally asynchronous and locally synchronous (GALS) based seed synchronization mechanism to seamlessly ensemble those base fuzzers and obtain better performance. For evaluation, we implement EnFuzz based on several widely used fuzzers such as QSYM and FairFuzz, and then we test them on LAVA-M and Google's fuzzing-test-suite, which consists of 24 widely used real-world applications. This experiment indicates that, under the same constraints for resources, these base fuzzers perform differently on different applications, while EnFuzz always outperforms other fuzzers in terms of path coverage, branch coverage and bug discovery. Furthermore, EnFuzz found 60 new vulnerabilities in several well-fuzzed projects such as libpng and libjpeg, and 44 new CVEs were assigned.

## 1 Introduction

Fuzzing is one of the most popular software testing techniques for bug and vulnerability detection. There are many fuzzers for academic and industrial usage. The key idea of fuzzing is to generate plenty of inputs to execute the target application and monitor for any anomalies. While each fuzzer develops its own specific fuzzing strategy to generate inputs, there are in general two main types of strategies. One is a generation-based strategy which uses the specification of input format, e.g. grammar, to generate complex inputs. For example, IFuzzer [33] takes a context-free grammar as specification to generate parse trees for code fragments. Radamsa [22] reads sample files of valid data and generates interesting different outputs from them. The other main strategy

is a mutation-based strategy. This approach generates new inputs by mutating the existing seeds (good inputs contributing to improving the coverage). Recently, mutation-based fuzzers are proposed to use coverage information of target programs to further improve effectiveness for bug detection. For example, libFuzzer [10] mutates seeds by utilizing the Sanitizer-Coverage [11] instrumentation to track block coverage, while AFL [39] mutates seeds by using static instrumentation to track edge coverage.

Based on the above mentioned two fuzzers, researchers have performed many optimizations. For example, AFLFast [16] improves the fuzzing strategy of AFL by selecting seeds that exercise low-frequency paths for additional mutations, and FairFuzz [26] optimizes AFL's mutation algorithm to prioritize seeds that hit rare branches. AFLGo [15] assigns more mutation times to the seeds closer to target locations. QSYM [38] uses a practical concolic execution engine to solve complex branches of AFL. All of these optimized fuzzers outperform AFL on their target applications and have already detected a large number of software bugs and security vulnerabilities.

However, when we apply these optimized fuzzers to some real-world applications, these fuzzing strategies are inconsistent in their performance, their effectiveness on different applications varies accordingly. For example, in our evaluation on 24 real-world applications, AFLFast and FairFuzz perform better than AFL on 19 applications, while AFL performs better on the other 5 applications. Compared with AFL, libFuzzer performs better on 17 applications but worse on the other 7 applications. For the parallel mode of fuzzing which is widely-used in industry, AFLFast and FairFuzz only detected 73.5% and 88.2% of the unique bugs of AFL. These results show that the performance of existing fuzzers is challenged by the complexity and diversity of real-world applications. For a given real-world application, we cannot evaluate which fuzzer is better unless we spend significant time analyzing them or running each of these fuzzers one by one. This would waste a lot of human and computing resources [25]. This indicates that many of the current fuzzing strategies have a lack of robustness — the property of being strong and stable consistently in constitution. For industrial practice, more robust fuzzing strategies are desired when applied across a large number of different applications.

In this paper, we systematically study the performance of an ensemble fuzzing approach. First, we define the diversity of base fuzzers focusing on three heuristics: diversity of coverage information granularity, diversity of input generation strategy, as well as diversity of seed mutation and selection strategy. Then, we implement an ensemble architecture with a global asynchronous and local synchronous (GALS) based seed synchronization mechanism to integrate these base fuzzers effectively. To enhance cooperation among different base fuzzers, the mechanism synchronizes interesting seeds (i.e., test cases covering new paths or triggering new crashes) periodically to all fuzzers running on the same target application. At the same time, it maintains a global coverage map to help collect those interesting seeds asynchronously from each base fuzzer.

For evaluation, we implement a prototype of EnFuzz, based on several high-performance base fuzzers, including AFL, AFLFast, FairFuzz, QSYM, libFuzzer and Radamsa. All fuzzers are repeatedly tested on two widely used benchmarks — LAVA-M and Google’s fuzzer-test-suite, following the kernel rules of evaluating fuzzing guideline [25]. The average number of paths executed, branches covered and unique crashes discovered are used as metrics. The results demonstrate that, with the same resource usage, the base fuzzers perform differently on different applications, while EnFuzz consistently and effectively improves the fuzzing performance. For example, there are many cases where the original AFL performs better on some real-world applications than the two optimized fuzzers FairFuzz and AFLFast. In all cases, the ensemble fuzzing always outperforms all other base fuzzers.

Specifically, on Google’s fuzzer-test-suite consisting of real-world applications with a code base of 80K-220K LOCs, compared with AFL, AFLFast, FairFuzz, QSYM, libFuzzer and Radamsa, EnFuzz discovers 76.4%, 140%, 100%, 81.8%, 66.7% and 93.5% more unique bugs, executes 42.4%, 61.2%, 45.8%, 66.4%, 29.5% and 44.2% more paths and covers 15.5%, 17.8%, 12.9%, 26.1%, 19.9% and 14.8% more branches respectively. For the result on LAVA-M consisting of applications with a code base of 2K-4K LOCs, it outperforms each base fuzzer as well. For further evaluation on more widely used and several well-fuzzed open-source projects such as Libpng and jpeg, EnFuzz finds 60 new real vulnerabilities, 44 of which are security-critical vulnerabilities and registered as new CVEs. However, other base fuzzers only detect 35 new vulnerabilities at most.

This paper makes the following main contributions:

1. While many earlier works have mentioned the possibility of using ensemble fuzzing, we are among the first to systematically investigate the practical ensemble fuzzing strategies and the effectiveness of ensemble fuzzing of various fuzzers. We evaluate the performance of typical fuzzers through a detailed empirical study. We define the diversity of base fuzzers and study the effects of diversity on their performance.
2. We implement a concrete ensemble approach with seed synchronization to improve the performance of existing fuzzers. EnFuzz shows a more robust fuzzing practice

across diverse real world applications. The prototype<sup>1</sup> is also scalable and open-source so as to integrate other fuzzers.

3. We apply EnFuzz to fuzz several well-fuzzed projects such as libpng and libjpeg from GitHub, and several commercial products such as libiec61850 from Cisco. Within 24 hours, 60 new security vulnerabilities were found and 44 new CVEs were assigned, while other base fuzzers only detected 35 new vulnerabilities at most. EnFuzz has already been deployed in industrial practice, and more new CVEs are being reported<sup>1</sup>.

The rest of this paper is organized as follows: Section 2 introduces related work. Section 3 illustrates ensemble fuzzing by a simple example. Section 4 elaborates ensemble fuzzing, including the base fuzzer selection and ensemble architecture design. Section 5 presents the implementation and evaluation of EnFuzz. Section 6 discusses the potential threats of EnFuzz, and we conclude in section 7. The appendix shows some empirical evaluations and observations.

## 2 Related Work

Here below, we introduce the work related to generation-based fuzzing, mutation-based fuzzing, fuzzing in practice and the main differences between these projects. After that we summarize the inspirations and introduce our work.

### 2.1 Generation-based Fuzzing

Generation-based fuzzing generates a massive number of test cases according to the specification of input format, e.g. a grammar. To fuzz the target applications that require inputs in complex format, the specifications used are crucial. There are many types of specifications. Input model and context-free grammar are the two most common types. Model-based fuzzers [1, 20, 34] follow a model of protocol. Hence, they are able to find more complex bugs by creating complex interactions with the target applications. Peach [20] is one of the most popular model-based fuzzers with both generation and mutation abilities. It develops two key models: the data model determines the format of complex inputs and the state model describes the concrete method for cooperating with fuzzing targets. By integrating fuzzing with models of data and state, Peach works effectively. Skyfire [34] first learns a context-sensitive grammar model, and then it generates massive inputs based on this model.

Some other popular fuzzers [21, 24, 31, 33, 37] generate inputs based on context free grammar. P Godefroid [21] enhances the whitebox fuzzing of complex structured-input applications by using symbolic execution, which directly generates grammar-based constraints whose satisfiability is examined using a custom grammar-based constraint solver. Csmith [37] is designed for fuzzing C-compilers. It generates plenty of random C programs in the C99 standard as the inputs. This tool can be used to generate C programs exploring a typical combination of C-language features while

<sup>1</sup><https://github.com/enfuzz/enfuzz>

being free of undefined and unspecified behaviors. LAVA [31] generates effective test suites for the Java virtual machine by specifying production grammars. IFuzzer [33] first constructs parse trees based on a language's context-free grammar, then it generates new code fragments according to these parse trees. Radamsa [22] is a widely used generation-based fuzzer. It works by reading sample files of valid data and generating interestingly different outputs from them. Radamsa is an extreme "black-box" fuzzer, it needs no information about the program nor the format of the data. One can pair it with coverage analysis during testing to improve the quality of the sample set during a continuous fuzzing test.

## 2.2 Mutation-based Fuzzing

Mutation-based fuzzers [2, 17, 23] mutate existing test cases to generate new test cases without any input grammar or input model specification. Traditional mutation-based fuzzers such as zzuf [23] mutate the test cases by flipping random bits with a predefined ratio. In contrast, the mutation ratio of SYMFUZZ [17] is assigned dynamically. To detect bit dependencies of the input, it leverages white-box symbolic analysis on an execution trace, then it dynamically computes an optimal mutation ratio according to these dependencies. Furthermore, BFF [2] integrates machine learning with evolutionary computation techniques to reassign the mutation ratio dynamically.

Other popular AFL family tools [15, 16, 26, 39] apply various strategies to boost the fuzzing process. AFLFast [16] regards the process of target application as a Markov chain. A path-frequency based power schedule is responsible for computing the times of random mutation for each seed. As with AFLFast, AFLGo [15] also proposes a simulated annealing-based power schedule, which helps fuzz the target code. FairFuzz [26] mainly focuses on the mutation algorithm. It only mutates seeds that hit rare branches and it strives to ensure that the mutant seeds hit the rarest one. (Wen Xu et al.) [36] propose several new primitives, speeding up AFL by 6.1 to 28.9 times. Unlike AFL family tools which track the hit count of each edge, libFuzzer [10] and honggfuzz [5] utilize the SanitizerCoverage instrumentation method provided by the Clang compiler. To track block coverage, they track the hit count of each block as a guide to mutate the seeds during fuzzing. SlowFuzz [30] prioritizes seeds that use more computer resources (e.g., CPU, memory and energy), increasing the probability of triggering algorithmic complexity vulnerabilities. Furthermore, some fuzzers use concolic executors for hybrid fuzzing. Both Driller [32] and QSYM use mutation-based fuzzers to avoid path exploration of symbolic execution, while concolic execution is selectively used to drive execution across the paths that are guarded by narrow-ranged constraints.

## 2.3 Cluster and Parallel Fuzzing in Industry

Fuzzing has become a popular vulnerability discovery solution in industry [28] and has already found a large number of dangerous bugs and security vulnerabilities across a wide range of systems so far. For example, Google's OSS-Fuzz [4] platform has found more than 1000 bugs in 5 months with

thousands of virtual machines [9]. ClusterFuzz is the distributed fuzzing infrastructure behind OSS-Fuzz, and automatically executes libFuzzer powered fuzzer tests on scale [12, 13]. Initially built for fuzzing Chrome at scale, ClusterFuzz integrates multiple distributed libFuzzer processes, and performs effectively with corpus synchronization. ClusterFuzz mainly runs multiple identical instances of libFuzzer on distributed system for one target application. There is no diversity between these fuzzing instances.

In industrial practice, many existing fuzzers also provide a parallel mode, and they work well with some synchronization mechanisms. For example, each instance of AFL in parallel mode will periodically re-scan the top-level sync directory for any test cases found by other fuzzers [3, 7]. libFuzzer in parallel will also use multiple fuzzing engines to exchange the corpora [6]. These parallel mode can effectively improve the performance of fuzzer. In fact, the parallel mode can be seen as a special example of ensemble fuzzing which uses multiple same base fuzzers. However, all these base fuzzers have a lack of diversity when using the same fuzzing strategy.

### 2.3.1 Main Differences

Unlike the previous works, we are not proposing a new concrete generation-based or mutation-based fuzzing strategy. Nor do we run multiple identical fuzzers with multiple cores or machines. Instead, inspired by the seed synchronization of ClusterFuzz and AFL in parallel mode, we systematically study the possibility of the ensemble fuzzing of diverse fuzzers mentioned in the earlier works. Referred to the kernel descriptions of the evaluating fuzzing guidelines [25], we empirically evaluate most state-of-the-art fuzzers, and identify some valuable results, especially for their performance variation across different real applications. To generate a stronger ensemble fuzzer, we choose multiple base fuzzers that are as diverse as possible based on three heuristics. We then implement an ensemble approach with global asynchronous and local synchronous based seed synchronization.

## 3 Motivating Example

To investigate the effectiveness of ensemble fuzzing, we use a simple example in Figure 1 which takes two strings as input, and crashes when one of the two strings is "Magic Str" and the other string is "Magic Num".

Many existing fuzzing strategies tend to be designed with certain preferences. Suppose that we have two different fuzzers  $fuzzer_1$  and  $fuzzer_2$ :  $fuzzer_1$  is good at solving the "Magic Str" problem, so it is better for reaching targets T1 and T3, but fails to reach targets T2 and T4.  $fuzzer_2$  is good at solving the "Magic Num" problem so it is better for reaching targets T2 and T6, but fails to reach targets T1 and T5. If we use these two fuzzers separately, we can only cover one path and two branches. At the same time, if we use them simultaneously and ensemble their final fuzzing results without seed synchronization, we can cover two paths and four branches. However, if we ensemble these two fuzzers with some synchronization mechanisms throughout the fuzzing process, then, once  $fuzzer_1$  reaches T1, it synchronizes the

```

void crash(char* A, char* B){
  if (A == "Magic Str"){           => T1
    if (B == "Magic Num") {       => T4
      bug();
    }else{                         => T3
      normal();
    }
  }else if (A == "Magic Num"){    => T2
    if (B == "Magic Str"){       => T5
      bug();
    }else{                         => T6
      normal();
    }
  }
}

```

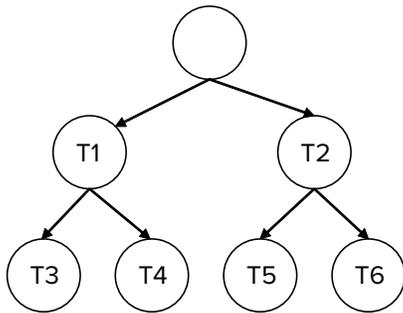

Figure 1: Motivating example of ensemble fuzzing with seed synchronization.

seed that can cover T1 to *fuzzer<sub>2</sub>*. As a result, then, with the help of this synchronized seed, *fuzzer<sub>2</sub>* can also reach T1, and because of its ability to solve the "Magic Num" problem, *fuzzer<sub>2</sub>* can further reach T4. Similarly, with the help of the seed input synchronized by *fuzzer<sub>2</sub>*, *fuzzer<sub>1</sub>* can also further reach T2 and T5. Accordingly, all four paths and all six branches can be covered through this ensemble approach.

Table 1: covered paths of each fuzzing option

| Tool                                                      | T1-T3 | T1-T4 | T2-T5 | T2-T6 |
|-----------------------------------------------------------|-------|-------|-------|-------|
| fuzzer1                                                   | ✓     |       |       |       |
| fuzzer2                                                   |       |       |       | ✓     |
| ensemble fuzzer1 and fuzzer2 without seed synchronization | ✓     |       |       | ✓     |
| ensemble fuzzer1 and fuzzer2 with seed synchronization    | ✓     | ✓     | ✓     | ✓     |

The ensemble approach in this motivating example works based on the following two hypotheses: (1) *fuzzer<sub>1</sub>* and *fuzzer<sub>2</sub>* expert in different domains; (2) the interesting seeds can be synchronized to all base fuzzers in a timely way. To satisfy the above hypotheses as much as possible, success-

ful ensemble fuzzers rely on two key points: (1) the first is to select base fuzzers with great diversity (as yet to be well-defined); (2) the second is a concrete synchronization mechanism to enhance effective cooperation among those base fuzzers.

## 4 Ensemble Fuzzing

For an ensemble fuzzing, we need to construct a set of base fuzzers and seamlessly combine them to test the same target application together. The overview of this approach is presented in Figure 2. When a target application is prepared for fuzzing, we first choose several existing fuzzers as base fuzzers. The existing fuzzing strategies of any single fuzzer are usually designed with preferences. In real practice, these preferences vary greatly across different applications. They can be helpful in some applications, but may be less effective on other applications. Therefore, choosing base fuzzers with more diversity can lead to better ensemble performance. After the base fuzzer selection, we integrate fuzzers with the globally asynchronous and locally synchronous based seed synchronization mechanism so as to monitor the fuzzing status of these base fuzzers and share interesting seeds among them. Finally, we collect crash and coverage information and feed this information into the fuzzing report.

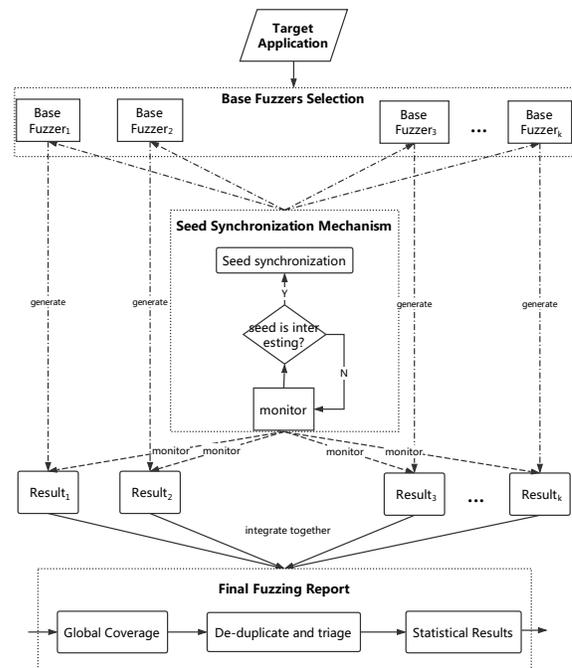

Figure 2: The overview of ensemble fuzzing consists of base fuzzer selection and ensemble architecture design. The base fuzzer selection contains the diversity heuristic definition, and the architecture design includes the seed synchronization mechanism as well as final fuzzing report.

## 4.1 Base Fuzzer Selection

The first step in ensemble fuzzing is to select a set of base fuzzers. These fuzzers can be generation-based fuzzers, e.g. Peach and Radamsa, or mutation-based fuzzers, e.g. libFuzzer and AFL. We can randomly choose some base fuzzers, but selecting base fuzzers with well-defined diversity improves the performance of an ensemble fuzzer.

We classify the diversity of base fuzzers according to three heuristics: seed mutation and selection strategy diversity, coverage information granularity diversity, inputs generation strategy diversity. The diversity heuristics are as follows:

1. Seed mutation and selection strategy based heuristic: the diversity of base fuzzers can be determined by the variability of seed mutation strategies and seed selection strategies. For example, AFLFast selects seeds that exercise low-frequency paths and mutates them more times, FairFuzz strives to ensure that the mutant seeds hit the rarest branches.
2. Coverage information granularity based heuristic: many base fuzzers determine interesting inputs by tracking different coverage information. Hence, the coverage information is critical, and different kinds of coverage granularity tracked by fuzzers enhances diversity. For example, libFuzzer guides seed mutation by tracking block coverage while AFL tracks edge coverage.
3. Input generation strategy based heuristic: fuzzers with different input generation strategies are suitable for different tasks. For example, generation-based fuzzers use the specification of input format to generate test cases, while the mutation-based fuzzers mutate initial seeds by tracking code coverage. So the generation-based fuzzers such as Radamsa perform better on complex format inputs and the mutation-based fuzzers such as AFL prefer complex logic processing.

Based on these three basic heuristics, we should be able to select a diverse set of base fuzzers with large diversity. It is our intuition that the diversity between the fuzzers following in two different heuristics is usually larger than the fuzzers that follows in the same heuristic. So, the diversity among the AFL family tools should be the least, while the diversity between Radamsa and AFL, between Libfuzzer and AFL, and between QSYM and AFL is should be greater. In this paper, we select base fuzzers manually based on the above heuristics. the base fuzzers will be dynamically selected according to the real-time coverage information.

## 4.2 Ensemble Architecture Design

After choosing base fuzzers, we need to implement a suitable architecture to integrate them together. As presented in Figure 2, inspired by the seed synchronization of AFL in parallel mode, one core mechanism is designed — the globally asynchronous and locally synchronous (GALS) based seed synchronization mechanism. The main idea is to identify the interesting seeds (seeds that can cover new paths or new branches or can detect new unique crashes) from different

base fuzzers asynchronously and share those interesting seeds synchronously among all fuzzing processes.

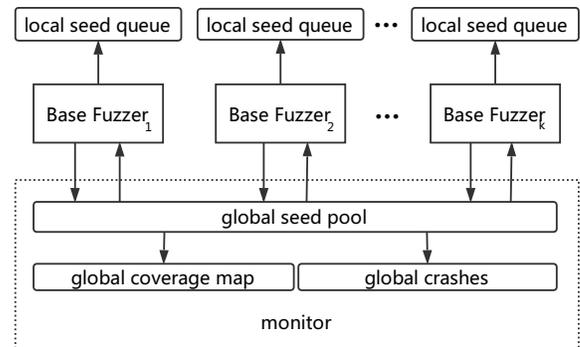

Figure 3: The data structure of global asynchronous and local synchronous based seed synchronization mechanism.

---

### ALGORITHM 1: Action of local base fuzzer

---

```

Input : Local seed pool of base fuzzer queue
1 repeat
2   foreach seed s of the queue do
3      $s' = \text{Mutate}(s)$ ;
4      $\text{Cover} = \text{Run}(s')$ ;
5     // if seeds  $s'$  causes new crash or have new
    // coverage, then store it in own seed pool and
    // push it to the global seed pool asynchronously;
6     if  $\text{Cover.causeCrash}()$  then
7        $\text{crashes.push}(s')$ ;
8        $\text{queue.push}(s')$ ;
9        $\text{GlobalSeedPool.push}(s')$ ;
10    else if  $\text{Cover.haveNewCoverage}()$  then
11       $\text{queue.push}(s')$ ;
12       $\text{GlobalSeedPool.push}(s')$ ;
13    end
14  end
15 until timeout or abort-signal;
Output : Global crashing seeds crashes

```

---

This seed synchronization mechanism employs a global-local style data structure as shown in Figure 3. The local seed queue is maintained by each base fuzzer, while the global pool is maintained by the monitor for sharing interesting seeds among all base fuzzers. In ensemble fuzzing, the union of these base fuzzers' results is needed to identify interesting seeds during the whole fuzzing process. Accordingly, the global coverage map is designed, and any new paths or new branches covered by the interesting seeds will be added into this global map. This global map can not only help decide which seeds to be synchronized, but also help de-duplicate and triage the results. Furthermore, to output the final fuzzing report after completing all fuzzing jobs, any interesting seeds which contribute to triggering unique crashes will be stored in the global crashes list.

First, let us take a look at the seed synchronization solution of the base fuzzer, which mainly describes how base fuzzers

contribute the interesting seeds asynchronously to the global pool. As presented in lines 2-4 of algorithm 1, for each single base fuzzer, it works with a local input seed queue and runs a traditional continuous fuzzing loop. It has three main steps: (1) Select input seeds from the queue, (2) mutate the selected input seeds to generate new candidate seeds, (3) run the target program with the candidate seeds, track the coverage and report vulnerabilities. Once the candidate seeds have new coverage or cause unique crashes, they will be regarded as interesting seeds and be pushed asynchronously into the global seed pool, as presented in lines 6-12.

---

**ALGORITHM 2:** Action of global monitor *sync*

---

```

Input : Base fuzzers list BaseFuzzers[]
         Initial seeds S
         Synchronization period period
1 // set up each base fuzzers ;
2 foreach base fuzzer f of the BaseFuzzers[] do
3 |   fuzzer.setup();
4 end
5 // set up thread monitor for monitoring ;
6 monitor.setup();
7 GlobalCover.initial();
8 GlobalSeedPool.initial();
9 GlobalSeedPool.push(S);
10 repeat
11 |   foreach seed s of the GlobalSeedPool do
12 |   |   // Skip synchronized seeds ;
13 |   |   if s.isSync() == False then
14 |   |   |   foreach base fuzzer f of the BaseFuzzers[] do
15 |   |   |   |   Cover = f.run(s) ;
16 |   |   |   |   // update the global coverage ;
17 |   |   |   |   newCover =
18 |   |   |   |   |   (Cover ∪ GlobalCover) − GlobalCover ;
19 |   |   |   |   |   GlobalCover = Cover ∪ GlobalCover;
20 |   |   |   |   |   // synchronize the seed s to base fuzzer f ;
21 |   |   |   |   |   if Cover.causeCrash() and
22 |   |   |   |   |   |   newCover.isEmpty() then
23 |   |   |   |   |   |   |   crashes.push(s);
24 |   |   |   |   |   |   |   f.queue.push(s);
25 |   |   |   |   |   |   |   else if newCover.isEmpty() then
26 |   |   |   |   |   |   |   |   f.queue.push(s);

28 |   |   |   |   |   |   |   |   continue;
29 |   |   |   |   |   |   |   end
30 |   |   |   |   |   |   |   end
31 |   |   |   |   |   |   |   end
32 |   |   |   |   |   |   |   s.setSync(True);
33 |   |   |   |   |   |   |   end
34 |   |   |   |   |   |   |   // waiting until next seed synchronization ;
35 |   |   |   |   |   |   |   sleep(period);
36 until timeout or abort-signal;
Output : Crashing seeds crashes

```

---

Second, let us see the seed synchronization solution of the monitor process, which mainly describes how the monitor process synchronously dispatches the interesting seeds in the global pool to the local queue of each base fuzzer. When all base fuzzers are established, a thread named `monitor` will be created for monitoring the execution status of these fuzzing

jobs, as in lines 2-6 of algorithm 2. It initializes the global coverage information to record the global fuzzing status of target applications by all the base fuzzer instances and then creates the global seed pool with the initial seeds, as in lines 7-9 of algorithm 2. It then runs a continuous periodically synchronizing loop — each base fuzzer will be synchronously dispatched with the interesting seeds from the global seed pool. Each base fuzzer will incorporate the seeds into its own local seed queue, once the seeds are deemed to be interesting seeds (seeds contribute to the coverage or crash and has not been generated by the local fuzzer), as in line 15-24. To lower the overhead of seed synchronization, a thread `monitor` is designed to work periodically. Due to this globally asynchronous and locally synchronous based seed synchronization mechanism, base fuzzers cooperate effectively with each other as in the motivating example in Figure 1.

## 5 Evaluation

To present the effectiveness of ensemble fuzzing, we first implement several prototypes of ensemble fuzzer based on the state-of-the-art fuzzers. Then, we refer to some kernel descriptions of evaluating fuzzing guideline [25]. We conduct thorough evaluations repeatedly on LAVA-M and Google’s fuzzer-test-suite, several well-fuzzed open-source projects from GitHub, and several commercial products from companies. Finally, according to the results, we answer the following three questions: (1) Can ensemble fuzzer perform better? (2) How do different base fuzzers affect `Enfuzz`? (3) How does `Enfuzz` perform on real-world applications

### 5.1 Ensemble Fuzzer Implementation

We implement ensemble fuzzing based on six state-of-the-art fuzzers, including three edge-coverage guided mutation-based fuzzers – AFL, AFLFast and FairFuzz, one block-coverage guided mutation-based fuzzer – libFuzzer, one generation-based fuzzer – Radamsa and one most recently hybrid fuzzer – QSYM. These are chosen as the base fuzzers for the following reasons (Note that `EnFuzz` is not limited to these six and other fuzzers can also be easily integrated, such as `honggfuzz`, `ClusterFuzzer` etc.):

- Easy integration. All the fuzzers are open-source and have their core algorithms implemented precisely. It is easy to integrate those existing fuzzers into our ensemble architecture. We do not have to implement them on our own, which eliminates any implementation errors or deviations that might be introduced by us.
- Fair comparison. All the fuzzers perform very well and are the latest and widely used fuzzers, as is seen by their comparisons with each other in prior literature, for example, QSYM outperforms similar fuzzers such as Angora [18] and VUzzer. We can evaluate their performance on real-world applications without modification.
- Diversity demonstration. All these fuzzers have different fuzzing strategies and reflect the diversity among correspondence with the three base diversity heuristics

Table 2: Diversity among these base fuzzers

| Tool      | diversity compared with AFL                                                                                                                                                                                                                                                                     |
|-----------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| AFLFast   | Seed mutation and selection strategy based rule: the times of random mutation for each seed is computed by a Markov chain model. The seed selection strategy is different.                                                                                                                      |
| FairFuzz  | Seed mutation and selection strategy based rule: only mutates seeds which hit rare branches and strives to ensure the mutant seeds hit the rarest one. The seed mutation strategy is different.                                                                                                 |
| libFuzzer | Coverage information granularity based rule: libFuzzer mutates seeds by utilizing the SanitizerCoverage instrumentation, which supports tracking block coverage; while AFL uses static instrumentation with a bitmap to track edge coverage. The coverage information granularity is different. |
| Radamsa   | Input generation strategy based rule: Radamsa is a widely used generation-based fuzzer which generates different inputs sample files of valid data. The input generation strategy is different.                                                                                                 |
| QSYM      | QSYM is a practical fast concolic execution engine tailored for hybrid fuzzing. It makes hybrid fuzzing scalable enough to test complex, real-world applications.                                                                                                                               |

mentioned in section 4.1: coverage information granularity diversity, input generation strategy diversity, seed mutation and selection strategy diversity. The concrete diversity among these base fuzzers is listed in Table 2.

To demonstrate the performance of ensemble fuzzing and the influence of diversity among base fuzzers, five prototypes are developed. (1) `EnFuzz-A`, an ensemble fuzzer only based on AFL, AFLFast and FairFuzz. (2) `EnFuzz-Q`, an ensemble fuzzer based on AFL, AFLFast, FairFuzz and QSYM, a practical concolic execution engine is included. (3) `EnFuzz-L`, an ensemble fuzzer based on AFL, AFLFast, FairFuzz and libFuzzer, a block-coverage guided fuzzer is included. (4) `EnFuzz`, an ensemble fuzzer based on AFL, AFLFast, libFuzzer and Radamsa, a generation-based fuzzer is further added. (5) `EnFuzz-`, with the ensemble of same base fuzzers (AFL, AFLFast and FairFuzz), but without the seed synchronization, to demonstrate the effectiveness of the global asynchronous and local synchronous based seed synchronization mechanism. During implementation of the proposed ensemble mechanism, we address the following challenges:

1) *Standard Interface Encapsulating* The interfaces of these fuzzers are different. For example, AFL family tools use the function `main`, but libFuzzer use a function `LLVMFuzzerTestOneInput`. Therefore, it is hard to ensemble them together. We design a standard interface to encapsulate the complexity of different fuzzing tools. This standard interface takes seeds from the file system, and writes the results back to the file system. All base fuzzers receive inputs and

produce results through this standard interface, through which different base fuzzers can be ensembled easily.

2) *libFuzzer Continuously Fuzzing* The fuzzing engine of libFuzzer will be shut down when it finds a crash, while other tools continue fuzzing until manually closed. It is unfair to compare libFuzzer with other tools when the fuzzing time is different. The persistent mode of AFL is a good solution to this problem. Once AFL sets up, the fuzzer parent will fork and execute a new process to fuzz the target. When the target process crashes, the parent will collect the crash and resume the target, then the process simply loops back to the start. Inspired by the AFL persistent mode, we set up a thread named `Parent` to monitor the state of libFuzzer. Once it shuts down, `Parent` will resume the libFuzzer.

3) *Bugs De-duplicating and Triaging* We develop a tool for crash analysis. We compile all the target applications with AddressSanitizer, and test them with the crash samples. When the target applications crash, the coredump file, which consists of the recorded state of the working memory will be saved. Our tool first loads coredump files, then gathers the frames of each crash; finally, it identifies two crashes as identical if and only if the top frame is identical to the other frame. The method above is prone to underestimating bugs. For example, two occurrences of heap overflow may crash at the cleanup function at exit. However, the target program is instrumented with AddressSanitizer. As the program terminates immediately when memory safety problems occur, the top frame is always relevant to the real bug. In practice, the original duplicate unique crashes have been drastically de-duplicated to a humanly check-able number of unique bugs, usually without duplication. Even though there are some extreme cases that different top frames for one bug, the result can be further refined by manual crash analysis.

4) *Seeds effectively Synchronizing* The implementation of the seed synchronization mechanism: all base fuzzers have implemented the communication logic following the standard interface. Each base fuzzer will put interesting seeds into its own local seed pool, and the monitor thread `sync` will periodically make each single base fuzzer pull synchronized seeds from the global seed pool through a communication channel. This communication channel is implemented based on file system. A shorter period consumes too many resources, which leads to a decrease in fuzzing performance. A longer period will make seed synchronizing untimely, which also affects the performance. After multiple attempts with different values, it is found that the synchronization interval affects the performance at the beginning of fuzzing, while little impact was observed in the long term. The interval of 120s is identified with the fastest convergence.

## 5.2 Data and Environment Setup

Firstly, we evaluate ensemble fuzzing on LAVA-M [19], which consists of four buggy programs, file, base64, md5sum and who. LAVA-M is a test suite that injects hard-to-find bugs in Linux utilities to evaluate bug-finding techniques. Thus the test is adequate for demonstrating the effectiveness of ensemble fuzzing. Furthermore, to reveal the practical performance of ensemble fuzzing, we also evaluate our work based on fuzzer-test-suite [8], a widely used benchmark from Google.

The test suite consists of popular open-source real-world applications. This benchmark is chosen to avoid the potential bias of the cases presented in literature, and for its great diversity, which helps demonstrate the performance variation of existing base fuzzers.

We refer to the kernel criteria and settings of evaluation from the fuzzing guidelines [25], and integrate the three widely used metrics from previous literature studies to compare the results on these real-world applications more fairly, including the number of paths, branches and unique bugs. To get unique bugs, we use crash’s stack backtraces to deduplicate unique crashes, as mentioned in the previous subsection. The initial seeds for all experiments are the same. We use the test cases originally included in their applications or empty seed if such initial seeds do not exist.

The experiment on fuzzer-test-suite is conducted ten times in a 64-bit machine with 36 cores (Intel(R) Xeon(R) CPU E5-2630 v3 @ 2.40GHz), 128GB of main memory, and Ubuntu 16.04 as the host OS with SMT enabled. Each binary is hardened by AddressSanitizer [11] to detect latent bugs. First, we run each base fuzzer for 24 hours with one CPU core in single mode. Next, since  $\text{EnFuzz-L}$ ,  $\text{EnFuzz}$  and  $\text{EnFuzz-Q}$  need at least four CPU cores to ensemble these four base fuzzers, we also run each base fuzzer in parallel mode for 24 hours with four CPU cores. In particular,  $\text{EnFuzz-A}$  and  $\text{EnFuzz-}$  only ensembles three types of base fuzzers (AFL, AFLFast and FairFuzz). To use the same resources, we set up two AFL instances, one AFLFast instance and one FairFuzz instance. This experimental setup ensures that the computing resources usage of each ensemble fuzzer is the same as any base fuzzers running in parallel mode. While most metrics converged to similar values during multithreaded fuzzing. The variation of those statistical test results is small (between -5% 5%), we just use the averages in this paper.

### 5.3 Preliminary Evaluation on LAVA-M

We first evaluate ensemble fuzzing on LAVA-M, which has been used for testing other systems such as Angora, T-Fuzz and QSYM, and QSYM shows the best performance. We run  $\text{EnFuzz-Q}$  (which ensembles AFL, AFLFast, FairFuzz and QSYM) on the LAVA-M dataset. To demonstrate its effectiveness, we also run each base fuzzer using the same resources — four instances of AFL in parallel mode, four instances of AFLFast in parallel mode, four instances of FairFuzz in parallel mode, QSYM with four CPU cores used in parallel mode (two instances of concolic execution engine and two instances of AFL). To identify unique bugs, we used built-in bug identifiers provided by the LAVA project. The results are presented in Table 3, 4 and 5, which show the number of paths executed, branches covered and unique bugs detected by AFL, AFLFast, FairFuzz, QSYM,  $\text{EnFuzz-Q}$ .

From Tables 3, 4 and 5, we found that AFL, AFLFast and FairFuzz perform worse due to the complexity of their branches. The practical concolic execution engine helps QSYM solve complex branches and find significantly more bugs. The base code of the four applications in LAVA-M are small (2K-4K LOCs) and concolic execution could work well on them. However, real projects have code bases that easily reach 10k LOCs. Concolic execution might perform

worse or even get hanged, as presented in the latter subsections. Furthermore, when we ensemble AFL, AFLFast, FairFuzz and QSYM together with the GALS based seed synchronization mechanism –  $\text{EnFuzz-Q}$  always performs the best in both coverage and bug detection. In total, compared with AFL, AFLFast, FairFuzz and QSYM,  $\text{EnFuzz-Q}$  executes 44%, 45%, 43% and 7.7% more paths, covers 195%, 215%, 194% and 5.8% more branches, and detects 8314%, 19533%, 12989% and 0.68% more unique bugs respectively. From these preliminary statistics, we can determine that the performance of fuzzers can be improved by our ensemble approach.

Table 3: Number of paths covered by AFL, AFLFast, FairFuzz, QSYM and  $\text{EnFuzz-Q}$  on LAVA-M.

| Project | AFL  | AFLFast | FairFuzz | QSYM | $\text{EnFuzz-Q}$ |
|---------|------|---------|----------|------|-------------------|
| base64  | 1078 | 1065    | 1080     | 1643 | <b>1794</b>       |

| total   | 14  | 6       | 9        | 1170 | <b>1178</b>       |

### 5.4 Evaluation on Google’s fuzzer-test-suite

While LAVA-M is widely used, Google’s fuzzer-test-suite is more practical with many more code lines and containing real-world bugs. To reveal the effectiveness of ensemble fuzzing, we run  $\text{EnFuzz}$  (which only ensembles AFL, AFLFast, LibFuzzer and Radamsa) on all of the 24 real-world applications of Google’s fuzzer-test-suite for 24 hours 10 times. As a comparison, we also run each base fuzzer in parallel mode with four CPU cores used. To identify unique bugs, we used stack backtraces to deduplicate crashes. The results are presented

in Tables 6, 7 and 8, which shows the average number of paths executed, branches covered and unique bugs detected by AFL, AFLFast, FairFuzz, LibFuzzer, Radamsa, QSYM and EnFuzz respectively.

Table 6: Average number of paths covered by each tool on Google’s fuzzer-test-suite for ten times.

| Project       | AFL           | AFLFast       | FairFuzz      | LibFuzzer     | Radamsa       | QSYM          | EnFuzz        |

The first six columns of Table 6 reveal the issue of the performance variation in those base fuzzers, as they perform variously on different applications. Comparing AFL family tools, AFL performs better than the other two optimized fuzzers on 14 applications. Compared with AFL, libFuzzer performs better on 15 applications, but worse on 9 applications. Radamsa performs better on 8 applications, but also worse on 16 applications. QSYM performs better on 9 applications, but also worse on 15 applications. Table 7 and Table 8 show similar results on branch coverage and bugs.

From Table 6, it is interesting to see that compared with those optimized fuzzers based on AFL (AFLFast, FairFuzz, Radamsa and QSYM), original AFL performs the best on 14 applications in parallel mode with 4 CPU cores. For the total number of paths executed, AFL performs the best and AFLFast performs the worst in parallel mode. While in single mode with one CPU core used, the situation is exactly the opposite, and the original AFL only performs the best on 5 applications, as presented in Table 14 of the appendix.

The reason for performance degradation of these optimizations in parallel mode is that their studies lack the consideration for synchronizing the additional guiding information. Take AFLFast for example, it models coverage-based fuzzing as Markov Chain, and the times of random mutation for each seed will be computed by a power scheduler. This strategy works well in single mode, but it would fail in parallel mode because the statistics of each fuzzer’s scheduler are limited in current thread. Our evaluation demonstrates that many optimized fuzzing strategies could be useful in single mode, but fail in the parallel mode even if this is the mode widely used in industry practice. This experiment has been missing

by many prior literature studies. A potential solution for this degradation is to synchronize the additional guiding information in their implementation, similar to the work presented in PAFL [27].

Table 7: Average number of branches covered by each tool on n Google’s fuzzer-test-suite for ten times.

| <b>Total</b>  | <b>34</b> | <b>25</b> | <b>30</b> | <b>37</b> | <b>31</b> | <b>33</b> | <b>60</b>    |
| Improvement   | -         | 26% ↓     | 12% ↑     | 6% ↓      | 9% ↑      | 3% ↓      | <b>76% ↑</b> |

From the fifth columns of Table 6 and Table 14, we find that compared with Radamsa in single mode, the improvement achieved by Radamsa is limited in parallel mode. There are two main reasons: (1) Too many useless inputs generated by Radamsa slow down the seed-sharing efficiency among all

instances of AFL. This seed-sharing mechanism does not exist in single mode. (2) Some interesting seeds can be created in parallel mode and shared among all instances of AFL. These seeds overlap with the inputs generated by Radamsa. So this improvement is limited in parallel mode.

For the `EnFuzz` which integrates AFL, AFLFast, libFuzzer and Radamsa as base fuzzers and, compared with AFL, AFLFast, FairFuzz, QSYM, LibFuzzer and Radamsa, it shows the strongest robustness and always performs the best. In total, it discovers 76.4%, 140%, 100%, 81.8%, 66.7% and 93.5% more unique bugs, executes 42.4%, 61.2%, 45.8%, 66.4%, 29.5% and 44.2% more paths and covers 15.5%, 17.8%, 12.9%, 26.1%, 19.9% and 14.8% more branches respectively. These statistics demonstrate that it helps mitigate performance variation and improves robustness and performance by the ensemble approach with globally asynchronous and locally synchronous seed synchronization mechanism.

## 5.5 Effects of Different Fuzzing Integration

To study the effects of the globally asynchronous and locally synchronous based seed synchronization mechanism, we conduct a comparative experiment on `EnFuzz-` and `EnFuzz-A`, both ensemble the same base fuzzers (two AFL, one AFLFast, one FairFuzz) in parallel mode with four CPU cores. To study the effects of different base fuzzers on ensemble fuzzing, we also run `EnFuzz-Q`, `EnFuzz-L` and `EnFuzz` on Google’s fuzzer-test-suite for 24 hours 10 times. To identify unique bugs, we used stack backtraces to deduplicate crashes. The results are presented in Tables 9, 10 and 11, which shows the average number of paths executed, branches covered and unique bugs detected by `EnFuzz-`, `EnFuzz-A`, `EnFuzz-Q`, `EnFuzz-L`, and `EnFuzz`, respectively.

Table 9: Average number of paths covered by each `Enfuzz` on Google’s fuzzer-test-suite for ten times.

Compared with `EnFuzz-A`, `EnFuzz-` ensembles the same base fuzzers (AFL, AFLFast and FairFuzz), but does not implement the seed synchronization mechanism. `EnFuzz-` performs much worse on all applications. In total, it only covers 68.5% paths, 78.3% branches and detects 32.4% unique bugs of `EnFuzz-A`. These statistics demonstrate that the globally asynchronous and locally synchronous based seed synchronization mechanism is critical to the ensemble fuzzing.

Table 10: Average number of branches covered by each `Enfuzz` on Google’s fuzzer-test-suite for ten times.

For `EnFuzz-A`, which ensembles AFL, AFLFast and FairFuzz as base fuzzers and implements the seed synchronization with global coverage map, compared with AFL, AFLFast and FairFuzz running in parallel mode with four CPU cores used (as shown in Table 6, Table 7 and Table 8), it always executes more paths and covers more branches on all applications. In total, it covers 11.3%, 25.9% and 13.9% more paths, achieves 7.2%, 9.3% and 4.8% more covered branches, and triggers 8.8%, 48% and 23% more unique bugs. It reveals that the robustness and performance can be improved even when the diversity of base fuzzers is small.

For the `EnFuzz-Q` which integrates AFL, AFLFast, FairFuzz and QSYM as base fuzzers, the results are shown in the fourth columns of Tables 9, 10 and 11. Compared with `EnFuzz-A`, `EnFuzz-Q` covers 1.1% more paths, executes 1.0% more branches and triggers 10.8% more unique bugs than `EnFuzz-A`. The improvement is significantly smaller on Google’s fuzzer-test-suite than on LAVA-M.

The reason for performance degradation between experiments on LAVA-M and Google fuzzer-test-suite is that the base codes of the four applications (who, uniq, base64 and md5sum) in LAVA-M are small (2K-4K LOCs). The concolic execution engine works well on them, but usually performs the opposite or even hangs on real projects in fuzzer-test-suite whose code base easily reaches 100k LOCs.

For the `EnFuzz-L` which integrates AFL, AFLFast, FairFuzz and libFuzzer as base fuzzers, the results are presented in the seventh columns of Tables 9, 10 and 11. As mentioned in section A, the diversity among these base fuzzers is much larger than with `EnFuzz-A`. Compared with `EnFuzz-A`, `EnFuzz-L` always performs better on all target applications. In total, it covers 23.6% more paths, executes 5.8% more branches and triggers 42.4% more unique bugs than `EnFuzz-A`.

For the `EnFuzz` which integrates AFL, AFLFast, libFuzzer and Radamsa as base fuzzers, the diversity is the largest because they cover all three diversity heuristics. Compared with `EnFuzz-L`, it performs better and covers 3.6% more paths, executes 1.8% more branches and triggers 13.2% more unique bugs. Both `EnFuzz` and `EnFuzz-L` performs better than `EnFuzz-Q`. These statistics demonstrate that the more diversity among these base fuzzers, the better the ensemble fuzzer should perform. For real applications with a large code base, compared with hybrid concolic fuzzing or ensemble fuzzing with symbolic execution, the ensemble fuzzing without symbolic execution may perform better.

## 5.6 Fuzzing Real-World Applications

We apply `EnFuzz` to fuzz more real-world applications from GitHub and commercial products from Cisco, some of which are well-fuzzed projects such as the image processing library libpng and libjpeg, the video processing library libwav, the IoT device communication protocol libiec61850 used in hundreds of thousands of cameras, etc. `EnFuzz` also performs well. Within 24 hours, besides the coverage improvements, `EnFuzz` finds 60 more unknown real bugs including 44 successfully registered as CVEs, as shown in Table 13. All of these new bugs and security vulnerabilities are detected in a 64-bit machine with 36 cores (Intel(R) Xeon(R) CPU E5-

2630 v3@2.40GHz), 128GB of main memory, and Ubuntu 16.04 as the host OS.

Table 12: Unique previously unknown bugs detected by each tool within 24 hours on some real-world applications.

| pbc             | 5        | 5       | 6        | 7         | 6        | <b>9</b>  |
| pngwriter       | 1        | 1       | 1        | 1         | 2        | <b>2</b>  |
| total           | 35       | 28      | 31       | 34        | 32       | <b>60</b> |

As a comparison, we also run each tool on those real-world applications to detect unknown vulnerabilities. The results are presented in table 12. `EnFuzz` found all 60 unique bugs, while other tools only found a portion of these bugs. Compared with AFL, AFLFast, FairFuzz, LibFuzzer and QSYM, `EnFuzz` detected 71.4%, 114%, 93.5%, 76.4%, 87.5% more unique bugs respectively. The results demonstrate the effectiveness of `EnFuzz` in detecting real vulnerabilities in more general projects. For example, in the well-fuzzed projects libwav and libpng, we can still detect 13 more real bugs, 7 of which are assigned as CVEs. We give an analysis of the project libpng for a more detailed illustration. libpng is a widely used C library for reading and writing PNG image files. It has been fuzzed many times and is one of the projects in Google’s OSS-Fuzz, which means it has been continually fuzzed by multiple fuzzers many times. But with `EnFuzz`, we detect three vulnerabilities, including one segmentation fault, one stack-buffer-overflow and one memory leak. The first two vulnerabilities were assigned as CVEs (CVE-2018-14047, CVE-2018-14550).

In particular, CVE-2018-14047 allows remote attackers to cause a segmentation fault via a crafted input. We analyze the vulnerability with AddressSanitizer and find it is a typical memory access violation. The problem is that in function `png_free_data` in line 564 of `png.c`, the `info_ptr` attempts to access an invalid area of memory. The error occurs in `png_free_data` during the free of text-related data with specifically crafted files, and causes reading of invalid or unknown memory, as show in Listing 1. The new vulnerabilities and CVEs in the IoT device communication protocol libiec6185 can also crash the service and have already been confirmed and repaired.

We also apply each base fuzzer (AFL, AFLFast, FairFuzz, libFuzzer and QSYM) to fuzz libpng separately, the above vulnerability is not detected. To trigger this bug, 6 function calls and 11 compares (2 for integer, 1 for boolean and 8 for

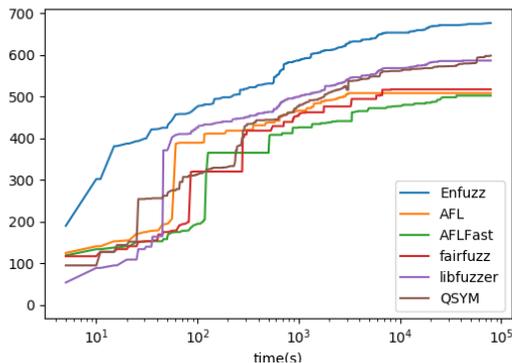

```

#ifdef PNG_TEXT_SUPPORTED
/* Free text item num or (if num == -1)
   all text items */
   if (info_ptr->text != NULL &&
       ((mask & PNG_FREE_TEXT) &
        info_ptr->free_me) != 0)

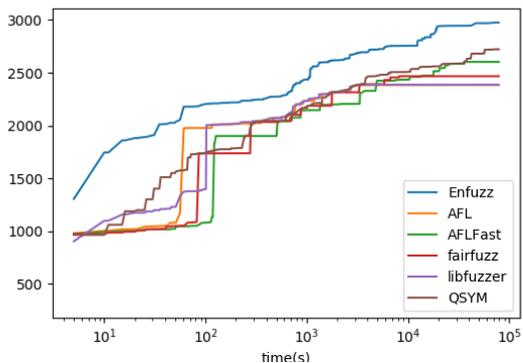

```

Listing 1: The error code of libpng for CVE-2018-14047

pointer) are required. It is difficult for other fuzzers to detect bugs in such deep paths without the seeds synchronization of EnFuzz. The performances of these fuzzers over time in libpng are presented in Figure 4. The results demonstrate that generalization and scalability limitations exist in these base fuzzers – the two optimized fuzzers AFLFast and FairFuzz perform worse than the original AFL for libpng, while EnFuzz performs the best. Furthermore, except for those evaluations on benchmarks and real projects, EnFuzz had already been deployed in industry practice, and more new CVEs were being continuously reported.

(a) Number of paths over time

(b) Number of branches over time

## 6 Discussion

Based on benchmarks such as LAVA-M and Google’s fuzzer-test-suite, and several real projects, we demonstrate that this ensemble fuzzing approach outperforms any base fuzzers. However, some limitations still threaten the performance of ensemble fuzzing. The representative limitations and the workarounds are discussed below.

The first potential threat is the insufficient and imprecise diversity of base fuzzers. Section 4.1 describes our base fuzzer selection, we propose three different heuristics to indicate diversity of base fuzzers, including diversity of coverage information granularity, diversity of input generation strategy, and diversity of seed mutation selection strategy. According to these three heuristics, we select AFL, AFLFast, FairFuzz, libFuzzer, Radamsa and QSYM as the base fuzzers. Furthermore, we implement four prototypes of ensemble fuzzing and demonstrate that the greater the diversity of base fuzzers, the better the ensemble fuzzer performs. However, these three different heuristics of diversity may be insufficient. More diversity measures need to be proposed in future work. For example, initial seeds determine the initial direction of fuzzing and, thus, are significantly important for fuzzing, especially for mutation-based fuzzers. Some fuzzers utilize initial seeds generated by symbolic execution [29, 35] while some other fuzzers utilize initial seeds constructed by domain experts or grammar specifications. However, we select base fuzzers manually according to the initial diversity heuristic, which is also not accurate enough.

A possible solution to this threat is to quantify the initial diversity value among different fuzzers for more accurate selection. As defined in [14], the variance or diversity is a measure of the distance of the data in relation to the average. The average standard deviation of a data set is a percentage that indicates how much, on average, each measurement differs from the other. To evaluate the diversity of different base fuzzers, we can choose the most widely used AFL and its path

coverage as a baseline and then calculate standard deviation of each tool from this baseline on the Google fuzzing-test-suite. Then we can calculate the standard deviation of these values as the initial measure of diversity for each base fuzzer, as presented in formula (2) and (1), where  $n$  means the number of applications fuzzed by these base fuzzers,  $p_i$  means the number of paths covered by the current fuzzer of the target application  $i$  and  $p_{A_i}$  means the number of paths covered by AFL of the application  $i$ .

$$mean = \frac{1}{n} \sum_{i=1}^n \frac{p_i - p_{A_i}}{p_{A_i}} \quad (1)$$

$$diversity = \frac{1}{n} \sum_{i=1}^n \left( \frac{p_i - p_{A_i}}{p_{A_i}} - mean \right)^2 \quad (2)$$

Take the diversity of AFLFast, FairFuzz, Radamsa, QSYM, and libFuzzer for example, as shown in the statistics presented in Table 14 of the appendix, compared with AFL on different applications, the diversity of AFLFast is 0.040; the diversity of FairFuzz is 0.062; the diversity of Radamsa is 0.197; the diversity of QSYM is 0.271; the diversity of libFuzzer is 11.929. In the same way, the deviation on branches covered and the bugs detected can be calculated. We can add these three values together with different weight for the final diversity quantification. For example, the bug deviation should be assigned with more weights, because from prior research, coverage metrics (the number of paths or branches) are not necessarily correlated well with bugs found. A more advanced way to evaluate the amount of diversity would be to count how many paths/branches/bugs were found by one fuzzer and not by any of the others.

The second potential threat is the mechanism scalability of the ensemble architecture. Section 4.2 describes the ensemble architecture design, and proposes the globally asynchronous and locally synchronous based seed synchronization mechanism. The seed synchronization mechanism focuses on enhancing cooperation among these base fuzzers during their fuzzing processes. With the help of seeds sharing, the performance of ensemble fuzzing is much improved and is better than any of the constituent base fuzzers with the same computing resources usage. However, this mechanism can still be improved for better scalability on different applications and fuzzing tasks. EnFuzz only synchronizes the coarse-grained information – interesting seeds, rather than the fine-grained information. For example, we could synchronize the execution trace and array index values of each base fuzzer to improve their effectiveness in cooperation. Furthermore, we currently select and mix base fuzzers manually according to three heuristics. When scaled to arbitrary number of cores, it should be carefully investigated with huge number of empirical evaluations. A possible solution is that the base fuzzers will be dynamically selected and initiated with different number of cores according to the real-time number of paths/branches/bugs found individually by each fuzzer. In the beginning, we have a set of different base fuzzers; then Enfuzz selects  $n$  (this number can be configured) base fuzzers randomly. If one fuzzer cannot contribute to coverage for a long time, then it will be terminated, and one new base fuzzer

from the sets will be setup for fuzzing or the existing live base fuzzer with better coverage will be allocated with more cores.

We can also apply some effective ensemble mechanisms in ensemble learning such as Boosting to ensemble fuzzing to improve the scalability. Boosting is a widely used ensemble mechanism which will reweigh the base learner dynamically to improve the performance of the ensemble learner: examples that are misclassified gain weight and examples that are classified correctly lose weight. To implement this idea in ensemble fuzzing, we could start up a *master* thread to monitor the execution statuses of all base fuzzers and record more precise information of each base fuzzer, then reassign each base fuzzer some interesting seeds accordingly.

For the number of base fuzzers and parameters in ensemble fuzzing implementation, it is scalable for integration of most fuzzers. Theoretically, the more base fuzzers with diversity, the better ensemble fuzzing performs. We only use four base fuzzers in our evaluation with four CPU cores. The more computing resources we get, higher performance the fuzzing practice acquires. Furthermore, in our implementation, we have tried different values of period time, and the results are very sensitive to the specific setting of this value. It only affects the performance in the beginning, but affects little in the end. Furthermore, referring to the GALS system design, we can also allocate a different synchronization frequency for each local fuzzer dynamically.

## 7 Conclusion

In this paper, we systematically investigate the practical ensemble fuzzing strategies and the effectiveness of ensemble fuzzing of various fuzzers. Applying the idea of ensemble fuzzing, we bridge two gaps. First, we come up with a method for defining the diversity of base fuzzers and propose a way of selecting a diverse set of base fuzzers. Then, inspired by AFL in parallel mode, we implement a concrete ensemble architecture with one effective ensemble mechanism, a seed synchronization mechanism. EnFuzz always outperforms other popular base fuzzers in terms of unique bugs, path and branch coverage with the same resource usage. EnFuzz has found 60 new bugs in several well-fuzzed projects and 44 new CVEs were assigned. Our ensemble architecture can be easily utilized to integrate other base fuzzers for industrial practice.

Our future work will focus on three directions: the first is to try some other heuristics and more accurate accumulated quantification of diversity in base fuzzers; the second is to improve the ensemble architecture with more advanced ensemble mechanism and synchronize more fine-grained information; the last is to improve the ensemble architecture with intelligent resource allocation such as dynamically adjusting the synchronization period for each base fuzzer, and allocating more CPU cores to the base fuzzer that shares more interesting seeds.

## A Preliminary demonstration of diversity among base fuzzers

To help select base fuzzers with larger diversity, we need to estimate the diversity between each base fuzzer. In general, the more differently they perform on different applications, the more diversity among these base fuzzers. Accordingly, we first run each base fuzzer in single mode, with one CPU core on Google’s fuzzer-test-suite for 24 hours. Table 14 and Table 15 show the number of paths and branches covered by AFL, AFLFast, FairFuzz, libFuzzer, Radamsa and QSYM. Table 16 shows the corresponding number of unique bugs. Below we present the performance effects of the three diversity heuristics proposed in Section 4.1 in detail.

1) *Effects of seed mutation and seed selection strategy—what kind of mutation and selection strategy you use, what kind of path and branch you would cover* The first three columns of Table 14 show the performance of the AFL family tools. Their differences are the seed mutation and seed selection strategies. The original AFL performs the best on 5 applications, but performs the worst on other 10 applications. AFLFast performs the best on 13 applications, and only performs the worst on 4 applications. FairFuzz also performs the best on 8 applications, but the worst on the other 9 applications. Although the total number of paths covered improves slightly, the performance variation on each application is huge, ranging from -57% to 38% in single cases.

From the first three columns in Table 15 and Table 16, we get the same observation that the performance of these optimized fuzzers varies significantly on different applications. Although the total number of covered branches and unique crashes improves slightly, the deviation of each application is huge. AFLFast selects seeds that exercise low-frequency paths to mutate more times. Take project lcms for example, this seed selection strategy exercises more new paths by avoiding covering “hot paths” too many times, but on project libarchive, its “hot path” may be the key to further paths. FairFuzz mutates seeds to hit rare branches. Take project libxml2 for example, the rare branch fuzzing strategy guides FairFuzz into deeper areas and covers more branches. However, on libarchive, this strategy fails. FairFuzz spends much time in deep paths and branches, ignoring breadth search. Unlike libxml2, the breadth first search strategy of other fuzzers is more effective on libarchive. In general, the mutation and selection strategy decides the depth and breadth of the covered branch and path.

2) *Effects of coverage information granularity—what kind of guided information you use, what kind of coverage metric you improve.* The diversity between AFL and libFuzzer is their coverage information granularity. According to the fourth column of Table 14, we find that compared with AFL, libFuzzer performs better on 17 applications, and covers 30.3% more paths in total. However, according to the fourth column of the Table 15, compared with AFL, libFuzzer only performs better on 11 applications, which means on 6 applications, libFuzzer covers more paths but less branches. For total branch count, AFL covers 7.3% more than libFuzzer. The reason is that AFL mutates seed by tracking edge hit counts while libFuzzer utilizes the SanitizerCoverage instrumentation to track block hit counts. AFL prefers to cover more branches

while libFuzzer is better at executing more paths. In general, edge-guided means more branches covered, and block-guided means more paths covered.

Table 14: Average number of paths for single mode.

3) *Effects of Input generation strategy—what kind of generation strategy you use, what kind of corresponding application you fuzz better.* The diversity between AFL and Radamsa is

the input generation strategy. From the fifth columns of Table 14 and Table 15, compared with AFL, the plenty of inputs generated by Radamsa have some side effects on most target applications (14 applications). Too many extra inputs will slow down the execution speed of the fuzzer. However, for some applications, the inputs generated by Radamsa will improve the performance effectively. Take libxml2 for example, Radamsa has some domain knowledge that prefers to generate some structured data and specific complex format data. These domain knowledge are not available in most mutation-based fuzzers, and this is a critical disadvantage of AFL. But with the help of generation-based fuzzers, the performance of AFL can be improved greatly.

Table 16: Average number of bugs for single mode.

| Project       | AFL      | AFLFast  | FairFuzz | libFuzzer | Radamsa  | QSYM     |
|---------------|----------|----------|----------|-----------|----------|----------|
| boringsssl    | 0        | 0        | 0        | <b>1</b>  | 0        | 0        |

**In conclusion:** Different base fuzzers perform variously on distinct target applications, showing the diversity for the base fuzzers. The more diversity of these base fuzzers, the more differently they perform on different applications. Furthermore, the above three types of effects should be considered and could be incorporated into the fuzzing evaluation guideline [25] to avoid biased test cases or metrics selection when evaluating different types of fuzzing optimization.

## B Does performance vary in different modes?

We choose AFL as the baseline, and compare other tools with AFL on path coverage to demonstrate the performance variation. Figure 5 shows the average number of paths executed on Google’s fuzzer-test-suite by each base fuzzer compared with AFL in single mode. We also collect the result of each base fuzzer running in parallel mode with four threads, and the result is presented in Figure 6. Figure 7 shows the average

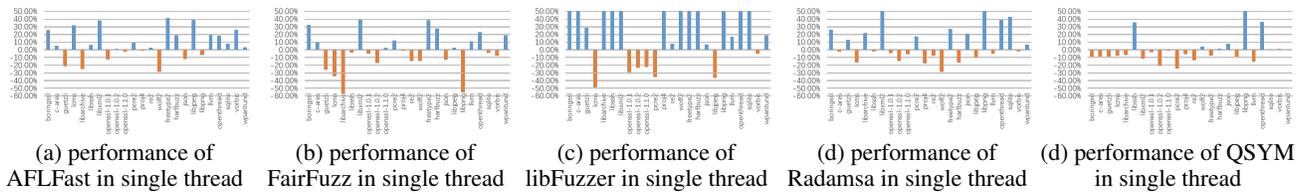

Figure 5: Paths covered by base fuzzers compared with AFL in single mode on a single core.

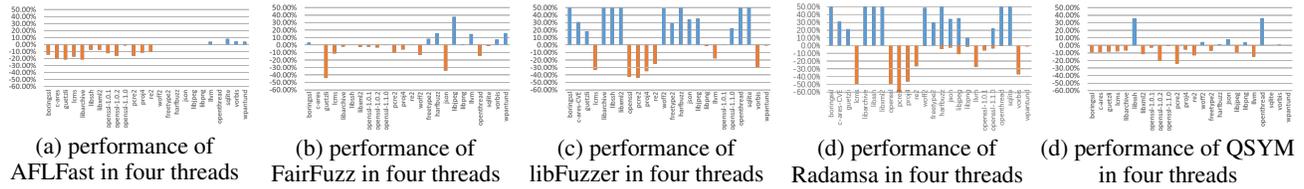

Figure 6: Paths covered by base fuzzers compared with AFL in parallel mode with four threads on four cores.

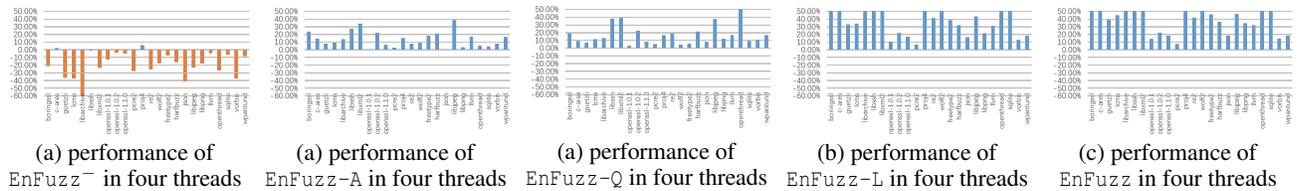

Figure 7: Paths covered by EnFuzz with four threads on four cores compared with AFL in parallel mode with four threads on four cores. EnFuzz<sup>-</sup> without the proposed seed synchronization performs the worst, and EnFuzz performs the best.

number of paths executed by EnFuzz compared with AFL in parallel mode with four CPU cores. From these results, we get the following conclusions:

- From the results of Figure 5 and Figure 6, we find that compared with AFL, the two optimized fuzzers AFLFast and FairFuzz, block coverage guided fuzzer libFuzzer, generation-based fuzzer Radamsa and hybrid fuzzer QSYM perform variously on different applications both in single mode and in parallel mode. It demonstrates that the performance of these base fuzzers is challenged by the diversity of the diverse real applications. The performance of their fuzzing strategies cannot constantly perform better than AFL. The performance variation exists in these state-of-the-art fuzzers.
- Comparing the result of Figure 5 and Figure 6, we find that the performance of these base fuzzers in parallel mode are quite different from those in single mode, especially for AFLFast and FairFuzz. In single mode, the other two optimized base fuzzers perform better than AFL in many applications. But in parallel mode, the result is completely opposite that the original AFL performs better on almost all applications.
- From the result of Figure 7, it reveals that EnFuzz-A, EnFuzz-L and EnFuzz always perform better than AFL on the target applications. For the same computing resources usage where AFL running in parallel mode with four CPU cores, EnFuzz-A covers 11.26% more paths than AFL, ranging from 4% to 38% in single cases,

EnFuzz-Q covers 12.48% more paths than AFL, ranging from 5% to 177% in single cases, EnFuzz-L covers 37.50% more paths than AFL, ranging from 13% to 455% in single cases. EnFuzz covers 42.39% more paths than AFL, ranging from 14% to 462% in single cases. Through ensemble fuzzing, the performance variation can be reduced.

- From the result of Figure 7, it reveals that EnFuzz<sup>-</sup> without seed synchronization performs worse than AFL parallel mode under the same resource constraint. Compared with EnFuzz-A, EnFuzz-Q covers 1.09% more paths, EnFuzz-L covers 23.58% more paths. For EnFuzz, it covers 27.97% more paths than EnFuzz-A, 26.59% more paths than EnFuzz-Q, 3.6% more paths than EnFuzz-L, and always performs the best on all applications. The more diversity among those integrated base fuzzers, the better performance of ensemble fuzzing, and the seed synchronization contributes more to the improvements.

**In conclusion:** the performance of the state-of-the-art fuzzers is greatly challenged by the diversity of those real-world applications, and it can be improved through the ensemble fuzzing approach. Furthermore, those optimized strategies work in single mode can not be directly scaled to parallel mode which is widely used in industrial practice. The ensemble fuzzing approach is a critical enhancement to the single and parallel mode of those optimized strategies.

# GRIMOIRE: Synthesizing Structure while Fuzzing

Tim Blazytko, Cornelius Aschermann, Moritz Schlögel, Ali Abbasi,

*Ruhr-Universität Bochum, Germany*

## Abstract

In the past few years, fuzzing has received significant attention from the research community. However, most of this attention was directed towards programs without a dedicated parsing stage. In such cases, fuzzers which leverage the input structure of a program can achieve a significantly higher code coverage compared to traditional fuzzing approaches. This advancement in coverage is achieved by applying large-scale mutations in the application’s input space. However, this improvement comes at the cost of requiring expert domain knowledge, as these fuzzers depend on structure input specifications (e. g., grammars). Grammar inference, a technique which can automatically generate such grammars for a given program, can be used to address this shortcoming. Such techniques usually infer a program’s grammar in a pre-processing step and can miss important structures that are uncovered only later during normal fuzzing.

In this paper, we present the design and implementation of GRIMOIRE, a fully automated coverage-guided fuzzer which works without any form of human interaction or pre-configuration; yet, it is still able to efficiently test programs that expect highly structured inputs. We achieve this by performing large-scale mutations in the program input space using grammar-like combinations to synthesize new highly structured inputs without any pre-processing step. Our evaluation shows that GRIMOIRE outperforms other coverage-guided fuzzers when fuzzing programs with highly structured inputs. Furthermore, it improves upon existing grammar-based coverage-guided fuzzers. Using GRIMOIRE, we identified 19 distinct memory corruption bugs in real-world programs and obtained 11 new CVEs.

## 1 Introduction

As the amount of software impacting the (digital) life of nearly every citizen grows, effective and efficient testing mechanisms for software become increasingly important. The publication of the fuzzing framework AFL [65] and its success at uncovering a huge number of bugs in highly relevant

software has spawned a large body of research on effective feedback-based fuzzing. AFL and its derivatives have largely conquered automated, dynamic software testing and are used to uncover new security issues and bugs every day. However, while great progress has been achieved in the field of fuzzing, many hard cases still require manual user interaction to generate satisfying test coverage. To make fuzzing available to more programmers and thus scale it to more and more target programs, the amount of expert knowledge that is required to effectively fuzz should be reduced to a minimum. Therefore, it is an important goal for fuzzing research to develop fuzzing techniques that require less user interaction and, in particular, less domain knowledge to enable more automated software testing.

**Structured Input Languages.** One common challenge for current fuzzing techniques are programs which process highly structured input languages such as interpreters, compilers, text-based network protocols or markup languages. Typically, such inputs are consumed by the program in two stages: parsing and semantic analysis. If parsing of the input fails, deeper parts of the target program—containing the actual application logic—fail to execute; hence, bugs hidden “deep” in the code cannot be reached. Even advanced feedback fuzzers—such as AFL—are typically unable to produce diverse sets of syntactically valid inputs. This leads to an imbalance, as these programs are part of the most relevant attack surface in practice, yet are currently unable to be fuzzed effectively. A prominent example are browsers, as they parse a multitude of highly-structured inputs, ranging from XML or CSS to JavaScript and SQL queries.

Previous approaches to address this problem are typically based on manually provided grammars or seed corpora [2, 14, 45, 52]. On the downside, such methods require human experts to (often manually) specify the grammar or suitable seed corpora, which becomes next to impossible for applications with undocumented or proprietary input specifications. An orthogonal line of work tries to utilize advanced program analysis techniques to automatically infer grammars

[4, 5, 25]. Typically performed as a pre-processing step, such methods are used for generating a grammar that guides the fuzzing process. However, since this grammar is treated as immutable, no additional learning takes place during the actual fuzzing run.

**Our Approach.** In this paper, we present a novel, fully automated method to fuzz programs with a highly structured input language, without the need for any human expert or domain knowledge. Our approach is based on two key observations: First, we can use code coverage feedback to automatically infer structural properties of the input language. Second, the precise and “correct” grammars generated by previous approaches are actually unnecessary in practice: since fuzzers have the virtue of high test case throughput, they can deal with a significant amount of noise and imprecision. In fact, in some programs (such as Boollector) with a rather diverse set of input languages, the additional noise even benefits the fuzz testing. In a similar vein, there are often program paths which can only be accessed by inputs *outside* of the formal specifications, e. g., due to incomplete or imprecise implementations or error handling code.

Instead of using a pre-processing step, our technique is directly integrated in the fuzzing process itself. We propose a set of generalizations and mutations that resemble the inner workings of a grammar-based fuzzer, without the need for an explicit grammar. Our generalization algorithm analyzes each newly found input and tries to identify substrings of the input which can be replaced or reused in other positions. Based on this information, the mutation operators recombine fragments from existing inputs. Overall, this results in synthesizing new, structured inputs without prior knowledge of the underlying specification.

We have implemented a prototype of the proposed approach in a tool called GRIMOIRE<sup>1</sup>. GRIMOIRE does not need any specification of the input language and operates in an automated manner without requiring human assistance; in particular, without the need for a format specification or seed corpus. Since our techniques make no assumption about the program or its environment behavior, GRIMOIRE can be easily applied to closed-source targets as well.

To demonstrate the practical feasibility of our approach, we perform a series of experiments. In a first step, we select a diverse set of programs for a comparative evaluation: we evaluate GRIMOIRE against other fuzzers on four scripting language interpreters (mruby, PHP, Lua and JavaScriptCore), a compiler (TCC), an assembler (NASM), a database (SQLite), a parser (libxml) and an SMT solver (Boollector). Demonstrating that our approach can be applied in many different scenarios without requiring any kind of expert knowledge, such as an input specification. The evaluation results show

<sup>1</sup>A *grimoire* is a magical book that recombines magical elements to formulas. Furthermore, it has the same word stem as the Old French word for grammar—namely, *gramaire*.

that our approach outperforms all existing coverage-guided fuzzers; in the case of Boollector, GRIMOIRE finds up to 87% more coverage than the baseline (REDQUEEN). Second, we evaluate GRIMOIRE against state-of-the-art grammar-based fuzzers. We observe that in situations where an input specification is available, it is advisable to use GRIMOIRE in addition to a grammar fuzzer to further increase the test coverage found by grammar fuzzers. Third, we evaluate GRIMOIRE against current state-of-the-art approaches that use automatically inferred grammars for fuzzing and found that we can significantly outperform such approaches. Overall, GRIMOIRE found 19 distinct memory corruption bugs that we manually verified. We responsibly disclosed all of them to the vendors and obtained 11 CVEs. During our evaluation, the next best fuzzer only found 5 of these bugs. In fact, GRIMOIRE found more bugs than all five other fuzzers combined.

**Contributions.** In summary, we make the following contributions:

- We present the design, implementation and evaluation of GRIMOIRE, an approach to fully automatically fuzz highly structured formats with no human interaction.
- We show that even though GRIMOIRE is a binary-only fuzzer that needs no seeds or grammar as input, it still outperforms many fuzzers that make significantly stronger assumptions (e. g., access to seeds, grammar specifications and source code).
- We found and reported multiple bugs in various common projects such as PHP, gnuplot and NASM.

## 2 Challenges in Fuzzing Structured Languages

In this section, we briefly summarize essential information paramount to the understanding of our approach. To this end, we provide an overview of different fuzzing approaches, while focusing on their shortcomings and open challenges. In particular, we describe those details of AFL (e. g., code coverage) that are necessary to understand our approach. Additionally, we explain how fuzzers explore the state space of a program and how grammars aid the fuzzing process.

Generally speaking, fuzzing is a popular and efficient software testing technique used to uncover bugs in applications. Fuzzers typically operate by producing a large number of test cases, some of which may trigger bugs. By closely monitoring the runtime execution of these test cases, fuzzers are able to locate inputs causing faulty behavior. In an abstract view, one can consider fuzzing as randomly exploring the state space of the application. Typically, most totally random inputs are rejected early by the target application and

do not visit interesting parts of the state space. Thus, in our abstract view, the state space has interesting and uninteresting regions. Efficient fuzzers somehow have to ensure that they avoid uninteresting regions most of the time. Based on this observation, we can divide fuzzers into three broad categories, namely: (a) blind, (b) coverage-guided and (c) hybrid fuzzers, as explained next.

## 2.1 Blind Fuzzing

The most simple form of a fuzzer is a program which generates a stream of random inputs and feeds it to the target application. If the fuzzer generates inputs without considering the internal behavior of the target application, it is typically referred to as a *blind fuzzer*. Examples of blind fuzzers are RADAMSA [29], PEACH [14], Sulley [45] and ZZUF [32]. To obtain new inputs, fuzzers traditionally can build on two strategies: *generation* and *mutation*.

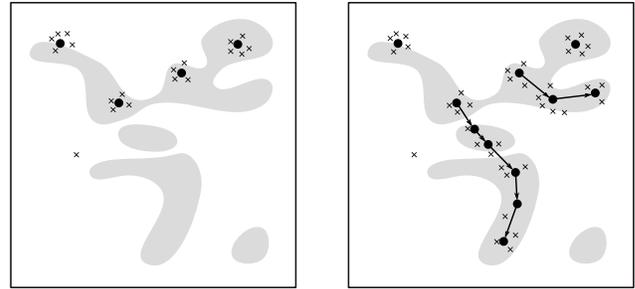

Fuzzers employing the former approach have to acquire a specification, typically a grammar or model, of an application’s expected input format. Then, a fuzzer can use the format specification to be able to generate novel inputs in a somewhat efficient way. Additionally, in some cases, a set of valid inputs (a so-called *corpus*) might be required to aid the generation process [46, 58].

On the other hand, fuzzers which employ a mutation-based strategy require only an initial corpus of inputs, typically referred to as *seeds*. Further test cases are generated by randomly applying various mutations on initial seeds or novel test cases found during fuzzing runs. Examples for common mutators include bit flipping, splicing (i. e., recombining two inputs) and repetitions [14, 29, 32]. We call these mutations *small-scale mutations*, as they typically change small parts of the program input.

Blind fuzzers suffer from one major drawback. They either require an extensive corpus or a well-designed specification of the input language to provide meaningful results. If a program feature is not represented by either a seed or the input language specification, a blind fuzzer is unlikely to exercise it. In our abstract, state space-based view, this can be understood as blindly searching the state space near the seed inputs, while failing to explore interesting neighborhoods, as illustrated in Figure 1(a). To address this limitation, the concept of coverage-guided fuzzing was introduced.

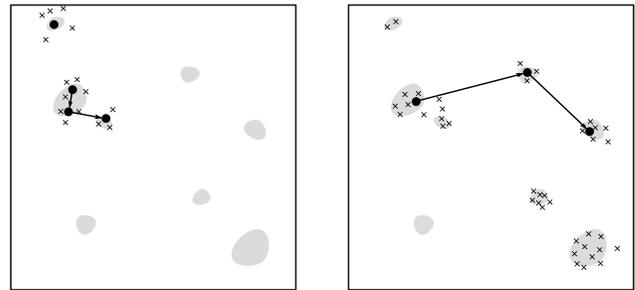

## 2.2 Coverage-guided Fuzzing

Coverage-guided fuzzers employ lightweight program coverage measurements to trace how the execution path of the application changes based on the provided input (e. g., by tracking which basic blocks have been visited). These fuzzers use this information to decide which input should be stored or discarded to extend the corpus. Therefore, they are able to evolve inputs that differ significantly from the original seed corpus

(a) Blind mutational fuzzers mostly explore the state space near the seed corpus. They often miss interesting states (shaded area) unless the seeds are good.

(b) Coverage guided fuzzers can learn new inputs (arrows) close to existing seeds. However, they are often unable to skip large gaps.

(c) Programs with highly structured input formats typically have large gaps in the state space. Current feedback and hybrid fuzzers have difficulties finding other interesting islands using local mutations.

(d) By introducing an input specification, fuzzers can generate inputs in interesting areas and perform large-scale mutations that allow to jump between islands of interesting states.

Figure 1: Different fuzzers exploring distinct areas in state space.

while at the same time exercising new program features. This strategy allows to gradually explore the state of the program as it uncovers new paths. This behavior is illustrated in Figure 1(b). The most prominent example of a coverage-guided fuzzer is AFL [65]. Following the overwhelming success of AFL, various more efficient coverage-guided fuzzers such as ANGORA [12], QSYM [64], T-FUZZ [47] or REDQUEEN [3] were proposed.

From a high-level point of view, all these AFL-style fuzzers can be broken down into three different components: (i) the input queue stores and schedules all inputs found so far, (ii) the mutation operations produce new variants of scheduled inputs and (iii) the global coverage map is used to determine whether a new variant produced novel coverage (and thus should be stored in the queue).

From a technical point of view, this maps to AFL as follows: Initially, AFL fills the input queue with the seed inputs. Then, it runs in a continuous fuzzing loop, composed of the following steps: (1) Pick an input from the input queue, then (2) apply multiple mutation operations on it. After each mutation, (3) execute the target application with the selected input. If new coverage was triggered by the input, (4) save it back to the queue. To determine whether new coverage was triggered,

AFL compares the results of the execution with the values in the global coverage map.

This global coverage map is filled as follows: AFL shares a memory area of the same size as the global coverage map with the fuzzing target. During execution, each transition between two basic blocks is assigned a position inside this shared memory. Every time the transition is triggered, the corresponding entry (one byte) in the shared memory map is incremented. To reduce overhead incurred by large program traces, the shared coverage map has a fixed size (typically  $2^{16}$  bytes). While this might introduce collisions, empirical evaluation has shown that the performance gains make up for the loss in the precision [66].

After the target program terminates, AFL compares the values in the shared map to all previous runs stored in the global coverage map. To check if a new edge was executed, AFL applies the so-called *bucketing*. During bucketing, each entry in the shared map is rounded to a power of 2 (i. e., at most a single bit is set in each entry). Then, a simple binary operation is used to check if any new bits are present in the shared map (but not the global map). If any new bit is present, the input is stored in the queue. Furthermore, all new bits are also set to 1 in the global coverage map. We distinguish between *new bits* and *new bytes*. If a new bit is set to 1 in a byte that was previously zero, we refer to it as a *new byte*. Intuitively, a new byte corresponds to new coverage while a new bit only illustrates that a known edge was triggered more often (e. g., more loop iterations were observed).

**Example 1.** For example, consider some execution a while after starting the fuzzer run for a program represented by its Control-Flow Graph (CFG) in Figure 2(a). Assume that the fictive execution of an input causes a loop between *B* and *C* to be executed 10 times. Hence, the shared map is updated as shown in (b), reflecting the fact that edges  $A \rightarrow B$  and  $C \rightarrow D$  were executed only once, while the edges  $B \rightarrow C$  and  $C \rightarrow B$  were encountered 10 (0b1010) times. In (c), we illustrate the final bucketing step. Note how 0b1010 is put into the bucket 0b1000, while 0b0001 is moved into the one identified by 0b0001. Finally, AFL checks whether the values encountered in this run triggered unseen edges in (d). To this end, we compare the shared map to the global coverage map and update it accordingly (see (e)), setting bits set in the shared but not global coverage map. As visualized in (f), a new bit was set for two entries, while a new byte was found for one. This means that the edge between  $C \rightarrow D$  was previously unseen, thus the input used for this example triggered new coverage.

While coverage-guided fuzzers significantly improve upon blind fuzzers, they can only learn from new coverage if they are able to guess an input that triggers the new path in the program. In certain cases, such as multi-byte magic values, the probability of guessing an input necessary to trigger a different path is highly unlikely. These kind of situations

occur if there is a significant gap between interesting areas in the state space and existing mutations are unlikely to cross the uninteresting gap. The program displayed in the Figure 1(b) illustrates a case with only one large gap in the program space. Thus, this program is well-suited for coverage-guided fuzzing. However, current mutation-based coverage-guided fuzzers struggle to explore the whole state space because the island in the lower right is never reached. To overcome this limitation, hybrid fuzzer were introduced; these combine coverage-guided fuzzing with more in-depth program analysis techniques.

## 2.3 Hybrid Fuzzing

Hybrid fuzzers typically combine coverage-guided fuzzing with program analysis techniques such as symbolic execution, concolic execution or taint tracking. As noted above, fast and cheap fuzzing techniques can uncover the bulk of the easy-to-reach code. However, they struggle to trigger program paths that are highly unlikely. On the other hand, symbolic or concolic execution does not move through the state space randomly. Instead, these techniques use an SMT solver to find inputs that trigger the desired behavior. Therefore, they can cover hard-to-reach program locations. Still, as a consequence of the precise search technique, they struggle to explore large code regions due to significant overhead.

By combining fuzzing and reasoning-based techniques, one can benefit from the strength of each individual technique, while avoiding the drawbacks. Purely symbolic approaches have proven difficult to scale. Therefore, most current tools such as SAGE [21], DRILLER [54] or QSYM [64] use concolic execution instead. This mostly avoids the state explosion problem by limiting the symbolic execution to a single path. To further reduce the computation cost, some fuzzers such as VUZZER [50] and ANGORA [12] only use taint tracking. Both approaches still allow to overcome the common multi-byte magic value problem. However, they lose the ability to explore behavior more globally.

While hybrid fuzzers can solve constraints over individual values of the input, they are typically not efficient at solving constraints on the *overall* structure of the input. Consider target programs such as a script interpreter. To uncover a new valid code path, the symbolic executor usually has to consider a completely different path through the parsing stage. This leads to a large number of very large gaps in the state space as illustrated in Figure 1(c). Therefore, concolic execution or taint tracking-based tools are unable to solve these constraints. In purely symbolic execution-based approaches, this leads to a massive state explosion.

## 2.4 Coverage-guided Grammar Fuzzing

Beside the problem of multi-byte magic values, there is another issue which leads to large gaps between interesting

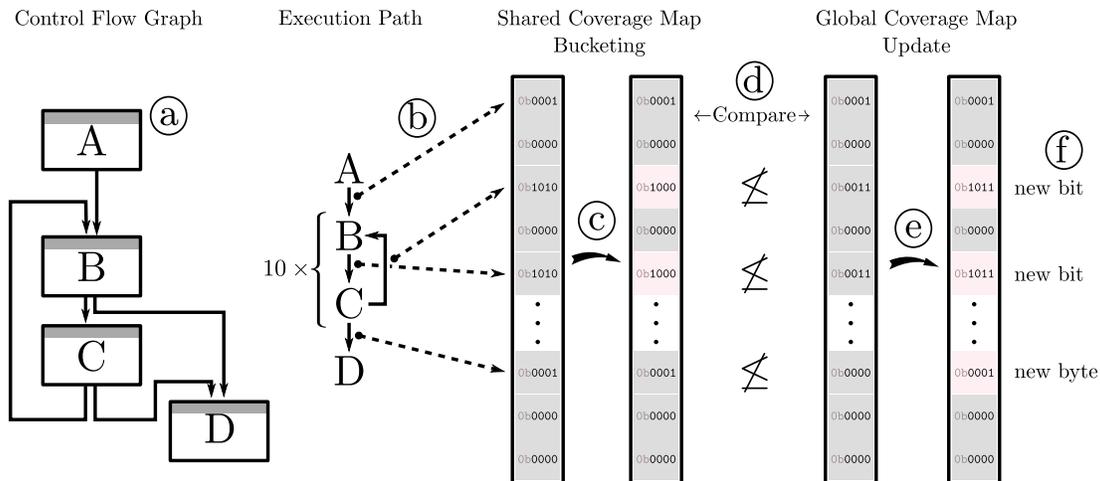

Figure 2: The process of tracing a path in a program and introducing new bits and bytes in the global coverage map.

parts of the state space: programs with structured input languages. Examples for such programs are interpreters, compilers, databases and text-based Internet protocols. As mentioned earlier, current mutational blind and coverage-guided as well as hybrid fuzzers cannot efficiently fuzz programs with structured input languages. To overcome this issue, *generational fuzzers* (whether blind, coverage-guided or hybrid) use a specification of the input language (often referred to as a *grammar*) to generate valid inputs. Thereby, they reduce the space of possible inputs to a subset that is much more likely to trigger interesting states. Additionally, coverage-guided grammar fuzzers can mutate inputs in this reduced subset by using the provided grammar. We call these mutations *large-scale mutations* since they modify large part of the input. This behavior is illustrated in Figure 1(d).

Therefore, the performance of fuzzers can be increased drastically by providing format specifications to the fuzzer, as implemented in NAUTILUS [2] and AFLSMART [48]. These specifications let the fuzzer spend more time exercising code paths deep in the target application. Particularly, the fuzzer is able to sensibly recombine inputs that trigger interesting features in a way that has a good chance of triggering more interesting behaviors.

Grammar fuzzers suffer from two major drawbacks. First, they require human effort to provide precise format specification. Second, if the specification is incomplete or inaccurate, the fuzzer lacks the capability to address these shortcomings. One can overcome these two drawbacks by automatically inferring the specification (grammar).

## 2.5 Grammar Inference

Due to the impact of grammars on software testing, various approaches have been developed that automatically can

generate input grammars for target programs. Bastani et al. [5] introduced GLADE, which uses a modified version of the target as a black-box oracle that tests if a given input is syntactically valid. GLADE turns valid inputs into regular expressions that generate (mostly) valid inputs. Then, these regular expressions are turned into full grammars by trying to introduce recursive replacement rules. In each step, the validity of the resulting grammar is tested using multiple oracle queries. This approach has three significant drawbacks: First, the inference process takes multiple hours for complex targets such as scripting languages. Second, the user needs to provide an automated testing oracle, which might not be trivial to produce. Third, in the context of fuzzing, the resulting grammars are not well suited for fuzzing as our evaluation shows (see Section 5.4 for details). Additionally, this approach requires a pre-processing step before fuzzing starts in order to infer a grammar from the input corpus.

Other approaches use the target application directly and thus avoid the need to create an oracle. AUTOGRAM [34], for instance, uses the original program and taint tracking to infer grammars. It assumes that the functions that are called during parsing reflect the non-terminals of the intended grammar. Therefore, it does not work for recursive descent parsers. PYGMALION [25] is based on simplified symbolic execution of Python code to avoid the dependency on a set of good inputs. Similar to AUTOGRAM, PYGMALION assumes that the function call stack contains relevant information to identify recursive rules in the grammar. This approach works well for hand-written, recursive descent parsers; however, it will have severe difficulties with parsers generated by parser generators. These parsers are typically implemented as table-driven automata and do not use function calls at all. Additionally, robust symbolic execution and taint tracking are still challenging for binary-only targets.

## 2.6 Shortcomings of Existing Approaches

To summarize, current automated software testing approaches have the following disadvantages when used for fuzzing of programs that accept structured input languages:

- **Needs Human Assistance.** Some techniques require human assistance to function properly. Either in terms of providing information or in terms of modifying the target program.
- **Requires Source Code.** Some fuzzing techniques require access to source code. This puts them at a disadvantage as they cannot be applied to proprietary software in binary format.
- **Requires a Precise Environment Model.** Techniques based on formal reasoning such as symbolic/concolic execution as well as taint tracking require precise semantics of the underlying platform as well as semantics of all used Operating System (OS) features (e. g., syscalls).
- **Requires a Good Corpus.** Many techniques only work if the seed corpus already contains most features of the input language.
- **Requires a Format Specification.** Similarly, many techniques described in this section require precise format specifications for structured input languages.
- **Limited To Certain Types of Parsers.** Some approaches make strong assumptions about the underlying implementation of the parser. Notably, some approaches are unable to deal with parses generated by common parser generators such as GNU Bison [15] or Yacc [37].
- **Provides Only Small-scale Mutations.** As discussed in this section, various approaches cannot provide mutations that cross large gaps in the program space.

Table 1: Requirements and limitations of different fuzzers and inference tools when used for fuzzing structured input languages. If a shortcoming applies to a tool, it is denoted with **X**, otherwise with **✓**.

|                       | PEACH | AFL | REDQUEEN | QSYM | ANGORA | NAUTILUS | AFLSMART | GLADE | AUTOGRAM | PYGMALION | GRIMOIRE |

We analyzed existing fuzzing methods, the results of this survey are shown in Table 1. We found that all current approaches have at least one shortcoming for fuzzing programs

with highly structured inputs. In the next section, we propose a design that avoids all the mentioned drawbacks.

## 3 Design

Based on the challenges identified above, we now introduce the design of GRIMOIRE, a fully automated approach that synthesizes the target’s structured input language during fuzzing. Furthermore, we present large-scale mutations that cross significant gaps in the program space. Note that none of the limitations listed in Table 1 applies to our approach. To emphasize, our design does not require any previous information about the input structure. Instead, we learn an ad-hoc specification based on the program semantics and use it for coverage-guided fuzzing.

We first provide a high-level overview of GRIMOIRE, followed by a detailed description. GRIMOIRE is based on identifying and recombining fragments in inputs that trigger new code coverage during a normal fuzzing session. It is implemented as an additional fuzzing stage on top of a coverage-guided fuzzer. In this stage, we strip every new input (that is found by the fuzzer and produced new coverage) by replacing those parts of the input that can be modified or replaced without affecting the input’s new coverage by the symbol  $\square$ . This can be understood as a generalization, in which we reduce inputs to the fragments that trigger new coverage, while maintaining information about *gaps* or *candidate positions* (denoted by  $\square$ ). These gaps are later used to splice in fragments from other inputs.

**Example 2.** Consider the input “if(x>1) then x=3 end” and assume it was the first input to trigger the coverage for a syntactically correct if-statement as well as for “x>1”. We can delete the substring “x=3” without affecting the interesting new coverage since the if-statement remains syntactically correct. Additionally, the space between the condition and the “then” is not mandatory. Therefore, we obtain the generalized input “if(x>1) $\square$ then  $\square$ end”.

After a set of inputs was successfully generalized, fragments from the generalized inputs are recombined to produce new candidate inputs. We incorporate various different strategies to combine existing fragments, learned tokens (a special form of substrings) and strings from the binary in an automated manner.

**Example 3.** Assume we obtained the following generalized inputs: “if(x>1) $\square$ then  $\square$ end” and “ $\square$ x= $\square$ y+ $\square$ ”. We can use this information in many ways to generate plausible recombinations. For example, starting with the input “if(x>1) $\square$ then  $\square$ end”, we can replace the second gap with the second input, obtaining “if(x>1) $\square$ then  $\square$ x= $\square$ y+ $\square$ end”. Afterwards, we choose the slice “ $\square$ y+ $\square$ ” from the second input and splice it into the fourth gap and obtain “if(x>1) $\square$ then  $\square$ x= $\square$ y+ $\square$ y+ $\square$ end”. In a last step,

we replace all remaining gaps by an empty string. Thus, the final input is “if(x>1) then x=y+y+end”.

One could think of our approach as a context-free grammar with a single non-terminal input  $\square$  and all fragments of generalized inputs as production rules. Using these loose, grammar-like recombination methods in combination with feedback-driven fuzzing, we are able to automatically learn interesting structures.

### 3.1 Input Generalization

We try to generalize inputs that produced new coverage (e. g., inputs that introduced new bytes to the bitmap, cf. Section 2.2). The generalization process (Algorithm 1) tries to identify parts of the input that are irrelevant and fragments that caused new coverage. In a first step, we use a set of rules to obtain fragment boundaries (Line 3). Consecutively, we remove individual fragments (Line 4). After each step, we check if the reduced input still triggers the same new coverage bytes as the original input (Line 5). If this is the case, we replace the fragment that was removed by a  $\square$  and keep the reduced input (Line 6).

---

**Algorithm 1:** Generalizing an input through fragment identification.

---

**Data:** input is the input to generalize, new\_bytes are the new bytes of the input, splitting\_rule defines how to split an input  
**Result:** A generalized version of input

```
1 start ← 0
2 while start < input.length() do
3   end ← find_next_boundary(input, splitting_rule)
4   candidate ← remove_substring(input, start, end)
5   if get_new_bytes(candidate) == new_bytes then
6     input ← replace_by_gap(input, start, end)
7   start ← end
8 input ← merge_adjacent_gaps(input)
```

---

**Example 4.** Consider input “pprint ’aaaa’” triggers the new bytes 20 and 33 because of the pprint statement. Furthermore, assume that we use a rule that splits inputs into non-overlapping chunks of length two. Then, we obtain the chunks “pp”, “ri”, “nt”, “ ’”, “aa”, “aa” and “’”. If we remove any of the first four chunks, the modified input will not trigger the same new bytes since we corrupted the pprint statement. However, if we remove the fifth or sixth chunk, we still trigger the bytes 20 and 33 since the pprint statement remains valid. Therefore, we reduce the input to “pprint ’ $\square\square$ ’”. As we have two adjacent  $\square$ , we merge them into one. The generalized input is “pprint ’ $\square$ ’”.

To generalize an input as much as possible, we use several fragmentation strategies for which we apply Algorithm 1 repeatedly. First, we split the input into overlapping chunks of

size 256, 128, 64, 32, 2 and 1 to remove large uninteresting parts as early as possible. Afterwards, we dissect at different separators such as ‘.’, ‘;’, ‘,’’, ‘\n’, ‘\r’, ‘\t’, ‘#’ and ‘ ’. As a consequence, we can remove one or more statements in code, comments and other parts that did not cause the input’s new coverage. Finally, we split at different kinds of brackets and quotation marks. These fragments can help to generalize constructs such as function parameters or nested expressions. In detail, we split in between of ‘()’, ‘[]’, ‘{}’, ‘<>’ as well as single and double quotes. To guess different nesting levels in between these pairs of opening/closing characters, we extend Algorithm 1 as follows: If the current index start matches an opening character, we search the furthestmost matching closing character, create a candidate by removing the substring in between and check if it triggers the same new coverage. We iteratively do this by choosing the next furthestmost closing character—effectively shrinking the fragment size—until we find a substring that can be removed without changing the new\_bytes or until we reach the index start. In doing so, we are able to remove the largest matching fragments from the input that are irrelevant for the input’s new coverage.

Since we want to recombine (generalized) inputs to find new coverage—as we describe in the following section—we store the original input as well as its generalization. Furthermore, we split the generalized input at every  $\square$  and store the substrings (tokens) in a set; these tokens often are syntactically interesting fragments of the structured input language.

**Example 5.** We map the input “if(x>1) then x=3 end” to its generalization “if(x>1) $\square$ then  $\square$ end”. In addition, we extract the tokens “if(x>1)”, “then ” and “end”. For the generalized input “ $\square$ x= $\square$ y+ $\square$ ”, we remember the tokens “x=” and “y+”.

### 3.2 Input Mutation

GRIMOIRE builds upon knowledge obtained from the generalization stage to generate inputs that have good chances of finding new coverage. For this, it recombines (fragments of) generalized inputs, tokens and strings (stored in a dictionary) that are automatically obtained from the data section of the target’s binary. On a high level, we can divide our mutations into three standalone operations: input extension, recursive replacement and string replacement.

Given the current input from the fuzzing queue, we add these mutations to the so-called *havoc phase* [3] as described in Algorithm 2. First, we use Redqueen’s havoc\_amount to determine—based on the input’s performance—how often we should apply the following mutations (in general, between 512 and 1024 times). First, if the input triggered new bytes in the bitmap, we take its generalized form and apply the large-scale mutations input\_extension and recursive\_replacement. Afterwards, we take the original input string (accessed by input.content()) and apply the

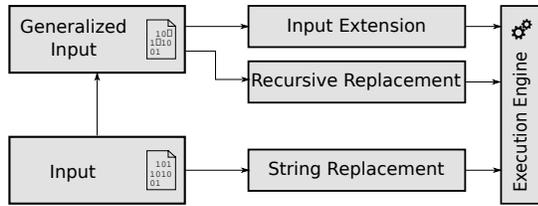

Figure 3: A high-level overview of our mutations. Given an input, we apply various mutations on its generalized and original form. Each mutation then feeds mutated variants of the input to the fuzzer’s execution engine.

string\_replacement mutation. This process is illustrated in Figure 3.

---

**Algorithm 2:** High-level overview of the mutations introduced in GRIMOIRE.

---

**Data:** input is the current input in the queue, generalized is the set of all previously generalized inputs, tokens and strings from the dictionary, strings is the provided dictionary obtained from the binary

```

1 content ← input.content()
2 n ← havoc_amount(input.performance())
3 for i ← 0 to n do
4   if input.is_generalized() then
5     input_extension(input, generalized)
6     recursive_replacement(input, generalized)
7   string_replacement(content, strings)

```

---

Before we describe our mutations in detail, we explain two functions that all mutations have in common—random\_generalized and send\_to\_fuzzer. The function random\_generalized takes as input a set of all previously generalized inputs, tokens and strings from the dictionary and returns—based on random coin flips—a random (slice of a) generalized input, token or string. In case we pick an input slice, we select a substring between two arbitrary □ in a generalized input. This is illustrated in Algorithm 3. The other function, send\_to\_fuzzer, implies that the fuzzer executes the target application with the mutated input. It expects concrete inputs. Thus, mutations working on generalized inputs first replace all remaining □ by an empty string.

---

**Algorithm 3:** Random selection of a generalized input, slice, token or string.

---

**Data:** generalized is the set of all previously generalized inputs, tokens and strings from the dictionary

**Result:** rand is a random generalized input, slice token or string

```

1 if random_coin() then
2   if random_coin() then
3     rand ← random_slice(generalized)
4   else
5     rand ← random_token_or_string(generalized)
6 else
7   rand ← random_generalized_input(generalized)

```

---

### 3.2.1 Input Extension

The input extension mutation is inspired by the observation that—in highly structured input languages—often inputs are chains of syntactically well-formed statements. Therefore, we extend an generalized input by placing another randomly chosen generalized input, slice, token or string before and after the given one. This is described in Algorithm 4.

---

**Algorithm 4:** Overview of the input extension mutation.

---

**Data:** input is the current generalized input, generalized is the set of all previously generalized inputs, tokens and strings from the dictionary

```

1 rand ← random_generalized(generalized_inputs)
2 send_to_fuzzer(concat(input.content(),
   rand.content()))
3 send_to_fuzzer(concat(rand.content(),
   input.content()))

```

---

**Example 6.** Assume that the current input is “pprint ‘aaaa’” and its generalization is “pprint ‘□’”. Furthermore, assume that we randomly choose a previous generalization “□x=□y+□”. Then, we concretize their generalizations to “pprint ‘\$\$’” and “x=y+” by replacing remaining gaps with an empty string. Afterwards, we concatenate them and obtain “pprint ‘\$\$’x=y+” and “x=y+pprint ‘\$\$’”.

### 3.2.2 Recursive Replacement

The recursive replacement mutation recombines knowledge about the structured input language—that was obtained earlier in the fuzzing run—in a grammar-like manner. As illustrated in Algorithm 5, given a generalized input, we extend its beginning and end by □—if not yet present—such that we always can place other data before or behind the input. Afterwards, we randomly select  $n \in \{2, 4, 8, 16, 32, 64\}$  and perform the following operations  $n$  times: First, we randomly select another generalized input, input slice, token or string. Then, we call replace\_random\_gap which replaces an arbitrary □ in the first generalized input by the chosen element. Furthermore, we enforce □ before and after the replacement such that these □ can be subject to further replacements. Finally, we concretize the mutated input and send it to the fuzzer. The recursive replacement mutator has a (comparatively) high likelihood of producing new structurally interesting inputs compared to more small-scale mutations used by current coverage-guided fuzzers.

**Example 7.** Assume that the current input is “pprint ‘aaaa’”. We take its generalization “pprint ‘□’” and extend it to “□pprint ‘□’□”. Furthermore, assume that we already generalized the inputs “if(x>1)□then □end” and “□x=□y+□”. In a first mutation, we choose to replace the first □ with the slice “if(x>1)□”. We extend the slice to “□if(x>1)□” and obtain “□if(x>1)□pprint

---

**Algorithm 5:** Overview of the recursive replacement mutation.

**Data:** input is the current generalized input, generalized is the set of all previously generalized inputs, tokens and strings from the dictionary

```
1 input ← pad_with_gaps(input)
2 for i ← 0 to random_power_of_two() do
3   rand ← random_generalized(generalized_inputs)
4   input ← replace_random_gap(input, rand)
5 send_to_fuzzer(input.content())
```

---

'□'□'. Afterwards, we choose to replace the third □ with "□x=□y+□" and obtain "□if(x>1)□pprint '□x=□y+□'□". In a final step, we replace the remaining □ with an empty string and obtain "if(x>1)pprint 'x=y+'".

### 3.2.3 String Replacement

Keywords are important elements of structured input languages; changing a single keyword in an input can lead to completely different behavior. GRIMOIRE's string replacement mutation performs different forms of replacements, as described in Algorithm 6. Given an input, it locates all substrings in the input that match strings from the obtained dictionary and chooses one randomly. GRIMOIRE first selects a random occurrence of the matching substring and replaces it with a random string. In a second step, it replaces all occurrences of the substring with the same random string. Finally, the mutation sends both mutated inputs to the fuzzer. As an example, this mutation can be helpful to discover different methods of the same object by replacing a valid method call with different alternatives. Also, changing all occurrences of a substring allows us to perform more syntactically correct mutations, such as renaming of variables in the input.

**Example 8.** Assume the "if(x>1)pprint 'x=y+' and that the strings "if", "while", "key", "pprint", "eval", "+", "=", and "-" are in the dictionary. Thus, the string replacement mutation can generate inputs such as "while(x>1)pprint 'x=y+'", "if(x>1)eval 'x=y+' or "if(x>1)pprint 'x=y-'". Furthermore, assume that the string "x" is also in the dictionary. Then, the string replacement mutation can replace all occurrences of the variable "x" in "if(x>1)pprint 'x=y+' and obtain "if(key>1)pprint 'key=y+'".

## 4 Implementation

To evaluate the algorithms introduced in this paper, we built a prototype implementation of our design. Our implementation, called GRIMOIRE, is based on REDQUEEN's [3] source code. This allows us to implement our techniques within a state-of-the-art fuzzing framework. REDQUEEN is applicable to both open and closed source targets running in user or kernel space, thus enabling us to target a wide variety of programs.

---

**Algorithm 6:** Overview of the string replacement mutation.

**Data:** input is the input string, strings is the provided dictionary obtained from the binary

```
1 sub ← find_random_substring(input, strings)
2 if sub then
3   rand ← random_string(strings)
4   data ← replace_random_instance(input, sub, rand)
5   send_to_fuzzer(data)
6   data ← replace_all_instances(input, sub, and)
7   send_to_fuzzer(data)
```

---

While REDQUEEN is entirely focused on solving magic bytes and similar constructs which are local in nature (i. e., require only few bytes to change), GRIMOIRE assumes that this kind of constraints can be solved by the underlying fuzzer. It uses global mutations (that change large parts of the input) based on the examples that the underlying fuzzer finds. Since our technique is merely based on common techniques implemented in coverage-guided fuzzers—for instance, access to the execution bitmap—it would be a feasible engineering task to adapt our approach to other current fuzzers, such as AFL.

More precisely, GRIMOIRE is implemented as a set of patches to REDQUEEN. After finding new inputs, we apply the generalization instead of the minimization algorithm that was used by AFL and REDQUEEN. Additionally, we extended the havoc stage by large-scale mutations as explained in Section 3. To prevent GRIMOIRE from spending too much time in the generalization phase, we set a user-configurable upper bound; inputs whose length exceeds this bound are not be generalized. Per default, it is set to 16384 bytes. Overall, about 500 lines were written to implement the proposed algorithms.

To support reproducibility of our approach, we open source the fuzzing logic, especially the implementation of GRIMOIRE as well as its interaction with REDQUEEN at <https://github.com/RUB-SysSec/grimoire>.

## 5 Evaluation

We evaluate our prototype implementation GRIMOIRE to answer the following research questions.

- RQ1** How does GRIMOIRE compare to other state-of-the-art bug finding tools?
- RQ2** Is our approach useful even when proper grammars are available?
- RQ3** How does our approach improve the performance on targets that require highly structured inputs?
- RQ4** How does our approach perform compared to other grammar inference techniques for the purpose of fuzzing?
- RQ5** How do our mutators impact fuzzing performance?

**RQ 6** Can GRIMOIRE identify new bugs in real-world applications?

To answer these questions, we perform three individual experiments. First, we evaluate the coverage produced by various fuzzers on a set of real-world target programs. In the second experiment, we analyze how our techniques can be combined with grammar-based fuzzers for mutual improvements. Finally, we use GRIMOIRE to uncover a set of vulnerabilities in real-world target applications.

## 5.1 Measurement Setup

All experiments are performed on an Ubuntu Server 16.04.2 LTS with an Intel i7-6700 processor with 4 cores and 24 GiB of RAM. Each tool is evaluated over 12 runs for 48 hours to obtain statistically meaningful results. In addition to other statistics, we also measure the effect size by calculating the difference in the median of the number of basic blocks found in each run. Additionally, we perform a Mann Whitney U test (using `scipy` 1.0 [38]) and report the resulting  $p$ -values. All experiments are performed with the tool being pinned to a dedicated CPU in single-threaded mode. Tools other than GRIMOIRE and REDQUEEN require source-code access; we use the fast `clang`-based instrumentation in these cases. Additionally, to ensure a fair evaluation, we provide each fuzzer with a dictionary containing the strings found inside of the target binary. In all cases, except NAUTILUS (which crashed on larger bitmaps), we increase the bitmap size from  $2^{16}$  to  $2^{19}$ . This is necessary since we observe more collisions in the global coverage map for large targets which causes the fuzzer to discard new coverage. For example, in `SQLite` (1.9 MiB), 14% of the global coverage map entries collide [66]. Since we deal with even larger binaries such as PHP which is nearly 19 MiB, the bitmap fills up quickly. Based on our empirical evaluation, we observed that  $2^{19}$  is the smallest sufficient size that works for all of our target binaries.

Furthermore, we disable the so-called *deterministic stage* [66]. This is motivated by the observation that these deterministic mutations are not suited to find new coverage considering the nature of highly structured inputs. Finally—if not stated otherwise—we use the same uninformed seed that the authors of REDQUEEN used for their experiments: "ABC...XYZabc...xyz012...789!".\$...~+\*".

As noted by Aschermann et al. [3], there are various definitions of a basic block. Fuzzers such as AFL change the number of basic blocks in a program. Thus, to enable a fair comparison in our experiments, we measure the coverage produced by each fuzzer on the same uninstrumented binary. Therefore, the numbers of basic blocks found and reported in our paper might differ from other papers. However, they are consistent within all of our experiments.

For our experiments, we select a diverse set of target programs. We use four scripting language interpreters (`mruby`-1.4.1 [41], `php`-7.3.0 [57], `lua`-5.3.5 [36]

and `JavaScriptCore`, commit "f1312" [1]) a compiler (`tcc`-0.9.27 [6]), an assembler (`nasm`-2.14.02 [56]), a database (`sqlite`-3.25 [31]), a parser (`libxml`-2.9.8 [59]) and an SMT solver (`boolector`-3.0.1 [44]). We select these four scripting language interpreters so that we can directly compare the results to NAUTILUS. Note that our choice of targets is additionally governed by architectural limitations of REDQUEEN which GRIMOIRE is based on. REDQUEEN uses Virtual Machine Introspection (VMI) to transfer the target binary—including all of its dependencies—into the Virtual Machine (VM). The maximum transfer size using VMI in REDQUEEN is set to 64 MiB. Programs such as Python [49], GCC [18], Clang [40], V8 [24] and SpiderMonkey [43] exceed our VMI limitation; thus, we can not evaluate them. We select an alternative set of target binaries that are large enough but at the same time do not exceed our 64 MiB transfer size limit. Hence, we choose JavaScriptCore over V8 and SpiderMonkey, `mruby` over `ruby` and `TCC` over `GCC` or `Clang`. Finally, we tried to evaluate GRIMOIRE with `ChakraCore` [42]. However, `ChakraCore` fails to start inside of the REDQUEEN Virtual Machine for unknown reasons. Still, GRIMOIRE performs well on large targets such as JavaScriptCore and PHP.

## 5.2 State-of-the-Art Bug Finding Tools

To answer RQ 1, we perform 12 runs on eight targets using GRIMOIRE and four state-of-the-art bug finding tools. We choose AFL (version 2.52b) because it is a well-known fuzzer and a good baseline for our evaluation. We select QSYM (commit "6f00c3d") and ANGORA (commit "6ff81c6"), two state-of-the-art hybrid fuzzers which employ different program analysis techniques, namely symbolic execution and taint tracking. Finally, we choose REDQUEEN as a state-of-the-art coverage-guided fuzzer, which is also the baseline of GRIMOIRE. As a consequence, we are able to directly observe the improvements of our method. Note that we could not compile `libxml` for ANGORA instrumentation. Therefore, ANGORA is missing in the `libxml` plot.

The results of our coverage measurements are shown in Figure 4. As we can see, in all cases GRIMOIRE provides a significant advantage over the baseline (unmodified REDQUEEN). Surprisingly, in most cases, neither ANGORA, REDQUEEN, nor QSYM seem to have a significant edge over plain AFL. This can be explained by the fact that REDQUEEN and ANGORA mostly aim to overcome certain "magic byte" fuzzing roadblocks. Similarly, QSYM is also effective to solve these roadblocks. Since we provide a dictionary with strings from the target binary to each fuzzer, these roadblocks become much less common. Thus, the techniques introduced in ANGORA, REDQUEEN and QSYM are less relevant given the seeds provided to the fuzzers. However, in the case of `TCC`, we can observe that providing the strings dictionary does not help AFL. Therefore, we believe that ANGORA and REDQUEEN

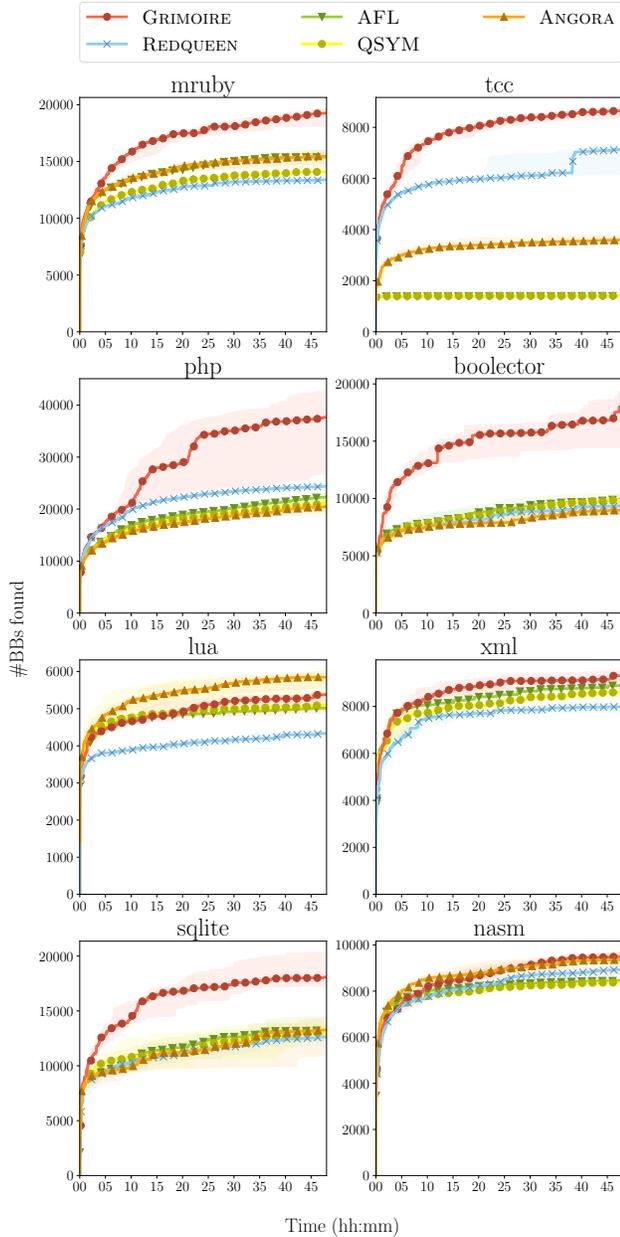

Figure 4: The coverage (in basic blocks) produced by various tools over 12 runs for 48h on various targets. Displayed are the median and the 66.7% intervals.

find strings that are not part of the dictionary and thus outperform AFL.

A complete statistical description of the results is given in the appendix (Table 7). We perform a confirmatory statistical analysis on the results, as shown in Table 2. The results show that in all but two cases (Lua and NASM), GRIMOIRE offers relevant and significant improvements over all state-of-the-art alternatives. On average, it finds nearly 20% more coverage than the second best alternative.

Table 2: Confirmatory data analysis of our experiments. We compare the coverage produced by GRIMOIRE against the best alternative. The effect size is the difference of the medians in basic blocks. In most experiments, the effect size is relevant and the changes are highly significant: it is typically multiple orders of magnitude smaller than the usual bound of  $p < 5.0E-02$  (bold).

| Target    | Best Alternative | Effect Size ( $\Delta = \bar{A} - \bar{B}$ ) | Effect Size in % of Best | p-value        |
|-----------|------------------|----------------------------------------------|--------------------------|----------------|
| mruby     | ANGORA           | 3685                                         | 19.3%                    | <b>1.8E-05</b> |
| TCC       | REDQUEEN         | 1952                                         | 22.6%                    | <b>7.8E-05</b> |
| PHP       | REDQUEEN         | 11238                                        | 31.6%                    | <b>1.8E-05</b> |
| Boolector | AFL              | 7671                                         | 43.9%                    | <b>1.8E-05</b> |

Lua accepts both source files (text) as well as byte code. GRIMOIRE can only make effective mutations in the domain of language features and not the bytecode. However, other fuzzers can perform on both; this is why ANGORA outperforms GRIMOIRE on this target. It is worth mentioning that GRIMOIRE outperforms REDQUEEN, the baseline on top of which our approach is implemented.

To partially answer **RQ 1**, we showed that in terms of *code coverage*, GRIMOIRE outperforms other state-of-the-art bug finding tools (in most cases). Second, to answer **RQ 3**, we demonstrated that GRIMOIRE significantly improves the performance on targets with highly structured inputs when compared to our baseline (REDQUEEN).

### 5.3 Grammar-based Fuzzers

Generally, we expect grammar-based fuzzers to have an edge over grammar inference fuzzers like GRIMOIRE since they have access to a manually crafted grammar. To quantify this advantage, we evaluate GRIMOIRE against current grammar-based fuzzers. To this end, we choose NAUTILUS (commit “dd3554a”), a state-of-the-art coverage-guided fuzzer, since it can fuzz a wide variety of targets if provided with a handwritten grammar. We evaluate on the targets used in NAUTILUS’ experiments, mruby, PHP and Lua, as their grammars are available. Unfortunately, GRIMOIRE is not capable of running ChakraCore, the fourth target NAUTILUS was evaluated on; thus, we replace it by JavaScriptCore and use NAUTILUS’ JavaScript grammar. We observed that the original version of NAUTILUS had some timeout problems during fuzzing where the timeout detection did not work properly. We fixed this for our evaluation.

For each of the four targets, we perform an experiment with the same setup as the first experiment (again, 12 runs for 48 hours). The results are shown in Figure 5. As expected, our completely automated method is defeated in most cases by NAUTILUS since it uses manually fine-tuned grammars.

Surprisingly, in the case of `mruby`, we find that GRIMOIRE is able to outperform even NAUTILUS.

To evaluate whether GRIMOIRE is still useful in scenarios where a grammar is available, we perform another experiment. We extract the corpus produced by NAUTILUS after half of the time (i. e., 24 hours) and continue to use GRIMOIRE for another 24 hours using this seed corpus. For these *incremental runs*, we reduce GRIMOIRE’s upper bound for input generalization to 2,048 bytes; otherwise, our fuzzer would mainly spend time in the generalization phase since NAUTILUS produces very large inputs. The results are displayed in Figure 5 (incremental). This experiment demonstrates that even despite manual fine-tuning, the grammar often contains blind spots, where an automated approach such as ours can infer the implicit structure which the program expects. This structure may be quite different from the specified grammar. As Figure 5 shows, by using the corpus created by NAUTILUS, GRIMOIRE surpasses NAUTILUS individually in all cases (RQ 2). A confirmatory statistical analysis of the results is presented in Table 3. In three cases, GRIMOIRE is able to improve upon hand written grammars by nearly 10%.

Table 3: Confirmatory data analysis of our experiment. We compare the coverage produced by GRIMOIRE against NAUTILUS with hand written grammars. The effect size is the difference of the medians in basic blocks in the incremental experiment. In three experiments, the effect size is relevant and the changes are highly significant (marked bold,  $p < 5.0E-02$ ). Note that we abbreviate JavaScriptCore with JSC.

| Target | Best Alternative | Effect Size ( $\Delta = \bar{A} - \bar{B}$ ) | Effect Size in % of Best | p-value        |
|--------|------------------|----------------------------------------------|--------------------------|----------------|
| mruby  | NAUTILUS         | 2025                                         | 10.0%                    | <b>1.8E-05</b> |
| Lua    | NAUTILUS         | 553                                          | 5.2%                     | 5.0E-02        |
| PHP    | NAUTILUS         | 5465                                         | 9.3%                     | <b>3.6E-03</b> |
| JSC    | NAUTILUS         | 15445                                        | 11.0%                    | <b>1.8E-05</b> |

Additionally, we intended to compare GRIMOIRE against CODEALCHEMIST and JSFUNFUZZ, two other state-of-the-art grammar-based fuzzers which specialize on JavaScript engines. Although these two fuzzers are not coverage-guided—making a fair evaluation challenging—we consider the comparison of specialized JavaScript grammar-based fuzzers to general-purpose grammar-based fuzzers as interesting. Unfortunately, JSFUNFUZZ was not working with JavaScriptCore out of the box as it is specifically tailored to SpiderMonkey. Since it requires significant modifications to run on JavaScriptCore, we considered the required engineering effort to be out of scope for this paper. On the other hand, CODEALCHEMIST requires an extensive seed corpus of up to 60,000 valid JavaScript files—which were not released together with the source files. We tried to replicate the seed corpus as described by the authors of CODEALCHEMIST. However, despite the authors’ kind help, we were unable to run CODEALCHEMIST with our corpus.

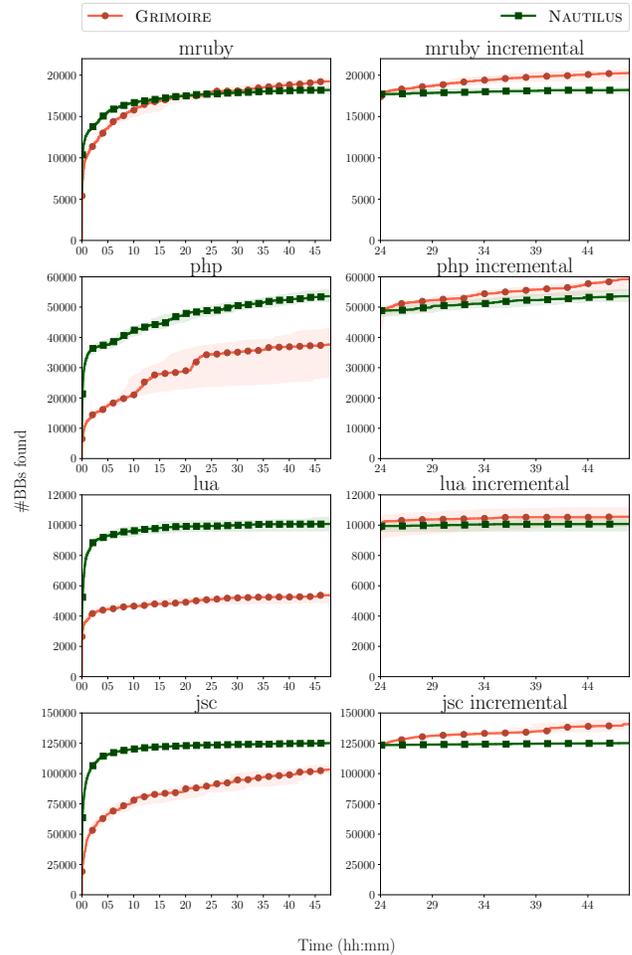

Figure 5: The coverage (in basic blocks) produced by GRIMOIRE and NAUTILUS (using the hand written grammars of the authors of NAUTILUS) over 12 runs at 48 h on various targets. The incremental plots show how running NAUTILUS for 48h compared to running NAUTILUS for the first 24h and then continue fuzzing for 24h with GRIMOIRE. Displayed are the median and the 66.7% confidence interval.

Overall, these experiments confirm our assumption that grammar-based fuzzers such as NAUTILUS have an edge over grammar inference fuzzers like GRIMOIRE. However, deploying our approach on top of a grammar-based fuzzer (incremental runs) increases code coverage. Therefore, we partially respond to RQ 1 and provide an answer to RQ 2 by stating that GRIMOIRE is a valuable addition to current fuzzing techniques.

## 5.4 Grammar Inference Techniques

To answer RQ 4, we compare our approach to other grammar inference techniques in the context of fuzzing. Existing work in this field includes GLADE, AUTOGRAM and PYGMALION. However, since PYGMALION targets only Python and AUTOGRAM only Java programs, we cannot evaluate

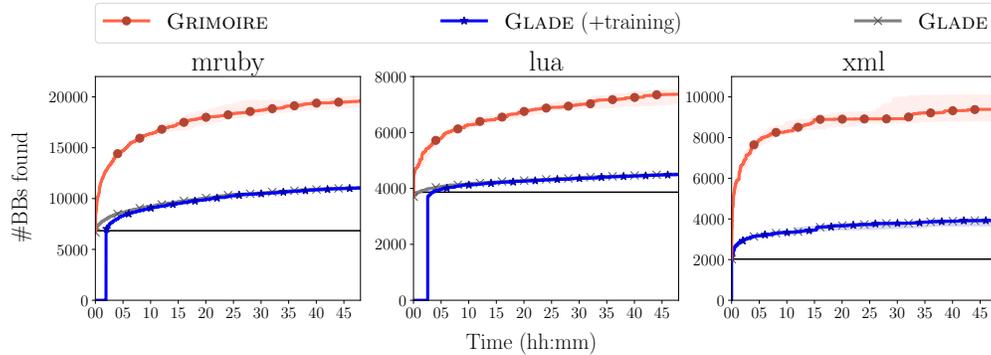

Figure 6: Comparing GRIMOIRE against GLADE (median and 66.7% interval). In the plot for GLADE +Training, we include the training time that glade used. For comparison, we also include plots where we omit the training time. The horizontal bar displays the coverage produced by the seed corpus that GLADE used during training.

them as GRIMOIRE only supports targets that can be traced with Intel-PT (since REDQUEEN heavily depends on it).

Therefore, for this evaluation, we use GLADE (commit “b9ef32e”), a state-of-the-art grammar inference tool. It operates in two stages. Given a program as black-box oracle as well as a corpus of valid input samples, it learns a grammar in the first stage. In the second stage, GLADE uses this grammar to produce inputs that can be used for fuzzing. GLADE does not generate a continuous stream of inputs, hence we modified it to provide such capability. We then use these inputs to measure the coverage achieved by GLADE in comparison to GRIMOIRE. Note that due to the excessive amount of inputs produced by GLADE, we use a corpus minimization tool—`af1-cmin`—to identify and remove redundant inputs before measuring the coverage [66].

Note, we have to extend GLADE for each target that is not natively supported and must manually create a valid seed corpus. For this reason, we restrict ourselves to the three targets `libxml`, `mruby` and `Lua`. From these, `libxml` is the only one that was also used in GLADE’s evaluation. Therefore, we are able to re-use their provided corpus for this target. We choose the other two since we want to achieve comparability with regards to previous experiments.

To allow for a fair comparison, we provide the same corpus to GRIMOIRE. Again, we repeat all experiments 12 times for 48 hours each. The results of this comparison are depicted in Figure 6. Note that this figure includes two different experiments of GLADE. In the first experiment, we include the time GLADE spent on training into the measurement while for the second measurement, GLADE is provided the advantage of concluding the training stage before measurement is started for the fuzzing process. As can be seen in Figure 6, GRIMOIRE significantly outperforms GLADE on all targets for both experiments. Similar to earlier experiments, we perform a confirmatory statistical analysis. The results are displayed in Table 4; they are in all cases relevant and statistically significant. If we consider only the new coverage found (beyond

what is already contained in the training set), we are able to outperform GLADE by factors from two to five. We therefore conclude in response to **RQ 4** that we significantly exceed comparative grammar inference approaches in the context of fuzzing.

We designed another experiment to evaluate whether GLADE’s automatically inferred grammar can be used for NAUTILUS and how it performs compared to hand written grammars. However, GLADE does not use the grammar directly but remembers how the grammar was produced from the provided test cases and uses the grammar only to apply local mutations to the input. Unfortunately, as a consequence, their grammar contains multiple unproductive rules, thus preventing their usage in NAUTILUS.

Table 4: Confirmatory data analysis of our experiments. We compare the coverage produced by GRIMOIRE against GLADE. The effect size is the difference of the medians in basic blocks. In all experiments, the effect size is relevant and the changes are highly significant: it is multiple orders of magnitude smaller than the usual bound of  $p < 5.0E-02$  (bold).

| Target | Best Alternative | Effect Size ( $\Delta = \bar{A} - \bar{B}$ ) | Effect Size in % of Best | p-value        |
|--------|------------------|----------------------------------------------|--------------------------|----------------|
| mruby  | GLADE            | 8546                                         | 43.6%                    | <b>9.1E-05</b> |
| Lua    | GLADE            | 2775                                         | 38.1%                    | <b>9.1E-05</b> |
| libxml | GLADE            | 5213                                         | 57.2%                    | <b>9.1E-05</b> |

## 5.5 Mutations Statistic

During the aforementioned experiments, we also collected various statistics on how effective different mutators are. We measured how much time was spent using GRIMOIRE’s different mutation strategies as well as how many of the inputs were found by each strategy. This allows us to rank mutation strategies based on the number of new paths found per time used. The strategies include a havoc stage, REDQUEEN’s Input-to-State-based mutation stage and our structural mutation stage. The times for our structural mutators include the

generalization process (including the necessary minimization that also benefits the other mutators).

As Table 5 shows, our structural mutators are competitive with other mutators, which answers **RQ 5**. As the coverage results in Figure 4 show, the mutators are also able to uncover paths that would not have been found otherwise.

Table 5: Statistics for each of GRIMOIRE’s mutation strategies (i. e., our structured mutations, REDQUEEN’s Input-to-State-based mutations and havoc). For every target evaluated we list the total number of inputs found by a mutation, the time spent on this strategy and the ratio of inputs found per minute.

| Mutation       | Target         | #Inputs | Time Spent (min) | #Inputs/Min  |
|----------------|----------------|---------|------------------|--------------|
| Structured     | mruby          | 9040    | 1531.18          | 5.90         |
|                | PHP            | 27063   | 2467.17          | <b>10.97</b> |

## 5.6 Real-World Bugs

We use GRIMOIRE on a set of different targets to observe whether it is able to uncover previously unknown bugs (**RQ 6**). To this end, we manually triaged bugs found during our evaluation. As illustrated in Table 6, GRIMOIRE found more bugs than all other tools in the evaluation combined. We responsibly disclosed all of them to the vendors. For these, 11 CVEs were assigned. Note that we found a large number of bugs that did not lead to assigned CVEs. This is partially because projects such as PHP do not consider invalid inputs as security relevant, even when custom scripts can trigger memory corruption. We conclude **RQ 6** by finding that GRIMOIRE is indeed able to uncover novel bugs in real-world applications.

## 6 Discussion

The methods introduced in this paper produce significant performance gains on targets that expect highly structured inputs without requiring any expert knowledge or manual work. As we have shown, GRIMOIRE can also be used to support grammar-based fuzzers with well-tuned grammars but

Table 6: Overview of submitted bugs and CVEs. Fuzzers which did not find the bug during our evaluation are denoted by **X**, while those who did are marked by **✓**. We indicate targets not evaluated by a specific fuzzer with ‘-’. We abbreviate Use-After-Free (UAF), Out-of-Bounds (OOB) and Buffer Overflow (BO).

| Target    | CVE        | Type      | GRIMOIRE | REDQUEEN | AFL | QSYM | ANGORA | NAUTILUS |

cannot outperform them on their own. In contrast to similar methods, our approach does not rely on complex primitives such as symbolic execution or taint tracking. Therefore, it can easily be integrated into existing fuzzers. Additionally, since GRIMOIRE is based on REDQUEEN, it can be used on a wide variety of binary-only targets, ranging from userland programs to operating system kernels.

Despite all advantages, our approach has significant difficulties with more syntactically complex constructs, such as matching the ID of opening and closing tags in XML or identifying variable constructs in scripting languages. For instance, while GRIMOIRE is able to produce nested inputs such as “<a><a><a>F00</a></a></a>”, it struggles to generalize “<a>□</a>” to the more unified representation “<A>□</B>” with the constraint  $A = B$ . A solution for such complex constructs could be the following generalization heuristic: (i) First, we record the new coverage for the current input. (ii) We then change only a single occurrence of a substring in our input and record its new coverage. For instance, consider that we replace a single occurrence of “a” by “b” in “<a><a><a>F00</a></a></a>” and obtain “<b><a><a>F00</a></a></a>”. This change results in an invalid XML tag which leads to different coverage compared to the one observed in (i). (iii) Finally, we change multiple instances of the same substring and compare the new coverage of the modified input with the one obtained in (i). If we

achieved the same new coverage in (iii) and (i), we can assume that the modified instances of the same substring are related to each other. For example, we replace multiple occurrences of “a” with “b” and obtain “<b><a><a>F00</a></a></b>”. In this example, the coverage is the same as for the original input since the XML remains syntactically correct.

Similarly, our generalization approach might be too coarse in many places. Obtaining more precise rules would help uncovering deeper parts of the target application in cases where multiple valid statements have to be produced. Consider, for instance, a scripting language interpreter such as the ones used in our evaluation. Certain operations might require a number of constructors to be successfully called. For example, it might be necessary to get a valid path object to obtain a file object that can finally be used to perform a read operation. A more precise representation would be highly useful in such cases. One could try to infer whether a combination is “valid” by checking if the combination of two inputs exercises the combination of the new coverage introduced by both inputs. For instance, assume that input “a□b” triggers the coverage bytes 7 and 10 and that input “□=□” triggers coverage byte 20. Then, a combination of these two inputs such as “□a□=□b” could trigger the coverage bytes 7, 10 and 20. Using this information, it might be possible to infer more precise grammar descriptions and thus generate inputs that are closer to the target’s semantics than it is currently possible in GRIMOIRE. While this approach would most likely further reduce the gap between hand-written grammars and inferred grammars, well-designed hand-written grammars will always have an edge over fuzzers with no prior knowledge: any kind of inference algorithm first needs to uncover structures before the obtained knowledge can be used. A grammar-based fuzzer has no such disadvantage. If available, human input can improve the results of grammar inference or steer its direction. An analyst can provide a partial grammar to make the grammar-fuzzer focus on a specific interesting area and avoid exploring paths that are unlikely to contain bugs. Therefore, GRIMOIRE is useful if the grammar is unknown or under-specified but cannot be considered a full replacement for grammar-based fuzzers.

## 7 Related Work

A significant number of approaches to improve the performance of different fuzzing strategies has been proposed over time. Early on, fuzzers typically did not observe the inner workings of the target application, yet different approaches were proposed to improve various aspects of fuzzers: different mutation strategies were evaluated [14, 29], the process of selecting and scheduling of seed inputs was analyzed [11, 51, 61] and, in some cases, even learned language models were used to improve the effectiveness of fuzzing [22, 27]. After the publication of AFL [65], the research focus shifted towards coverage-guided fuzzing techniques. Similarly to the previ-

ous work on blind fuzzing, each individual component of AFL was put under scrutiny. For example, AFLFAST [8] and AFLGo [7] proposed scheduling mechanisms that are better suited to some circumstances. Both, COLLAFL [16] and InsTrim [35], enhanced the way in which coverage is generated and stored to reduce the amount of memory needed. Other publications improved the ways in which coverage feedback is collected [23, 53, 55, 62]. To advance the ability of fuzzers to overcome constraints that are hard to guess, a wide array of techniques were proposed. Commonly, different forms of symbolic execution are used to solve these challenging instances [9, 10]. In most of these cases, a restricted version of symbolic execution (concolic execution) is used [19–21, 26, 54, 60]. To further improve upon these techniques, DigFuzz [67] provides a better scheduling for inputs to the symbolic executor. Sometimes, instead of using these heavy-weight primitives, more lightweight techniques such as taint tracking [12, 17, 26, 50], patches [3, 13, 47, 60] or instrumentation [3, 39] are used to overcome the same hurdles.

While these improvements generally work very well for binary file formats, many modern target programs work with highly structured data. To target these programs, generational fuzzing is typically used. In such scenarios, the user can often provide a grammar. In most cases, fuzzers based on this technique are blind fuzzers [14, 33, 45, 52, 63].

Recent projects such as AFLSMART [48], NAUTILUS [2] and ZEST [46] combined the ideas of generational fuzzing with coverage guidance. CODEALCHEMIST [28] even ventures beyond syntactical correctness. To find novel bugs in mature JavaScript interpreters, it tries to automatically craft syntactically and semantically valid inputs by recombining input fragments based on inferred types of variables. All of these approaches require a good format specification and—in some cases—good seed corpora. CODEALCHEMIST even needs access to a specialized interpreter for the target language to trace and infer type annotations. In contrast, our approach has no such preconditions and is thus easily integrable into most fuzzers.

Finally, to alleviate some of the disadvantages that the mentioned grammar-based strategies have, multiple approaches were developed to automatically infer grammars for given programs. GLADE [5] can systematically learn an approximation to the context-free grammars parsed by a program. To learn the grammar, it needs an oracle that can answer whether a given input is valid or not as well as a small set of valid inputs. Similar techniques are used by PYGMALION [25] and AUTOGRAM [34]. However, both techniques directly learn from the target application without requiring a modified version of the target. AUTOGRAM still needs a large set of inputs to trace, while PYGMALION can infer grammars based solely on the target application. Additionally, both approaches require complex analysis passes and even symbolic execution to produce grammars. These techniques cannot easily be scaled

to large binary applications. Finally, all three approaches are computationally expensive.

## 8 Conclusion

We developed and demonstrated the first fully automatic algorithm that integrates large-scale structural mutations into the fuzzing process. In contrast to other approaches, we need no additional modifications or assumptions about the target application. We demonstrated the capabilities of our approach by evaluating our implementation called GRIMOIRE against various state-of-the-art coverage-guided fuzzers. Our evaluation shows that we outperform other coverage-guided fuzzers both in terms of coverage and the number of bugs found. From this observation, we conclude that it is possible to significantly improve the fuzzing process in the absence of program input specifications. Furthermore, we conclude that even when a program input specification is available, our approach is still useful when it is combined with a generational fuzzer.

## A Statistics on Basic Block Coverage

Table 7: Statistics on basic block coverage for tested fuzzers. In the column “Best Coverage”, we provide the highest number of basic blocks a run found and the percentage relative to the number of basic blocks obtained from IDA Pro [30].

| Target    | Best Coverage (#BBS / %) | Fuzzer   | Mean (%) | Median (%) | Median (#BBS) | Std Deviation | Skewness | Kurtosis |
|-----------|--------------------------|----------|----------|------------|---------------|---------------|----------|----------|
| mruby     | 20258 / 70.5%            | GRIMOIRE | 66.1%    | 66.6%      | 19137         | 4.55          | -0.54    | -0.76    |
|           |                          | AFL      | 53.7%    | 53.4%      | 15355         | 4.28          | 0.14     | -0.27    |
|           |                          | ANGORA   | 53.3%    | 53.8%      | 15452         | 4.87          | 0.17     | -0.96    |
|           |                          | QSYM     | 49.2%    | 49.0%      | 14084         | 2.20          | 0.33     | 0.95     |
|           |                          | REDQUEEN | 45.9%    | 46.4%      | 13339         | 4.64          | -0.98    | 0.05     |
| TCC       | 9211 / 77.6%             | GRIMOIRE | 71.8%    | 72.9%      | 8647          | 5.71          | -1.89    | 3.68     |
|           |                          | AFL      | 11.8%    | 11.8%      | 1397          | 3.80          | 1.27     | 1.14     |
