based on their data and provide no indication to the message’s sender. Another significant challenge in mapping a CAN bus is the broadcast nature of the CAN protocol; we cannot tell which ECUs have received a message. A CAN message is not explicitly addressed to its recipients, but a node can indicate it has correctly received a message (§3).

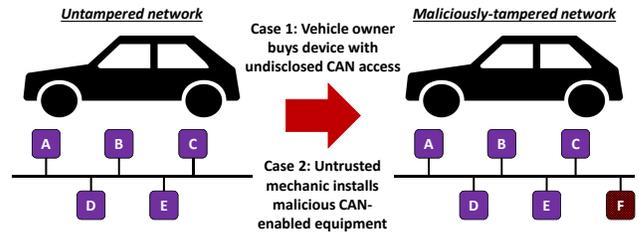

In this paper, we present *CANvas*, a system that demonstrates a *fast* and *inexpensive* automotive network mapper without resorting to vehicle disassembly (§4). Rather than require physically isolating each ECU, our key insight is to extract message information by re-purposing two observations from prior work:

- **Identifying message source** (§5): Prior work by Cho et al. [11] state that clock skew is a unique characteristic to a given ECU and thus build an intrusion detection system (IDS) that measures this skew from the timestamps of periodic CAN messages. Using this insight, we envision a mapper that computes clock skew per unique message and uses skew to group messages from the same sender. Unfortunately, due to shortcomings of their approach in our mapping context, we instead track the clock offset of two messages over time to determine their source.
- **Identifying message destination(s)** (§6): In another prior work [10], the authors propose a denial-of-service (DoS) attack that exploits CAN’s error-handling protocol to disable a target ECU. Using this insight, the mapper could disable all but one ECU via this DoS attack and observe what messages are correctly received by the isolated ECU. However, due to shortcomings in their method w.r.t. our context, we develop a method to forcefully isolate each ECU and detect which messages the ECU receives despite the broadcast nature of CAN.

We implement the *CANvas* mapper on the open-source Arduino Due microcontroller with a clock speed of 84 MHz and an on-board CAN controller. We evaluate our mapper on five real vehicles (2009 Toyota Prius, 2017 Ford Focus, 2008 Ford Escape, 2010 Toyota Prius, and 2013 Ford Fiesta) and on extracted ECUs from three Ford vehicles. We show that *CANvas* accurately identifies ECUs in the network and the source and destinations of each unique CAN message in under an hour (§7).

**Contributions and roadmap:** In summary, this paper makes the following contributions:

- Designing an accurate message source identification algorithm that tracks a message’s relative clock offset (§5);
- Engineering a reliable message destination identification method by isolating ECUs with a forced shutdown technique (§6);
- A real implementation that maps five real vehicles and extracted ECUs (§7) along with two real examples of motivating use cases for mapping (§2).

**Figure 1: A network mapper could discover potentially malicious ECUs from an untrusted party.**

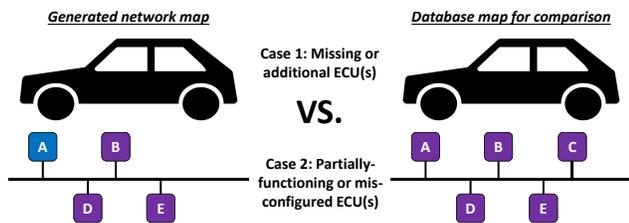

After defining the automotive network mapping problem and describing typical CAN bus setups (§3), we highlight the challenges of identifying message information via the CAN protocol and provide an overview of our approach (§4). Finally, we discuss open issues and limitations (§8) and related work (§9) before concluding the paper (§10).

## 2 Motivation

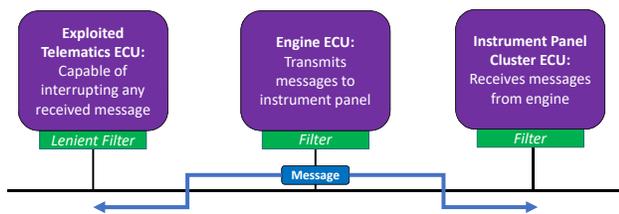

In this section, we discuss motivating scenarios for mapping in the context of intra-vehicular networks and describe characteristics of an ideal version of this security tool. To guide our design, we draw an analogy to Nmap [21], a popular network scanning tool that discovers hosts, services, and their interconnections in traditional computer networks. We identify a number of automotive-specific scenarios to illustrate the potential benefits of mapping, although this is not meant to be a comprehensive list.

**Malicious ECU discovery:** One main feature of Nmap is its ability to discover hosts, i.e. enumerate devices on the network. In the context of automotive networks, these “devices” are equivalent to a vehicle’s ECUs. One major automotive cybersecurity concern (depicted in Figure 1) is the potential for an attacker to gain access to a physical network and add a new device [26], which could be a malicious ECU installed by an untrusted party or even by a vehicle owner who installs a CAN-enabled device purchased from an untrusted source. For an attacker that aims to insert this ECU into the network under the guise of a new equipment installation, the ECU could connect to the existing CAN bus and gain unfettered access to the CAN. If a defender performs a mapping through the vehicle’s lifetime, they could verify changes to the network’s ECUs. We provide an example of this scenario in §7 where we discover a previously unknown ECU that was installed in a modified 2009 Toyota Prius.

**Continuous network attestation:** Another popular use for Nmap is performing security audits to identify changes to a network [21]. Where such audits would identify new servers or a modification in a server’s open ports, an audit in an automotive context could identify changes to the ECUs and their communication channels. With future over-the-air update capabilities, automakers will install new firmware or activate

**Figure 2: A network mapper could compare a generated map to one found on an online database. Differences between these maps could identify changes in ECUs (Case 1) and/or their message configurations (Case 2).**

**Figure 3: Assume that only the instrument cluster should receive messages from the engine. If the exploited telematics ECU is able to receive engine messages, then an attacker [10] could shutdown the engine ECU via the exploited telematics ECU.**

different features in an existing vehicle. As the configuration of the network can change over time, it is necessary for vehicle owners to attest to the vehicle’s expected configuration. If a user does not own the vehicle over its lifetime as in the *malicious ECU discovery* scenario, we could implement an online database where vehicle owners could upload the outputs of their network maps for comparison against maps generated from brand-new vehicles. Any differences from the expected maps could indicate malicious or accidental network changes.

**Lenient filter identification:** Nmap is often used to perform port scanning to identify open ports [21], which are potential vulnerabilities. These “open ports” are analogous to the set of CAN messages that an ECU is able to correctly receive, which we refer to as the ECU’s message-receive filter. Now consider an attacker who aims to target a safety-critical ECU (e.g. engine ECU) as depicted in Figure 3. If gaining direct access to the engine ECU proves infeasible, the attacker could access an ECU that is less critical and potentially has access to remote networks (e.g. telematics ECU). Using the ECU shutdown attack as discussed in recent work [10], our attacker can shutdown the engine ECU by gaining control of the telematics ECU and reprogramming it; the attacker simply needs to receive a message from the victim ECU to target it. To combat this, a defender could perform a similar analysis via network

mapping and implement filters that prevent the message from being received to limit the damage from a potential shutdown attack. We provide an example of this scenario in §7 where we discover lenient message-receive filters in a 2017 Ford Focus.

**Goals:** In designing a useful automotive network mapper, we must consider a few requirements that we impose to ensure practicality in the context of our motivating scenarios:

*Fast:* First, we want to limit the amount of time a vehicle (and its ECUs) are turned on. Also, a fast mapping process will make it more practical for a user to verify the state of their vehicle’s network after a repair. Considering these reasons, we aim to achieve a mapping time of under one hour.

*Inexpensive:* To permit greater access to the mapper, the mapper should consist of relatively inexpensive components and should avoid expensive tools, such as oscilloscopes and logic analyzers. We aim to limit costs to under \$100; a low-cost approach to network mapping will permit more users for our system.

*Vehicle-agnostic:* Every vehicle has a different setup of ECUs on the CAN bus and can employ additional features of the CAN protocol. For our mapper to be practical, it must work on many makes and models of vehicles as well as rely on only standard CAN features.

*Minimally-intrusive and non-destructive:* One extreme approach for mapping a vehicle requires physical disassembly, which is a very intrusive process and requires a great deal of access to the target vehicle. We should limit this access to simply connecting to a diagnostics port on the vehicle. If a CAN bus is not exposed on this port, we describe a method of getting access to these buses with minimal disassembly in §8. Additionally, the mapper must not cause any permanent damage to the vehicle or its network. Any of our methods can put the network into a non-ideal state (warning lights on, gear shift disabled, etc.), but as long as restarting the vehicle undoes any imposed errors, we satisfy this constraint.

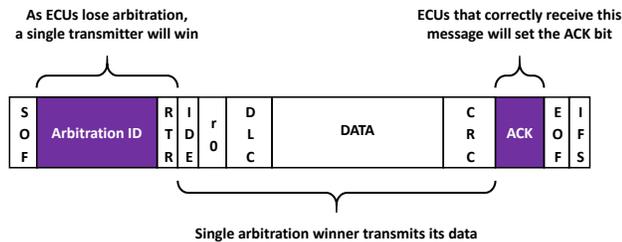

### 3 Problem Overview

In this section, we give a concrete problem formulation for the network mapper and discuss technical challenges. We preface with some necessary background on CAN to understand the overall problem and mapping challenges.

#### 3.1 CAN basics

To better understand the message information we hope to gain using a network mapper and the associated challenges in acquiring that information, we first discuss some necessary background on how the CAN protocol works.

**CAN in modern vehicles:** All vehicles produced for the U.S. market in 2008 and after are required to implement the CAN protocol for diagnostics purposes [4]. Many vehicles will often employ either one, two or three CAN buses. In the event of three CAN buses, it is likely that the vehicle has one bus for powertrain components (engine, transmission, etc.),

**Figure 4: Each CAN frame is transmitted on the bus bit-by-bit. A single transmitter wins arbitration and will listen to receiving ECUs during the ACK slot.**

one bus for infotainment components (radio, etc.) and another for body components (door controller, headlights, etc.). These CAN buses are usually exposed through a vehicle’s On-Board Diagnostics (OBD-II) port as detailed in §8.

**Message broadcast bus:** The CAN protocol [13–15, 32, 33] is defined as a message broadcast bus, which means that ECUs in the network communicate with each other via *messages*. These ECUs are connected to a shared network where all ECUs can receive all transmissions. Due to the nature of this broadcast bus, it is not possible to send a message to a specific ECU. In the CAN protocol, after a message is broadcast to the network, devices that correctly receive this message will acknowledge their reception.

**Typical CAN setup:** A typical CAN setup for a vehicle will grant each ECU with a unique set of IDs and each message will be labeled with an ID, which is then transmitted onto the bus. An ECU will be responsible for a subset of the message IDs seen in the network, and each message ID will only be sent by a single ECU. Each message is queued by a software task, process or interrupt handler on the ECU, and each ECU will queue a message when the message’s associated event occurs.

**CAN frame format:** Each CAN message from an ECU uses its assigned message ID (interchangeably referred to as the ID or the arbitration ID), which determines its priority on the CAN bus and may serve as an identifier for the message’s contents. These messages are transmitted and received at the physical layer by an ECU’s CAN controller as CAN data frames in the format depicted in Figure 4. The key fields in the CAN data frame, as relevant to our work, are: the start-of-frame (SOF) bit, the arbitration/message ID field, the acknowledgement (ACK) slot and the end-of-frame (EOF) bits.

All ECUs in the network with a queued message simultaneously start to transmit their message at the same time. During the arbitration ID field, all but one ECU will eventually stop transmitting based on CAN’s arbitration resolution. Once an ECU has won arbitration on the bus, it will be the only sender and transmit the remainder of the CAN data frame until the ACK slot. During the ACK slot, the transmitter now becomes

Scenario	Enum.	Src. map	Dest. map
Malicious ECU discovery	✓	✓	
Continuous network attestation	✓	✓	✓
Lenient filter identification	✓		✓

**Table 1: Mapping requirements for motivating scenarios**

a receiver on the bus and all other ECUs in the network that correctly receive a message will simultaneously send a dominant bit on the network. This slot is then followed by the EOF and the inter-frame space (IFS).

**Message arbitration:** To understand how ECUs communicate on the CAN bus, it is necessary to discuss the CAN message arbitration process [13–15, 33]. CAN is designed to support collision detection and bit-wise arbitration on message priority to allow higher-priority messages to dominate the network. The arbitration of these messages is performed on the message ID field of a data frame, where a lower ID indicates a higher priority. This priority-based arbitration process sets a 0-bit as dominant and a 1-bit as recessive. Since a 0-bit is dominant, a message with a lower ID will get priority on the CAN bus and will be sent before a message with a higher ID that is queued at the same time.

### 3.2 Mapping requirements

Unlike most traditional packet-switched networks, CAN messages do not have fields that identify the message’s source and destination(s), which makes the mapping problem difficult. To develop a mapper that will aid in the motivating scenarios of §2, we formulate three required outputs for *CANvas*:

**ECU enumeration:** The importance of enumerating ECUs is evident in all of our provided scenarios as seen in Table 1; enumeration highlights new or absent ECUs. Note that in all of these scenarios, it is *not* necessary to know an ECU’s type (engine, transmission, etc.) or its functionality (fan speed control, tire pressure sensing, etc.).

Formally, let  $E_i$  denote ECU  $i$  in a given vehicle that contains  $n$  total ECUs that are CAN-enabled. For each  $E_i$  in a vehicle’s set of ECUs,  $E_{1:n}$ , the ECU is responsible for sending a specific set of  $m$  messages labeled with a unique arbitration ID from the set,  $I_{E_i,1:m}$ . This set of IDs is unique to  $E_i$  and no other ECU in the network should send the same ID. Given a CAN traffic dump from a vehicle, *CANvas*’ enumerator should determine the number of ECUs,  $n$ , and differentiate between them to determine the set of ECUs  $E_{1:n}$  for that particular vehicle.

**Message source identification (§5):** In the *malicious ECU discovery* and *continuous network attestation* scenarios, changes to the set of transmitted messages for each ECU can pinpoint a potentially malicious reconfiguration. This means that a goal for our mapper is to map each message ID to its source ECU.

Formally, given a CAN traffic dump from which we extract the set of uniquely-ID’d messages where  $l$  is the number of total unique message/arbitration IDs and  $I_{1:l}$  is the set of

unique IDs, we should be able to determine which ECU  $E_i$  sent each unique message. This step is very closely related to ECU enumeration; once we know which ECU  $E_i$  that an arbitrary ID  $I_j$  originates from, we can produce a mapping of the ID to its source ECU,  $I_j \in E_i$ . Using this mapping, we can group the IDs with a common source ECU and complete our enumeration.

**Message destination identification (§6):** For the *continuous network attestation* scenario, we want to look for changes in what messages an ECU correctly receives as this could also indicate a potentially malicious reconfiguration. This component plays an important role in the *lenient filter identification* scenario, where an attacker could shutdown an ECU from an unintended message recipient.

We assume that at least one ECU in the network will correctly receive each message in the network. Formally, given the set of  $l$  unique IDs,  $I_{1:l}$ , from a traffic dump, we should be able to determine the set of ECUs,  $E_{1:k}$ , that correctly receive a message labeled with an arbitrary  $I_j$ . The expected output of this component should be a mapping of an ID to its destination ECUs,  $I_{j,E_{1:k}}$ .

### 3.3 Challenges in an automotive context

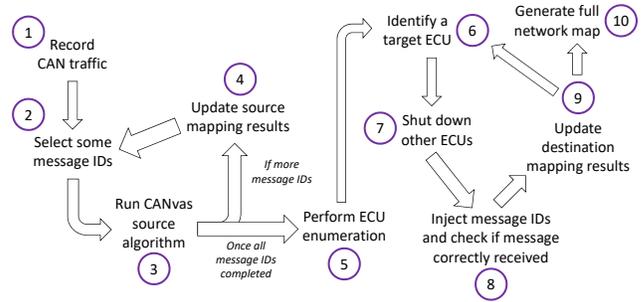

However, to achieve these mapping goals, we encounter two major challenges to determining the source and destination ECUs for CAN messages: (a) CAN lacks identifying source information and (b) CAN implements a broadcast protocol, which naturally implies that all nodes receive all messages. We discuss how we approach and solve these challenges in §5 and §6.

**Lack of source information:** If a message sent from ECU  $E_i$  has no identifying information, then it is non-trivial to determine that  $E_i$  sent the message. Since CAN messages are considered to be “contents-addressed” [13–15, 33], the value of the message ID is only related to the message’s data and priority. In practice, the source ECU has no weight in determining the chosen arbitration ID for a particular message.

**Broadcast protocol:** We define destination as an ECU that correctly receives a message at the CAN controller level. Unfortunately, determining which ECUs correctly receive a message is non-trivial as an ECU connected to the CAN bus cannot detect which of its messages are received by certain ECUs. The ACK bit itself only indicates that some ECU has received the message, not which particular ECU(s) have received it. As multiple ECUs will set the ACK bit when a message is received, we cannot simply use this ACK bit to determine the set of ECUs  $E_{1:k}$  that receive an arbitrary  $I_j$ .

## 4 System Overview

In this section, we provide a high-level overview of the *CANvas* network mapper.

**Figure 5: *CANvas* obtains source mapping results by step 4. Then, it will enumerate the ECUs in step 5. *CANvas* then performs destination mapping and generates the full map at step 10.**

### 4.1 High-level idea

***CANvas* mapping overview:** We split *CANvas* into two main components: (1) a source mapper and (2) a destination mapper. As detailed in §3, we satisfy our ECU enumeration requirement by simply using the output of source mapping. For (1), we passively collect several minutes of CAN traffic. After an offline data collection, the source mapper uses the data to produce a mapping of each unique CAN ID to its source ECU and subsequently, by grouping IDs with a shared source, a list of all active source ECUs on the bus. For (2), we interact with the network directly and perform an online analysis to determine message destination. *CANvas* systematically isolates each ECU, which will most likely cause the vehicle to enter a temporary error state that the user can reset.

**User capabilities:** We assume that the user has access to the OBD-II port of the vehicle and can connect the *CANvas* mapper directly to the CAN bus with the ability to read and write to the bus. We also assume that the vehicle even has a CAN bus and that the standard CAN protocol is implemented, which most vehicles will reflect [11]. The user should also be able to transition the vehicle’s ignition switch between the LOCK, ACC and ON positions as the user will have to reset the vehicle after each iteration to exit the error state.

**Scope and evasion:** We assume that the vehicle does not implement countermeasures that will alter timing of message transmissions, potentially to prevent intruders from identifying transmitting ECUs. We also assume that the vehicle cannot identify a maliciously-triggered error and prevent intruders from abusing CAN’s error-handling protocol to shutdown an ECU. The vehicle should not employ an intrusion detection system capable of preventing an ECU suspension. We further discuss adversarial evasion and other scenarios for bus configurations in §8.

### 4.2 *CANvas* workflow

The workflow of *CANvas* involves four major steps seen in Figure 5:

1. *Data collection*: The CAN pins of the OBD-II port provide access to the frame-level signals and the message-level data. *CANvas* will read this traffic for several minutes and timestamp each received message. From this traffic, we will obtain the set of unique message IDs observed in the network and a set of timestamped data for each ID.
2. *Source mapping*: With the list of all unique message IDs, the source mapper will extract the timestamped CAN traffic for each ID and determine which IDs share the same source as detailed in §5. To do this, we select two message IDs and run their CAN traffic through our comparison algorithm, which will determine if the two IDs originate from the same ECU.
3. *ECU enumeration*: Using the set of matching ID pairs from source mapping, the enumerator will simply group pairs that originate from the same ECU. The output of this step will be a list of ECUs and associated source IDs.
4. *Destination mapping*: Using the ECU enumeration output, the destination mapper will identify the ECUs that correctly receive a given message ID. *CANvas* will isolate a target ECU by performing a shutdown on all other ECUs, which we discuss in §6. Once an ECU is isolated, we inject all unique observed message IDs and determine which ECUs receive the message.

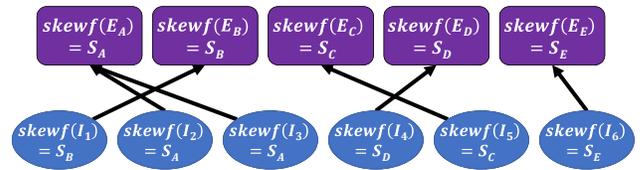

## 5 ID Source Mapping

In this section, we describe an approach to map each CAN message to its source.

**Intuition:** Due to the absence of source information in a CAN message, we must rely on some uniquely identifying characteristic that can be tied to a particular ECU. Following observations from prior work [11, 29] and CAN documentation [2, 14], we consider *clock skew* as a candidate fingerprinting mechanism. In particular, time instants for in-vehicle ECUs rely on a quartz crystal clock [14], and we can use the relationship between these clocks to identify a transmitting ECU. We first define the following terms considering two clocks,  $\mathbb{C}_1$  and  $\mathbb{C}_2$ :

- **Clock frequency:** The number of cycles per true second, e.g. if  $\mathbb{C}_1$  operates at 16kHz, then  $\mathbb{C}_1$  cycles 16,000 times every one true second.
- **Relative clock offset:** The difference in time reported by  $\mathbb{C}_1$  and  $\mathbb{C}_2$ , e.g. if  $\mathbb{C}_1$  reports time  $t_1$  of 4.1ms and  $\mathbb{C}_2$  reports  $t_2$  of 4.2ms, their offset  $O_{\mathbb{C}_1, \mathbb{C}_2}$  is 0.1 ms. Where only one clock is denoted for relative offset, the other clock is the clock of the receiving node.
- **Relative clock skew:** The difference in clock frequencies of two clocks, or the first derivative of offset w.r.t. true time, e.g. if  $\mathbb{C}_1$  operates at 16kHz and  $\mathbb{C}_2$  operates at 16.1kHz, their skew  $S_{\mathbb{C}_1, \mathbb{C}_2}$  is 100Hz. Where only one clock is denoted for relative skew, the other clock is the clock of the receiving node.

Two clocks with a relative clock offset of 0 are consid-

**Figure 6:** *CANvas* aims to cluster message IDs with a similar relative skew or offset.

ered to be *synchronized*, and two clocks with a nonzero relative clock skew are said to “skew apart,” or have an increasing relative offset over time [2]. Since the CAN protocol does not implement a global clock, it is considered to be unsynchronized as each ECU relies on its own local clock.

---

**Observation 1:** *The clock offset and skew of an ECU relative to any other ECU is distinct, thus providing us with a uniquely identifying characteristic for source mapping.*

---

**High-level idea:** To map each unique ID to its transmitting ECU, we break the module into two steps as Figure 6 illustrates: (1) computing either the skew  $skewf(I_i)$  or offset  $offsetf(I_i)$  of each ID  $I_i$  and (2) then clustering IDs with the same skew or offset where each cluster denotes a distinct source ECU,  $E_{src}$ . This module outputs a mapping of source ECUs to their set of source IDs. The main input to this module is a passively-logged CAN traffic dump, which contains entries in the form of  $(I_i, t_{i,n})$  where  $I_i$  is the ID of the message and  $t_{i,n}$  is the timestamp of the  $n^{\text{th}}$  occurrence of  $I_i$ .

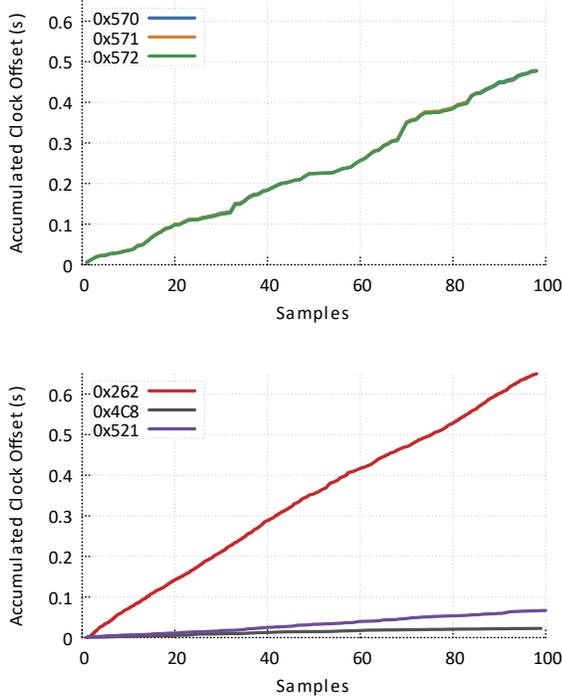

### 5.1 Prior work and limitations

Cho et al. [11] use clock skew as a means of building an intrusion detection mechanism to identify an attack by a malicious ECU. Specifically, this work uses timestamps of periodically-received message IDs and posit that IDs with the same skew originate from the same ECU.

To compute the clock skew of an ID  $I_i$  over time, Cho et al. [11] perform the following steps: (1) compute  $I_i$ ’s expected period,  $\mu_{T_i}$ , (2) compute the offset,  $O_i$ , by subtracting the expected timestamp (using  $\mu_{T_i}$  from the actual timestamp), (3) take the average of  $O_i$  over a batch of  $N$  messages, (4) add  $O_{i,avg}$  to an accumulated offset,  $O_{acc}$ , and (5) then compute the skew,  $S_{I_i}$ , by taking the slope of  $O_{acc}$  versus time. This work uses the Recursive Least Squares algorithm to minimize the errors. After every batch of  $N$  messages,  $O_{acc}$  increases by  $O_i$ , where  $k$  is the  $k^{\text{th}}$  batch. From this plot, since  $O_i$  should be constant, their formula for skew w.r.t. batch size sets  $S_{I_i}$  to:

$$skewf_i^{cho}(N) = \frac{kO_i}{kN} = \frac{O_i}{N} \quad (1)$$

As an extension to this work, Sagong et al. [29] note that the skew of Equation 1 varies significantly based on  $N$  and use

**Figure 7:**  $E_A$  transmits IDs 0x570, 0x571 and 0x572 at the same period and  $E_B$  transmits IDs 0x262, 0x4C8 and 0x521 at different periods. Above are plots of accumulated clock offset vs. samples for  $E_A$  and  $E_B$  using the algorithm by Cho et al. [11].

an updated formula for  $S_{I_i}$  w.r.t. batch size:

$$skewf_i^{Sagong}(N) = N \cdot \frac{kO_i}{kN} = O_i \quad (2)$$

Using data from a real vehicle, we now highlight a key limitation of Equations 1 and 2. Consider Figure 7: (1)  $E_A$  is the source of IDs 0x570, 0x571 and 0x572, which share the same period and (2)  $E_B$  is the source of IDs 0x262, 0x4C8 and 0x521, which each have different periods. In Figure 7, we use  $skewf_i^{Cho}$  with  $N = 20$  to plot the skew of all six IDs;  $skewf_i^{Sagong}$  produces similar results. We can correctly conclude from Figure 7 that the IDs of  $E_A$  originate from a single ECU. However, from Figure 7, we will incorrectly conclude that IDs 0x262, 0x4C8 and 0x521 originate from three separate ECUs. Our analysis and experiments shed light on why these approaches fail—the skew value they compute is *period-dependent*.

As such, we update Equations 1 and 2 w.r.t. period  $T$  and batch size  $N$ :

$$skewf_i^{Cho}(N, T) = \frac{kO_i}{kTN} = \frac{O_i}{TN} \quad (3)$$

$$skewf_i^{Sagong}(N, T) = N \cdot \frac{kO_i}{kTN} = \frac{O_i}{T} \quad (4)$$

To potentially fix this issue, we can attempt a strawman that is not dependent on period or batch size.

$$skewf_i^{Straw}(N, T) = TN \cdot \frac{kO_i}{kTN} = O_i \quad (5)$$

Ideally, accounting for both batch-size and message-period (essentially batch-period,  $NT$ ) using Equation 5 should give us a unique value that is common only among IDs from the same ECU. We apply Equation 5 for all  $I_i$  of a vehicle, and we attempt to establish distinct groupings of the computed skew for each ID,  $S_{I_i}$ , which would identify which  $I_i$  share the same  $E_{src}$ .

Unfortunately, this is a difficult task as  $I_i$  from the same  $E_{src}$  still do not have similar skews. This issue is further demonstrated as  $S_{I_i}$  varies across different data dumps or even segments of a given dump. Upon further inspection, we find that the measured  $S_{I_i}$  is affected by the deviation in an ID’s period. This deviation in the period,  $\sigma_{p_i}$ , is attributed to sources of “noise”, i.e. the period of a given message varies due to scheduling, queuing and arbitration delay. We also find that some  $I_i$  produce  $S_{I_i}$  with more deviation than others and produce widely-varying skew values, thus making our straw-man solution an unlikely candidate for source mapping.

---

**Observation 2:** We need a method of extracting the clock skew invariant that is: (a) independent of the period of  $I_i$  and (b) robust to noise in the period.

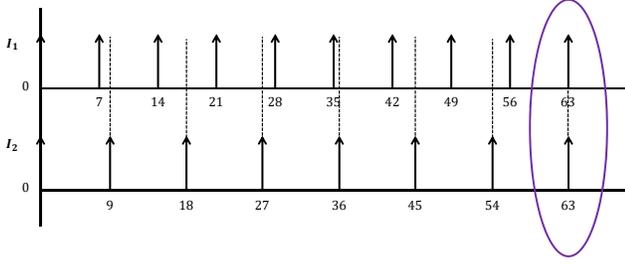

---

## 5.2 Pairwise offset tracking

**Issue with straw-man:** In Equation 5, it is clear that, relative to the receiver, this “skew” function computes offset rather than true skew. Following our definitions in §5, a plot of relative offset over time should either be linearly increasing or decreasing if there is a nonzero skew between two clocks. In other words, if the relative skew between an  $E_{src}$  and the receiver is non-zero, then we should observe a gradual change in the offset. However, previous work [11, 29] fails to capture this change in offset over time.

**Relative offset as a unique identifier:** As mentioned in §5, clock offset and skew of an ECU relative to another ECU is distinct. We must note that the clock offset measured from one ID,  $I_1$ , of an  $E_{src}$  may not be the same as the offset of another ID,  $I_2$ , from  $E_{src}$ . If the initial transmission time of  $I_1$  differs from that of  $I_2$ , the  $O_{I_1}$  could not equal  $O_{I_2}$ . Rather, the invariant here is the *change in relative offset*,  $\Delta O_{I_i}$ ; as the skew of  $E_{src}$  relative to the receiver is a constant nonzero value, the  $\Delta O_{I_i}$  will be a constant nonzero as well (the derivative of offset is skew).

By measuring this change in offset, we can uniquely identify an  $E_{src}$ , but we must ensure our method of extracting this change in offset is (a) robust to a noisy period and (b) period-independent. To address the issue of noise in the period of  $I_i$ ,  $p_{I_i}$ , we compute the relative offset between a pair

**Figure 8: Timeline of two message IDs,  $I_1$  and  $I_2$ , that have periods,  $p_1 = 7\text{ms}$  and  $p_2 = 9\text{ms}$ . Their hyper-period occurs every 63ms.**

of two different IDs denoted by  $O_{I_1, I_2}$ . By performing this computation pair-wise, we expect  $O_{I_1, I_2}$  to have a deviation of approximately 0 if  $I_1, I_2 \in E_{src}$  as the sources of noise for  $I_1, I_2$  should mostly be shared. In reality, this deviation is very close but not exactly equal to 0; we define a practical threshold for this deviation in §7.

With a pairwise approach to computing  $O_{I_1, I_2}$  and the requirement for a period-independent approach, we face a new challenge: determining at what point in time to observe this relative offset regardless of the period of  $I_1$  or  $I_2$ .

---

**Observation 3: Compute offset at the hyper-period of  $I_1$  and  $I_2$ , or the least common multiple of their periods.**

---

**Measuring offset at the hyper-period:** To guide our algorithm design for computing  $\Delta O_{I_1, I_2}$  over time, we first model two periodically-transmitted IDs observed on the CAN bus. Consider two IDs,  $I_1$  and  $I_2$ , from the same  $E_{src}$  which transmit at a period of  $p_1$  and  $p_2$ , respectively. For example, let  $p_1$  be 7ms and  $p_2$  be 9ms. For now, we assume that the relative offset between  $I_1$  and  $I_2$  is 0. This offset should not change over time as they originate from the same  $E_{src}$ . To accurately compute the relative offset of these two IDs,  $O_{I_1, I_2}$ , we must select a time instant when the expected offset should also be 0: the hyper-period of  $I_1$  and  $I_2$ , or the least common multiple of  $p_1$  and  $p_2$ . As seen in Figure 8, this time instant occurs at 63ms, or the  $lcm(7, 9)$ . Therefore, by computing the difference between the times reported from  $I_1$  and  $I_2$  every 63ms, or the hyper-period of  $I_1$  and  $I_2$ , we can track the value of relative offset over time. If this relative offset is a nonzero constant, then the two IDs originate from the same ECU.

With an input of several minutes of timestamped CAN data to Algorithm 1, we can track relative offset over the timeline of two message IDs. Note that each timestamp has a noise component that stems from scheduling, queuing and arbitration delay. To compare whether two message IDs originate from the same ECU, we first assume that they are sent by separate ECUs. The two message IDs,  $I_1$  and  $I_2$ , have periods,  $p_1$  and  $p_2$ , and they have relative offsets,  $O_{I_1}$  and  $O_{I_2}$ . We draw the following relationships between these variables:

---

**Algorithm 1** Pairwise offset tracking

---

```

1: function PAIRWISECOMPARE( $I_1, I_2, \log_{I_1}, \log_{I_2}$ )
2:    $p_1 = \lfloor \text{ComputeAveragePeriod}(\log_{I_1}) \rfloor$ 
3:    $p_2 = \lfloor \text{ComputeAveragePeriod}(\log_{I_2}) \rfloor$ 
4:    $n = \text{lcm}(p_1, p_2) / p_1$ 
5:    $m = \text{lcm}(p_1, p_2) / p_2$ 
6:    $pos_{I_1} = 0, pos_{I_2} = 0$ 
7:    $\Delta_{I_1, I_2} = []$ 
8:   while  $pos_{I_1} < \text{len}(\log_{I_1})$  and  $pos_{I_2} < \text{len}(\log_{I_2})$  do
9:      $\Delta_{I_1, I_2}.\text{append}(\log_{I_1}[pos_{I_1}] - \log_{I_2}[pos_{I_2}])$ 
10:     $pos_{I_1} + = n$ 
11:     $pos_{I_2} + = m$ 
12:   return true if  $\sigma(\Delta_{I_1, I_2}) < \text{threshold}$  else false
13:   end function

```

---

- $p_2 = lp_1$ , where  $l$  is the ratio of the periods.
- $O_{I_2} = jO_{I_1}$ , where if  $j=1$ , then both IDs sent by same ECU; otherwise, they were sent by different ECUs.
- $n = ml$ , where  $LCM(n, m) = l$  as depicted in Figure 8.

By computing the difference between every  $n$  occurrences of  $I_1$  and every  $m$  occurrences of  $I_2$ , which occurs at the *hyper-period* of  $I_1$  and  $I_2$ , we produce the following equation:

$$O_{I_1, I_2} = (mp_2 + O_{I_2} + i_2) - (np_1 + O_{I_1} + i_1)$$

We find that when we average the result of the above equation across the entire data log, the expected value is 0 if  $I_1$  and  $I_2$  originate from the same ECU. In reality, this value is close to 0 due to the deviation of a message's period. From experimental data, we define a threshold of 1ms for the change in relative offset, where a value under the threshold will classify the two IDs with the same source ECU. Using this approach to revisit the setup described in Figure 7, we correctly conclude that IDs 0x262, 0x4C8 and 0x521 originate from the same ECU.

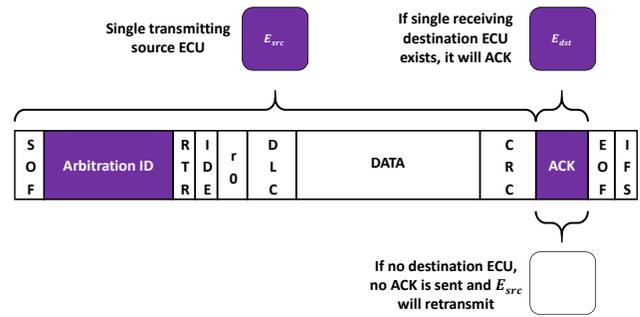

**Practical challenges:** While the above approach is correct, there are a number of other practical challenges we need to address to ensure accurate mapping:

1. *Large hyper-period:* Consider a hyper-period that is “large”, or on the scale of several minutes, e.g. the hyper-period of  $p_1 = 980\text{ms}$  and  $p_2 = 5008\text{ms}$  is over 20 minutes. Since we only extract one relative offset value per hyper-period, we would need hours of CAN traffic to produce a valid result. To ensure that our mapper is fast, this length of traffic log is unreasonable; we want to produce a full network map in under an hour. Fortunately, with a pairwise approach, we can choose to *not* attempt a comparison when the hyper-period is large; for example, if we assume that the  $E_{src}$  of  $I_1$  also transmits another ID,  $I_3$ , where the hyper-period of  $I_1$  and  $I_3$  is small, we can still determine that  $I_1, I_3 \in E_{src}$ .
2. *Large period deviation,  $\sigma_{p_i}$ :* In early experiments, we discovered messages that had a large measured  $\sigma_{p_i}$  (we define

large as  $\sigma_{p_i} \geq 0.1 p_i$ ) and, at first, assumed that these messages were either aperiodic or sporadic (aperiodic with a hard deadline). However, upon closer inspection, we noticed that these messages appeared to be periodic in nature. We observed three different patterns that altered the measured  $\sigma_{p_i}$ : (1) the period simply had a large  $\sigma_{p_i}$ , (2) periodic messages would occasionally stop transmitting for some time, and (3) periodic messages were missing their deadlines. With a large enough  $\sigma_{p_i}$ , the deviation would conceal an inconstant  $\Delta O_i$  and make it difficult to detect a mismatch. We experimentally find that a  $\sigma_{p_i}$  greater than 8% of  $p_i$  results in incorrect outputs. Therefore, *CANvas* will choose to test  $I_i$  on the following cases when its  $\sigma_{p_i}$  is under a defined threshold, which we set to  $\sigma_{p_i} \leq 0.08 p_i$  from our experiments.

3. *Periodic messages that occasionally stop*: We find that some  $I_i$  are periodic and will stop transmitting for some time, causing a measured  $\sigma_{p_i}$  to be large. To combat this issue, we only perform pairwise offset tracking when the given message was actively transmitting. In the event we compare two  $I_i$  that both occasionally stop and there is no overlap of active transmissions, we then rely on our pairwise approach to match the  $I_i$  to another ID from the same  $E_{src}$ .
4. *Messages that miss deadlines*: For some  $I_i$  with a large  $\sigma_{p_i}$ , we observe two different inter-arrival times:  $p_i$  and  $2p_i$ . When a task on one of the ECUs misses its deadline and cannot produce a message on time, it will skip that cycle and transmit during the next cycle [2]. Thus, when a deadline is missed, we will observe an inter-arrival time of  $2p_i$ . In this situation, there are two options: (1) perform relative offset tracking on portions of the log when deadlines are not missed or (2) interpolate the missed inter-arrival times. If a message frequently misses its deadline, the first option is not viable. To interpolate a missed arrival time, we insert a pseudo-entry in the traffic log with a timestamp equal to the average of the preceding and the following timestamp.

**Factors for mapping time:** For source mapping, we experimentally find that 30 minutes of data provides enough samples for larger hyper-periods to map accurately. While this stage has static run-time, the variation in time requirements will be dependent on the number of observed messages IDs. The more message IDs that exist in the network, the longer the mapping time takes; vehicles with more message IDs take longer to complete mapping due to an increase in message-pairs. However, to further reduce mapping time, mapping messages with small periods requires much less traffic data. To save additional time if necessary, it is recommended to reduce the traffic log length for high-frequency messages. Also, if there are few large periodic messages or if those messages are not relevant for whatever reason, the length of the initial traffic log can be reduced as necessary instead of the recommended 30 minutes.

**Figure 9: Observing ACK bit with single ECU in network.**

## 6 ID Destination Mapping

The goal of the destination mapping module is to accurately associate each ID with its set of receiving ECUs. The key consideration here is to maximize the accuracy of our mappings within our defined time constraint. In this section, we describe an approach to map each CAN message to one or more destination ECUs as defined in §4 and then present a systematic procedure that reliably determines which messages an ECU correctly receives.

### 6.1 Problem formulation

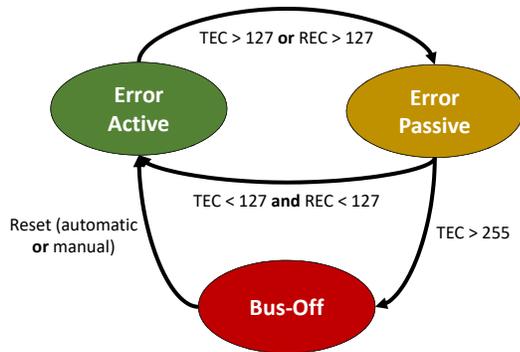

**Intuition:** As defined in §4, the destination(s) of a particular CAN message are those ECUs who correctly receive a given message. Despite the broadcast nature of CAN, if an ECU does not correctly receive a message, it will not set the ACK bit; however, if other ECUs receive this message, they will set the dominant ACK bit. Unfortunately, an ACK observed by the transmitting ECU only means that *some* active ECU correctly received the message. Therefore, with multiple active ECUs in the network, we cannot identify which ECUs were the destination for a given message.

Consider the scenario in Figure 9 where there was only one active destination ECU,  $E_{dst}$ , in the network other than the transmitting source ECU,  $E_{src}$ . For each message sent by  $E_{src}$ , a set ACK bit (performed only by  $E_{dst}$ ) would indicate that only one ECU received the message:  $E_{dst}$ . Thus, in this scenario,  $E_{src}$  could simply inject all possible  $I_i$  and detect which messages have a set ACK bit. The major challenge here is identifying a method of isolating an  $E_{dst}$  and “removing” all other ECUs from the network. We define the bare minimum of “removal” as preventing an ECU from participating in the acknowledgement process.

---

**Observation 4:** *Our idea for performing this removal is to transition an ECU into an error-state that prevents it from setting the ACK bit for any message.*

---

**Figure 10: CAN transitions between three error states: error-active, error-passive and bus-off.**

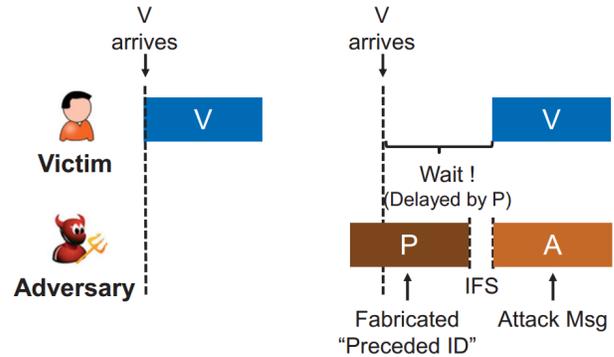

We now introduce the error-handling mechanism for CAN [2, 10], which follows the state diagram in Figure 10. Each ECU has two error counters: one for errors detected as a receiver (the Receive Error Counter, or REC), and another for errors detected as a transmitter (the Transmit Error Counter, or TEC). The TEC increments much faster than the REC as the transmitter is more likely to be at fault; the TEC increments by 8 while the REC increments by 1. If a message is received correctly, the error counter will decrease by 1. We describe the three CAN error-states and, under what conditions, the ECU will transition:

- **Error-active:** When an error is detected by an ECU in error-active, it will transmit an active error flag, or 6 dominant bits, that destroy the bus traffic. When either the TEC or REC increments past 127, the ECU transitions to error-passive.
- **Error-passive:** When an error is detected in error-passive, the ECU transmits a passive error flag, or 6 recessive bits, that do *not* destroy the bus traffic. Once the TEC or REC increases above 255, the ECU goes to bus-off.
- **Bus-off:** In this state, the ECU effectively removes itself from the network; it will not transmit anything onto the bus, including setting the ACK bit.

Thus, it is evident that we can isolate an ECU by transitioning all other ECUs to the bus-off state.

## 6.2 Limitations of prior work

**Imposing bus-off state:** The challenge in transitioning an ECU to bus-off is to determine what kind of error to produce and how to produce it. We look to previous work [10] that aims to shutdown an ECU for the purpose of an attack. The authors aim to shutdown an ECU by causing an error in the target ECU. By exploiting the error-handling protocol in CAN, where bus-off effectively removes an ECU from the network, they choose to increment the error counter of a target by causing a bit error. This error occurs when a transmitting

**Figure 11: Injecting a fabricated message to impose a bus-off [10].**

ECU reads back each bit it writes; when the actual bit is different, the ECU invokes an error.

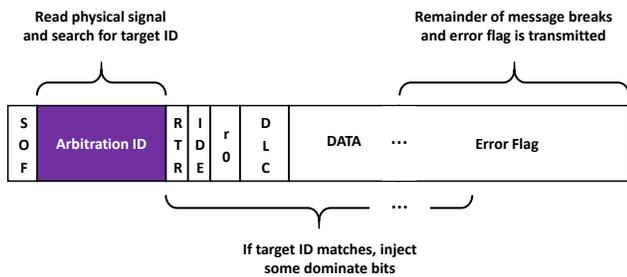

Since only one ECU is expected to win the bus arbitration as detailed in §2, the authors point out that two winners would potentially cause a bit error. For example, suppose that the victim ECU transmits a message with ID 0x262. If the attacker ECU also transmits ID 0x262 at the exact same time as the victim, both ECUs will win arbitration. However, to ensure that the victim has a bit error, the attacker’s message will set its DLC, or data length count, to 0 (most practical messages contain at least some data). After a sufficient number of these attack messages, the victim ECU will transition into the bus-off state.

The main challenge here is synchronizing the attack message with the victim message so they both enter arbitration simultaneously. Their insight as depicted in Figure 11 is to inject a message of higher priority around the time when the victim should transmit. The higher priority message will block the victim until the bus is idle, where it will then transmit. The attacker will load its attack message immediately after the higher priority message is transmitted, thus allowing both the victim and attack message to arbitrate simultaneously. Since there is noise in the true transmission time of the victim’s first attempt at transmitting, there is a chance that the attacker will need to make multiple attempts to cause an error. The number of injection attempts needed to cause a single bit error,  $\kappa$ , is defined as the following where  $\mathbb{I}$  is a confidence attack parameter (high parameter value means higher confidence in attack),  $\sigma_{p_v}$  is the jitter deviation of the victim’s period, and  $S_{bus}$  is the speed of the bus in Kbps:

$$\kappa = \left\lceil \frac{2\sqrt{2}\mathbb{I}\sigma_{p_v}S_{bus}}{124} \right\rceil \quad (6)$$

The authors state that only one of these injections is needed to cause a bit error if setting  $\mathbb{I} = 3$  and at most 2 if setting  $\mathbb{I} = 4$ , given that the period deviation is 0.025ms.

**Straw-man limitations:** Suppose we used the above ap-

**Figure 12: CANvas identifies target message by end of ID field and injects dominant bits during the DATA field.**

proach to cause a bus-off in a real vehicle. Unfortunately, in sample traffic dumps from two real vehicles, the smallest deviation that we observed was approximately 0.15ms. Using the equation given by Cho et al. [10], the number of preceded message injections per error is 8 when the period deviates by at least 0.205ms; if 8 injections are required, any successful bit error would be undone by successful message transmissions. We look at available traffic logs used in the works by Miller et al. [24]. For this traffic log, the majority of the messages have a period deviation over 0.205ms. In other words, assuming the best case scenario of 0.15ms, we would need to inject at least 6 higher-priority messages, or preceded messages, for a bus speed of 500Kbps. Considering that each successful transmission by the victim ECU decrements the TEC by 1, we would effectively only increase the TEC by 2 with each successful attack (instead of the expected 8). Since the majority of messages have a period deviation greater than 0.205ms, it is highly unlikely to use this method for isolating an ECU.

---

**Observation 5: We need a method of transitioning an ECU into the bus-off state that is reliable and robust even when the period deviates by more than 0.025ms.**

---

### 6.3 Forced ECU isolation

**High-level idea:** To map each unique ID to its set of destination ECUs, we break the module into two steps. We repeat these two steps for all  $n$  ECUs in the network. The first step is to isolate the target ECU and shut off all others by transitioning the non-target ECUs to the bus-off state. As there are  $n$  ECUs in the network, we will need to “bus-off”  $n - 1$  ECUs for each ECU, i.e. we will need to perform the bus-off at least  $n(n - 1)$  times. Once we isolate an ECU, we then inject the set of all  $I_i$  and observe which messages have a set ACK bit, thus identifying the set of  $I_i$  where the target ECU is an  $E_{dst}$ .

**Inducing a direct bit-error:** Isolating an ECU via the bus-off method requires a quick and effective approach. Since we are not limited to operating through the interface of a CAN controller, we can directly view the CAN frames in real-time via digital I/O pins. However, since we are using

a microcontroller that operates at the same voltage of the CAN controller, we do not operate at the true CAN voltage. Instead, we tap directly between the interface of the Arduino’s CAN controller and the CAN transceiver, where we can safely access the bus data. At this junction, we observe that the data on the line is within the Arduino’s voltage and contains the full data frame, including SOF, ACK and EOF bits. With this access to the full data frame rather than just the components of the CAN message, we can directly induce an error on the bus and thus achieve the bus-off attack as seen in Figure 12.

---

**Observation 6: By reading the ID of the message in real-time, we can choose to attack any ID by simply driving a dominant bit to the CAN transceiver.**

---

Note that the bus-off method requires attacking a message ID every time it occurs until the ECU enters the bus-off state. However, in the event that a message has a very long period, the time to perform the bus-off will not satisfy our speed requirement. As such, we can employ the result of CANvas’ source mapping component by identifying the ID with the smallest period per ECU and attacking just that ID. In practice, we have found that every real ECU we have encountered has at least one ID that operates under 100ms. Thus, this approach makes the destination mapping component of CANvas fast.

**Determining message receive filter:** Now that we can isolate a single ECU in the network, we can simply inject all messages in the observed ID space and determine which messages are correctly received by the ECU. However, to view the ACK bit at the network level, which is not visible to the user, the obvious option is to use a logic analyzer. As this does not satisfy our requirement for low-cost mapping, we seek an alternative. We observed that if a message is sent to a single ECU and it does not correctly receive the message, the transmitter will re-attempt to send the message until it is received correctly. As such, if we transmit a message and see a continuous stream of the same ID from our transmitter, then we may conclude that the message ID is not received by the isolated ECU.

**Practical challenges of mapping a real vehicle:** Since our approach to destination mapping involves shutting off multiple ECUs at a time, we encounter a couple of challenges in a real vehicle setting: (1) ECUs that auto-recover and (2) ECUs that are persistently active. We now define these scenarios and provide a detailed approach to addressing these practical challenges:

1. *ECUs that auto-recover:* In our earlier experiments, we performed a simple experiment to verify the potential of an isolation method. We attempted to transition all ECUs in the network to the bus-off state by shorting the CAN bus pins, which would effectively cause a transmit error for all ECUs and force them into bus-off. However, after removing the short, we saw that some CAN messages were still transmitted onto the network, clearly indicating that some

ECUs left the bus-off state. We find that these ECUs would wait a predefined amount of time before re-transmitting again as these ECUs were critical to the vehicle’s power-train (engine, hybrid, etc.) [14]. In this situation, we would transmit a portion of the injected messages onto the bus and then re-isolate our target ECU when a non-target starts to transmit again. This approach is only reasonable for recovery times on the scale of seconds.

2. *ECUs that are persistently active:* Out of the set of ECUs that did auto-recover, we also noticed that one ECU seemed to be persistently active. In other words, there appeared to be no delay between a transition into the bus-off state and the next transmission from the ECU. Upon closer inspection, we found that this ECU would auto-recover only after 128 occurrences of 11 recessive bits [27]. In this situation, we must “hold” the bus open by constantly transmitting false messages from our device to trick the recovering ECU into thinking that the bus is still active.

**Factors for mapping time:** For destination mapping, the run-time is dependent on the number of ECUs and increases with more ECUs. We acknowledge the potential of long run-times for vehicles with 70+ ECUs if all were CAN-enabled. To combat this, we suggest performing the bus-off on the ID with the smallest period per ECU to reduce the time attributed to achieving ECU isolation. Also, for our two vehicles, all observed IDs were active when the vehicle was simply in ACC rather than ON so there may be no need to crank the engine per ECU.

## 7 Evaluation

In this section, we show that *CANvas*:

1. identifies an unexpected ECU in a ‘09 Toyota Prius,
2. identifies lenient message-receive filters in a ‘17 Ford Focus,
3. produces a sound source mapping of two real vehicles and accurately identifies the source of approximately 95% of all  $I_i$  in the network and a complete destination mapping with an isolation technique that is 100% reliable,
4. successfully demonstrate our forced ECU isolation on three extracted ECUs,
5. and produces source mapping of three additional vehicles.

**Setup and methodology:** Our experimental setup includes five real vehicles and several synthetic networks to demonstrate the above benefits. Below is a brief description of the *CANvas* hardware implementation, five real vehicles and our synthetic network of real ECUs:

- *Mapping device:* To interface with a CAN bus, our mapping device consists of three components: an Arduino Due microcontroller with an 84 MHz clock and an on-board CAN controller, a TI VP232 CAN transceiver, and a 120Ω resistor. To gain direct write access to the bus for destination mapping, we connect a digital I/O pin to the driver input pin of the transceiver.

- *‘09 Toyota Prius and ‘17 Ford Focus:* The Prius contains eight original ECUs that transmit on a single CAN bus at 500 kbps. The Focus contains eleven original ECUs that transmit on three CAN buses at varying speeds; as our model of the Focus is the standard edition, only the high-speed 500 kbps bus has more than one active ECU. We obtain ground truth for our experiments by physically taking apart the car and gaining direct access to the ECUs by splicing directly into the CAN wires as seen in Figure 13. We use a paid subscription to both Toyota and Ford’s mechanics’ manuals [3, 6] for guidance on disassembly of vehicle components. Due to the non-destructive design of *CANvas*, our interaction does not impose any permanent errors to the vehicle.
- *‘08 Ford Escape, ‘10 Toyota Prius and ‘15 Ford Fiesta* We obtain CAN traffic from three additional vehicles for testing only our source mapper, as we did not have permission to inject data. We use data from the ‘09 Prius and ‘17 Focus to partially confirm our source mapping output without disassembling these vehicles.
- *Synthetic networks:* To further validate the capability of our mapper, we perform additional experiments on three real engine ECUs extracted from a ‘12 Ford Focus, ‘13 Ford Escape and ‘14 Ford Escape.

### 7.1 Discovering an unexpected ECU

We now describe a real scenario where, in the process of designing *CANvas*, we discovered an unexpected ECU in our Prius. Using the results of our source mapping on the ‘09 Prius as seen in Table 2, we noticed that there were a total of nine ECUs when only eight were expected. Even after manually disconnecting all eight known ECUs, we still observed CAN traffic, specifically IDs  $I_{570-572}$ , coming from a single ECU. By looking at the history of the vehicle and systematically disconnecting various systems, we discovered that this ECU was installed as part of a modification from several years ago. The Prius had an additional battery installed to grant it all-electric capabilities, and with the use of the network mapper, we now know that a new CAN-enabled device was added. If we took a network map of the vehicle when first purchased or used an online database as mentioned in §2, we could easily compare our results with published results and identify the unexpected ECU. We confirm that these IDs are new by comparing our IDs to a same-generation Prius [23].

### 7.2 Identifying lenient filters

As detailed in §2, a real concern for network security is the ability to shut-down an ECU by simply receiving the target’s CAN messages. Using the results of *CANvas*’ destination mapping, we can identify several instances where an ECU is expected to only receive messages from a subset of other ECUs but still receives all other messages. We have found that all ECUs in the Focus and Prius do not employ any filter on the receipt of incoming messages. In Ford’s Motorcraft TechInfo

I	570, 571, 572	<i>Unknown ECU</i>

**Table 2: 2009 Toyota Prius source mapping output**

Service [3], we can see simple diagrams of how the ECUs communicate as part of the vehicle’s systems. For example, the Focus’ braking system involves communication between the instrument panel cluster, the transmission ECU, the body control ECU and the engine ECU. Now suppose an attacker takes over the infotainment unit of the Focus, has complete access to rewrite the ECU’s code and gains the ability to inject CAN messages as described in §2. The attacker can launch a bus-off attack and shut-down the transmission ECU simply because the infotainment ECU receives its messages. It is evident that these devices need filters on what messages are received by their CAN controllers.

### 7.3 Mapping our test vehicles

We now present results and observations from mapping both the Prius and Focus.

**Source mapping results:** Using a threshold of 1ms and 30 minutes of traffic collection, we get a false positive rate of 0% for both vehicles, permitting us to get a sound source mapping output. Out of a total of 59 unique message IDs, our pairwise timing comparison resulted in 102 matching pairs for the Prius. By performing a simple grouping of these pairs as detailed in §5, we get the output as seen in Table 2. While the majority of the IDs observed on the Prius have a strong periodic characteristic, we discuss some special cases we encountered. Most of the messages were under five seconds except for  $I_{57F}$  with a period of 5 seconds and  $I_{602}$  with a

period of 60 seconds. The majority of our messages matched with multiple IDs from the same ECUs but due to the large period of  $I_{57F}$  and  $I_{602}$ , they only had a single match. However, due to our pairwise approach, we can still map these two IDs using a shared matching pair as discussed in §5. We also encounter a few examples of messages that miss their deadline and wait until the next cycle to re-transmit. For the Focus, we observe messages that miss their deadlines and either transmit two messages on the next cycle or drop the missed message and wait for the next cycle. In these cases, we simply remove the inter-arrival times that exceed two standard deviations from the average period and interpolate for the removed timestamps as discussed in §5.

**Destination mapping results:** With a CAN bus running at 500 kbps, we discover that all of the ECUs in the Prius do not implement any filtering between the network and the CAN controller. When each ECU is isolated, we see that all IDs are properly acknowledged by the receiving ECU. We do observe two ECUs that recover quickly from the bus-off method, specifically the engine control module and the skid control ECU. With the other ECUs in the vehicle, it was sufficient to perform our bus-off once and the ECU would stop transmitting. For these two ECUs, we selected the smallest period ID and held the bus open by injecting false messages to keep the two ECUs from auto-recovering. Additionally, we discovered that the Focus also do not implement any sort of filtering for the IDs we observe on the CAN. From these

findings, we can conclude that attacking via the reception of a message for these vehicles could prove trivial due to the lack of filtering between the network and the controller. In general, the maximum number of manual transitions of the ignition switch is equal to the number of detected CAN-enabled ECUs in the vehicle. For the keyless ignition of the 2009 Prius, we transition the ignition 7 times as two ECUs recover on their own (the Prius has 9 total CAN-enabled ECUs). For the keyed ignition of the 2017 Focus, we transition the ignition 7 times as two ECUs recover on their own (the Focus has 9 total CAN-enabled ECUs).

## 7.4 Mapping additional vehicles

**Mapping real extracted Ford ECUs:** We also obtained three Ford engine ECUs from a '12 Focus, '13 Escape and '14 Escape. By collecting data from these three ECUs, we found that they shared the many of the same message IDs and conclude that they are based off of the same engine controller configuration. As they all auto-recover, they were prime candidates for testing our forced ECU isolation technique.

We use *CANvas* on three other vehicles to look for data that seems logical to our findings from the test cars. For the Ford vehicles, we look for similarities with our extracted engine ECUs. For the '08 Escape, we found a set of IDs that we believe is the engine ECU and only has a subset of those found on our extracted ECU. For the '15 Fiesta, we also found a likely candidate for an engine ECU that has more IDs than our extracted ECUs. Since these vehicles range over three different Ford generations, it seems logical that the newer engine ECUs transmit more IDs. Additionally, we find a few similarities between the '09 and '10 Prius. We found an ECU on the '10 that is likely to be the skid control ECU, which has similar IDs to the '09 Prius. These findings potentially demonstrate *CANvas*' source mapping capabilities.

## 8 Discussion

**Adversarial evasion:** For *CANvas*' source mapping, an adversary could attempt to modify the timestamps to trick *CANvas* into thinking that a pair of IDs originate from the same ECU when in fact the opposite is true, and vice versa. We acknowledge that an attacker who aims to spoof IDs from an implanted or compromised ECU breaks the assumption for message-source analysis. If the attacker performs an active attack (i.e. attack occurs during data capture) or simultaneously transmits with the spoofed ECU, then IDSes from several previous works could detect such an attack and thus we did not perform such experiments. *CANvas* instead could discover ECUs that do not actively inject messages but rather change the ID-ECU source mapping (a new ECU or existing ECU that sends different IDs). We also make the assumption that ECUs do not intentionally alter their timing due to the challenges that arise from scheduling real-time embedded systems. There are numerous challenges that automakers already face in achieving reliable and robust scheduling for their vehicles

and any modification to the timing of CAN messages would add a great amount of complexity to the already complex challenge of scheduling. Additionally, as our destination mapping approach deals with the error-handling mechanism, it would also not be practical to change these basics of CAN.

**Avoiding permanent damage:** We take care to avoid any damage to our test vehicles. Even with our active interaction with the bus in destination mapping, most dash lights that turn on are simply reset by power cycling the car; it may sometimes be necessary to drive the car for a few minutes so the ECUs can identify the absence of a real error. After mapping, all of our vehicles operate with no error codes once the above steps have been followed. Sometimes, a persistent Diagnostic Trouble Code may exist in the network as indicated by the Malfunction Indicator Light (MIL, commonly known as a "check engine light"). To remedy this, a simple OBD-II scan tool can be used to reset these lights with no harm to the vehicle. In the event of network communication failure (e.g. bus-off), manufacturers implement a "limp-home" mode where ECUs will default to secondary programming and allow the vehicle to operate with limited capabilities [7]. It is possible for the CAN bus to be shorted (effectively causing a bus-off on all ECUs) during faults, repairs, etc. so this mode protects the vehicle from our methods. In our experiments, the engine did not need to be running as all ECUs became active with the ignition at ACC. However, this may not apply to all vehicles so it is possible that the ignition will need to be ON.

**Multiple CAN buses:** For the typical OBD-II port, the CAN bus uses pins 6 and 14 on the connector. While many vehicles only have one CAN bus using these pins, it is possible for additional CANs to exist. These CAN buses may not be connected and they may employ different bus speeds. Sometimes, vehicles may also employ a gateway which handles how and which messages are passed between the various buses for reasons of fault confinement and network security. These CAN buses are often accessible at the OBD-II port but on different pins that are vendor optional: pins 3 and 11 and pins 1 and 8/9. In the case that a CAN bus is not exposed to the OBD-II, it is possible to access this bus by simply removing the door panel of a car and accessing the connector between the door assembly and the car body. This connector will likely contain the unexposed bus, which can be discovered as suggested by others [30].

**Message acceptance filtering:** CAN controllers have the option to employ a programmable acceptance filter where a message that is received by the controller can either be sent to the application layer or dropped after the message is received. It is possible to define message destination as a message that is "accepted" by an ECU rather than correctly received. This definition provides finer granularity on message destination and can prove useful for many other security scenarios; however, to identify what messages are accepted by an ECU, this

may require vendor-specific methods. For example, in our experimental setup, we enable a CAN protocol feature called the overload frame [32]. If a vendor chooses to enable this feature, an accepted message can be determined by flooding the bus as fast as possible with a given message ID. When the receiving ECU gets behind on processing these messages, it will transmit an overload frame, indicating its acceptance filter allows the injected message ID; if the ID is dropped, then no overload frame will be present.

**Non-transmitting ECUs:** *CANvas* expects ECUs to transmit their messages periodically, but it is possible for ECUs to only activate under certain conditions or simply read from the network. As all ECUs that receive messages but have the ability to write to the network must participate in the ACK process, *CANvas*' forced ECU isolation technique can be used to identify the presence of a non-transmitting ECU. *CANvas* should detect these ECUs prior to starting to ensure that the detected ECUs do not interfere with destination mapping.

## 9 Related Work

We already discussed several of the key related work with respect to source and destination mapping. We discuss other related efforts here.

**Automotive attacks:** There have been a number of efforts at demonstrating vulnerabilities of automotive networks, including work on injecting messages [20], attacking keyless entry systems [8, 16, 28], and specific components such as TPMS [17, 18]. Our work can better inform such attack efforts and defenses by proactively identifying possible attack channels.

**Intrusion detection for automotive:** Given the growing security concerns, related work has also developed intrusion detection and firewall capabilities akin to traditional networks (e.g., [11, 19, 22, 29, 31]). Some of these may interfere with mapping efforts. More generally, however, these may have blind spots that a network mapper can highlight.

**Alternative source identification:** We acknowledge previous efforts that aim to identify message sources [12, 27]. While these efforts may prove valid, they either require many hours of data or require physical access to the bus for just source mapping. *CANvas* permits source mapping using a passively-recorded timestamped traffic log.

**Authentication in CAN:** We acknowledge that authentication for CAN devices may implicitly solve the source mapping problem. However, proposed authentication methods are rarely employed in real vehicles due to either the permanent addition of new devices or changes to the existing CAN protocol. Prior work, such as the TCAN system [5], requires the addition of a new device, access to two locations on the bus and a static authentication table. *CANvas*, however, acknowledges that timing characteristics can and will change due to clock drift. By comparing clock offsets, *CANvas* does not rely on static timing characteristics. *CANvas* does not even

need physical access to the bus for source mapping as we only require a hardware-timestamped traffic log, and we operate solely from the OBD-II port without an additional permanent device.

**Other work on ECU fingerprinting:** Following initial efforts on fingerprinting [14, 27], other work has improved on their basic approach by identifying potential pitfalls [11, 12, 29]. As we show in our work, all of these still suffer from the same limitations in our context as they still assume either active access to the bus or very long traffic dumps.

## 10 Conclusions

In this work, we develop *CANvas*, a fast and inexpensive automotive network mapper. We have released our code and data under open-source licenses to enable further work in this area. A natural direction of future work is to add richer functionality, e.g. identifying the function of an ECU (transmission ECU, engine ECU, etc.), identifying gateway ECUs that potentially bridge multiple CAN buses and identifying vendor-specific message acceptance filters. Future work should also investigate network mapping on other automotive protocols, e.g. automotive Ethernet.

## Acknowledgements

This work was funded in part by the PITAXVIII PITA award and the CNS-1564009 NSF IoT award. We gratefully acknowledge support from Technologies for Safe and Efficient Transportation (T-SET) University Transportation Center. This work was also supported in part by the CONIX Research Center, one of six centers in JUMP, a Semiconductor Research Corporation (SRC) program sponsored by DARPA. We thank the anonymous reviewers and our shepherd Konrad Rieck for their helpful suggestions.

## Availability

This work is made available [1] to encourage the community to add richer functionality and use *CANvas* to further the creation of automotive security tools.

## Abstract

Electric vehicles (EVs) are proliferating quickly, along with the charging infrastructure for them. A new generation of charger technologies is emerging, handling more sensitive data and undertaking more complex interactions, while using the charging cable as the communication channel. This channel is used not only for charging control, but will soon handle billing, vehicle-to-grid operation, internet access and provide a platform for third-party apps — all with a public interface to the world.

We highlight the threat posed by wireless attacks on the physical-layer of the Combined Charging System (CCS), a major standard for EV charging that is deployed in many thousands of locations worldwide and used by seven of the ten largest auto manufacturers globally. We show that design choices in the use of power-line communication (PLC) make the system particularly prone to popular electromagnetic side-channel attacks. We implement the first wireless eavesdropping tool for PLC networks and use it to observe the ISO 15118 network implementation underlying CCS, in a measurement campaign of 54 real charging sessions, using modern electric vehicles and state-of-the-art CCS chargers. We find that the unintentional wireless channel is sufficient to recover messages in the vast majority of cases, with traffic intercepted from an adjacent parking bay showing 91.8% of messages validating their CRC32 checksum.

By examining the recovered traffic, we further find a host of privacy and security issues in existing charging infrastructure including plaintext MAC-layer traffic recovery, widespread absence of TLS in public locations and leakage of private information, including long-term unique identifiers. Of particular concern, elements of the recovered data are being used to authorise billing in existing charging implementations.

We discuss the implications of pervasive susceptibility to known electromagnetic eavesdropping techniques, extract lessons learnt for future development and propose specific improvements to mitigate the problems in existing chargers.

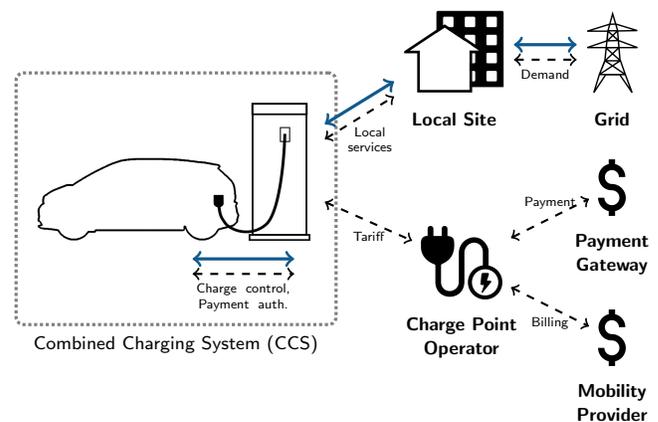

Figure 1: Overview of EV charging with V2G and payment options shown. Solid, blue lines indicate power flow whilst dashed, black lines indicate communication.

## 1 Introduction

The rise of electric vehicles (EVs) as a contemporary and future transport mechanism has been swift in recent years and continues to accelerate, helped by prevailing attitudes, technological advances and notable personalities contributing in the area. There are already widespread government plans to eradicate fossil-fuel vehicles in cities [61], states [28] and countries [9] in the coming years.

As EV technology advances rapidly, the availability of charging infrastructure has become a challenge for users, who require access both to private charging points at home and public ones on longer journeys. The lack of sufficient charging points is noted as a slowing influence on adoption of electric mobility [62] and this has prompted endeavours to expand the infrastructure, both from governments recognising the potential public good and from competing EV manufacturers who understand that having the best infrastructure makes their vehicles more appealing to purchasers. There are already multi-billion dollar public deployment plans in

progress [18] and predictions of worldwide numbers exceed 50 million chargers by 2025 if private systems are included [2].

With several major charging standards in existence, the race to become the dominant one has reached a fervour in recent years and a new generation of high-power charging systems has emerged. But the pressure to achieve rapid expansion has so often been seen to inhibit secure implementation. Users demand charging systems that are consistent and convenient, but with such drive for the adoption of electric mobility, it is critical that they are also secure. The security community has raised concerns in the past that standards do not fully address security and privacy issues [4, 8, 72], as well as noting vulnerabilities in back-end and payment systems of earlier charging system deployments [35, 19].

Meanwhile the complexity of developing all the infrastructure required for a secured charging network is enormous. As Figure 1 shows, vehicle charging involves interaction between the vehicle, the owner, the charger operator, a payment gateway and the grid regulator. This requires establishing communication links capable of supporting the higher-level protocols for this interaction, within a dynamic and untrusted environment, where many thousands of users come and go. It also necessitates trust relationships between all the participants to ensure each is acting legitimately.

In light of the challenges this infrastructure development faces and the acknowledged side-channel vulnerabilities that exposed cabling presents, we undertook to investigate the security of the charging cable communication.

We make the following specific contributions:

1. *Demonstrate that the use of powerline communication, and its specific configuration in CCS, makes systems particularly vulnerable to EM eavesdropping*
2. *Develop an eavesdropping system for HomePlug GP and the ISO15118 PHY-layer*
3. *Conduct a real-world measurement campaign, demonstrating the widespread nature of the problem*
4. *Highlight the potential for privacy violation and user tracking with existing systems*
5. *Propose countermeasures to mitigate the capabilities of an eavesdropper*

Our findings are relevant to thousands of chargers across Europe and North America [29, 67], along with having implications for ongoing deployments both in public locations and private homes.

## 2 Background

The availability of EV charging infrastructure is growing enormously. Early, simple alternating-current chargers are

being superseded by a new generation of charging technologies that provide greater charging power and advanced functionality. The greater power is provided by the use of direct-current (DC) charging, allowing an enormous increase in current delivery over previous alternating-current designs. Public DC charging stations currently well exceed the 3kW power levels commonly available in a home, with 50kW supplies plentiful and those providing up to 350kW soon to appear [30][38]. But the improvements in *power* are only part of the benefit of this new generation of technologies. The *communication* capabilities are also vital to enable a host of new uses:

**Reactive charging** allows a vehicle to vary its charging process based on electricity price or expected time of departure.

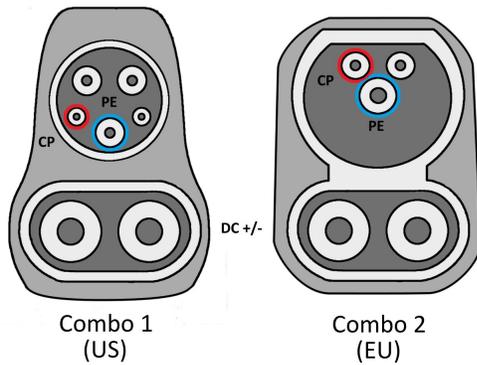

**Automatic billing** or “plug-and-charge” allows a vehicle to authorise billing of its owner for charging, without the owner explicitly interacting with it. Aside from the obvious convenience benefit, the same capability also allows the user to ‘roam’ between charging providers with a seamless experience as cross-provider billing is handled automatically as well.

**Vehicle-to-Grid** (V2G) makes use of bidirectional power flow to allow the vehicle to deliver energy as well as consume it. As energy prices fluctuate with demand, the vehicle can either act as a storage battery for a user’s home or sell energy back to the grid on demand. This can bring economic benefits for the user and stability improvement for the grid operator.

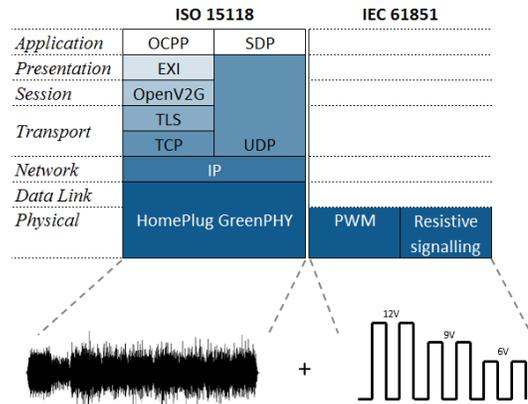

**External payment** is commonly provided by RFID cards [19], apps that communicate with the charger separately or card payment terminals. Additional systems exist though, for payment through separate providers or via a blockchain network [64, 74, 6, 26].

**Additional services** that operate in conjunction with charging are proposed [47]. In a private environment this might comprise access to the local network to communicate with smart-home devices or make use of domestic internet service and avoid mobile network charges. At public charging stations site-specific services such as loyalty schemes, to-vehicle delivery, parking charges or ‘where-have-I-parked’ reminders can operate, with middleware layers to support an app ecosystem in commercial development [22]. Internet access can also be made available for connected vehicles in areas without mobile network coverage, such as underground parking complexes.

Examples of each are in production use and deployment is

(a) Two charging cables are used by CCS. The Combo 1 and Combo 2 plugs are dominant in the US and Europe respectively, while other locations adopt one or the other. DC power is delivered by the large conductors at the bottom of the plug, meanwhile communication happens over the Control Pilot and Protective Earth lines (red and blue, respectively).

(b) CCS high-level and low-level signalling share the same communication lines. The corresponding ISO 15118 PLC and IEC 61851 systems have their signals superposed at the physical layer. The PLC provides a standard IP stack for use by charging traffic and other services.

Figure 2: Illustrations of the physical connectors for CCS charging, along with the network stack used for communication.

becoming more widespread. The underpinning communication mechanisms go beyond indicating presence and readiness to charge, also providing a general-purpose channel for software operating in the vehicle and charger. Figure 1 shows the potential extent of communication during charging. The vehicle can demand current flow, the charger can provide tariff information for reactive charging or reverse current demands for vehicle-to-grid, and the two can interact with external parties for automatic billing or to provide additional services.

Four major next-generation charging systems exist: CHAdeMO<sup>1</sup>, Supercharger<sup>2</sup>, GB/T 20234<sup>3</sup> and the Combined Charging System (CCS)<sup>4</sup>. Each uses the charging cable for primary communication: CHAdeMO, Supercharger and GB/T 20234 make use of CAN-Bus, whilst CCS makes use of powerline communication (PLC).

We examine the CCS standard as it has the most extensive, current functionality (supporting reactive charging, automatic billing and additional services) and has been adopted by seven out of the ten largest automobile manufacturers by production numbers [57]. In addition it is being integrated by competing manufacturers, such as Tesla [42].

## 2.1 Combined Charging System (CCS)

The Combined Charging System (CCS) is an amalgamation of standards governing all physical and logical elements of the charging infrastructure; from the physical connector to

the protocols for automated billing. Figure 2a shows the charging plug, while Figure 2b illustrates the communications undertaken. The communication between vehicle and charger is standardised as ISO 15118. This uses powerline communication (PLC) over the Control Pilot (CP) and Protective Earth (PE) lines of the charging cable. The PLC shares the lines with the older IEC 61851 signalling system for backwards-compatibility reasons, with the signals superposed at the physical layer. The specific PLC implementation is HomePlug GreenPHY (HPGP) [5], a derivative of the commonplace broadband LAN technologies sold to consumers, that has been modified to support pairing between devices with no pre-shared key, and to be more robust to noise. Atop the PLC, ISO 15118 communication provides a full IP stack to act as the general-purpose channel. The same standard also defines interactions for identification, authorisation, tariff provision and control. Communication persists throughout the duration of charging and allows charge parameters to be varied quickly.

CCS provides reactive charging by allowing a charger to present current and future tariff information to the vehicle, which can then make charging requests based on a user's settings. The user may have a price preference or timing constraints for when the vehicle should be charged. Contract-based automated billing is implemented by having a user's contract with a charging provider represented by a public-key certificate stored on the vehicle. A complex public-key infrastructure (PKI) then allows the vehicle to authenticate the charger, the charger to validate the charging contract and the provider to produce verifiable metering receipts. The same PKI is used to underpin the TLS tunnel for protecting traffic.

<sup>1</sup>An open standard developed by Nissan and dominant in Japan

<sup>2</sup>A proprietary standard developed by Tesla Motors

<sup>3</sup>A nationwide standard in China

<sup>4</sup>An open standard backed by the European Union

Competing automated billing approaches do exist however, that do not use the contract-based approach, nor rely on the PKI. Blockchain-based payment systems, seeking to protect the user’s privacy from charging operators, simply use the communication channel as a building block for their own service [6, 26]. A system named “AutoCharge” [58] is also used in some networks [33, 56] to enable automated billing for even those users whose vehicles do not support the required certificates. The AutoCharge system is based on a simplified ISO 15118 use-case [52] that uses only vehicle-provided identifiers to match the vehicle to a customer record at the provider.

As there is a general-purpose channel, any IP communication is supported for additional functionality. Fast internet access is suggested in the ISO 15118 standard and a selection of data collection, targeted marketing, on-demand entertainment and third-party app platforms are emerging to take advantage of this [6, 22].

## 2.2 CCS Security

Communication security is considered in many of the systems making up CCS standard; with traffic encryption available at the PHY layer, TLS at the Transport layer and XML Security at the Application layer [55, 48].

At the PHY layer, the HPGP PLC network maintains a shared secret key called the Network Membership Key (NMK), with ephemeral Network Encryption Keys (NEKs) rotated periodically. All MAC-layer traffic is encrypted via AES-128 using the NEK. However, HPGP security is based upon a private-network model, while EV charging is fundamentally a public-network model. To adapt the technology to the use case, additions were made to HPGP to incorporate an initial association protocol<sup>5</sup>, during which the vehicle and charger verify that they are connected to each other and are not communicating with the wrong party due to crosstalk on their communication cable. The determination is known as Signal-Level Attenuation Characterisation (SLAC) and is illustrated in Figure 3. The protocol involves the vehicle sending a series of sounding messages, for which the charger reports the measured attenuation. If multiple chargers respond due to crosstalk, the one reporting the least attenuation is selected and communication commences. Once a charger is selected, a Network Membership Key is created by the charger and used to establish a private network. The key is then sent to the vehicle in the final CM\_SLAC\_MATCH.CNF message of the protocol. The SLAC protocol can operate in a secure mode, with mutual authentication and encrypted communication, but this capability is optional if supported by both parties. Indeed, despite the availability of this mechanism, the ISO 15118 standard specifies that SLAC only operates in its plaintext mode, leaving message security to TLS.

<sup>5</sup>The comprehensively-named GreenPPEA, or “GreenPHY Plug-in-electric-vehicle Electric-vehicle-supply-equipment Association”

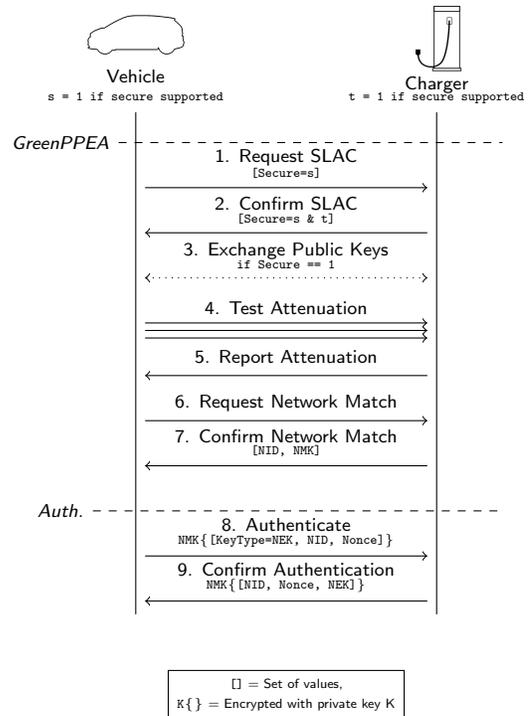

Figure 3: An overview of vehicle-to-charger network establishment in HomePlug GreenPHY. If the secure mode is supported by both parties and enabled in initialisation then step 3 occurs, allowing the messages in steps 5–7 to be signed and the one in step 7 also encrypted.

Once a network is established, a TLS connection is only created under certain conditions. If contract-based automated billing is used then TLS is required, similarly for the discovery of additional services, but only when they are ones defined in the ISO 15118 use cases. When charging is externally authorised, no TLS is required for the control traffic [48]. The options for external authorisation are open; including RFID cards, mobile-app networks, manual authorisation by a charger operator or some other service operating on the charger. The method need not be external to the charger, only external to the ISO 15118 scope. For all other traffic not managed through a standard use case, security is left to the implementer. In the alternative payment example of [26], independent IP communication is undertaken completely outside the scope of ISO 15118 (although secured in an SSH tunnel in that case).

## 3 Related Work

The privacy and security issues surrounding EV charging are the subject of ongoing work; with attempts to devise architectures that protect each stakeholder [32, 40] and analyses of the security of upcoming standards [4, 10, 8]. These works

are theoretical in nature, however, and leave aside implementation issues. They also assume a wireline threat model for attacks on the vehicle-to-charger communication, discussing where an attacker must use “a modified cable or an adapter plug installed on the [charger]” [8]. By contrast, we consider a wireless threat model that permits deniability on the part of the attacker.

Practical attacks have been demonstrated on previous-generation infrastructure, particularly against RFID authorisation [35, 19], but require the attacker to clone a user’s physical token or access debug ports on an unlocked charger.

Since electromagnetic emissions security was brought from a military discipline into academic study by van Eck’s work on eavesdropping video displays [68], efforts have been devoted to studying a wide range of systems [7]. Recent work has focused primarily on extracting secrets from operating devices [3, 13], although the emissions security of digital communication systems have been studied in the context of eavesdropping on RS232 serial devices [66] and 100BaseT ethernet [63], along with use as a covert channel for USB [39]. While radiated emissions from powerline communication have been studied from an electromagnetic compatibility perspective [71], we demonstrate the first practical wiretap attack using these emissions.

Vehicle tracking using unique identifiers has been studied in the context of electronic license plates [41], tire-pressure monitoring systems [46] and vehicular ad-hoc networks [49], highlighting the impact upon individuals’ location privacy and inspiring this work on new charging technologies. Practical attacks have also been demonstrated to wirelessly compromise in-vehicle systems [17], to unlock vehicles for theft via remote keys [70] or passive entry [34, 37] and to misdirect drivers to unwanted locations [73]. These attacks consider an active attacker with different goals to those studied here and as such could be considered orthogonal to our work.

Energy monitoring has been shown to enable the tracking of individuals [54] and this has prompted proposals to mask energy signatures, such as by using rechargeable vehicle batteries [69], which assumes that data about vehicle power flow cannot be monitored.

## 4 A Near-Ideal Side-Channel

The underlying principles of electromagnetic (EM) side-channels are very well-explored and their study has informed modern security design [7]. Despite this, we describe here how the use of PLC and its specific arrangement within CCS exacerbates the vulnerability to EM attacks.

The design of PLC technologies assumes differential signalling; wherein two identical transmission lines that are located in close proximity are driven with equal but opposite signals, such that those fields largely cancel and no residual electric field exists. Practical challenges often break these underlying assumptions for in-home PLC

deployments, leading to EM interference and susceptibility thereto [71]. Despite EV charging requiring simpler and more constrained wiring than domestic electrics, these assumptions are still broken in CCS. A design choice to incorporate backwards compatibility with an earlier low-power charging standard led to a PLC circuit design that connects one transmission line to ground (see Fig. 2b and App. A). This renders the signalling *single-ended instead of differential*. With no inverse field, the charging circuit functions as a suitable antenna for emissions or interference.

The nature of the PLC waveform itself, however, makes it ideal for wireless observation and interaction. It can be seen in Figure 4, operating as a single-ended system alongside single-ended CAN-Bus communications for comparison. The radiated signal represents the gradient of the original signal: only the changes in voltage. This introduces a minor problem for an attacker whenever they wish to observe and a major one when they wish to inject signals with constant voltage levels, most notably the square waves used ubiquitously in digital communication (and in other EV charging communication based on CAN-Bus). In observation the static voltage produces no response, so only state transitions are detectable. The attacker uses these where they can or hopes for the signal to leak elsewhere in the circuit and be modulated onto a more easily-observable one [7]. In injection the attacker cannot directly induce the desired static voltage level and instead must exploit nonlinearities in components or undersampling effects in order to synthesize the signal at the victim [51]. The absence of components to subvert, or the presence of filtering in the target circuit, limit the attacker’s opportunities.

Broadband PLC technologies predominantly use orthogonal frequency division multiplexing (OFDM); in which the data are modulated in the frequency domain before constructing a time-domain waveform using an inverse Fourier transform. The resulting, transmitted waveform is a finite sum of sinusoids and does not exhibit any non-zero static voltage levels. *The observed emissions simply form a phase-shifted replica of the original signal.* The attacker therefore does not need to make inferences to determine the original signal from eavesdropped observations, nor predict what transformations an injected signal will undergo in the receiver. They need only contend with the characteristics of the channel itself.

## 5 Threat Model

While we discuss the channel properties in a bidirectional sense above, we focus our further investigation and practical attacks on passive eavesdropping. Testing on deployed infrastructure restricts us to only passive operation.

The attacker listens to the unintended electromagnetic radiation of the EV charging communication. Their goal is to eavesdrop on the general-purpose channel established be-

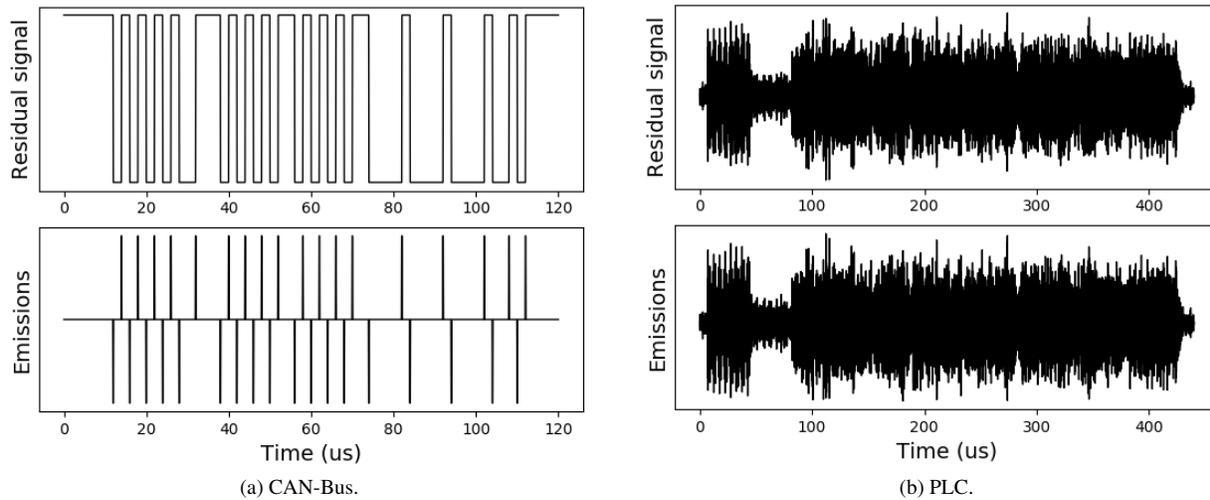

Figure 4: Example single-ended signals, with the radiated emissions that result. As the emissions are the gradient of the signal, the square wave produces only impulses while the OFDM waveform is all but unchanged.

tween the vehicle and the charger; such that they obtain access to private data it carries. The attacker can approach close to the target vehicle and charger but cannot modify or interfere with the equipment. They perform their attack either *in-person* from a nearby location, or by *situating a device* at the site and leaving it unattended.

We justify this model on the basis of deniability and access. Interfering with a vehicle or charger is an immediately suspicious activity that would draw attention from the owner, people nearby and operators reviewing CCTV footage. The charging equipment is also handled regularly by drivers, so a cable modification or plug insert is more likely to be noticed. By contrast parking near another vehicle at a public station or briefly visiting a private property appear to be benign actions.

## 6 PLC Eavesdropping Tool

Given the properties described in Section 4, the passive attacker’s task is the same as that of a legitimate receiver; to maximise the signal-to-noise ratio (SNR) and bandwidth (BW) of the received signal. In a real setting, additional complicating factors exist. While the exposed components are the most obvious targets, any element of the communication circuit (i.e., charging plug, cabling, vehicle, charger), or indeed multiple elements, could act as an unintentional antenna(s). The size of the equipment makes potential antennas physically distant from one another, so it can be difficult to predict the location that optimises the SNR and BW for each target. Similarly, electric vehicles and chargers are powerful electrical devices and even minor imperfections can introduce significant interference levels, which must be suitably

mitigated by careful positioning or filtering.

Exploiting the properties and design choices of CCS, we developed a tool for wireless eavesdropping of the underlying physical layer; a HomePlug GreenPHY (HPGP) network. The tool is applicable to monitoring any HPGP network as well as network management traffic in HomePlug AV and AV2 networks, although the vehicle charging scenario is particularly beneficial for the reasons discussed above. The tool is available open-sourced under the MIT licence<sup>6</sup>.

The eavesdropping tool broadly resembles a normal HPGP receiver. While the HPGP standard is public, all compatible implementations are proprietary and implemented as integrated circuits. Our pure-software implementation allowed far greater insight and flexibility during captures however, particularly for experimenting with different preprocessing steps to improve reception and collecting partial data that would be discarded by a black-box implementation. The receiver architecture can be seen in Figure 5. Given that Wi-Fi shares the same OFDM underpinnings, the overall structure bears many similarities to a Wi-Fi receiver, albeit distinct in details to match the HPGP protocol specification.

As the signal processing chain is complicated we describe it briefly here but elide full details from the main text, providing them in Appendix B instead. The signal is captured and digitally filtered to suppress local interference. Messages, known as PHY-layer Protocol Data Units (PPDUs), are identified using a power detector and correlation of the signal preamble against the known preamble structure. As an OFDM technology, data are represented in individual *symbols* throughout the Frame Control and Payload sections of

<sup>6</sup><https://gitlab.com/rbaker/hpgp-emis-rx>

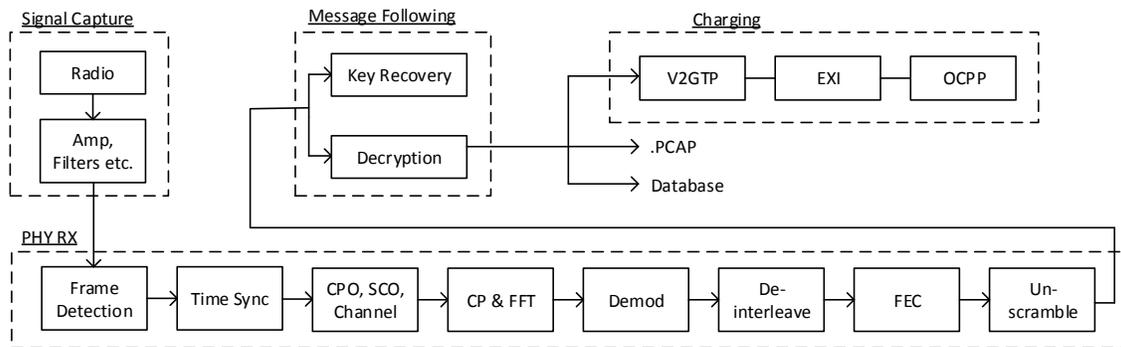

Figure 5: Architecture of PLC monitoring tool. The signal is captured and prefiltered, before moving through a software receiver chain to recover messages. The message following behaviour extracts security-relevant data and stores all messages. Charging traffic can be further processed, while traffic using other protocols will need separate onwards processing.

the PPDU. Once the receiver is time synchronised to the PPDU, each symbol is processed in turn; with channel estimation and frequency offset correction applied before demodulation. With complete messages the Turbo Code error correction is processed to reduce errors and the Cyclic-Redundancy Check checksums are calculated (a CRC24 for the Frame Control and a CRC32 for the Payload). The application of the Turbo Code decoder is limited in our tool, owing primarily to the computational cost of the process. A Turbo Code is intended to be decoded by iterating a probabilistic decoder over various rearrangements of the received bits. We use only a single pass of the decoder and its application already dominates the message reception time; exceeding the rest of the software processing chain. As such we suffer from reduced error-correction performance compared with an arrangement using multiple repetitions. Such an arrangement could be expected to receive more messages correctly in all circumstances.

## 7 Real-World Measurement Campaign

To explore the accessibility of the wireless side channel, we undertook a data collection campaign with three fully-electric vehicles: a BMW i3, a Jaguar I-PACE and a Volkswagen e-Golf. The campaign comprised over 800 miles of driving and spanned six major administrative regions of the UK. A total of 54 unique charging sessions were conducted, at locations including service stations, highway rest stops, superstores and hotels.

During charging sessions, we monitored radiated emissions to measure the extent of signal leakage and the ability of an attacker to eavesdrop it. Where we were able to receive sufficient emissions we used the tool detailed in Section 6 to recover the original transmissions and examine the communication itself. For the majority of our testing we monitored

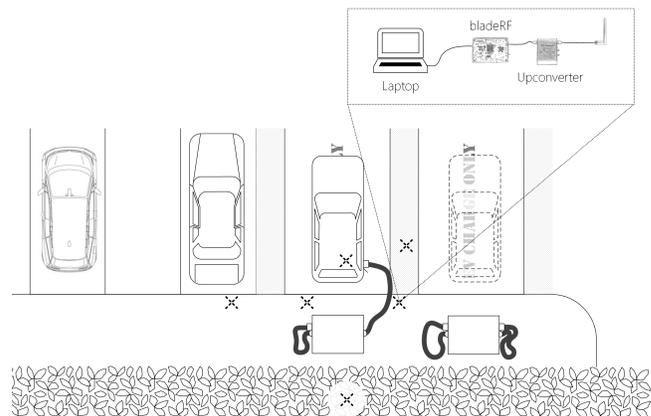

Figure 6: A composite diagram showing the experiment layout. The five antenna locations are denoted with a dashed  $\times$  symbol.

one vehicle at a time, although we did conduct testing with multiple vehicles to examine the effects of cross-traffic. Further details of the locations and installed hardware are given in Table 1, while examples can be seen in Figures 7 and 8. All of the chargers are state-of-the-art at the time of writing. We tested only public chargers due to their availability, but equivalent chargers for private use are also on sale [25]. As the chargers were public, we did not modify or interfere with the equipment in any way. The vehicle, charger and associated cabling remained entirely untouched. While this prevented us from injecting messages or capturing ground-truth via a directly-connected receiver, it was necessary to conduct a widespread survey of existing infrastructure.

At each site, the vehicle was parked and connected to the charger for a series of charging sessions<sup>7</sup>. The receiving an-

<sup>7</sup>Care was taken to ensure we only observed signals from our own vehi-

Table 1: Details of all tested charging locations, across the southern United Kingdom. There were a total of 54 unique charging sessions. Multiple signal captures were taken during each session; at initialisation, during charging and at shutdown. At sites **F** and **H**, two vehicles were charged and monitored simultaneously.

tenna was placed at various locations to investigate the reception capabilities. As noted in Section 6, deriving an optimal attack location beforehand is challenging, so this placement was exploratory. The locations are illustrated with a dashed  $\times$  symbol in Figure 6. Locations near the cable itself, on the outside of the vehicle, within the vehicle, hidden in a nearby hedge and on a nearby car were all tested. As each site had a different layout, Figure 6 is a composite to show the arrangements, rather than a meticulous depiction of any one site.

The data were collected using a bladeRF software-defined radio, an RF Explorer Upconverter and a GNU Radio flowgraph running on a Lenovo Thinkpad X1 Carbon laptop. We made use of an electrically-short monopole antenna to collect the signal. Owing to the long wavelengths involved, testing with a suitably-tuned directed antenna was not possible. The equipment for our experiments cost approximately \$800, although equivalent setups are available for less than \$300. The collected signal was passed through 25dB amplification and upconversion (+530MHz) to bring it into the tunable range of the bladeRF. Initial filtering and packet detection was performed with further GNURadio flowgraphs, while subsequent processing was implemented using Python and NumPy libraries. We tuned the receiver’s interference-rejection filter by observation at each site, but left all other reception parameters constant throughout.

## 8 Results

In this section we examine the results of our testing in real environments, both in terms of raw observable signal and message recovery.

cles. Upon arrival we waited for any other users to leave before capturing traffic and aborted immediately if another arrived.

### 8.1 Eavesdropped Communications

Table 2 details the observations for each site. It indicates the peak signal-to-noise ratio (SNR) over all the sessions, along with the widest bandwidth (BW) with a positive SNR. It then lists the count of all PPDUs detected, the number of data PPDUs, the rate at which messages were well-formed and the rate at which messages had a correct CRC32 checksum.

Every site displayed some form of unintentional wireless channel from the PLC communication, with properties that exceeded our expectations. The weakest signal showed 9dB from the peak to the background and spanned a bandwidth of 4.5MHz. In the best case 25MHz could be seen, up to a peak of 35dB. This was true irrespective of charger manufacturer, indeed varying notably between sites with the same charger hardware antenna location. This would seem to confirm the expectation that the site layout and variations in parking have a substantial impact upon reception.

Figure 9 shows spectrograms of the captured signal at a selection of sites, covering each tested antenna location. Overlaid on each subfigure is the utilised HPGP spectrum, showing the regions of the band in which transmission occurs. A transmission will originally have a frequency-domain representation that matches the spectral mask, with a peak power of -50dBm in utilised regions. Apparent power levels up to approximately -70dBm we observed, although the receiver was not calibrated against a reference scale so this value is uncertain. The degradation of signal across the band is clear in every case; the flat-topped spectral usage of the transmission is observable as a jagged range with many subcarriers severely attenuated, particularly at lower frequencies. This correlates well with studies of the wireline channel that legitimate receivers (with a conductive connection) experience, albeit with a different noise profile [53].

Table 2: Eavesdropping results, from all sites and antenna locations. Raw signal properties are quantified as Peak SNR and Bandwidth. PDU counts are given and the observance of bidirectional traffic and session startup is indicated. The rates of well-formed messages are then shown, along with the rates of CRC32 checksum validations. The worst and best performance for each antenna location is highlighted in **bold** († indicates joint-worst).

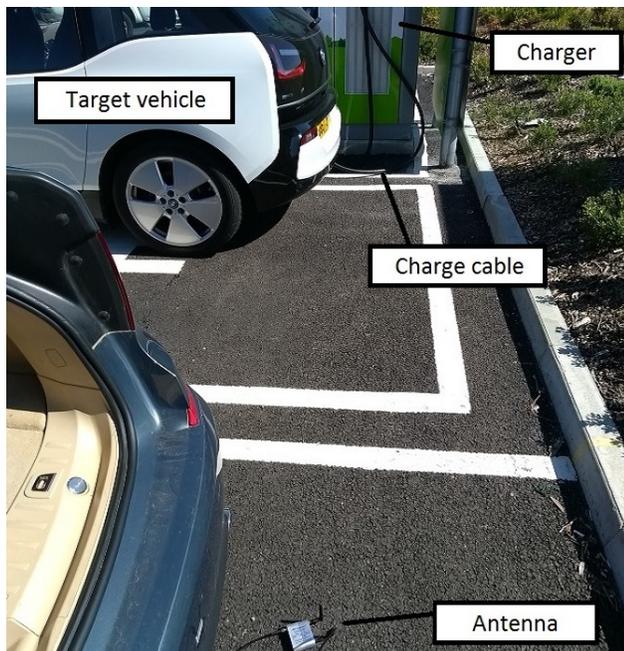

Figure 7: Eavesdropping from the next parking bay (site G), more than 4 metres away on the other side to the charging cable. In this arrangement 91.8% of messages were received successfully.

Figure 8: Two vehicles charging simultaneously. With the eavesdropper between the two vehicles 42.5% of messages were received successfully, including the NMK key establishment for both vehicles.

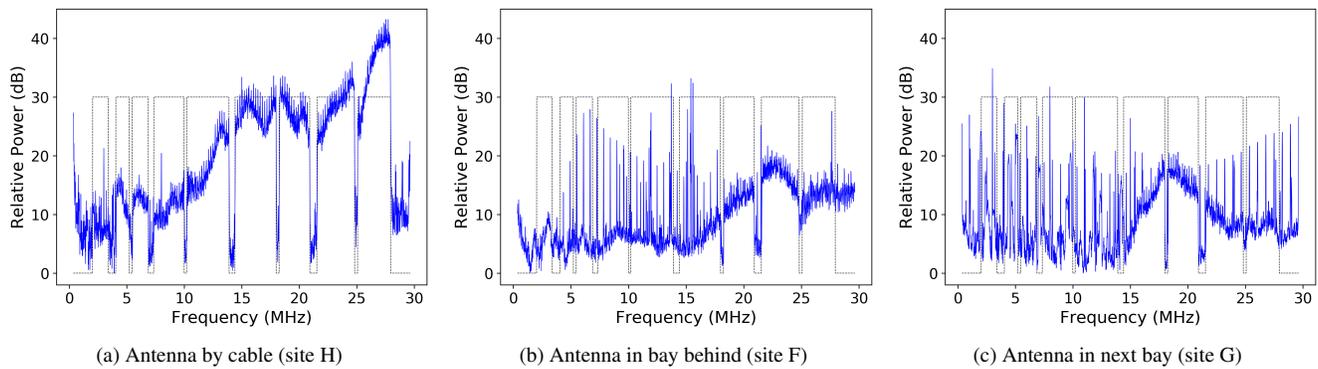

Figure 9: Observed signal across the HPGP bandwidth, at each antenna location. The HPGP spectral mask is overlaid to indicate the regions in which transmission occurs, although no valid comparison can be made with its power value as the measurement was not calibrated. Signal degradation and noise ingress is visible in every case, although far more prominently in (b) and (c).

## 8.2 Effects of Location

While systematic examination of performance by location was not our goal, we were able to observe trends across tested antenna positions, with the fidelity of the wireless channel varying substantially. The closest representation of the transmitted signal is that shown in Figure 9a, obtained approximately 0.5m from the charging cable. At other antenna positions the signal loss was more pronounced, both inside and outside of the vehicle, and in isolated cases the signal was swamped by interference more than a short distance from the cabling. Making general predictions about the channel gain at specific distances is not feasible due to the low frequencies at which the PLC operates (2 – 28MHz). Even at 28MHz the wavelength is still 10.7m and so all observations were taken well within the near field of the transmitter. In this region, common path loss calculations like the Friis equation [36] are not defined and near-field effects can change the channel gain drastically from position to position. Nevertheless, Figures 9b and 9c show the results of tests at the greatest distances; 4.2m in the latter case when the antenna was positioned by a vehicle in an adjacent parking bay (shown in Figure 7). Interference is still substantial at these distances (e.g., everything below 15MHz in Figs. 9b and 9c), but in the higher reaches of the band signal still easily visible.

The consistency of observed leakage across different charger hardware indicates that the issue is not isolated to a single implementation; supporting the claim that the design choices in CCS make a wireless side-channel for the PLC communication a systemic problem.

## 8.3 Message Recovery

With such a clear channel, message recovery proved highly successful, with hundreds of complete messages captured even in short sessions. In the best case, at site **I**, 100.0%

of received messages had correct CRC32 checksums, more surprisingly 91.8% were still received when the antenna was located in the next parking bay. Reception rates were broadly correlated with raw SNR and BW, with improvements to either benefiting the performance. However this was not universal, as the very poor performance at sites **B** and **K** shows. Site **B** showed poor results despite far higher SNR and BW than Site **K**. Reception performance is broken down by location in Table 2, with the lowest minimum and highest maximum for each location highlighted in bold. Without ground-truth for the number of messages sent by each party, we cannot determine the number of messages missed entirely (only those received with errors), although the only unreported messages would be those that did not even trigger the packet detection algorithm (see Appendix B). Examining Frame Control headers showed that traffic was observed bidirectionally between vehicle and charger in all but two cases.

As charging stations, at least in public, are busy venues, we tested whether multiple simultaneous charging sessions caused interference that affected the wireless channel quality. Two vehicles (a Jaguar I-PACE and a VW e-Golf) charged simultaneously in 5 charging sessions at 2 locations, one of which is shown in Figure 8. In each case, one vehicle initiated charging first and then the second did so. The eavesdropper’s antenna was located between the two vehicles and attempted to listen to both. In all cases, the eavesdropper was able to listen to traffic from both vehicles, albeit with varying success. At worst, 24.3% of messages were received with correct CRC32, at best 94.8% (mean 59.7%).

## 9 Security Analysis

In this section we analyse the captured communications and their security implications.

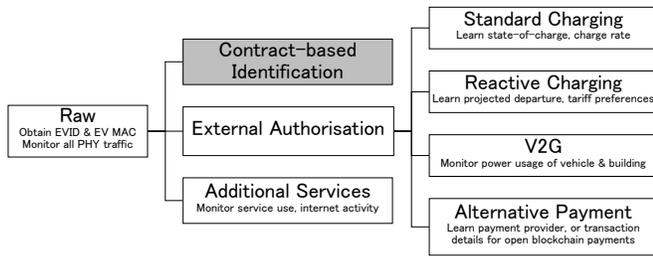

Figure 10: Tree diagram indicating the potential data available under a range of communication scenarios.

## 9.1 Unencrypted Communications

Where our testing campaign captured the initialisation of a charging session, we were able to examine the NMK exchange to form a network. In line with the ISO 15118 standard, every SLAC interaction we observed operated in insecure form. As such, the NMK was delivered in plaintext and the only barrier to acquiring it was receiving the message intact. We were able to intercept the `CM_SLAC_MATCH.CNF` message in 31 cases and acquire the NMK. Testing two vehicles side-by-side, in 4 sessions the attacker was able to extract an NMK value for one vehicle, meanwhile in one session both NMK values were extracted. In 9 cases, the subsequent `CM_GET_KEY.CNF` message was also recovered to obtain the ephemeral NEK and permit *passive decryption of physical-layer traffic*.

Examining compromised sessions, we saw the expected behaviour as the vehicle and charger established a network, the vehicle undertook the discovery protocol to find a charge controller and the two established a TCP connection. *No TLS tunnel was established in any charging session we observed*, leaving the high-level protocols exposed. Where external authorisation is employed, as it was in our testing, the use of TLS is optional under ISO 15118. Yet its complete absence from any vehicle or charger came as a surprise, especially given the charging locations were all public.

As a result we confirm that a passive attacker can wirelessly monitor all traffic at the PHY layer and that this ability *results from standards-compliant behaviour*, suggesting it is persistent. Likewise, the option to forego TLS means charging data is also left in the clear. We discuss this situation and its implications in Section 10.

## 9.2 Private Data

Figure 10 provides a breakdown of potential data available when eavesdropping, under various charging conditions or in the presence of different services. The PHY-layer traffic is always available and permits access to any higher-level communication, such as charging or internet access, that does not take additional steps to secure itself. Two unique identifiers for the vehicle are also available: its EV ID and its MAC address. These identifiers are persistent for the entire lifetime of the vehicle, including between owners, and are globally unique. They have been noted as personal data in previous privacy studies [40] and are covered by the European Union’s GDPR as data that can be easily combined with other sources to identify an individual.

With contract-based billing, we do not expect charging traffic to be available, as TLS is always required in this case. However as we have seen, when it is optional to omit TLS, this has consistently been done. Currently, this leaves the majority of charging traffic in the clear at public locations, although these are likely to be the earliest adopters of contract-based billing (or some alternative). The long-term omission of TLS at private locations is of greater concern. Indeed it is in this case that there is more potential for behavioural profiling, due to the vehicle staying far longer at the user’s home or workplace and with the emerging Reactive Charging and V2G systems far more beneficial to them there. The introduction of ‘Vehicle-to-Home’ capabilities, for instance, is prioritised for introduction as early as 2020 by the CCS standards body [16]. Resulting indicators of the user’s day-to-day behaviour such as the vehicle’s state-of-charge and projected departure time are contained within normal charging traffic, while reverse power flow data in a V2G system yields insights into the power usage of the building.

In addition to internet access for in-vehicle entertainment systems, third-party apps and alternative payment networks, the traffic of any local services would also be available at public locations, as would smart home integration traffic in private ones.

## 9.3 Charging Attacks

A reliable eavesdropping capability presents a range of opportunities for an attacker, both immediate and longer-term in their impact. We consider here a selection of potential attacks using these techniques. Although we did not perform the attacks against public chargers, we describe how they would be conducted.

**AutoCharge** Extant AutoCharge systems, such as one operating in production across a 60-location network in three European countries [33] are at particular risk from wireless eavesdropping. The use of the vehicle’s charge-controller MAC address for billing identification [58, 56], while highly questionable from a purely-security standpoint, was undertaken for compatibility and convenience benefits (and has been lauded as such by customers). What may be an acceptable trade-off when physical interference is required to extract the values, is far less so when this can be done from another vehicle without any observable signs. The identifiers of the vehicles are shown partially-masked below (none is a customer of an AutoCharge system):

Vehicle	MAC
BMW i3	f0:7f:0c:02:●●:●●
VW e-Golf	00:7d:fa:01:●●:●●
Jaguar I-PACE	00:1a:37:70:●●:●●

We were able to obtain the identifiers in 41 cases (76%)<sup>8</sup> from a variety of locations including the two-car arrangement shown in Figure 8. Here the identifiers for both vehicles were acquired from the same antenna position, suggesting that an attacker could simply park next to a charging station and collect identifiers as other users arrive subsequently providing them<sup>9</sup> in order to obtain free charging on another user’s account. As the charging spots are operated by a single provider, the attacker can be confident of targeting valid customers.

**User Tracking** In the simplest attack, charging sessions are linked by monitoring a number of busy public chargers for the appearance of vehicle identifiers. From time-of-day, charge duration and location information, behavioural profiles can be inferred. The invasiveness of the attack increases where the attacker is able to match a vehicle identity to other data. Popular charger-sharing schemes [60] allow anyone to register their home or business charger as a public site; any user booking to charge can then be associated with their vehicle identifier and tracked at any monitored station. Monitoring a charger near a sensitive event such as a union meeting, protest gathering or compromising night-spot would reveal more personal information about an individual’s habits.

With a wireless attack, a wardriving approach also allows an attacker to associate a vehicle with a street address. This could easily be conducted by a delivery driver or postal worker as they visit properties regularly. Known MAC allocations to manufacturers provide a coarse-grained indication of the vehicle as well, such as identifying expensive vehicles and then determining when they have been left in a public car park, or indeed when their owner is out of the house.

## 10 Lessons Learnt

The refinement of EV charging systems is still ongoing. In light of our observations, we have distilled a set of security lessons that can improve existing and future designs.

### 10.1 Wireless Threats

The most notable finding here is that the design of CCS communication allows a wireless attacker to observe it at a dis-

<sup>8</sup>31 cases from SLAC initialisation messages and 10 more from network management messages

<sup>9</sup>Typically updating the MAC setting using `open-plc-utils` [45] and a serial debug port over UART or SPI [21]

tance without prior interaction or tampering. In this case the attack was entirely passive, but has similar implications for the potential of active attacks that would currently be far more invasive. As in-vehicle wireless systems have been plagued by attacks in recent years, our results indicate that a testing model which considers emissions security as well as unwanted interference is crucial in future development.

### 10.2 Reliance on a Non-Existent PKI

The ISO 15118 security model, and thus that of CCS, relies on the existence of a complex PKI, to underpin TLS at the Transport Layer and XML Security for external message values at the Application Layer. The merits of that infrastructure are an ongoing topic of academic study [8, 72, 52], but its complexity also presents a more practical problem. At the time of writing, no widespread ISO 15118 PKI is deployed. While small-scale pilots have been attempted, there is still open debate about provision of the infrastructure and the authors are aware of public proposals from three different commercial entities to provide transaction brokerage and act as the Root Certification Authority [27]. There is even disagreement about the model the PKI will take; whether it will derive from a single root of trust, a consortium of trusted entities or some more open model [50]. Meanwhile the competing pressures to provide new functionality remain, spurring alternative solutions such as AutoCharge and encouraging service development without underlying security provision.

Even once a PKI is operating for public chargers in large charging networks, it remains unclear to what extent private units in individual homes or offices will benefit. A capacity for self-signed contract certificates to be manually installed into vehicles by users does exist, but unless contract-based billing is used ISO 15118 exempts charging installations from any security requirements; instead relying on the physical security of the location and cabling — which we have demonstrated to be insufficient. Manufacturer choices (and indeed user willingness) will determine whether private chargers can enjoy these security benefits.

It is important therefore to provide at least some security implementation that is decoupled from the need for access to a PKI. We discuss such an approach in Section 11.

### 10.3 Available PHY Security Disabled

The HomePlug GreenPHY (HPGP) PLC technology supports a *Secure SLAC* mode that protects the pairing and NMK distribution process, but this is disabled by specification in the ISO 15118 standard, relying instead on TLS for all security properties. While this can meet the charging use cases outlined in that standard, it leaves an opportunity for a pervasive security baseline completely ignored, despite proposing the communication channel for general use. All too of-

ten history has shown that leaving security to individual developers atop insecure platforms produces widespread security problems, even more so when the channel is considered physically private.

## 11 Countermeasures

To mitigate the unintended wireless channel, familiar emissions security mechanisms such as chokes or shielding can be applied to reduce leakage [7], although hardware modifications for existing systems are costly and time-consuming. Some proposals for future, high-power chargers include liquid-cooled charging cables and we would expect this to attenuate the signals if the cooling jacket wraps the communication lines as well as the power-delivery ones. This would not eliminate emissions from the vehicle or charger circuitry however, nor is it likely to exist in smaller, private chargers.

At a network level, we have argued for the use of the available HPGP security mechanisms above, but note that in their present form they are still reliant on a PKI to function. In addition the HPGP key distribution behaviour itself introduces an unnecessary risk of interception. Whether the SLAC protocol operates in its secure mode or not, it is still unilateral: the charger generates a network key and then provides it to the vehicle. However, the SLAC process is typically implemented in software by the same devices that undertake the higher-level ISO 15118 communication, including possible TLS sessions, and as such require the capabilities for an Elliptic Curve Diffie-Hellman key derivation for AES128 [48].

We propose additional steps in the SLAC initialisation, as a fallback to provide confidentiality from the MAC-layer upwards in the event that PKI access is unavailable. Figure 11 shows the modified protocol. Upon receiving a network match request, the charger generates an Elliptic-Curve key-pair  $(d_C, Q_C)$  and instructs the vehicle to commence a key exchange, along with  $Q_C$ . If the vehicle also supports the protocol then it generates  $(d_V, Q_V)$  and responds with  $Q_V$ . The derived key becomes the new NMK and the charger blanks the NMK field in the subsequent CM\_SLAC\_MATCH.CNF message. If the vehicle does not support the protocol then the unrecognised message will be dropped. The charger maintains a timeout counter after step 6.1 and, upon expiry, falls back to the existing protocol's step 7.

While it cannot provide authentication and therefore cannot mitigate man-in-the-middle attacks, the threat of passive eavesdropping is eliminated using this approach. By building only on existing functionality, the protocol is deployable in existing vehicles as well as new ones.

## 12 Conclusion

We have demonstrated that use of PLC in EV charging and the design of the CCS standard lead to a uniquely high-

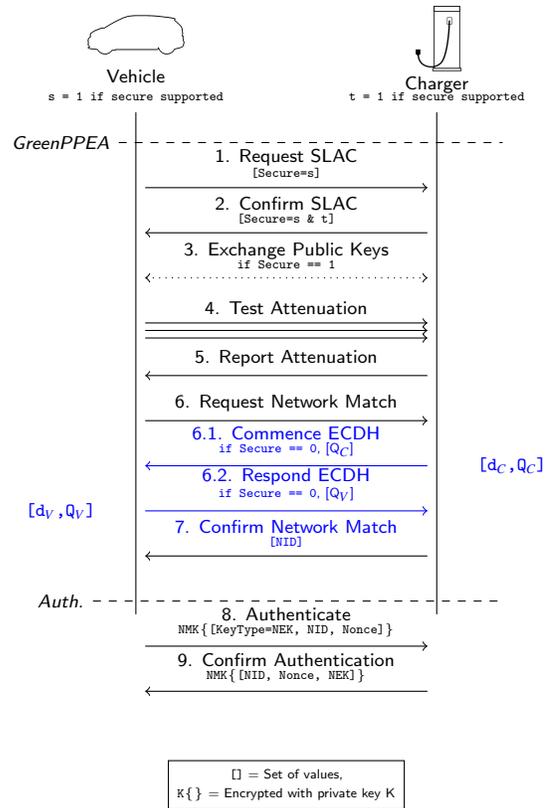

Figure 11: The modified SLAC network establishment. Steps 6.1 and 6.2 are new, while step 7 has been modified.

quality, unintentional wireless channel. We have evaluated the susceptibility of real-world chargers and found a reliable channel in every case. Although conditions vary substantially between sites, for eavesdropping we achieved a peak successful recovery rate of 100% in one case and could intercept traffic several metres from the target, in a different parking bay, with a rate of 91.8%. We showed how a series of further design choices allow recovery of network keys and passive monitoring of all traffic in plaintext. We presented lessons learnt and potential improvements to mitigate the problems so that they do not hinder the secure adoption of global EV charging infrastructure by the growing number of EV owners worldwide.

## Appendices

### A CCS Circuit Design

Figure 12 shows the communication circuit for PLC in CCS charging systems, including the connection of the circuit to the Control Pilot and Protective Earth lines, along with the additional components affecting the Control Pilot line due to the need for backwards-compatibility with the IEC 61851 communication that shares the lines.

### B HomePlug GreenPHY Receiver

In this section we describe our eavesdropping tool in detail. As noted in Section 6, the tool is effectively a modified receiver design, although newly-implemented entirely in software. Since HomePlug GreenPHY (HPGP) [5] is an orthogonal frequency-division multiplexing (OFDM) technology, many elements of the tool structure are similar to a Wi-Fi receiver.

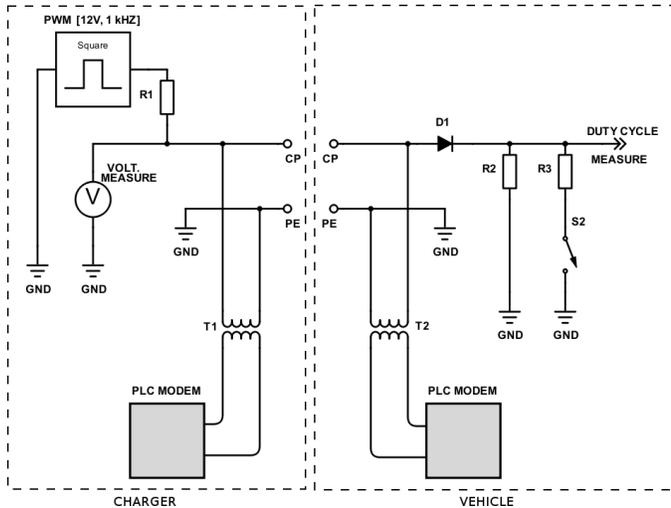

Figure 12: A diagram of the CCS communication circuit. The loads on each line connected to the PLC modem are not balanced. Resistors R2 & R3 alter the voltage in the low-level communication, but also vary the imbalance further.

Raw signals are first collected using a suitable capture device. A Rigol DSA-2302A oscilloscope was used in our testbed arrangement, as can be seen in Figure 13. Even here the radiated emissions were easily observed; the yellow line in the figure represents the conducted signal, while the blue line is the radiated signal received by a short random-wire antenna. Although the distance shown here is very short, we were still able to observe the signal from the other side of the lab, several metres away. We later employed software-defined radios for signal capture, for their ability to receive and stream a captured signal in real time.

The captured signal is filtered in the frequency domain, benefiting from knowledge of the active regions of the HPGP band and the ability to survey initially an individual site's leakage before eavesdropping in earnest. A sharp-edged digital filter is used to remove regions with notable interference ingress or where channel gain is so low as to provide no useful information. The signal is then resampled into the HPGP native timebase of 75MHz.

**Frame Detection and Time Alignment** With the signal suitably pre-filtered and digitised, the PPDUs are detected using a *Double Sliding-Window* power detector; a design that accurately identifies the rise in power that accompanies the start of a packet. The detector calculates the power of the incoming signal and maintains two windows A and B of equal length  $L$  that are arranged with a time lag such that calculated power levels are included in window A at time  $t$ , subsequently passing out of window A and into window B at time  $t + L$  and out of the detector entirely at time  $t + 2L$ . At each sample, the power in each window is updated and

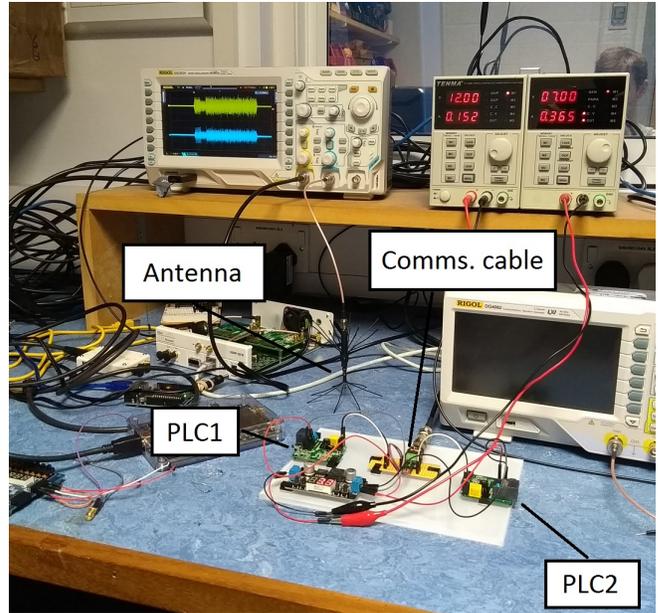

Figure 13: HomePlug AV adaptors communicating across a short wire. Conducted signals and radiated emissions can be seen on the oscilloscope (top in yellow and bottom in blue, respectively).

the total power in A is divided by that in B. This configuration causes the output signal to spike quickly on increases in power levels, while remaining stable at equal power levels (i.e., prior to or during a frame). By selecting an appropriate value of  $L$  (based on the frame's structure), transient noise can be prevented from triggering a frame.

OFDM requires precise time synchronisation in order to demodulate correctly. We performed this by correlating the entire preamble against a template, which provided sample-accurate alignment.

**CPO, SCO & Channel Estimation** In practice, a transmitter and receiver in an OFDM system will have neither precisely-aligned oscillators nor synchronised sample clocks, leading to Carrier Phase Offset (CPO) and Sampling Clock Offset (SCO). CPO causes an apparent frequency offset for the entire received signal, meaning that the frequency-domain representation exhibits a phase rotation. Meanwhile, SCO leads to an apparent phase drift across subcarriers in the frequency domain. Both phenomena hamper demodulation and must be corrected beforehand. Channel estimation is also crucial to successful reception; assessing the gain and phase alterations that have been experienced by the signal due to the propagation environment.

Our receiver estimates the CPO using a method derived from Bloessel et. al.'s work; estimating the CPO using the seven full-amplitude SYNCP preamble symbols in place of the Wi-Fi short-training sequence [11] (omitting the initial

192 as they have been windowed in symbol shaping):

$$cpo_{est} = \frac{1}{384} \text{Arg} \left( \sum_{i=0}^{7 \cdot 384} x[i] \bar{x}[i+384] \right)$$

where  $x$  is the received signal samples.

From the extracted section of the preamble, complex samples are multiplied with the conjugate of the same sample in the next SYNC block. This produces an estimate of the phase progression introduced between those SYNC blocks by the mismatch between transmitter and receiver (plus noise). Dividing through by the length of the SYNC block gives an estimate of the phase offset per sample. The length of the sequence (2688) and the number of repetitions (7) permit an accurate CPO estimate. The per-sample CPO estimate can then be used to correct the remainder of the captured signal.

$$x[i] \leftarrow x[i] \cdot e^{-jcpo_{est}i}$$

As the estimated CPO will not precisely match the actual CPO, ongoing correction is applied to each received symbol by estimating the CPO between the cyclic prefix and the symbol tail, with a suitable correction being applied over that symbol.

$$cpo_{estcp} = \frac{1}{3072} \text{Arg} \left( \sum_{i=0}^{GI} x[i] \bar{x}[i+3072] \right)$$

where  $GI$  is the guard interval (with four values depending on the symbol and system settings).

The channel estimation is performed in the frequency domain, by comparing the received preamble symbols to a locally-computed template. HPGP provides no pilot symbols so all estimation must be performed from the preamble and maintained across the PPDU. The results for each preamble symbol are averaged and a channel estimate from the active preamble subcarriers computed. From this a channel estimate for the full channel is derived by interpolation, while the SCO is estimated from the slope of the phase differences in the channel estimate. As the CPO and SCO are due to hardware imperfections in the transmitter and receiver, rather than channel properties, estimates are maintained between received PDUs by way of a moving average. The channel estimate, by contrast, is discarded after a PDU has been received.

**Demodulation** Demodulation takes place in the frequency domain (via a 3072-point DFT), after the removal of the cyclic prefix for the symbol and correction for the channel effects at each subcarrier. As HPGP uses QPSK modulation, the receiver compares the measured value for the subcarrier in the in-phase and quadrature channels to the nominal values and estimates, under an additive white Gaussian noise assumption, the likelihood of the transmitted value having

been a 0 or 1 bit. These probabilities are expressed as a ratio, the Log Likelihood Ratio (LLR) and then scaled according to the gain for the subcarrier in the channel estimate, such that the uncertainty inherent in weakly-received subcarriers is represented.

**Post Processing** Demodulated soft bits are combined by averaging to benefit from HPGP's redundancy schemes. They are then rearranged in read-by-row-write-by-column fashion to undo the channel interleaving process.

The FEC decoding is applied to produce hard decisions about the bit values. HPGP uses an unpunctured Turbo code with two systematic, rate  $\frac{2}{3}$  constituent codes. Each pair of input bits ( $i, j$ ) produces a codeword ( $i, j, p, q$ ), where  $p$  and  $q$  are parity bits,  $p$  from the in-order input and  $q$  from an interleaved input.

Finally, the bits are unscrambled by XORing with the same generator polynomial used in the transmitter to recover the original sequence.

The CRC checks are computed over the received bits to determine if the contents have been received successfully, however the PHY-layer bits are delivered to the higher layers irrespective as even messages containing errors may provide useful information.

Each stage of the receiver is configurable with a wide range of parameters. In particular, the power threshold to trigger PPDU capture, the frequency-domain filtering, the initial CPO estimate and the estimated noise variance for demodulation all permit tailoring the receiver to a given scenario.

Considering the emissions as a wireless channel, the simple modulation and redundancy in HomePlug GreenPHY's robust ("ROBO") transmission modes mean the attacker need not match the channel characteristics of any particular receiver; they need only to receive the transmissions with enough of the signal intact. Specifically, the attacker requires a positive signal-to-noise ratio (SNR) over some fraction  $B$  of the transmitted bandwidth. The selection of  $B$  depends upon the transmissions mode in use and the effectiveness of any error-correction mechanisms, however for a rough estimate the level of redundancy can be used. Thus for MINI\_ROBO, STD\_ROBO, HS\_ROBO  $B$  can be taken as 5.2MHz, 6.5MHz, 13MHz ( $\frac{1}{5}$ ,  $\frac{1}{4}$  and  $\frac{1}{2}$  of the 26 MHz HPGP bandwidth) respectively.

# RVFUZZER: Finding Input Validation Bugs in Robotic Vehicles Through Control-Guided Testing

## Abstract

Robotic vehicles (RVs) are being adopted in a variety of application domains. Despite their increasing deployment, many security issues with RVs have emerged, limiting their wider deployment. In this paper, we address a new type of vulnerability in RV control programs, called input validation bugs, which involve missing or incorrect validation checks on control parameter inputs. Such bugs can be exploited to cause physical disruptions to RVs which may result in mission failures and vehicle damages or crashes. Furthermore, attacks exploiting such bugs have a very small footprint: just one innocent-looking ground control command, requiring no code injection, control flow hijacking or sensor spoofing. To prevent such attacks, we propose RVFUZZER, a vetting system for finding input validation bugs in RV control programs through control-guided input mutation. The key insight behind RVFUZZER is that the RV control model, which is the generic theoretical model for a broad range of RVs, provides helpful semantic guidance to improve bug-discovery accuracy and efficiency. Specifically, RVFUZZER involves a control instability detector that detects control program misbehavior, by observing (simulated) physical operations of the RV based on the control model. In addition, RVFUZZER steers the input generation for finding input validation bugs more efficiently, by leveraging results from the control instability detector as feedback. In our evaluation of RVFUZZER on two popular RV control programs, a total of 89 input validation bugs are found, with 87 of them being zero-day bugs.

## 1 Introduction

Robotic vehicles (RVs), such as commodity drones, are a type of cyber-physical system for autonomous transportation. They are typically equipped with a computing board with control hardware (e.g., micro-controller) and software (e.g., real-time control program). The on-board control program continuously senses the vehicle's physical state (e.g., position and velocity) and actuates the motors to control the vehicle's

movement to accomplish a given mission. RVs have emerged in various application domains such as commercial, industrial, entertainment, and law enforcement. For instance, logistics companies (e.g., USPS, DHL, and Amazon) have introduced drone delivery services to meet the rapidly growing demand in e-commerce [6, 10, 13, 27].

With their increasing adoption in real-world applications, RVs are facing threats of cyber and cyber-physical attacks that exploit their attack surface. More specifically, an RV's attack surface spans multiple aspects, such as (1) physical vulnerabilities of its sensors that enable external sensor spoofing attacks [72, 77, 80]; (2) traditional "syntactic" bugs in its control program (e.g., memory corruption bugs) that enable remote or trojaned exploits [75]; and (3) control-semantic bugs in its control program that enable attacks via remote control commands. For attacks exploiting (1) and (2), there have been research efforts in defending against them [30, 38, 40, 50, 52, 70, 76]; whereas those exploiting (3) have not received sufficient attention. As a result, the RV's attack surface in the aspects of (1) and (2) is expected to get smaller, which may prompt attackers to increasingly look at the control-semantic vulnerabilities for new exploits.

In this paper, we focus on an important type of control-semantic bugs in RV control programs, called *input validation bugs*. An input validation bug involves an incorrect or missing validity check on a control parameter-change input. Such an input is provided to the control program via a remote control command, which could trigger RV controller malfunction and ultimately lead to physical impacts on the vehicle, such as mission disruption, vehicle instability, or even vehicle damage/crash. Finding input validation bugs is a new research problem because they are largely orthogonal to the traditional "syntactic" bugs (e.g., buffer overflow and use-after-free bugs) which can be detected by existing software testing/fuzzing techniques.

Input validation bugs, on the other hand, are created semantically via incorrect setting of control parameters. In an RV, the control program can be configured through *control parameters*, which are adjustable numerical inputs that de-

termine certain aspects of the control function’s behavior (e.g., controller gain and default flight speed). We can further categorize input validation bugs into two sub-categories: (1) Incorrect or missing parameter range checks in the control program, which would accept illegitimate setting of control parameter values, are called *range implementation bugs*. (2) Incorrect specification of control parameter ranges, even if correctly implemented, may cause RV controller malfunction. We call such specification-level errors (implemented in the control program) *range specification bugs*.

Most RVs have a remote control interface [21] for operators to set or adjust control parameters during a flight. Unfortunately, such an interface can be leveraged by attackers [9, 55, 67, 68] to exploit input validation bugs and deliberately mis-configure certain control parameters. As an example (details in Section 6.3.3), an RV control program allows operators to dynamically adjust a parameter for the vehicle’s angular control and suggests a range of valid values in its specification. However, the range is erroneously determined and implemented. Knowing this bug, an attacker can issue a malicious command to reset the parameter using an illegitimate value that falls into the “valid” range, consequently crashing the vehicle.

Testing RV control programs to find input validation bugs is challenging. Popular RV control software (e.g., ArduPilot [15], PX4 [24], and Paparazzi [23]) supports many different RV models (e.g., quadcopters and ground rovers) with a large number of hardware, software and control configuration options. Generating accurate control parameter value ranges requires thorough testing of hundreds of control parameters for each RV model. With the growing number of RV models supported by control software, such testing is increasingly difficult to scale and automate. To overcome this challenge, especially without assuming source code access, one might think of leveraging automated black-box software testing methods, such as fuzzing [14, 17, 19, 71]. However, traditional software fuzzing techniques are not directly applicable to RV control programs because: (1) With hundreds of configurable parameters, the control program has an extremely large input space to explore and (2) there is no uniform and obvious condition to automatically decide that a control program is malfunctioning. Many input validation bugs do not exhibit system-level symptoms until certain control and physical conditions are met at run-time.

Our solution to finding input validation bugs – without control program source code – is motivated by the following ideas: (1) The impacts of attacks exploiting input validation bugs can be manifested by the victim vehicle’s control state; and (2) such state can be efficiently reproduced by combining the RV control program and a high-fidelity RV simulation framework, which is readily available [7, 8].

Based on these ideas, we develop RVFUZZER, an automated RV control program testing system to find input validation bugs. RVFUZZER supports input-driven testing of a

subject control program’s binary, which runs in an RV simulator – for safety and efficiency. Unlike a traditional program bug (e.g., a memory corruption or divide-by-zero bug) that can result in an obvious program execution failure, automatically determining if the control program is ill-behaving based on the simulated vehicle’s physical state is not straightforward. To address the problem, RVFUZZER involves a *control instability detector* based on a standard control stability measurement formula [47] to detect vehicle control malfunction. More importantly, RVFUZZER leverages this detector to quantify control (in)stability as feedback to guide input mutation, so that bugs can be found more efficiently by covering a large portion of the input space in a reasonable number of test runs. Our control-guided input mutation method is based on the following control property: When RV control instability starts to be observed while increasing (decreasing) the value of a control parameter, further increase (decrease) of the parameter value will only maintain or intensify such instability (Section 4.3.2). Finally, RVFUZZER mutates environmental factors such as trajectory curve or wind condition during testing, as attackers may leverage predictable environmental factors as probabilistic attack-triggering conditions.

We have implemented a prototype of RVFUZZER and applied it to ArduPilot [15] and PX4 [24], which are two popular RV control software suites used in many commodity RVs [32, 45, 58, 69]. RVFUZZER finds a total of 89 input validation bugs that can cause RV control malfunction: Two of them are known input validation bugs that were previously patched by developers; whereas the remaining 87 bugs are zero-day bugs which we have reported to the developers. In response to our report, eight bugs have been confirmed and seven of them have been patched. The contributions of our work are as follows:

- We introduce input validation bugs, a new type of RV control-semantic vulnerability that can be exploited by attackers.
- We develop RVFUZZER, a control-guided program vetting system to discover input validation bugs with safety, efficiency, and automation.
- We apply RVFUZZER to two popular RV control software suites and find 89 input validation bugs including 87 zero-day bugs.

## 2 Background

**RV Control Model** The RV control model is the generic theoretical underpinnings that control the vehicle’s movements and operations during its missions (e.g., flying in a trajectory with multiple waypoints). The RV’s movements are along its six degrees of freedom (6DoF), which include the x, y, and z-axes for movement and the roll, pitch, and yaw for rotation (Fig. 1). The control model consists of multiple controllers, each for a specific degree of the 6DoF. For example, the x-axis

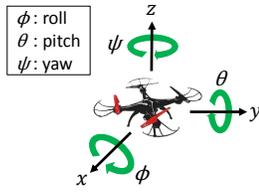

Figure 1: An RV's six degrees of freedom (6DoF).

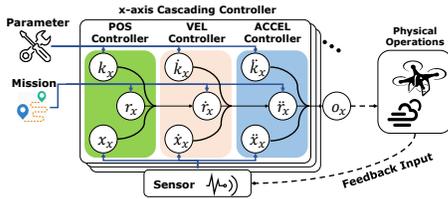

Figure 2: The x-axis controller (with three primitive controllers).

controller is shown in Fig. 2.

Inside the x-axis controller, there are three primitive controllers in a cascade, which are responsible for controlling the vehicle's position, velocity, and acceleration along the x-axis, respectively. Each primitive controller takes two state inputs: a reference state ( $r(t)$ ) computed by its upstream primitive controller; and an observed state ( $x(t)$ ) reported by sensors. The goal of the controller is to keep the observed state close to the reference state, via its core function of *control state stabilization*. The output of the function is the reference state for its downstream primitive controller. Each primitive controller has multiple adjustable parameters and accepts high-level mission directives (e.g., change of target location or speed).

Overall the RV control model involves complex dependencies between the 6DoF controllers, each having multiple parameters and accepting mission directives. Moreover, the controllers, sensors, and the vehicle's physical operations (e.g., those of motors) create a feedback loop, which enables the periodic, iterative working of the controllers.

**RV Control Program** An RV control program implements the RV control model. Correspondingly, it involves the following main modules: (1) a sensor module to collect sensor inputs (e.g., from GPS, inertial measurement unit, etc.) for periodic vehicle state observation, (2) a controller module to generate control output based on current mission, reference state, and sensor input, and (3) a mission module to interpret mission directives and execute them. These modules execute iteratively in the periodic control epochs.

During a flight, the RV communicates with a ground control station (GCS), which may issue a variety of GCS commands to the control program. Many of those commands allow RV operators to dynamically adjust the controller and mission parameters. We note that such a dynamic parameter change may be necessary to improve vehicle control performance (e.g., enhancing stability), in response to mission dynamics such as payload change and non-trivial external disturbances.

In addition to the control and communication functions, most RV control programs have a run-time control state log-

ging function, for record-keeping and troubleshooting purposes. Real-world commodity RVs (e.g., Intel Aero [18], 3DR IRIS+ [12], and DJI drone series [16]), as well as their simulators, log in-flight control states in persistent storage. RVFUZZER leverages such logs for automatic determination of controller malfunction.

**Control Parameters** Because of the complexity and generality of RV control model and program, a large number (hundreds) of configurable parameters exist in the control program. Many of them are dynamically adjustable at run-time via the GCS command interface. For example, in the ArduPilot software suite [15], there are 247 configurable control parameters, including 111 parameters for the x-, y-axis controller, 119 for the z-axis controller, 29 for the roll controller, 29 for the pitch controller, 30 for the yaw controller, 103 for motor control, and 40 for mission specification. We note that, while the total number of the parameters is 247, some of the parameters are shared by multiple controllers. When receiving a GCS command to adjust one of these parameters, the control program is supposed to perform an input validity check to determine if the new value is within the safe range of that parameter. Unfortunately, such a check may be missing or based on an erroneous value range.

### 3 Attack Model

**Attack Model and Assumptions** Attacks that exploit input validation bugs are characterized as follows: Knowing an adjustable control parameter with incorrect or missing range check logic in the control program<sup>1</sup>, the attacker concocts and issues a seemingly innocent – but actually malicious – parameter-change GCS command to the victim RV. Without correct input validation, the illegitimate parameter value will be accepted by the control program and cause at least one of the RV's 6DoF controllers to malfunction – either immediately or at a later juncture, inflicting physical impacts on the RV. When planning an attack, the attacker may also opportunistically exploit a certain environmental condition (e.g., strong wind) under which a parameter-change command would become dangerous. For example, he/she might wait for the right wind condition (e.g., by following weather forecast) to launch an attack with high success probability. Such a case will be presented in Section 6.3.3.

The attacker can be either an external attacker or an insider threat. In the case of an external attacker, we assume that he/she is able to perform GCS spoofing to issue the malicious command, which is justified by the known vulnerabilities in the wireless/radio communication protocols between RV and GCS [9, 55, 67, 68, 78]. In the case of an insider threat, we assume that the insider is a rogue RV operator (not a developer), who does not have access to control program

<sup>1</sup>The attacker may acquire such knowledge via a program vetting tool (such as RVFUZZER).

source code and cannot update the control program firmware.

**Attack Model Justifications** Our attack model is realistic (and attractive) to attackers for the following reasons: (1) Such an attack incurs a very small footprint – just one innocent-looking command, without requiring code injection/trojaning, memory corruption, or sensor/GPS spoofing; (2) The attack can still be launched even after the control program has been hardened against traditional software exploits [1, 2, 39, 52]; (3) The attack looks like an innocent “accident” because the malicious parameter value passes the control program’s validity check. In some cases (i.e., range specification bugs), it is even in the valid range set in the control program’s specification.

Why would the attacker bother to manipulate control parameter values, instead of just taking control of, or crashing the vehicle? A key observation provides the answer: If the attacker is not aware of – and hence does not manipulate – illegitimate-but-accepted control parameter values, it would actually *not* be easy to disrupt or crash an RV with minimum footprint<sup>2</sup>. This is because both the RV control program and control model already achieve a level of robustness for the RV to resist being commanded into instability or danger: The control program can identify and reject many illegitimate commands; and the control model can filter or mitigate the impacts of some commands that escape the control program’s check [11, 48]. Moreover, an internal attacker is also motivated to exploit illegitimate control parameter values that are erroneously considered normal in the RV’s specification (i.e., range specification bugs), as the attacker could evade attack investigation by claiming that he/she was following RV control specification when issuing the command in question.

We do acknowledge that there exist scenarios where attackers can successfully launch attacks without exploiting input validation bugs. For example, an insider could hijack an RV by changing its trajectory, when working alone without a co-operator (who might otherwise catch the attack in action).

## 4 RVFUZZER Design

In this section, we present the design of RVFUZZER. We first give an overview of RVFUZZER’s architecture (Section 4.1) and then present detailed design of two key components of RVFUZZER: (1) the control-guided instability detector that monitors the vehicle’s control state to detect controller malfunction (Section 4.2) and (2) the control-guided input mutator that generates control program inputs for efficient program testing (Section 4.3).

### 4.1 Overview

RVFUZZER is designed to (1) detect physical instability of the RV during testing and (2) generate test inputs iteratively to

<sup>2</sup>The minimum footprint would help avoid detection before the attack succeeds.

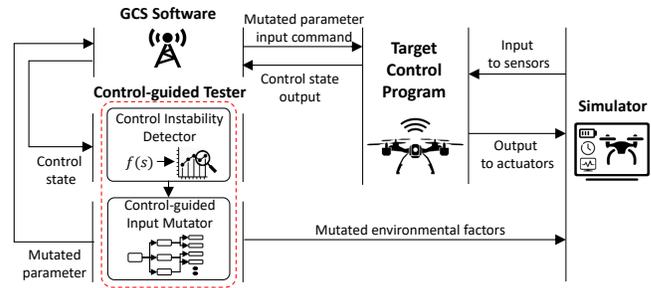

Figure 3: Overview of RVFUZZER.

achieve high testing efficiency and coverage. Fig. 3 presents an overview of RVFUZZER, which consists of four main components: a GCS program, the subject control program, a simulator, and a control-guided tester – the core component of RVFUZZER. The roles of the first three components are as follows: the GCS software is responsible for issuing RV control parameter-change commands; the subject control program, as the testing target, controls the operations of the (simulated) RV; and the simulator emulates the physical vehicle and its operating physical environment. We note that (1) the GCS and RV control programs are from real-world GCS and RV; and (2) our simulators [7, 8] are widely adopted for robotic vehicle design and testing.

RVFUZZER’s control-guided tester consists of two sub-modules: (1) control instability detector and (2) control-guided input mutator. During testing, the control instability detector detects non-transient physical disturbances of the target RV (e.g., crash and deviation), as indication of control program execution anomaly caused by an input validation bug. The control-guided input mutator is a feedback-driven input mutator for efficient mutation of control parameter and environmental factor values. Using the results of the control instability detector as feedback, the mutator adaptively mutates control parameter values via a well-defined RV control interface (i.e., GCS commands created and issued by the GCS software). In addition, it mutates environmental factors (e.g., wind) by re-configuring the simulator.

### 4.2 Control Instability Detector

The goal of the control instability detector is to continuously monitor RV control state to determine if a specific GCS command has induced non-transient physical disturbance. Such a physical disturbance can be considered as an indication of an input validation bug. We note that input validation bugs may not lead to program crash, a common indicator of traditional bugs (e.g., memory corruption).

We first define a rule to detect physical disturbances, which is tailored for input validation bugs. We then describe the mechanism to monitor the RVFUZZER’s 6DoF control states for detecting such a disturbance.

**Indication of Control State Deviation** Exploitation of an input validation bug will cause an RV’s failure to stabilize

its control states and/or complete its mission. To accurately detect bug-induced physical disturbance, RVFUZZER must be equipped with the capability of control state deviation detection. Among the possible physical disturbances experienced by an RV, there are two types of control state deviation: (1) observed state deviation and (2) reference state deviation. Accordingly, we define a detection rule to determine if one of the two types of control state deviation has occurred.

The first type – observed state deviation – is the case where a controller (e.g., the primitive x-axis velocity controller) fails to stabilize its observed state ( $x(t)$ ) according to its reference state ( $r(t)$ ). In the theoretical control model, a controller always tries to keep  $x(t)$  close to  $r(t)$  (Section 2). Consequently, if the difference between  $x(t)$  and  $r(t)$  keeps increasing and exceeds a certain threshold, the observed state will be considered deviating from the reference state. To quantify the observed state deviation, we leverage the integral absolute error (IAE) formula [47] which is widely used as a stability metric in control systems.

$$deviation(t) = \int_t^{t+w} \frac{|r(s) - x(s)|}{w} ds \quad (1)$$

Given a time window  $w$  and starting from a certain time instance  $t$ , the formula quantifies the level of deviation ( $deviation(t)$ ). If  $deviation(t)$  is larger than a pre-determined threshold  $\tau$ , our rule will determine that there is a control state deviation starting at  $t$ . We will describe how to experimentally determine  $w$  and  $\tau$  for each 6DoF control state in Appendix A.

The second type – reference state deviation – is the case where an RV deviates from its given mission. A controller is expected to adjust its reference state to track its mission. If a controller fails to do that, it is considered malfunctioning. To detect such a deviation, our rule will check whether the difference between the reference state and the mission target becomes persistently greater than a threshold.

We note that our detection rule only considers non-transient control state deviation. An RV may experience transient control state deviation during normal operation but can effectively recover from it, thanks to the robustness features of the controllers such as the extended Kalman filter [46, 51, 60].

**Control Instability Detection** We now apply our “observed-reference” and “reference-mission” deviation determination rule to detect control instability. During a test mission, the control program readily logs all its 6DoF control states (Section 2). The log data can be retrieved by the GCS software, which will then be accessed by the Control Instability Detector and applied to the evaluation of the detection rule (Fig.3). Note that the control states include those of the three primitive controllers (for position, velocity, and acceleration control) inside each 6DoF controller; and each primitive controller logs its observed, reference and mission states. As such, the Control Instability Detector can apply the detection rule to detect control state deviation at any primitive controller.

## 4.3 Control-Guided Input Mutator

A software testing system needs to judiciously generate program inputs to achieve high bug coverage while reducing the number of the subject program’s test runs. In other words, the set of generated testing inputs should be representative to produce the same or similar results when other untested inputs were provided to the program. We first define RVFUZZER’s input mutation space (i.e., types and value ranges of dynamically adjustable control parameters). We then describe our control-guided input mutation strategy to generate representative testing inputs, with consideration of environmental factors that affect the RV operation and control.

Our input generation method considers both control parameters and environmental factors<sup>3</sup>. For control parameters, we first define their value mutation spaces (Section 4.3.1). We then present the feedback-driven input mutator which generates a reduced set of control parameter-change test inputs (Section 4.3.2). The mutator also mutates the external environmental factors and tests the control program under different combinations of input control parameter values and environment factor values.

### 4.3.1 Control Parameter Mutation Space

The input mutation space of the subject control program consists of: (1) the list of dynamically adjustable control parameters, (2) the range of all possible values for each parameter, and (3) the default value of each parameter.

The list of control parameters is obtained from the specification of control program and the GCS command interface. We note that this is public information even for a close-source control program. The three most popular control software suites (i.e., ArduPilot [15], PX4 [24], and Paparazzi [23]) all support a common parameter tuning interface defined in MAVLink [21], the de facto protocol for RV-GCS communications.

The value ranges of control parameters can be decided (1) by the data type of the control parameter and (2) by polling the control program itself. For a control parameter, its data type generically sets its value range. For example, the range of a 32-bit integer parameter is  $[-2^{31}, 2^{31} - 1]$ . Interestingly, the ranges of many control parameters can be narrowed by polling the control program. This can be done by first sending a parameter-change command with a very large/small value; and then querying the actual value of that parameter, which now becomes the maximum/minimum value of the parameter defined in the control program. While the possibility of such a probe is specific to control program implementation, we do observe such implementation logic in ArduPilot and PX4.

The mutator also selects a default value within the range of each control parameter. Such a default value will be used

<sup>3</sup>Environmental factors are not program input but physical context in which the RV operates.

in the input space search during mutation (Section 4.3.2). We note that the set of default values of control parameters is normally made available by RV vendors (e.g., 3DR, DJI, and Intel), as a guidance to RV users when tuning the control parameters.

### 4.3.2 Feedback-Driven Parameter Input Mutator

RVFUZZER's input mutator accepts two inputs: the control parameter mutation space and the result of the Control Instability Detector from the previous run of the control program. The output of the mutator is the testing input for the program's next run. The efficiency of the control program vetting process depends on how well the mutated inputs are generated to trigger input validation bugs without launching too many program test runs with different inputs. To explain our mutation strategy and methods, we first introduce the underlying intuition of our strategy and then describe our feedback-driven testing process with two steps: one-dimensional mutation and multi-dimensional mutation.

**Input Space Reduction Strategy** The purpose of RVFUZZER is to find vulnerable – i.e., illegitimate but accepted – values for each dynamically adjustable control parameter. However, it is infeasible to test all possible values of a parameter. To improving testing efficiency, RVFUZZER must be able to selectively skip certain ranges of parameter values, if they lead to the same or similar outcome as the tested values. The value range-skipping idea is feasible thanks to the following observation: When control instability starts to be observed while increasing (decreasing) the value of a control parameter, further increase (decrease) of the parameter value will only maintain or intensify the instability.

We note that the aforementioned observation is generally valid. More specifically, in a control model, controllers and filters can be lumped together as part of its dynamics. Based on Root Locus [54], the trajectory of the loci always follows some asymptote. Hence, the change of a parameter will cause a *monotonic* change in stability. Sensor calibration can be considered as a constant disturbance, which will cause system response to degrade as the magnitude of the disturbance increases. Mission parameters will have different effects: Some can be grouped as part of the dynamics based on Root Locus; Some others, such as angle limitations, could cause an excessive response that introduces undesirable overshoot. This can be viewed as an integral windup, with a larger limit causing a larger overshoot.

Based on this observation, we propose two features for the mutator. (1) It will report valid/invalid value ranges — not individual values. Such a range will have a lower (minimum) and upper (maximum) bound. Any parameter value outside the range will cause control instability. (2) The mutator will be driven by feedback from the Control Instability Detector (Section 4.2) to determine the next testing input.

Such feedback-driven mutation will be able to skip certain parameter value ranges for efficiency.

**One-dimensional Mutation** In the first step of control software vetting, RVFUZZER's input mutator determines the valid/invalid range for each control parameter *independently*. The mutator isolates the impact of the target parameter on the control state deviation by setting the values of all other parameters to their *default* values.

We present the one-dimensional mutation procedure in Algorithm 1. For each target control parameter, the mutator determines the upper and lower bounds of the valid value range by utilizing a mutation-based binary search method. We elaborate the method (Algorithm 1) to find the upper bound of the valid range as follows. We note that the mutator follows a syntactically similar method to find the lower bound of the valid range.

To find the upper bound, the mutator will iteratively launch test runs, using the binary search method to set the next run's *input value* and to update the *working range*. It will set the initial *min-limit* of the working range as the default value of the target parameter; the initial *max-limit* of the working range as the maximum possible value of the target parameter (Section 4.3.1); and the initial input value as the mid-point between the *min-limit* and *max-limit* values. Thereafter, in each run, the mutator obtains the output of the Control Instability Detector under the current input value, and updates the working range in the next run by considering the following two cases based on the detector's output (Line 14).

- **Case 1** (Line 17-18): If the mutator observes that the current input value does not cause any deviation, it skips the lower half of the working range in the next run and sets the new *min-limit* as the current input value. This decision is justified by our earlier observation on the monotonic property of control instability. For the next run, the mutator will again set the new input value as the mid-point between *min-limit* and *max-limit*.
- **Case 2** (Line 15-16): If the current input value leads to control state deviation, the mutator concludes that there are other values lower than the current input value which can also cause deviation. Hence, for the next run, the mutator will skip the upper half of the working range by setting *max-limit* as the current input value and the new input value as the mid-point between *min-limit* and *max-limit*.

We highlight that, after each run, the mutator skips the values corresponding to one half of the working range. This input space reduction strategy ensures that the mutator covers all possible values of the target control parameter efficiently. After determining the working range for the next run, the mutator sets the input value for the next run as the mid-point of the new working range (Line 19), following the binary search method. The mutator continues the (detector) feedback-driven

6: function ONEMUTATION( $M, P, E, \tau, bound$ )
7:   if  $bound = U$  then  $\triangleright$  'U' indicates an upper-bound search
8:      $\{test, max-limit, min-limit\} \leftarrow \{(P.Max - P.Default)/2, P.Max, P.Default\}$ 
9:   else  $\triangleright$  'L' indicates a lower-bound search
10:     $\{test, max-limit, min-limit\} \leftarrow \{(P.Default - P.Min)/2, P.Default, P.Min\}$ 
11:    $MinDiff \leftarrow 0$ 
12:   do
13:      $test' \leftarrow test$   $\triangleright$  Store the testing value before mutation
14:      $Dev \leftarrow$  RUNANDDEVIATIONCHECK( $M, P, test, E, \tau$ )
15:     if ( $bound = U$  and  $Dev = True$ ) or ( $bound = L$  and  $Dev = False$ ) then
16:        $max-limit \leftarrow test$   $\triangleright$  Change the testing range
17:     else
18:        $min-limit \leftarrow test$   $\triangleright$  Change the testing range
19:      $test \leftarrow (max-limit + min-limit)/2$   $\triangleright$  Mutate the testing value
20:     while  $|test' - test| > MinDiff$   $\triangleright$  Check the exit condition
21:   return GETINVALIDRANGE( $test, test', bound, Dev$ )
```

---

search method, until the difference between the input values in the current and the next runs is less than a pre-determined threshold  $MinDiff$  (Line 20). Finally, the mutator determines the valid value range and the corresponding vulnerable value range (i.e., invalid range) for the target control parameter.

**Multi-dimensional Mutation** RVFUZZER also performs a more advanced form of input mutation: multi-dimensional mutation, which finds extra invalid parameter value ranges that one-dimensional mutation may not find. Such extra invalid parameter values are introduced because a target control parameter may have *dependencies* on other parameters. In other words, different (non-default) setting of such other parameters may expand the invalid range of the target parameter.

To test the impact of other parameters ( $P_{others}$ ), RVFUZZER performs the multi-dimensional mutation for each target parameter ( $P_{target}$ ) as described in Algorithm 2. In this algorithm, RVFUZZER utilizes the results from the one-dimensional mutation (Algorithm 1) of all control parameters ( $P_{all}$ ) (i.e., the lower and upper bounds of their valid ranges). For the target parameter, RVFUZZER sets the initial working range as its valid value range obtained from one-dimensional mutation (Line 2). Thereafter, the mutation of the values of the other parameters (Line 8-15) and the target parameter (Line 18-21) are performed recursively.

In each recursion, the value of each of the other parameters is mutated among only three values: the default value, the lower bound of its valid value range and the corresponding upper bound (Line 11). We note that setting the values of one/more of the other parameters to their lower/upper bound values leads to an extreme scenario which can potentially exacerbate the impact of the target parameter on the control state deviation.

After setting the values of the other parameters (Line 18), the mutator follows a procedure similar to the one-

---

**Algorithm 2** Multi-dimensional Mutation.

```
Input: Input mission ( $M$ ), target testing input parameter ( $P_{target}$ ), a set of all input parameters including one-dimensional search results ( $PS_{all}$ ), test environmental factor ( $E$ ), control state deviation threshold set for all primitive controllers ( $\tau$ )
Output: An invalid range for a target parameter ( $R$ )

1: function MULTIDIMENSIONALMUTATION( $M, P_{target}, E, PS_{all}, \tau$ )  $\triangleright$  Main function
2:    $R \leftarrow$  GETINVALIDRANGE( $P_{target}$ )  $\triangleright$  Results from the previous step
3:    $PS_{others} \leftarrow PS_{all} - \{P_{target}\}$   $\triangleright$  A set of other parameters except for  $P_{target}$ 
4:    $PS_{mut} \leftarrow \emptyset$   $\triangleright$  Initialize the mutated parameter set
5:    $R \leftarrow$  DEPMUTATION( $M, P_{target}, E, PS_{others}, PS_{mut}, R, \tau$ )

```

---

dimensional mutation. It employs the mutation-based binary search method to determine and update the lower and upper bounds of the valid value range of the target parameter (Line 20-21). The new (in)valid range is then updated (Line 21).

In essence, as RVFUZZER mutates the values of multiple control parameters together, it can identify additional values of the target parameter that will cause control state deviation under specific value setting of the other parameters. If such invalid values lie outside the one-dimensional invalid value range, the multi-dimensional mutation will conditionally expand the invalid value range to include those values, subject to the setting of the other parameters. As such, the result of the multi-dimensional mutation can be considered as an incomplete set of constraints on the values of multiple control parameters.

### 4.3.3 Environmental Factors

In real-world missions, the RV interacts with the physical environment with external factors such as physical obstacles and wind. Such factors influence RV's control state and performance. We note that an external factor (e.g., wind) could make an otherwise valid parameter value cause control state deviation. This means that such values can be exploited by attackers. To detect such influence, RVFUZZER mutates and simulates the impact of environmental factors along with multi-dimensional mutation of parameter values. We categorize the environmental factors into two types: geography and disturbances.

Typical geographical factors of interest are obstacles encountered by an RV during its missions. The RV will need to take actions to avoid such an obstacle. The actions may entail changes in the parameter values to enable a change of trajectory. This may expand the invalid range of the parameter

values that will cause control state deviation. To expose such input validation bugs, RVFUZZER defines and simulates RV missions in which the RV needs to avoid obstacles via sudden, sharp trajectory changes. An attack case triggered by obstacle avoidance will be presented in Section 6.3.3.

External disturbances such as wind and turbulence may also disrupt the RV's operation. RVFUZZER simulates the wind gusts and mutates the wind speed and direction based on real-world wind conditions. Details of the wind factor setup are given in Section 6.2.2. The attack case presented in Section 6.3.3 also exploits the wind condition.

## 5 Implementation

To evaluate RVFUZZER experimentally, we have implemented a prototype of RVFUZZER. The implementation details of its main components are described as follows.

**Subject Control Programs** We choose the quadcopter as our subject vehicle as the quadcopter operates in all of the 6DoF and it is one of the most widely adopted types of RVs [49, 62, 64]. We point out that the implementation of RVFUZZER is not specific to a certain RV type or model as RVFUZZER only needs the physical quantities (e.g., weight and inertial parameters) and the corresponding simulator to support a vehicle. This means that RVFUZZER can be reconfigured to support other types of RVs, such as hexacopters and rovers.

We apply RVFUZZER to vet two control programs that both support the quadcopter: ArduPilot 3.5 and PX4 1.8. The default vehicle control model supported by both programs is that of the 3DR IRIS+ quadcopter [12]. All vetting experiments (on both ArduPilot and PX4) are performed using a desktop PC with quad-core 3.4 GHz Intel Core i7 CPU and 32 GB RAM running Ubuntu 64-bit.

**Simulator** To simulate the physical vehicle and environment, we utilized the APM simulator [8] and Gazebo [7, 42, 53] for ArduPilot and PX4, respectively. We note that RVFUZZER's control instability detection and input mutation functions can easily inter-operate with these simulators via the interfaces between the simulators and the control and GCS programs.

**GCS Program** We used QGroundControl [26] and MAVProxy [22] as the ground control station software for PX4 and ArduPilot, respectively.

**Control-Guided Tester** The control-guided tester is the core component of RVFUZZER. It is written in Python 2.7.6 with 5,722 lines of code. To implement the key functions in RVFUZZER, we leveraged the *Pymavlink* library [25], which provides APIs to remotely control the RV via the MAVLink communication protocol [21]. MAVLink is the de-facto communication protocol for robotic vehicles, which is used not only by ArduPilot and PX4, but also by other platforms such as Paparazzi [23], DJI [16], and LibrePilot [20]. MAVLink supports a wide range of GCS commands (e.g., for mission

assignment, run-time control state monitoring, and parameter checking and adjustment) that are leveraged and tested by RVFUZZER.

To test the control performance of the subject vehicle, we adopted the *AVC2013* [5] mission which is an official mission provided by ArduPilot and used in autonomous vehicle competitions to test the control and mission execution capabilities of RVs. To improve the testing efficiency of RVFUZZER, we adjusted that mission by removing the overlapping flight courses, reducing the distance between each pair of waypoints, and increasing the vehicle's velocity.

To classify and generate the bug discovery results, we leverage a list of dynamically adjustable control parameters provided by ArduPilot and PX4 [28, 29]. Such a list is usually provided in the Extensible Markup Language (XML) format in the source code and can be easily parsed.

## 6 Evaluation

We now present evaluation results from our experiments with the RVFUZZER prototype. The three main questions that we want to answer are: (1) How effective is RVFUZZER at finding input validation bugs (Section 6.1); (2) How do different input mutation schemes of RVFUZZER contribute to the discovery of input validation bugs (Section 6.2); and (3) How can RVFUZZER be applied to discover input validation bugs that would otherwise be exploited to launch stealthy attacks (Section 6.3).

### 6.1 Finding Input Validation Bugs

We present a summary of the input validation bugs discovered by RVFUZZER from ArduPilot and PX4. These bugs are the result of a 8-day, non-stop testing session running RVFUZZER on the two control programs.

#### 6.1.1 Classification of Input Validation Bugs

The validity of an input value of a control parameter is checked based on the *specified* range that has been determined and documented by developers during the development of the control program. Our subject control programs (ArduPilot and PX4) have the specified ranges of all the control parameters publicly available on their developer community websites [28, 29]. Leveraging these public range specifications, RVFUZZER found a number of input validation bugs through the 8-hour testing session. We classify these input validation bugs into two categories based on their root causes: range implementation bugs and range specification bugs.

**Range Implementation Bugs** Assuming that the specified valid range of a control parameter is correct, any value outside the specified range should be caught and rejected by the control program. If the implementation of the control program fails to enforce that, an out-of-range parameter value may

Table 1: Summary of input validation bugs found by RVFUZZER (RIB and RSB denote the number of range implementation and range specification bugs, respectively).

Module	Sub-module	ArduPilot		PX4	
		RIB	RSB	RIB	RSB
Controller	x, y-axis position	1	0	1	1
	x, y-axis velocity	2	1	1	1
	z-axis position	1	0	1	1
	z-axis velocity	1	0	1	0
	z-axis acceleration	3	0	0	0
	Roll angle	1	0	1	1
	Roll angular rate	5	0	3	3
	Pitch angle	1	0	1	1
	Pitch angular rate	5	0	3	3
	Yaw angle	1	0	2	2
Sensor	Motor	6	0	3	3
	Inertia sensor	3	3	0	0
Mission	x, y-axis velocity	1	1	2	0
	z-axis velocity	2	0	4	0
	z-axis acceleration	2	0	0	0
	Roll, Pitch	1	1	1	1
Total	-	36	6	27	20

be maliciously provided and accepted by the program, causing control state deviations. This is the nature of the range implementation bug which, based on our observation, arises from a lack of or an incorrect implementation of range check logic in the program. To discover range implementation bugs, RVFUZZER employs the one-dimensional mutation strategy. It mutates the value of each target parameter and issues the parameter-change GCS command with the mutated value to the control program. If the Control Instability Detector reports a control state deviation, RVFUZZER will report a range implementation bug associated with the target parameter.

**Range Specification Bugs** Ideally, the specified valid range of a parameter should correctly scope the value of the parameter. Unfortunately, this turns out not always the case. To reveal such problems, RVFUZZER first performs one-dimensional mutation and then performs multi-dimensional mutation on each target parameter, determining its invalid value range that will cause control state deviation. We observe that for some control parameters, their valid value ranges are erroneously specified by developers, allowing dangerous values in the specified – and subsequently implemented – ranges. This is the nature of the range specification bug. Based on our analysis, such bugs exist because a control program enforces a *fixed* valid value range for a control parameter, without considering three critical factors: (1) the difference between hardware models and configurations, (2) inter-dependencies between control parameters, and (3) impact of environmental factors. RVFUZZER reveals that the range of the valid input values of a target parameter tends to “shrink” under these factors, giving rise to range specification bugs.

### 6.1.2 Detection of Input Validation Bugs

Table 1 summarizes the range implementation bugs (RIB) and range specification bugs (RSB) discovered by RVFUZZER in ArduPilot and PX4. The detailed list of the 63 control parameters that are affected by these bugs is presented in Appendix B. For coherent presentation in Table 1, the control parameters in each of the two control programs are categorized into three modules (i.e., controller, sensor, and mission) and further into their sub-modules. Table 1 shows that RVFUZZER detected a total of 89 input validation bugs (42 bugs in ArduPilot and 47 bugs in PX4). We note that some of the control parameters are associated with *both* range implementation and the range specification bugs. Hence, the total number of input validation bugs (89) is higher than the total number of affected control parameters (63).

We highlight that only two of the 89 bugs discovered by RVFUZZER were detected and correctly patched by the developers *before* we reported our results to them. Out of the remaining 87 bugs, the developers have so far independently confirmed 8 bugs and patched 7 of them. The remaining bugs are under review. The delayed response of the developers brings forth an important point: Compared to the traditional “syntactic” bugs (e.g., buffer overflow), discovering, validating and patching input validation bugs require more time and effort. This is because the exploitability of each input validation bug must be fully verified under a spectrum of vehicle configurations and operating environments. In such a scenario, RVFUZZER can be utilized by developers as a helpful tool to automate the discovery and confirmation of input validation bugs.

### 6.1.3 Impact of Input Validation Bugs

We now detail the physical impacts (on the vehicle’s operation) of the attacks that exploit the bugs found by RVFUZZER. We consider four levels of physical impact: crash, trajectory deviation, unstable movement, and frozen control states. Appendix B presents possible physical impact(s) of attacks that exploit each of the vulnerable control parameters. Here, we summarize the results by analyzing the impact on the modules of the control program. Specifically, we present the causality of the bugs in a bottom-up fashion and assess its impact on the control state deviation which is detected by RVFUZZER’s Control Instability Detector.

**Controller Module** Among the control parameters related to the controller module, RVFUZZER discovered 27 range implementation bugs and 1 range specification bug in ArduPilot, and 20 range implementation bugs and 19 range specification bugs in PX4 (Table 1). These bugs can be used to maliciously set invalid parameter values or exploit environmental factors, which would directly affect the primitive controllers and corrupt the control states in the 6DoF. For example, if one of the control parameters related to the z-axis velocity is set to

a value in the invalid range due to an input validation bug, the manipulated parameter will corrupt the reference state of the (downstream) z-axis acceleration. As a result, the z-axis acceleration controller will attempt to bring its observed state closer to the corrupted reference state, which will cause control instability of the vehicle. Such instability may eventually lead to a crash.

**Sensor Module** For this module, while RVFUZZER found 3 range implementation bugs and 3 range specification bugs in ArduPilot, it did not find any input validation bug in PX4 (Table 1). We note that the vulnerable control parameters of the sensor module are related to either a sensor calibrator or a sensor filter for noise/disturbance. While the calibrator compensates for manufacturing errors in sensors and adjusts the observed state accordingly, the filter smooths out the sensor values and helps the controllers in robustly responding to physical interactions [73]. Hence, if an invalid value is assigned to a control parameter related to a sensor calibrator/filter due to an input validation bug, the primitive controller that consumes the sensor values will compute a corrupted observed state. Such corruption will also propagate to its output reference state, and from there to other dependent primitive controllers, leading to unstable movement of the vehicle.

**Mission Module** For this module, RVFUZZER discovered 6 range implementation bugs and 2 range specification bugs in ArduPilot, and 7 range implementation bugs and 1 range specification bug in PX4 (Table 1). Recall that this module is responsible for setting the mission parameters (e.g., speed and tilting angles) which define or adjust the vehicle’s mission. However, if a parameter related to the mission module is manipulated with an invalid value by exploiting an input validation bug, the corresponding controllers will generate misguided reference states. Such mission corruption will mislead one or more of the 6DoF controllers and prevent the vehicle from fulfilling its intended mission (e.g., not moving to the intended destination or at the intended speed), even if the vehicle does not experience any immediate danger.

## 6.2 Effectiveness of Input Mutation

RVFUZZER employs the control-guided input mutation strategy to generate control parameter value inputs and set environmental factors. We evaluate the effectiveness of this mutation strategy in enabling efficient discovery of input validation bugs.

### 6.2.1 Control Parameter Mutation

RVFUZZER discovers the range implementation bugs using the one-dimensional mutation strategy which detects the erroneous implementation of the parameter’s range check logic. Through the extensive black-box-based (i.e., without source code) testing of the control parameters, RVFUZZER discov-

ered a total of 63 range implementation bugs: 36 bugs in ArduPilot and 27 bugs in PX4.

To detect the incorrectly specified ranges of the parameters and find the range specification bugs, RVFUZZER employs one-dimensional mutation followed by the multi-dimensional mutation strategy. We demonstrate the effectiveness of RVFUZZER’s mutation strategies in discovering the range specification bugs in Fig. 4, which presents the valid and invalid value ranges (detected using one-dimensional and multi-dimensional mutation) for the affected control parameters.

**One-dimensional Mutation** RVFUZZER discovered a total of 26 range specification bugs using one-dimensional mutation: 6 bugs in ArduPilot and 20 bugs in PX4 (Fig. 4). For example, for parameter `MC_TPA_RATE_P` in PX4, the specified range was between 0 and 1, and the default value was 0. However, RVFUZZER detected control state deviations with values between 0.1 and 1, and hence found 90% of the values in the specified range belonging to the invalid range. We note that almost 100% of the values in the specified range of the three parameters, `MC_PITCHRATE_FF`, `MC_ROLLRATE_FF` and `MC_YAWRATE_FF`, in PX4 are invalid. This is because, while each of these parameters can be independently configured with a wide range of input values, there is a smaller range of values that are valid when the other parameters take their default values.

**Multi-dimensional Mutation** Recall that the multi-dimensional mutation further expands the invalid range of the target parameter to include the additional values that cause control state deviation under specific, non-default settings of the other parameters. In Fig. 4, we observe that the multi-dimensional mutation expands the invalid ranges of 10 out of 26 range specification bugs found using one-dimensional mutation. For instance, RVFUZZER found that the invalid range of the `MC_ROLL_P` parameter in PX4 was expanded from 1.7% to 51.7% when multi-dimensional mutation was employed. We highlight that for some parameters, RVFUZZER reported a significant increase of invalid range with multi-dimensional mutation. In particular, compared to the invalid ranges detected using one-dimensional mutation, the invalid ranges of the `MC_PITCHRATE_MAX` and `MC_ROLLRATE_MAX` parameters in PX4 increased from 0.4% to 88.1% and from 0.1% to 87.9%, respectively. These results demonstrate that the multi-dimensional mutation strategy can discover invalid values of control parameters with stronger awareness of the inter-parameter dependencies (discussed further in Section 8).

### 6.2.2 Environmental Factor Mutation

RVFUZZER further found that the invalid ranges of some control parameters expand when environmental conditions are taken into account. This is important because the developers may not completely consider the impact of various environmental conditions when specifying the valid range of a pa-

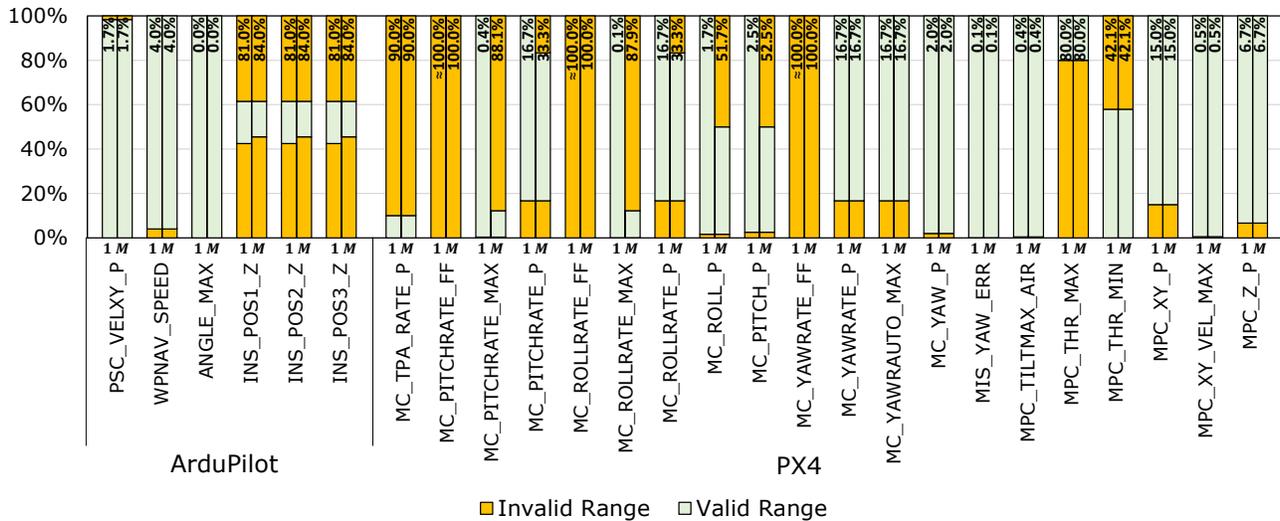

Figure 4: Invalid control parameter ranges discovered by RVFUZZER, normalized to the specified value ranges (1: One-dimensional mutation, M: Multi-dimensional mutation). Percentage of invalid ranges (%) within the specified value ranges are noted at the top of the bars.

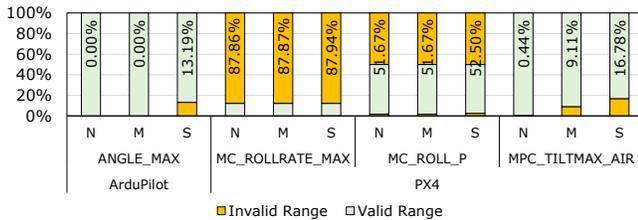

Figure 5: Normalized invalid ranges within the specified value ranges under different wind conditions (N: No wind, M: Medium wind, S: Strong wind).

parameter. Based on our observation, two factors may widen the invalid ranges: (1) geographical factor and (2) external disturbance (e.g., strong wind), as described in Section 4.3.3. RVFUZZER found four cases which can be exploited with realistic environmental factors.

We performed tests based on existing wind analysis statistics [33, 41, 59] and simulated various wind conditions. The wind conditions were divided into three categories: no wind, medium wind (with a horizontal wind component of 5 m/s or a vertical wind component of 1 m/s), and strong wind (with a horizontal wind component of 10 m/s or a vertical wind component of 3 m/s). For each wind condition, the wind gust was simulated from 0 to 360 degrees with 30-degree increments. Simulations were also performed where the wind gust was designed to come in at every 30-degree angle between the horizontal tests and the vertical tests, such that the tested wind vectors approximately formed an ellipsoid. These wind settings enrich our standard test mission (Section 5), which already reflects geographical factors as it emulates flight paths with sharp turns for obstacle avoidance.

Fig. 5 presents the impact of three different wind conditions on the four parameters which cause control state deviations. RVFUZZER discovered these four input validation

bugs using multi-dimensional mutation over the four parameters. We observe that the impact of environmental factors expands the invalid ranges of those parameters. In particular, when the wind conditions were not considered, ANGLE\_MAX did not have any invalid range under both one-dimensional and multi-dimensional mutations. However, with wind conditions, RVFUZZER reveals that this parameter can be exploited when strong wind is present.

Such an input validation bug is exploitable because a large angular change is required to alter the direction of the vehicle. Specifically, if the maximum allowed angle or angular speed is not large enough (even within the specified value ranges), the vehicle’s motors cannot generate enough force to change the direction or resist the wind gusts. As a result, the vehicle may fail to change its direction at sharp turns or it might drift in the wind’s direction in the worst case.

We note that the results with environmental factor mutation may be affected by other factors, such as the control model, configuration, and physical attributes (e.g., motor power and the size of the vehicle). For example, if the vehicle is capable of turning with a larger roll angle, has a smaller size, or has stronger motors, it may be able to resist wind gusts when changing its flight direction. Hence, these conditions need to be tested by RVFUZZER for each specific type of vehicle.

### 6.3 Case Studies

We present three representative case studies of input validation bugs. We also discuss how an attacker can exploit these bugs, and how RVFUZZER can proactively discover them. The three cases cover different affected controllers, cause different impacts on the RV, and require different components of RVFUZZER’s testing techniques to detect. Specifically, the bug discussed in Case I (Section 6.3.1) affects the x and

```

1 #define WPNVAV_WP_SPEED_MIN 100 //Buggy code 2
2 #define WPNVAV_WP_SPEED_MIN 20 //Patched code 2
3 ...
4 void AC_WPNVAV::set_speed_xy(float speed_cms){
5 -if (_wp_speed_cms >= WPNVAV_WP_SPEED_MIN){ //Buggy code 1
6 +if (speed_cms >= WPNVAV_WP_SPEED_MIN){ //Patched code 1
7     _wp_speed_cms = speed_cms;
8     _pos_control.set_speed_xy(_wp_speed_cms);
9     ...

```

Listing 1: Input validation bug case on x, y-axis mission velocity. The parameter can be dynamically changed by either a mission speed-change command or a speed parameter-change command.

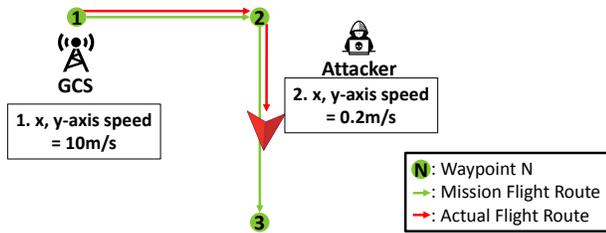

Figure 6: Illustration of Case Study I: An RV cannot recover its normal speed for the segment from Waypoint 2 to Waypoint 3.

y-axes controllers and causes unrecoverable slowdown, but can be discovered by RVFUZZER using the one-dimensional mutation technique. Case II (Section 6.3.2) presents a bug that affects the pitch controller, leads to a crash, and can only be found via multi-dimensional mutation strategy. Finally, the bug in Case III (Section 6.3.3) adversely affects the roll controller and causes significant deviation from the assigned mission, but can be discovered by mutating an environmental factor (wind force).

### 6.3.1 Case Study I: Bug Causing “Unrecoverable Vehicle Slowdown” Discovered by One-Dimensional Mutation

**Attack** We consider an RV that is assigned the mission of express package delivery (Fig. 6). Because of the urgency, the operator sets the RV’s mission speed to 10 m/s at Waypoint 1. During the mission, while the RV slows down to make a turn at Waypoint 2, the attacker sends a seemingly innocent, but malicious, command to the RV to change its mission speed to 0.2 m/s (the minimum *specified* speed is 0.2 m/s). After the turn, however, the operator will not be able to resume the 10 m/s mission speed by issuing speed-change commands. This attack exploits an input validation bug in ArduPilot, illustrated in Listing 1.

**Root Cause** Listing 1 presents the code that runs in the RV when it receives a new speed-change input (denoted by `speed_cms`) during its mission. The specified minimum speed (in cm/s) is denoted by the `WPNVAV_WP_SPEED_MIN` parameter (Line 1). We note that the *current* mission speed (denoted by `_wp_speed_cms`) is compared with the minimum mission speed (Line 5). This means that if (and only if) the current

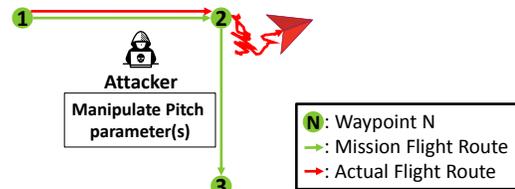

Figure 7: Illustration of Case Study II: The attack launched at Waypoint 2 causes an RV to oscillate due to failing control of the pitch angle.

mission speed is equal to or higher than the minimum mission speed, it can be replaced by the new mission speed in the input command; If the current mission speed is lower than the minimum mission speed, it cannot be changed. Hence, this is the bug which can be exploited by the attacker, by sending a speed-change command with a value lower than the minimum mission speed while the current mission speed is higher than the minimum mission speed. This bug has been patched recently by the developers by correcting the value of the minimum mission speed (Line 2) and setting the comparison of the minimum mission speed with the input speed (Line 6).

**Bug Discovery** This bug was discovered by RVFUZZER while performing one-dimensional mutation of the input mission speed parameter. For input mission values above 1 m/s, the RV successfully changed its current mission speed. However, if the current mission speed dropped below 1 m/s, RVFUZZER can no longer change the current mission speed by setting the input mission speed parameter. The failure to change the current mission speed led to the incorrect execution of the mission, resulting in control state deviation, simulated and detected by RVFUZZER. Hence, RVFUZZER reported this deviation-triggering parameter as an input validation bug, which is confirmed by the related source code in Listing 1 (as ground truth of our evaluation).

### 6.3.2 Case Study II: Bug Causing “Oscillating Route and Crash” Discovered by Multi-Dimensional Mutation

**Attack** We consider an RV that is assigned the same mission as in Case Study I. As shown in Fig. 7, at Waypoint 2 of the mission, the attacker sends a malicious command to the RV to change one of the four pitch control parameters: `MC_PITCH_P`, `MC_PITCHRATE_P`, `MC_PITCHRATE_P`, and `MC_PITCHRATE_FF`. Because of the inter-dependency between these parameters, such a malicious command, which looks innocent, can cause the RV to fail to stabilize its pitch angle, resulting in unrecoverable oscillation and deviation from its route.

**Root Cause** The unrecoverable oscillation on the RV’s route is caused by the failure of its pitch controller to track the reference state of the pitch. The pitch controller utilizes four inter-dependent parameters: the P con-

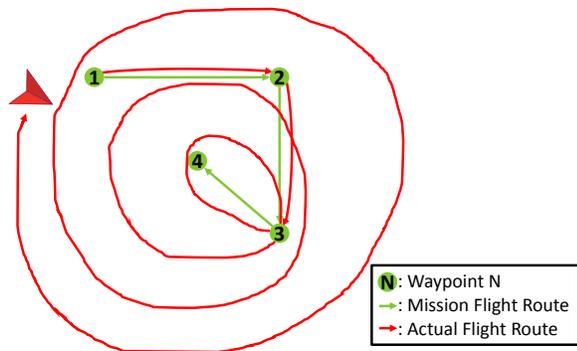

Figure 8: Illustration of Case Study III: An RV fails to complete a simple mission from Waypoint 1 to Waypoint 4 due to the impact of environmental factors.

control gain of pitch angle ( $MC\_PITCH\_P$ ), the P control gain of the pitch angular speed ( $MC\_PITCHRATE\_P$ ), the maximum pitch rate ( $MC\_PITCHRATE\_MAX$ ), and the feed-forward pitch rate ( $MC\_PITCHRATE\_FF$ ). For example, a high value of  $MC\_PITCHRATE\_FF$  helps track the reference state of the pitch when  $MC\_PITCH\_P$  is low. When both  $MC\_PITCHRATE\_FF$  and  $MC\_PITCH\_P$  have high values, the RV may perform overly aggressive stabilization operations. In that case, a low value of the maximum pitch rate ( $MC\_PITCHRATE\_MAX$ ) is desirable to mitigate the impact of such operations.

We point out that such dependencies can be exploited by an attacker to affect the RV’s operations by corrupting the value of just *one* parameter. Let us assume that the RV is already configured with high values of  $MC\_PITCHRATE\_FF$  and  $MC\_PITCH\_P$ . If the attacker sets  $MC\_PITCHRATE\_MAX$  to a high value, the pitch controller will start to respond to the minuscule difference between the reference state and the observed state of the pitch angle with extreme sensitivity. As a result, the RV will not be able to strictly follow its flight path. We note that this type of bug can only be discovered when the dependencies between multiple parameters are considered in the test.

**Bug Discovery** This bug was found by RVFUZZER while performing multi-dimensional mutation (Algorithm 2) of the parameters related to the pitch controller. RVFUZZER mutated the target parameter ( $MC\_PITCHRATE\_MAX$ ), while setting high values for  $MC\_PITCH\_P$  and  $MC\_PITCHRATE\_FF$  parameters. Unlike the one-dimensional mutation, which determined the parameter’s valid range to be between 6.7 and 1800, the multi-dimensional mutation determined that the valid range of  $MC\_PITCHRATE\_MAX$  is to be between 6.7 and 220.1. RVFUZZER detected and reported the expanded invalid range of  $MC\_PITCHRATE\_MAX$  as an input validation bug.

### 6.3.3 Case Study III: Bug Causing “Diverging Route” Discovered by Wind Force Mutation

**Attack** In this case study, we consider an RV assigned a mission to deliver a food item to a customer via the path

presented in Fig. 8. The RV is required to follow the path around tall buildings on a windy day with the wind direction towards the west. Since the item (e.g., soup) might spill if the RV changes its attitude drastically, the operator tries to prevent sudden changes in the roll angle by limiting the maximum angular-change speed ( $MC\_ROLLRATE\_MAX$ ) to a small value. When the vehicle is approaching Waypoint 2, the attacker sends a command to set the maximum tilting angle ( $MPC\_TILTMAX\_AIR$ ) to a low value. We note that the RV is supposed to make a 120-degree turn to avoid a tall building at Waypoint 3. However, the RV fails to make the correct turn at Waypoint 3 and hence cannot reach the destination (Waypoint 4) after multiple attempts to correct the diverging path. We note that the value of the maximum tilting/roll angle parameter is accepted by the control program because it is within the *specified* valid range, yet the value causes control state deviation due to the strong wind condition.

**Root Cause** There are three causes that induce the vehicle’s unexpected flight path divergence: (1) the mission route with sharp turns, (2) the roll controller’s parameter value that is not responsive enough to change the direction in time, and (3) the strong wind that expands the invalid ranges of the roll controller’s parameters. In this case study, the combination of these three factors disrupts the vehicle’s maneuver and trajectory, resulting in a failed mission (and a hungry customer).

**Bug Discovery** RVFUZZER discovered this bug in PX4 by mutating the wind condition during the AVC2013 mission (Section 5) which involves many sharp turns of the vehicle. As the input values of the roll controller parameters were mutated under a strong wind condition, RVFUZZER detected control state deviation between the reference state and the mission (Fig. 5). Hence, RVFUZZER reported this as an input validation bug contingent upon the influence of an external factor (wind).

## 7 Related Work

**Control Semantics-Driven RV Protection** There exists a body of work that leverages control semantics to protect RVs from attacks during flights and missions [38, 40, 50]. Blue-Box [40] detects abnormal behaviors of an RV controller by running a shadow controller in a separate microprocessor that monitors the correctness of the primary controller, based on the same control model. CI [38] extracts control-level invariants of an RV controller to detect physical attacks. Similarly, Heredia et al. [50] propose using a fault detection and isolation model extracted from a target RV controller and enforces the model to detect anomalies during flights.

Another line of work focuses on deriving finite state models to detect abnormal controller behaviors [37, 61]. Orpheus [37] automatically derives state transition models using program analysis for run-time anomaly detection. Bruids [61] relies on

a manual specification of RV behaviors to derive a behavioral model to detect run-time anomalies.

Other approaches utilize machine learning techniques to derive benign behavioral models of an RV controller. Abbaspour et al. [31] apply adaptive neural network techniques to detect fault data injection attacks during flight. Samy et al. [70] use neural network techniques to detect sensor faults. Two related efforts [30, 76] leverage a similar approach but detect both sensor and actuator faults.

Complementing the prior efforts, RVFUZZER leverages control semantics to *proactively* find input validation bugs that may be exploited by RV attackers. Unlike the previous works that aim to detect abnormal behaviors *during* flights, our work focuses on identifying input validation bugs in RV control programs *before* flights via off-line RV simulation and program vetting. Control semantics are leveraged to reduce the input value mutation space and simulators are adopted to render the impacts of control parameter and external factor changes on control states.

**Feedback-directed Testing** RVFUZZER is inspired by many existing feedback-driven testing/fuzzing systems for conventional program testing [14, 17, 19, 34–36, 43, 44, 56, 57, 63, 66, 71, 74, 79]. These solutions leverage different mutation strategies to increase the coverage of testing/fuzzing. Several systems [14, 17, 19, 71] mutate input values with varying granularity (e.g., bit, byte-level) driven by the tested code’s coverage achieved during each test run, using the code coverage as feedback. Another line of work [63, 74] adopts a hybrid approach to increase code coverage using both dynamic and symbolic execution. Finally, many efforts leverage taint analysis [36, 43, 56, 57, 79] or a combination of taint analysis and symbolic execution [34, 35, 44, 66] for high testing coverage. Such approaches mutate inputs with awareness of the dependencies between program input and logic.

Testing techniques for conventional, non-cyber-physical programs rely on well-established mechanisms for (1) bug detection and (2) input mutation. Specifically, these testing techniques leverage generic, easy-to-detect symptoms of program failures (e.g., segmentation faults) as indication of a triggered bug and mutate program input following information (e.g., code coverage) agnostic to domain semantics. Compared with conventional software testing, RVFUZZER addresses new problems and opportunities when finding (semantic) input validation bugs in RV control. Many such bugs do not cause an immediate, easy-to-detect crash of the control program, especially when running with an RV simulator. Meanwhile, control-theoretical properties offer hints to reduce the input value mutation space.

## 8 Discussion

**Control Parameter Inter-dependencies** As revealed by multi-dimensional mutation, the control parameters may have

dependencies on one another. A specific value of one parameter can increase or decrease the (in)valid value ranges of other parameters. The ground truth on such inter-parameter dependencies can only be derived from full knowledge about the underlying control model and the control program implementation, given the large number of control variables (including hundreds of parameters), the wide ranges of their values, and the influence from various environmental factors. As a result, it is challenging to fully and accurately capture the control parameter inter-dependencies, with only the binary of a control program. In this work, we consider the subject control program binary as a black box and take a pragmatic approach by only revealing *part of* such inter-dependencies. A more generic approach to control parameter dependency derivation – possibly based on source code and a formal control model – is left as future work.

**Standard Safety Testing and Certification** For the safety of avionics software for airborne systems, there exist standard safety tests and software certifications such as DO-178B/C [4] and ISO/IEC 15408 [3]. To the best of our knowledge, however, there has been no standard safety testing framework created for RVs. We believe that RVFUZZER’s post-production, black-box-based (i.e., without source code) vetting will serve as a useful complement to standardized safety testing during RV design and production.

## 9 Conclusion

Robotic vehicles (RVs) are facing cyber and cyber-physical attacks launched via various attack vectors. In this paper, we identify a new, small-footprint attack against RVs, where an attacker remotely issues a control parameter-change command with an illegitimate parameter value to disrupt the RV’s control and mission. Such a value is erroneously accepted by the RV control program because of an input validation bug associated with the control parameter. The attack requires no code injection, control flow hijacking, or sensor spoofing hence cannot be defeated by existing RV security solutions. To proactively discover input validation bugs in a control program binary, we develop RVFUZZER, a control program testing system that reveals illegitimate-yet-accepted value ranges of dynamically adjustable control parameters. RVFUZZER adaptively mutates the input control parameter values to determine the (in)valid value ranges, driven by the detection of control state deviations in the simulated RV. Furthermore, it considers the impact of external factors by mutating their values and presence. RVFUZZER has discovered 89 real input validation bugs in two of the most popular RV control software suites, with mutation efficiency and automation.

## 10 Acknowledgment

We thank our shepherd, Nolen Scaife and the anonymous reviewers for their valuable comments and suggestions. We also thank Vireshwar Kumar for his detailed feedback and edits which have improved the quality of the paper. This work was supported in part by ONR under Grant N00014-17-1-2045. Any opinions, findings, and conclusions in this paper are those of the authors and do not necessarily reflect the views of the ONR.

## A Thresholds for Control State Deviation

We present how to determine the threshold values used by our control instability detector to detect control state deviation (Section 4.2). We use the AVC2013 mission (Section 5) and thirty other experimental missions in our experiments, similar to existing work [38]. Specifically, the thresholds are determined by applying the three-sigma rule [65] on the top deviation values. For the time window ( $w$ ) in the IAE formula, we set it to the duration of each mission segment (i.e., flight segment between two consecutive waypoints) within a mission. The list of the threshold values that we use for each control state is presented in Table 2.

We note that we do not monitor control state deviation in the second derivative states of the 6DoF (i.e., acceleration of any of the 6DoF). This is because, if their observed states are oscillating, they can potentially cause false positives. In fact, for the same reason, some control programs do not control acceleration in some 6DoF controllers (e.g., ArduPilot does not control the angular acceleration of roll, pitch, and yaw). However, RVFUZZER can detect their control state deviation via the indirect impacts on the *dependent* states. The control state deviation in the second derivative states are propagated to their integral states (e.g., the first derivative states of the 6DoF), as their controls are intrinsically related.

Table 2: List of threshold values for each control state.

Control Program	ArduPilot	PX4
Latitude/Longitude Position	11.62 <i>m</i>	10.08 <i>m</i>
Latitude/Longitude Velocity	1.23 <i>m/s</i>	4.71 <i>m/s</i>

## B Physical Impacts Caused by Input Validation Bug Exploitation

We present more details about the input validation bugs found by RVFUZZER and the implications of the attacks that exploit them in Tables 3 (for ArduPilot) and Table 4 (for PX4). The columns of each table shows: (1) the control program modules where the bugs belong (Control Program Module), (2) the vulnerable control parameters (Parameter, i.e., with erroneous range specification or range implementation), and (3) the possible physical impacts caused by the attacks exploiting the bugs (Physical Impacts). While the two tables list a total of 63 parameters, some of the parameters are associated with *both* range implementation and specification bugs. This explains why the total number of bugs (89) is higher than the number of vulnerable parameters.

Depending on the specific (malicious) value of the control parameter, the impact of an attack may vary. Here the possible impacts are categorized into four types as shown in the four

sub-columns of the “Physical Impacts” column: “C” – vehicle crash; “D” – deviation from trajectory; “U” – unstable vehicle movement; and “S” – vehicle getting “stuck” at a certain location or speed. All of these impacts are non-transient and cannot be recovered by the controllers.

Table 4: Input validation bugs in PX4 and implications of attacks exploiting them.

# Seeing is Not Believing: Camouflage Attacks on Image Scaling Algorithms

Qixue Xiao<sup>\*1,4</sup>, Yufei Chen<sup>\*2,4</sup>, Chao Shen<sup>2</sup>, Yu Chen<sup>1,5</sup>, and Kang Li<sup>3</sup>

<sup>1</sup>*Department of Computer Science and Technology, Tsinghua University*

<sup>5</sup>*Peng Cheng Laboratory*

## Abstract

Image scaling algorithms are intended to preserve the visual features before and after scaling, which is commonly used in numerous visual and image processing applications. In this paper, we demonstrate an automated attack against common scaling algorithms, i.e. to automatically generate camouflage images whose visual semantics change dramatically after scaling. To illustrate the threats from such camouflage attacks, we choose several computer vision applications as targeted victims, including multiple image classification applications based on popular deep learning frameworks, as well as mainstream web browsers. Our experimental results show that such attacks can cause different visual results after scaling and thus create evasion or data poisoning effect to these victim applications. We also present an algorithm that can successfully enable attacks against famous cloud-based image services (such as those from Microsoft Azure, Aliyun, Baidu, and Tencent) and cause obvious misclassification effects, even when the details of image processing (such as the exact scaling algorithm and scale dimension parameters) are hidden in the cloud. To defend against such attacks, this paper suggests a few potential countermeasures from attack prevention to detection.

## 1 Introduction

Image scaling refers to the resizing action on a digital image, while preserving its visual features. When scaling an image, the downscaling (or upscaling) process generates a new image with a smaller (or larger) number of pixels compared to the original one. Image scaling algorithms are widely adopted in various applications. For example, most deep learning computer vision applications use pre-trained convolutional neural network (CNN) models, which take data with a fixed size defined by the input layers of those models. Hence, input images have to get scaled in the data preprocessing procedure to meet

with specific model input size. Popular deep learning frameworks, such as Caffe [17], TensorFlow [13] and Torch [26], all integrate various image scaling functions in their data preprocessing modules. The purpose of these built-in scaling functions is to allow the developers to use these frameworks to handle images that do not match the model's input size.

Although scaling algorithms are widely used and are effective to normal inputs, the design of common scaling algorithms does not consider malicious inputs that may intentionally cause different visual results after scaling and thus change the "semantic" meaning of images. In this paper, we will see that an attacker can utilize the "data under-sampling" phenomena occurring when a large image is resized to a smaller one, to cause "visual cognition contradiction" between human and machines for the same image. In this way, the attacker can achieve malicious goals like detection evasion and data poisoning. What's worse, unlike adversarial examples, this attack is independent from machine learning models. The attack indeed happens before models consume inputs, and hence this type of attacks affects a wide range of applications with various machine learning models.

This paper characterizes this security risk and presents a camouflage attack on image scaling algorithms (abbreviated as *scaling attack* in the rest of the paper). To successfully launch a scaling attack, attackers need to deal with two technical challenges: (a) First, an adversary needs to decide where to insert pixels with deceiving effects by analyzing the scaling algorithms. It is tedious and practically impossible to use manual efforts to determine exact pixel values to achieve a desired deceiving effect for realistic images. Therefore, a successful attack needs to explore an automatic and efficient camouflage image generation approach. (b) Second, for cloud-based computer vision services, the exact scaling algorithm and input size of their models are transparent to users. Attackers need to infer scaling-related parameters of the underneath algorithms in order to successfully launch such attacks.

To overcome these challenges, we first formalize the process of scaling attacks as a general optimization problem. Based on the generalized model, we propose an automatic

<sup>\*</sup>Co-first authors. This work was completed during their internship program at 360 Security Research Labs.

generation approach that can craft camouflage images efficiently. Moreover, this work examines the feasibility of this attack in both the white-box and black-box scenarios, including applications based on open deep learning frameworks and commercial cloud services:

- In the white-box case (see Section 6.1 for more details), we analyze common scaling implementations in three popular deep learning frameworks: Caffe, TensorFlow and Torch. We find that nearly all default data scaling algorithms used by these frameworks are vulnerable to the scaling attack. With the presented attack, attackers can inject poisoning or deceiving pixels into input data, which are visible to users but get discarded by scaling functions, and eventually being omitted by deep learning systems.
- In the black-box case (see Section 6.2 for more details), we investigate the scaling attack against cloud-based computer vision services. Our results show that even when the whole image processing pipeline and design details are hidden from users, it is still possible to launch the scaling attack to most existing cloud-based computer vision services. Since image scaling modules are built upon open image processing libraries or open interpolation algorithms, possible ways of image scaling implementation are relatively limited. Attackers can design a brute-force testing strategy to infer the scaling algorithm and the target scale. In this paper, we exhibit a simple but efficient testing approach, with successful attack results on Microsoft Azure<sup>1</sup>, Baidu<sup>2</sup>, Aliyun<sup>3</sup> and Tencent<sup>4</sup>.
- Interestingly, we also discover and discuss the range of the attacking influence extends to some computer-graphic applications, such as mainstream web browsers shown in Section 6.3.

We provide a video to demonstrate the attack effects, which is available at the following URL: <https://youtu.be/Vm2N0mb14Ow>.

This paper studies the commonly used scaling implementations, especially for image scaling algorithms employed in popular deep learning frameworks, and reveals potential threats to the image scaling process. Our contributions can be summarized as follows:

- This paper reveals a security risk in image scaling process in computer vision applications. We validate and testify the image scaling algorithms commonly used in popular deep learning (DL) frameworks, and our results

<sup>1</sup><https://azure.microsoft.com/en-us/services/cognitive-services/computer-vision/?v=18.05>

<sup>4</sup><https://ai.qq.com/product/visionimgidy.shtml#tag>

indicate that the security risk affects almost all image applications based on DL frameworks.

- This paper formalizes the scaling attack into a constrained optimization problem, and presents the corresponding implementation to generate camouflage images automatically and efficiently.
- Moreover, we prove that the presented attack is still effective for cloud vision services, where the implementation details of image scaling algorithms and parameters are hidden from users.
- To eliminate the threats from the scaling attack, we suggest several potential defense strategies from two aspects: attack prevention and detection.

## 2 Image Scaling Attack Concept and Attack Examples

In this section, we first present a high level overview of image scaling algorithms, followed by the concept of image scaling attacks. Then, we exhibit some examples of the image scaling attack, and finally we conduct an empirical study of the image scaling practices in deep learning based image applications.

### 2.1 An Overview of Image Scaling Algorithms

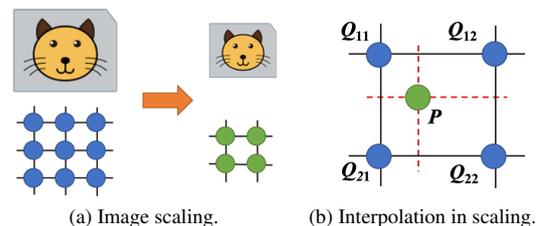

Figure 1: The concept of image scaling.

Image scaling algorithms are designed to preserve the visual features of an image while adjusting its size. Fig.1 presents the general concept of a common image scaling process. A scaling algorithm infers value of each “missing point” by using interpolation methods. Fig.1b shows an example of constructing pixel  $P$  in the output image based on the pixels of  $Q_{11}$ ,  $Q_{12}$ ,  $Q_{21}$  and  $Q_{22}$  in the original image. A scaling algorithm defines which neighbor pixels to use in order to construct a pixel of the output image, determines the relative weight values assigned to each individual neighbor pixels. For example, for each pixel in the output image, a nearest neighbor algorithm only picks a single pixel (the nearest one) from the input to replace it. A bilinear algorithm considers a set of neighbor pixels surrounding the target pixel as the

Figure 2: An example showing deceiving effect of the scaling attack. (Left-side: what humans see; right-side: what DL models see)

basis. It then calculates a weighted average of the neighbor pixel values as the value assigned to the target pixel.

Such scaling algorithms often assume that pixel values in an image are results from natural settings, and they do not anticipate pixel-level manipulations with malicious intents. This paper demonstrates that an attacker can use scaling algorithms to alter an image’s semantic meaning by carefully adjusting pixel-level information.

## 2.2 Attack Examples

The scaling attack potentially affects all applications that apply scaling algorithms to preprocess input images. To demonstrate potential risks and deceiving effects of the scaling attack, here we provide two attack examples of the scaling attack on practical applications.

Fig.2 presents the first attack example for a local image classification application *cppclassification* [16], a sample program released by the Caffe framework. For the classification model with an input size of 224\*224, we specially craft input images of a different size (672\*224). The image in the left column of Fig.2 is one input to the deep learning application, while the image in the right column is the output of the scaling function, i.e., the *effective image* fed into the deep learning model. While the input in the left column of Fig.2 visually presents a sheep-like figure, the deep learning model takes the image in the right column as the actual input and classifies it as an instance of “White Wolf”.

To validate the deceiving effect on deep learning applications, we build one image classification demo based on the BAIR/BVLC GoogleNet model [8], which assumes the input data are of the scale of 224\*224. When an image with a different size is provided, the application triggers the native `resize()` function built in the Caffe framework to rescale the image to fit the input size of the model (224\*224). The exact classification setup details and the program outputs are presented in Appendix A.

Fig.3 exhibits one attack example against the Baidu image classification service. The attack image is crafted from a sheep image, with the aim to lead people to regard it as a sheep but the machine to regard it as a wolf. The results

Figure 3: A scaling attack example against Baidu image classification service.

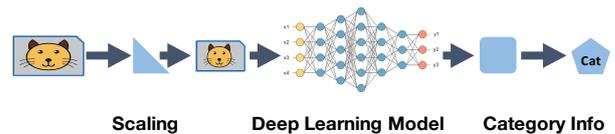

Figure 4: How data get processed in image classification systems.

returned by the cloud service API<sup>5</sup> show that the attack image is classified as the “Grey Wolf” with a high confidence score (achieving 0.938829), indicating that our attack is effective. More examples of the scaling attack against more cloud-based computer vision services are presented in Table 3. In fact, image scaling algorithms are commonly used by a wide range of computer-graphic applications, rather than limited to deep-learning-based computer vision systems. Therefore, they are all potentially threatened by this type of security risk.

## 2.3 Empirical Study of Image Scaling Practices in Deep Learning Applications

Data scaling is actually a common action in deep learning applications. Fig.4 shows how the scaling process is involved in open-input applications’ data processing pipelines, such as image classification as an Internet service. For design simplicity and manageable training process, a deep learning neural network model usually requires a fixed input scale. For image classification models, images are usually resized to 300\*300 to ensure high-speed training and classification. As shown in Table 1, we examine nine popular deep learning models and all of them use a fixed input scale for their training and classification process.

For deep learning applications that receive input data from fixed input sources, such as video cameras, the input data formats are naturally determined. Even in such situation, we find that the image resizing is still needed in certain cases.

One common situation we observe is the use of pre-trained models. For example, NVIDIA offers multiple self-driving sample models [6], and all these models use a specific input

<sup>5</sup>The original API response is presented in Chinese. Here we translate it into English.

Table 1: Input sizes of various deep learning models.

Model	Size (pixels*pixels)
LeNet-5	32*32
VGG16, VGG19, ResNet, GoogleNet	224*224
AlexNet	227*227
Inception V3/V4	299*299
DAVE-2 Self-Driving	200*66

size 200\*66. However, for the recommended camera [24] specification provided by NVIDIA, the size of generated images varies from 320\*240 to 1928\*1208. None of the recommended cameras produce output that matches the NVIDIA’s model input size. Therefore, for system developers that do not want to redesign or retrain their models, they have to employ scaling functions in their data processing pipeline to fit the pre-trained model’s input scale. Recent research work, such as the sample applications used in DeepXplore [25], also shows that the resizing operation is commonly used in self-driving applications to adjust original video frames’ size to the input size of models.

Most deep learning frameworks provide data scaling functions, as shown in Table 2. Programmers can handle images with different sizes without calling scaling function explicitly. We examined several sample programs released by popular deep learning frameworks, such as Tensorflow, Caffe, and Torch, and we have found all of them implicitly trigger scaling functions in their data processing pipelines. Appendix B provides several examples.

### 3 Related Work

This section briefly reviews some related work and makes a comparison with our approach.

#### 3.1 Information Hiding

Information hiding is a significant topic in information security [2, 9, 15, 18, 19, 21, 27, 30, 31]. Information hiding methods achieve reversible data hiding by image interpolation, but these are different from our attack method: First, the goals are different. The information hiding methods conceal data in a source image to make the secret information unnoticed by human, and image applications operate on the complete data. Our presented attack hides a target image in a source image to cause a visual cognition contradiction between human and image applications. The core components (such as deep learning classifiers) of the victim applications operate on a partial data (i.e. the scaling output). Second, information hiding efforts often impose a customized coding method (such as LSB and NIP [21]) in order to conceal and recover hidden information. This coding scheme is often kept as a

secret known only to the designer of the specific information hiding method. In contrast, a scaling attack is based on the interpolation algorithm built within the victim application to achieve the deceiving effect. The main task for an attacker is to reverse engineering the scaling algorithms and design the pixel replacement policy.

#### 3.2 Adversarial Examples

The research of adversarial examples attract growing public attentions with the reviving popularity of Artificial Intelligence. An adversarial image fools the Artificial Intelligence by inserting perturbations into the input image, which are hard to be noticed by human eyes. For example, Goodfellow *et al.* [14] presented a linear explanation of adversarial examples and revealed that such attack is effective for current sufficiently linear deep networks. In addition to the theoretical analysis, Alexey *et al.* [20] added the perturbations into the physical world and successfully launched the attack. It should be noted that the attack target of existing adversarial examples essentially aims at machine learning models, while our method focuses on the data preprocessing step, concretely, the image scaling action. Vulnerabilities in code implementation, such as control-flow hijacking, also could lead to recognition evasions [32]. However, we exploit the weakness of scaling algorithms in this work other than code implementation.

#### 3.3 Invisible/Inaudible Attacks

Some researchers investigate potential attacks beyond the human sensing ability. Ian Markwood *et al.* [22] showed a content masking attack against the Adobe PDF standard. By tampering the font files, the attacker can insert secret information into PDF files without being noticed by human. They demonstrated such attack against state-of-the-art information-based services. Besides the attacks in vision fields, Zhang *et al.* [34] presented the *DolphinAttack* against speech recognition (SR) systems. They created secret voice commands on ultrasonic carriers that are inaudible for human beings, but can be captured and sensed by voice controllable systems. In this way, an attacker can control SR systems “silently”. It has been proved that the widely used SR systems, like Apple Siri and Google Now, are vulnerable to such attack. Our attack is like a reverse of such invisible/inaudible attacks. The attacker leverage the difference between the input and output of the scaling function. Most part of the content visible to human is not consumed by the component that uses the scaling output.

### 4 Formalizing the Scaling Attack

This section describes the goal of a typical scaling attack and how we design a method to automatically create attack images with deceiving effects. The autonomous attack image crafting

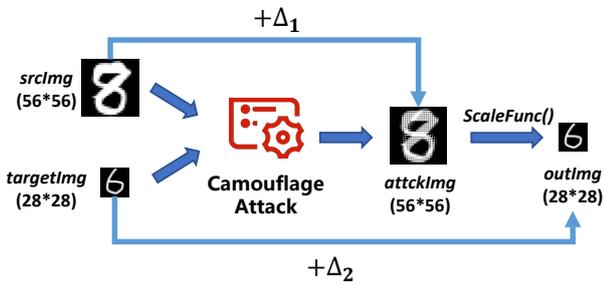

Figure 5: Automatic attack image crafting.

framework is shown in Fig.5, and details are presented in Section 4.2.

#### 4.1 Attack Goals

The goal of the scaling attack is to create a deceiving effect with images. Here the deceiving effect refers to the case that an image partially or completely presents a different meaning to humans before and after a scaling action. In such case, we call the input file to the scaling action the *attack image*.

To describe the process of a scaling attack, we define the following four conceptual objects involved in one attack.

- source image (or *srcImg*)  $S_{m*n}$  – the image that an attacker wants the attack image to look like.
- attack image (or *attackImg*)  $A_{m*n}$  – the crafted image eventually created and fed to the scaling function.
- output image (or *outImg*)  $D_{m'*n'}$  – the output image of the scaling function.
- target image (or *targetImg*)  $T_{m'*n'}$  – the image that the attacker wants the *outImg* to look like.

In some cases, some of these objects are identical. For example, it is often possible for an attacker to generate an out image that is identical to the target image.

The process of performing a scaling attack is to craft an *attackImg* under visual similarity constraints with *srcImg* and *targetImg*. Based on the intent and constraints on source images, we define the image scaling attack into two attack modes.

The first attack mode is when both the source and target images are specified, i.e. the attacker wants to scale an image that looks like a specific source image to an image that looks like a specific target image. In this mode the attacker launches a **source-to-target attack**, where the semantics of *srcImg* and *targetImg* are controlled as he/she wants. However, posing constraints on the looks of both the source and target images makes this attack mode more challenging. We call this mode of attack the *strong attack form*.

The second attack mode is when only the target image is specified. In that case, the attacker just wants to cause a vision contradiction during image scaling, as long as it is related to a certain concept (such as any images of sheep). In some extreme cases, the image content could be meaningless, e.g., just to create a negative result to an image classifier. Without a specific source image, the attacker’s goal is to increase the dissimilarity before and after image scaling as much as possible. In this mode, the similarity constraints get relaxed and we call this mode of attack the *weak attack form*.

## 4.2 An Autonomous Approach on Attack Image Generation

We are interested to develop a method to automatically create scaling attack images in both the strong and weak attack forms. In order to achieve such goal, we first formalize the description of the data transition process among the four conceptual objects, and then we seek an algorithmic solution to create attack images.

The relationship between the four conceptual objects can be described in the following formulas.

First, the transition between *srcImg* and *attackImg* can be represented by a perturbation matrix  $\Delta_1$ , and so does the difference between *outImg* and *targetImg*. These transition can be represented by

$$A_{m*n} = S_{m*n} + \Delta_1 \quad (1)$$

For the transition between *attackImg* and *outImg*, we consider the scaling effect as a function  $\text{ScaleFunc}()$ , which converts an  $m * n$  input image  $A_{m*n}$  to an  $m' * n'$  output image  $D_{m'*n'}$ <sup>6</sup>.

$$\text{ScaleFunc}(A_{m*n}) = D_{m'*n'} \quad (2)$$

$\text{ScaleFunc}()$  is a surjective function, i.e. there exist multiple possible inputs  $A_{m*n}$  that all result in the same output  $D_{m'*n'}$ .

To perform a scaling attack, attackers need to craft an attack image  $A_{m*n}$ , which is the source image  $S_{m*n}$  plus a perturbation matrix  $\Delta_1$ . In the meanwhile, the scaling result of the attack image, i.e., the output image  $D_{m'*n'}$ , needs to be visually similar with the target image  $T_{m'*n'}$ . Here we use  $\Delta_2$  to evaluate the difference between  $D_{m'*n'}$  and  $T_{m'*n'}$ .

$$\begin{aligned} A_{m*n} &= S_{m*n} + \Delta_1 \\ \text{ScaleFunc}(A_{m*n}) &= D_{m'*n'} \\ D_{m'*n'} &= T_{m'*n'} + \Delta_2 \end{aligned} \quad (3)$$

Let us consider the strong attack form of scaling attack as in Fig.5, where both source  $S_{m*n}$  and target image  $T_{m'*n'}$

<sup>6</sup>Conventionally, we say a matrix of  $m * n$  dimension has  $m$  rows and  $n$  columns, while an image of  $m * n$  size consists of  $m$  columns and  $n$  rows. For convenience sake, in this paper we use a matrix  $X_{m*n}$  of  $m * n$  dimension to refer to “an  $m * n$  image”.

are specified. The attacker’s task is to find an attack image  $A_{m*n}$  being able to cause deceiving effect. Considering Eq.3, we can find multiple possible candidate matrices as solutions for  $A_{m*n}$  that satisfy the whole set of formulas. This is due to the surjection effect of  $\text{ScaleFunc}()$ . What the attacker wants to find is the matrix that produces the best deceiving effect among all possible solutions for  $A_{m*n}$ . One strategy is to find an  $A$  that is the most similar with  $S$ , while limiting the difference between  $D$  and  $T$  within an upper bound.

To find the best deceiving effect, we theoretically define an objective function that compares all solutions of  $A_{m*n}$ . To seek an algorithmic solution, we choose the  $L$ -norm distance<sup>7</sup> to capture the pixel-level differences as an approximation for measuring how close two images are.

In the strong attack form, we want to minimize the difference between  $A_{m*n}$  and  $S_{m*n}$ , and limit the difference between  $D_{m'*n'}$  and  $T_{m'*n'}$  within a threshold. Consequently, when the source image  $S_{m*n}$  and target image  $T_{m'*n'}$  are given, the best result can be found by solving the following objective function.

$$\begin{aligned} A_{m*n} &= S_{m*n} + \Delta_1 \\ \text{ScaleFunc}(A_{m*n}) &= D_{m'*n'} \\ D_{m'*n'} &= T_{m'*n'} + \Delta_2 \\ \|\Delta_2\|_\infty &\leq \epsilon * IN_{max} \\ \text{Objective function} &: \min(\|\Delta_1\|^2) \end{aligned} \quad (4)$$

where  $IN_{max}$  is the maximum pixel value in the current image format.

For the weak attack form, i.e. only the target image  $T_{m'*n'}$  is given, what an attacker wants to optimize is to pick the attack image that visually has the largest difference from the target image. Thus, the best result should be found by solving the following objective function:

$$\begin{aligned} R_{m*n} &= \text{ScaleFunc}(T_{m'*n'}) \\ A_{m*n} &= R_{m*n} + \Delta_1 \\ \text{ScaleFunc}(A_{m*n}) &= D_{m'*n'} \\ D_{m'*n'} &= T_{m'*n'} + \Delta_2 \\ \|\Delta_2\|_\infty &\leq \epsilon * IN_{max} \\ \text{Objective function} &: \max(\|\Delta_1\|^2) \end{aligned} \quad (5)$$

Notice that in the above constraints, we apply  $\text{ScaleFunc}()$  twice. The first call of  $\text{ScaleFunc}()$  is actually scaling the target image to the size of the attack image, i.e., upscaling an image from dimension  $m' * n'$  back to  $m * n$ .

## 5 Creating Scaling Attack Images

After building up the formalized model of the scaling attack, in this section we investigate how to generate attack images automatically.

<sup>7</sup>In this paper,  $\|\cdot\|$  denotes the  $L^2$ -norm, while  $\|\cdot\|_\infty$  denotes the  $L^\infty$ -norm.

## 5.1 Empirical Analysis of Scaling Functions

In our implementation, we first need to find an appropriate expression of `ScaleFunc()`. We studied the implementation details of commonly used image processing packages. All of the scaling functions we studied perform the interpolation in two steps, one direction in each step. We design our attack algorithm with the assumption that the target scaling algorithm first resizes inputs horizontally and then vertically. Empirically the popular algorithms take this order (see Table 2, and more detailed analysis and examples are provided in Appendix C.). In case the scaling algorithm takes vertical order first, the attack method just needs to change accordingly. Hence, the `ScaleFunc()` in Eq.2 can be presented as:

$$\text{ScaleFunc}(X_{m*n}) = CL_{m'*m} * X_{m*n} * CR_{n*n'} \quad (6)$$

In Eq.6,  $CL_{m'*m}$  and  $CR_{n*n'}$  are two constant coefficient matrices determined by the interpolation algorithm, related to horizontal scaling ( $m*n \rightarrow m*n'$ ) and vertical scaling ( $m*n' \rightarrow m'*n'$ ), respectively.

With Eq.4 and Eq.6, we eventually build a relationship among the source image, the target image, and the perturbation:

$$\begin{aligned} CL_{m'*m} * (S_{m*n} + \Delta_1) * CR_{n*n'} &= D_{m'*n'} \\ D_{m'*n'} &= T_{m'*n'} + \Delta_2 \end{aligned} \quad (7)$$

## 5.2 Attack Image Crafting: An Overview

The main idea of automated scaling attack generation is to craft the attack image by two steps. The first step is to obtain the coefficient matrices in Eq.7. Section 5.3 presents a practical solution to find  $CL$  and  $CR$ , implemented as `GetCoefficient()`. The second step is to find the perturbation matrix  $\Delta_1$  to craft the attack image. We perform the attack image generation along each direction, in **reverse** order that we assume `ScaleFunc()` uses. Further, we decompose the solution of the perturbation matrix into the solution of a few perturbation vectors. By this way, we can significantly reduce the computational complexity for large size images. Section 5.4 provides more details of the second step, based on which we implement `GetPerturbation()` to find the perturbation vectors. Algorithm 1 and Algorithm 2 illustrate the attack image generation in the weak attack form and the strong attack form, respectively.

**Weak attack form** (Algorithm 1)<sup>8</sup>. First, we obtain the coefficient matrices by calling `GetCoefficient()` (line 2), which receives the size of  $S_{m*n}$  and  $T_{m'*n'}$ , and returns coefficient matrices  $CL_{m'*m}$  and  $CR_{n*n'}$ , and then generate an intermediate source image  $S_{m*n}^*$  from  $T_{m'*n'}$ . Then, we call `GetPerturbation()`, which receives the column vectors from  $S_{m*n}^*$  and  $T_{m'*n'}$ , with the coefficient matrix  $CL$  and the object option ('max'), and returns the optimized perturbation matrix  $\Delta_1^v$ , to solve the perturbation matrix column-wisely and craft out

<sup>8</sup>To clarify, here we use  $X[i,:]$  and  $X[:,j]$  to represent the  $i$ -th row and  $j$ -th column of matrix  $X$  respectively.

---

### Algorithm 1 Image Crafting of the Weak Attack Form

---

**Input:** scaling function `ScaleFunc()`, target image  $T_{m'*n'}$ , source image size ( $width_s, height_s$ ), target image size ( $width_t, height_t$ )

**Output:** attack image  $A_{m*n}$

- 1:  $m = height_s, n = width_s, m' = height_t, n' = width_t$
- 2:  $CL_{m'*m}, CR_{n*n'} = \text{GetCoefficient}(m, n, m', n')$
- 3:  $\Delta_1^v = \mathbf{0}_{m*n'}$   $\triangleright$  Perturbation matrix of vertical attack.
- 4:  $S_{m*n}^* = \text{ScaleFunc}(T_{m'*n'})$   $\triangleright$  Intermediate source image.
- 5: **for**  $col = 0$  to  $n' - 1$  **do**
- 6:    $\Delta_1^v[:, col] = \text{GetPerturbation}(S^*[:, col], T[:, col], CL, obj='max')$   $\triangleright$  Launch the vertical scaling attack.
- 7: **end for**
- 8:  $A_{m*n}^* = \text{unsigned int}(S^* + \Delta_1^v)$
- 9:  $S_{m*n} = \text{ScaleFunc}(T_{m'*n'})$   $\triangleright$  Final source image.
- 10:  $\Delta_1^h = \mathbf{0}_{m*n}$   $\triangleright$  Perturbation matrix of horizontal attack.
- 11: **for**  $row = 0$  to  $m - 1$  **do**
- 12:    $\Delta_1^h[row, :] = \text{GetPerturbation}(S[row, :], A^*[row, :], CR, obj='max')$   $\triangleright$  Launch the horizontal scaling attack.
- 13: **end for**
- 14:  $A_{m*n} = \text{unsigned int}(S + \Delta_1^h)$
- 15: **return**  $A_{m*n}$   $\triangleright$  Get the crafted attack image.

---

$A_{m*n}^*$  (line 5 to 8). Similarly, we solve another perturbation matrix  $\Delta_1^h$  row-wisely and construct the final attack image  $A_{m*n}$  (line 9 to 15).

**Strong attack form** (Algorithm 2). The strong attack form follows a similar procedure, except of two parts different from the weak attack form: The first one is that the input in this form includes two independent images  $S_{m*n}$  and  $T_{m'*n'}$ , while the second one is that the optimization problem transforms from maximizing the object function into minimizing the object function (line 6 and line 11).

## 5.3 Coefficients Recovery

Here we investigate the design of `GetCoefficient()` function, i.e., how does an attacker obtain the coefficient matrix  $CL_{m'*m}$  and  $CR_{n*n'}$ .

For public image preprocessing methods/libraries, the attacker is able to acquire the implementation details of `ScaleFunc()`. Hence, in theory, the attacker can compute each element in  $CL_{m'*m}$  and  $CR_{n*n'}$  precisely.

Eq.8 is a coefficient recovery result from the open-source package Pillow. In the bilinear interpolation algorithm, the coefficient matrices from 4\*4 image to 2\*2 image are:

$$CL_{m'*m} = \begin{bmatrix} \frac{3}{7} & \frac{3}{7} & \frac{1}{7} & 0 \\ 0 & \frac{3}{7} & \frac{3}{7} & \frac{1}{7} \end{bmatrix}, \quad CR_{n*n'} = \begin{bmatrix} \frac{3}{7} & 0 \\ \frac{3}{7} & \frac{1}{7} \\ \frac{1}{7} & \frac{3}{7} \\ 0 & \frac{3}{7} \end{bmatrix} \quad (8)$$

Though it is possible to retrieve coefficient matrices precisely, the pre-mentioned procedure may become challenging

---

**Algorithm 2** Image Crafting of the Strong Attack Form

---

**Input:** scaling function  $\text{ScaleFunc}()$ , source image  $S_{m*n}$ , target image  $T_{m'*n'}$ , source image size  $(width_s, height_s)$ , target image size  $(width_t, height_t)$

**Output:** attack image  $A_{m*n}$

```
1:  $m = height_s, n = width_s, m' = height_t, n' = width_t$ 
2:  $CL_{m'*m}, CR_{n*n'} = \text{GetCoefficient}(m, n, m', n')$ 
3:  $\Delta_1^v = \mathbf{0}_{m*n'}$   $\triangleright$  Perturbation matrix of vertical attack.
4:  $S_{m*n}^* = \text{ScaleFunc}(S_{m*n})$   $\triangleright$  Intermediate source image.
5: for  $col = 0$  to  $n' - 1$  do
6:    $\Delta_1^v[:, col] = \text{GetPerturbation}(S^*[:, col], T[:, col], CL,$ 
    $obj='min')$   $\triangleright$  Launch the vertical scaling attack.
7: end for
8:  $A_{m*n}^* = \text{unsigned int}(S^* + \Delta_1^v)$ 
9:  $\Delta_1^h = \mathbf{0}_{m*n}$   $\triangleright$  Perturbation matrix of horizontal attack.
10: for  $row = 0$  to  $m - 1$  do
11:    $\Delta_1^h[row, :] = \text{GetPerturbation}(S[row, :], A^*[row, :], CR,$ 
    $obj='min')$   $\triangleright$  Launch the horizontal scaling attack.
12: end for
13:  $A_{m*n} = \text{unsigned int}(S + \Delta_1^h)$ 
14: return  $A_{m*n}$   $\triangleright$  Get the crafted attack image.
```

---

when the coefficient matrices grow large and the interpolation method becomes complex. To reduce the human effort for extracting the coefficient values, we introduce an easy approach to deduce the those matrices. The idea is to infer these coefficient matrices from input and output pairs.

First, we establish the following equation:

$$\begin{aligned} CL_{m'*m} * (I_{m*m} * IN_{max}) &= CL_{m'*m} * IN_{max} \\ (I_{n*n} * IN_{max}) * CR_{n*n'} &= CR_{n*n'} * IN_{max} \end{aligned} \quad (9)$$

where  $I_{m*m}$  and  $I_{n*n}$  are both identity matrices.

Then, if we set the source image  $S = I_{m*m} * IN_{max}$  and scale it into an  $m' * m$  image  $D_{m'*m}$ , we can obtain

$$\begin{aligned} D &= \text{ScaleFunc}(S) = \text{unsigned int}(CL_{m'*m} * IN_{max}) \\ \rightarrow CL_{m'*m}(appr) &\approx D / IN_{max} \end{aligned} \quad (10)$$

In the theoretical formulation, the sum of elements in each row of  $CL_{m'*m}$  should be equal to one.

Finally, we do the normalization for each row (Eq. 11). In fact, the type cast from float-point values to unsigned integers in Eq. 10 will cause a slight precision loss. What we acquired is an approximation of  $CL_{m'*m}$ , but in practice our experimental results show that the precision loss can be ignored.

$$\begin{aligned} CL_{m'*m}(appr)[i, :] &= \frac{CL_{m'*m}(appr)[i, :]}{\sum_{j=0}^{m'-1} (CL_{m'*m}(appr)[i, j])} \\ (i = 0, 1, \dots, m' - 1) \end{aligned} \quad (11)$$

The inference of  $CR_{n*n'}$  follows a similar procedure. When

scaling  $S' = I_{n*n} * IN_{max}$  into  $D'_{n*n'}$ , we have

$$\begin{aligned} D' &= \text{ScaleFunc}(S') = \text{unsigned int}(IN_{max} * CR_{n*n'}) \\ \rightarrow CR_{n*n'}(appr) &\approx D' / IN_{max} \end{aligned} \quad (12)$$

Hence, we can obtain the estimated  $CR$ :

$$\begin{aligned} CR_{n*n'}(appr)[:, j] &= \frac{CR_{n*n'}(appr)[:, j]}{\sum_{i=0}^{n-1} (CR_{n*n'}(appr)[i, j])} \\ (j = 0, 1, \dots, n' - 1) \end{aligned} \quad (13)$$

So far, we have found a practical approach to recover coefficient matrices. In the next step, we focus on constructing the perturbation matrix  $\Delta_1$ .

## 5.4 Perturbation Generation via Convex-Concave Programming

In the threat model established in Section 4.2,  $\Delta_1$  is a matrix with dimension  $m * n$ . The optimization problem tends to be complex when the attack image is large. This part illustrates how to simplify the original problem and find the perturbation matrix efficiently.

### 5.4.1 Problem Decomposition

Generally speaking, the complexity of an  $n$ -variable quadratic programming problem is no less than  $O(n^2)$ , as it contains complex computation operations, such as solving the Hessian matrix. The optimization is computationally expensive when the image size grows large. Here we simplify and accelerate the image crafting process by two feasible steps, only sacrificing the computing precision slightly.

Firstly, we separate the whole scaling attack into two sub-routines. The image resizing in each direction is equivalent, because the resizing of  $S$  in the vertical direction can be regarded as the resizing of the source image's transpose  $S^T$  in the horizontal direction. Therefore, we only need to consider how to generate  $\Delta_1$  in one direction (here we choose the vertical resizing as the example). Suppose we have an input image  $S_{m*n}$  and an target image  $T_{m'*n'}$ , and we have recovered the resizing coefficient matrix  $CL_{m'*m}$ , with the aim to craft the attack image  $A_{m*n} = S_{m*n} + \Delta_1$ .

Secondly, we decompose the calculation of the perturbation matrix into the solution of a few vectors. In fact, the image transformation can be rewritten as:

$$\begin{aligned} CL_{m'*m} * A &= \\ [ CL * A[:, 0]_{(m*1)} \quad \dots \quad CL * A[:, n-1]_{(m*1)} ] \end{aligned} \quad (14)$$

In this way, our original attack model has been simplified into several column-wise sub optimization problems:

$$\begin{aligned} \mathbf{obj}: & \min/\max(\|\Delta_1[:, j]\|^2) \\ \mathbf{s.t.} & CL * A[:, j]_{(m*1)} = T[:, j]_{(m' * 1)} + \Delta_2 \\ & \|\Delta_2\|_{\infty} \leq \epsilon * IN_{max} \\ & (j = 0, 1, \dots, n - 1) \end{aligned} \quad (15)$$

### 5.4.2 Optimization Solution

We formulate our model in Eq.15 into a standard quadratic optimization problem.

**Constraints.** First there is a natural constraint that each element in the attack image  $A$  should be within  $[0, IN_{max}]$ . We have the following constraints:

$$\begin{aligned} 0 \leq A[:, j]_{m*1} \leq IN_{max} \\ \|CL * A[:, j]_{m*1} - T[:, j]_{m'*1}\|_{\infty} \leq \epsilon * IN_{max} \end{aligned} \quad (16)$$

**Objective function.** Our objective function is also equivalent to

$$\min/\max(\Delta_1[:, j]^T I_{m'*m'} \Delta_1[:, j]) \quad (j = 0, 1, \dots, n - 1) \quad (17)$$

where  $I_{m'*m'}$  is the identity matrix. Then, combining the objective function (Eq.17) and constraints (Eq.16), we finally obtain an  $m'$ -dimensional quadratic programming problem with inequality constraints.

**Problem Solution.** Back to the two attack models proposed in section 4.2, the strong attack model refers to a convex optimization problem while the weak model refers to a concave optimization problem. We adopt the Disciplined Convex-Concave Programming toolbox *DCCP* developed by Shen et al. [33] to solve the optimization problem. The results exhibited in Appendix D validate that this approach is feasible.

## 6 Experimental Results of Scaling Attack

In this section, we report attack results on three kinds of applications: local image classification applications, cloud computer vision services and web browsers.

### 6.1 White-box Attack Against Local Computer Vision Implementations

Many computer vision applications expose the model's input size and scaling algorithm to attackers. We regard this scenario as our white-box threat model.

**White-box Threat Model.** In our white-box threat model, we assume that the attacker has full knowledge of the target application's required input size and the scaling algorithm implementation. This can be achieved by inspecting the source codes, reverse engineering the application, or speculating based on open information. For instance, there is an image classification application claiming that it is built upon Caffe and uses the GoogleNet model. The attacker can ensure the input size is 224\*224 (Table 1), and guess that the OpenCV.Bilinear (default for Caffe, see Table 2) is the scaling function with a high confidence. With the automatic attack image generation approach proposed in Section 5, the attacker can achieve the deceiving effect without much effort in the white-black threat model.

**Results.** We validate our attack image generation approach on the interpolation algorithms built within three popular deep learning frameworks: Caffe, Tensorflow, and Torch. For each framework, we write an image classification demo based on the BAIR/BVLC GoogleNet model, whose required input size is 224\*224. We launch the attack with a 672\*224 sheep-like image as the source image, and a 224\*224 wolf-like image as the target image, under a tight constraint where we set  $\epsilon = 0.01$ . If the generated attack image satisfies the constraints and deceives the application, we consider the attack is successful, and otherwise it fails. The results reported in Table 2 show that our attack method is effective for all the default scaling algorithms in these frameworks.

Notice that our approach does not generate successful attack images for some less commonly used algorithms. There are two factors affecting these attacks. First, some of these algorithms might pose more constraints during the scaling process. And because they are not popularly used, we have not yet studied the detail of these implementations. Second, in this paper, we only applied a tight constraint on our optimization task (Eq.16 and Eq.17), for the purpose of threat demonstration. There is a trade-off between the deceiving effect and image generation difficulty. Even if the automatic image generation process fails for some algorithms, by no means these algorithms should be considered as safe.

### 6.2 Black-box Attack Against Cloud Vision Services

Cloud-based computer vision services, provided by Microsoft, Baidu, Tencent and others, have arisen broadly, which simplify the deployment of computer vision systems. By sending queries to these powerful cloud vision APIs, users can obtain detailed image information, e.g., tags with confidence values and image descriptions. In this case, the pre-trained models are usually packaged as black boxes isolated from users, and users only are able to access these services through APIs. This section shows that the commercial cloud vision services are threatened by the scaling attack, even in the black-box scenario where the input size and scaling method are unknown.

**Black-box Threat Model.** In our black-box threat model, the goal of an attack is to deceive the image recognition service running on the cloud server, resulting in a mis-recognition for input images. But the input scale and scaling method is unknown to the attacker, making the attack more challenging.

#### 6.2.1 Attack Roadmap

The attack against black-box vision services mainly includes two steps. The first step is scaling parameter inference – the attacker estimates the input size and scaling algorithm used by the classification model. The second step is to craft attack images based on the inferred scaling parameters.

**Scaling Parameter Inference.** We design the scaling parameter inference strategy based on two empirical observations. First, from Table 1 we can see that for most commonly used CNN models, the input is a square-sized image with a side length in the range of [201,300]. Second, by comparing and analyzing the source codes of popular DL frameworks in Table 2, we found the most commonly used default scaling algorithm is Nearest, Bilinear, or Bicubic. Therefore, a naive approach by the adversary is to infer the scaling parameters via exhaustive tests. An adversary can send a series of  $m$  probing images  $\{probeImg_i\}, (i = 1, 2, \dots, m)$ , crafted by the scaling attack method with various scaling parameters. The attacker can infer the scaling parameters by watching the classification results. If one query returns with the correct classification result, the corresponding scaling parameters are likely to be used by the target service. Then the attacker can try to launch the attack with the inferred parameters. This procedure is shown in Algorithm 3.

The inference efficiency can be increased by using a complex attack image involving several sub-probing images. These sub-probing images can only be recovered with their corresponding scaling parameters.

Here we show one simple approach to achieve this goal. First, the attacker collects  $n$  sub-probing images each belonging to different categories, and determines the input size range  $SizeRange$  and the scaling algorithms  $AlgSet$  to test. The search space  $S$  can be defined as  $S = \{S_i\} = SizeRange \times AlgSet = \{size_i\} \times \{alg_i\}$ . Second, the attacker chooses a large blank white image (with #FF as the pixel value) as the background, and divides it into  $n$  non-overlapped probing regions. Third, the attacker repeats the following procedure: he/she fills the  $j$ -th probing region of the blank image with the  $j$ -th sub-probing image respectively, next scales it with the scaling parameter  $S_i^j$ , and then conducts the scaling attack with the original blank image as the  $sourceImg$  and the resized image as the  $targetImg$ . Finally, the attacker combines all the output images to create the  $probeImg_i$ . In this way, when  $probeImg_i$  is resized, the  $j$ -th sub-probing image will be recovered if and only if the scaling parameter is set as  $S_i^j$ . Fig.6 gives an example of the  $probeImg$ . Note that the larger  $n$  is, the fewer  $probeImgs$  are needed, but the recognition accuracy of sub-probing images might be reduced as the area of each probing region decreases.

**Image Crafting.** After retrieving the possible input size and scaling algorithm, the adversary can generate attack images as described in Section 5, and launch the scaling attack to cloud vision services .

## 6.2.2 Results

To show the feasibility of the scaling attack against black-box cloud vision services, we choose Microsoft Azure, Baidu,

---

### Algorithm 3 Scaling Parameter Inference

---

**Input:** cloud vision API  $f$ , scaling algorithms  $AlgSet = \{alg_1, alg_2, \dots\}$ , input size range  $SizeRange = \{size_1, size_2, \dots\}$ , source image  $sourceImg$ , target image  $targetImg$   
**Output:** the inferred input size  $size^*$  and scaling algorithm  $alg^*$

- 1: **for**  $alg$  in  $AlgSet$  **do**
- 2:   **for**  $size$  in  $SizeRange$  **do**
- 3:      $testImg = \text{resize}(targetImg, size)$
- 4:      $probeImg = \text{ScalingAttack}(alg, sourceImg, testImg) \triangleright$  Can be recovered once resized into  $size$  by  $alg$ .
- 5:     **if**  $\text{argmax}(f(testImg)) == \text{argmax}(f(probeImg))$  **then**
- 6:         Return  $size, alg$       $\triangleright$  Get a feasible answer.
- 7:     **end if**
- 8:   **end for**
- 9: **end for**
- 10: Return NULL, NULL      $\triangleright$  No match during the search.

---

Aliyun, and Tencent cloud vision services as our test beds<sup>9</sup>.

In our experiment, each  $probeImg$  contains four sub-images (classified as “zebra”, “dog”, “rat” and “cat”) for different input parameters. For the input size, the  $SizeRange$  is set from 201 to 300, while the scaling algorithm options include two libraries OpenCV and Pillow with Nearest, Bilinear and Cubic interpolation methods. Considering the trade-off between efficiency and recognition accuracy, we set  $n = 4$ . Hence, the total amount of queries is  $100 (\#input\ size) * 2 (\#scaling\ library) * 3 (\#interpolation\ method) / 4 (\#probing\ region) = 150 (\#probeImg)$ . As we can see, the searching space is extremely small and it consumes just up to several minutes to obtain the results. We provide the scaling parameter inference results and one scaling attack sample in Table 3.

Moreover, to verify the effectiveness of the proposed attack strategy, we collected 935 images from Internet, including 17 categories except of sheep or sheep-like animals, and cropped them into the 800\*600 size holding the main object, as our  $sourceImg$  dataset. Then for each of the 935  $sourceImgs$ , we generated one attack image with the same  $targetImg$  containing a sheep in the center, setting the scaling attack parameter  $\epsilon = 0.01$ .

For Baidu, Aliyun and Tencent, all the attack images are classified as “sheep” or “goat” with the highest confidence value compared with other classes, while for Azure the result becomes more complex. In our experiment we requested the Azure cloud vision service API to respond with four fea-

---

<sup>9</sup> As part of the responsible disclosure etiquette, we have reported this issue and received replies from these companies. The latter three have confirmed this problem as are now in the process of fixing it. Microsoft Azure has also acknowledged the issue and is discussing with us about possible solutions.

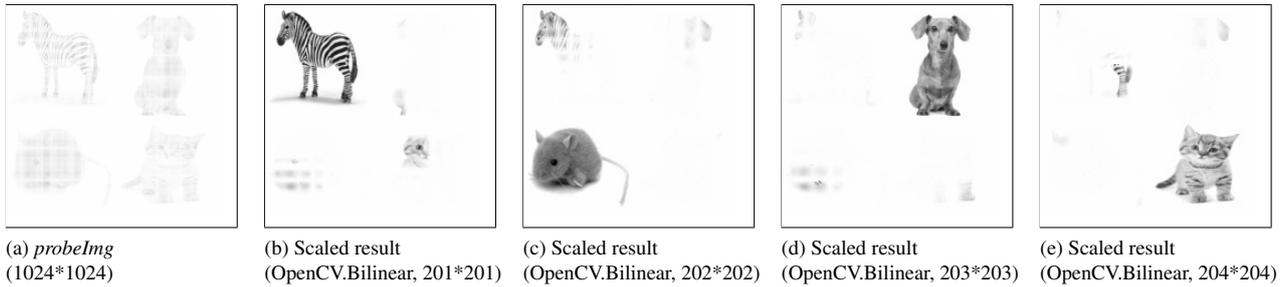

Figure 6: An example of the *probeImg*. (a) is a *probeImg* containing 4 subfigures, and (b) to (e) are the results when the *probeImg* is scaled under different scaling settings.

tures: “description”, “tags”, “categories”, and “color”. We find that for attack images, the word “sheep” may appear in the “description” or “tags” with a confidence value. Hence, we computed the CDF (cumulative distribution function) of attack images’ confidence values of “tags” and “description” respectively, and plot the two CDF curves in Fig.7 (we assume the confidence value as 0 if “sheep” is absent in the API response). The result shows that for the “tags” feature, more than 60% attack images are classified as “sheep” with a confidence value higher than 0.9, which implies the effectiveness of our proposed attack.

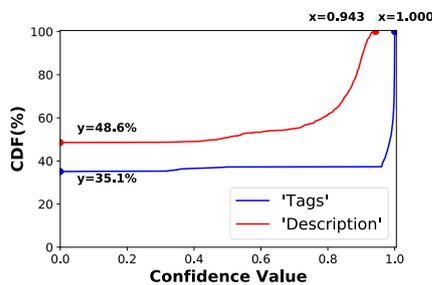

Figure 7: The CDF curve of responses from Azure.

### 6.3 Deceiving Effect on Web Browsers

Web browsers provide the page zooming function to scale the contents, including texts and images. Hence, an attacker may be able to utilize scaling functions in web browsers to achieve deceiving or phishing attacks.

We have evaluated such effect on several mainstream browsers running on different platforms. We generated an attack image (with a 672\*224 sheep image as the source image, a 224\*224 wolf image as the target image, using OpenCV.Bilinear as the scaling method,  $\epsilon = 0.01$ ), and used HTML tags to control its rendering size in browsers. The result is presented in Table 4, indicating the potential victims of scaling attack are beyond the scope of deep learning computer

vision applications. One potential problem is that scaling attacks can cause inconsistency between different screen resolutions, when the browser’s auto/adaptive-zooming function is enabled.

### 6.4 Factors that Might Interfere with Scaling Attacks

Image processing applications often contain a complex preprocessing pipeline. Besides scaling, an image processing applications might use cropping, filtering, and various other image transformation actions. If these additional image preprocessing actions occur prior to the scaling action, they might pose additional challenges to scaling attacks.

The following list presents an overview of common image preprocessing actions and discusses their potential impact on scaling attacks.

- **Cropping** – truncate certain regions of the input image, for the purpose of data augmentation or background removing. Cropping usually changes the source image aspect ratio, and if a scaling attack was designed under a wrong dimension, the automatic generated image would not scale to the right target image. Therefore, attackers need to know precisely which region in the input is expected to be cropped. Only under some special cases, such as the cropping preserves the aspect ratio and the underneath algorithm is Nearest, deceiving effect can be preserved. Certainly the degree of impact also depends on the relative size being cropped. If the pixels that are used to generate the targeted image are chopped, then the effect of scaling attack is definitely affected.
- **Filtering** – is to blur or sharpen an image, adjust its color palette. Image filtering changes the pixel values and thus directly interferes with scaling attacks, because the attack is based on the manipulation of “average” values of neighbor pixels used by the interpolation algorithms. For simple scaling algorithms, such as Nearest, the output image might still present deceiving effect as the result is

Table 3: Deceiving effect on four cloud vision services.

Table 4: Proof-of-Concept sample image and the rendering effect under different browser settings. (The HTML file uses an IMG tag to specify the image rendering size.)

Browsers	Original Image	Firefox, Edge	IE11	Chrome	Safari
Image					
Size	672*224	224*224	224*224	224*224	224*224
Version	Firefox: 59.0.2, IE: 11.0.9600.18977 Chrome: 63.0.3239.84, Edge: 41.16299.371.0 Safari: 8.0 (10600.1.25.1)	Firefox: 59.0.2 Edge: 41.16299.371.0	IE: 11.0.9600.18977	Chrome: 63.0.3239.84	Safari: 8.0 (10600.1.25.1)

like the original target with a filtering effect. However, for complex scaling algorithms, such as Bilinear and Bicubic, the output image will likely not present as the intended target image.

- **Affine transformations** – is to rotate or mirror the input image. Rotation in an arbitrary degree likely breaks the calculation used by the automatic attack image crafting. However, flipping images in 180 degree, mirror images might have no impacts on the scaling attack which mainly depends on the size of the inputs and the scaling algorithms. Some scaling algorithms are orientation independent, i.e. the output is same regardless the scan of pixels is from left to right or the opposite order. In those cases, a flip or mirror action would not affect scaling attacks.
- **Color transformations** – to change the color space, like convert an RGB image to grayscale. Color transformation can be considered as a special type of filtering, and thus the impact to scaling attack is similar to filtering.

Although the above transformation actions all directly interfere with scaling attacks, the interference can be overcome by the attackers if they know these transformation details. In fact, each of these operations can be described by a transformation matrix. Once an attacker ensures the exact content of the transformation matrix and if there exists a corresponding reverse transformation matrix, the attacker can apply the reverse matrix to generated attack image before feeding

it to the targeted application. In the black-box case, the attacker has to infer the transformation matrix. Therefore, these transformation actions would increase the attack difficulty.

The deceiving effect of scaling attacks is also subject to some native limitations, especially size and brightness, of source and target images. An attacker needs to find an appropriate pair of the source and target images to achieve a successful attack image.

- **Size:** Sizes of the source and target images decide how many redundant pixels can be leveraged to launch the attack. If the size differences between scaling input and output are very close, the information attenuation due to resampling may be insufficient to achieve a successful deceiving effect.
- **Brightness:** Brightness or color of the source and target images decides how tight the constraints are. In the worst case, it is hard to find a feasible solution given a full white source and a full black target. Even we generate an attack image successfully, it is hard to deceive human without noticing dark dots distributed in the white image.

## 6.5 Practical Attack Scenarios

This paper presents the risk of scaling attacks through a set of limited experiments with proof-of-concept images. We have shown these proof-of-concept images can achieve deceiving effect in deep-learning based image applications, web

browsers, as well as cloud-based visual recognition and classification services. Although these proof-of-concept images, such as the wolf-in-sheep set, do not cause any real damage, we believe the risks of scaling attacks are real. This section describes a few motivating scenarios to illustrate possible real life threats.

- **Data poisoning.** Many image based applications rely on label training sets and there are many large image datasets, such as ImageNet [12], on the Internet. Many deep learning developers rely on these datasets to train their models. Although data poisoning as a concept is known, developers and model trainers rarely consider data poisoning is a real threat on these public datasets since these datasets are public, and humans are expected to notice obvious genre mistakes and a large set of mislabels. However, with scaling attacks, people with malicious intent could conceal a hidden category of images (e.g. wolf) while providing mistaken labels as another category (e.g. sheep). We do not have evidence of such activities, but we envision that scaling attacks definitely make data poisoning more stealthy.
- **Detection evasion and Cloaking.** Content moderation is one of the most widely used computer vision applications. Many vendors provide content filtering services, such as Google [11], Amazon AWS [3] and Microsoft Azure [4]. ModerateContent claims that it is trusted by 1000's of sites to prevent offensive content [23]. An attacker may leverage the scaling attack to evade these content moderators to spread inappropriate images, which may raise serious problems in online communities. For example, suppose an attacker wants to advertise illegal drugs to users on the iPhone XS. The attacker can use the scaling attack to create a cloaking effect, so that the scaling result on the iPhone XS browser is the intended drug image while the image in the original size contains benign content. Certainly cloaking can also be achieved by using other approaches such as browser sensitive Javascript. However, scaling attacks create an alternative approach as no additional code is used to manage the rendering effect.
- **Fraud by Leveraging Inconsistencies between Displays.** An attacker can create a deceptive digital contract using the scaling attacks. An attacker can create an image document that contains a scanned contract but renders to different content when scaling to different ratios. The attacker can then get two parties to share the same document. If they each use different browsers, the content being displayed will be different. This inconsistency can become the basis of potential financial fraud activities.

## 7 Countermeasures

In this section, we discuss potential defense strategies to mitigate the threat from scaling attacks. First, we discuss possible countermeasures as the attack prevention in the image preprocessing procedure. Second, we discuss some approaches to detect scaling attacks.

### 7.1 Attack Prevention

A naive way to avoid the scaling attack is to omit inputs whose sizes are different from the input size used by the deep learning models. This approach is appropriate for applications that deal with the inputs collected by sensors in specific formats. However, this strategy is infeasible for many Internet services, since the input images uploaded by users are often in various sizes.

Another solution is that we can randomly remove some pixels (by line or by column) from the image before scaling it. This random cropping operation makes the scaling coefficient matrices unpredictable, and therefore, it can increase the attack difficulty effectively. However, we should carefully design the pixel removing policy to maintain the image quality.

### 7.2 Attack Detection

The scaling attack achieves the deceiving effect by causing dramatic changes in visual features before and after the scaling action. One potential solution is to detect such obvious changes of input features during the scaling process, such as the color histogram and the color scattering distribution.

#### 7.2.1 Color-histogram-based Detection

The color histogram counts the amount of pixels for color ranges of a digital image. It presents the color distribution in an image, and is commonly used as a measurement of image similarity. The main advantage of the color-histogram-based detection approach is that it can measure the color distribution change easily and quickly. It is a simple solution when the data processing speed is the main concern, especially when the system throughput is high. In our experiments, we convert the image into grayscale to examine the effectiveness of color-histogram-based detection, i.e., pixel values ranging from 0 to 255. Eventually, the color histogram of one image can be represented as a 256-dimension vector  $v^{his}$ , and we adopt the cosine similarity to measure the color-histogram similarity of two images  $s^{his} = \cos(v_1^{his}, v_2^{his})$ .

#### 7.2.2 Color-scattering-based Detection

The color-histogram-based detection can only present a rough distribution of pixel values, disregarding the color spatial distribution information. The color scattering could become a

supplementary to the histogram, which presents the color distribution measured with the distance between pixels and the image center. In our experiments, we also convert the image to grayscale to evaluate the effectiveness the color-scattering-based detection approach. Specifically, we calculate the distance histogram as the color scattering measurement, and define a statistical metric to evaluate the similarity: First, we compute the average distance from pixels which belong to the same pixel value to the center of the image and we present the result with a 256-dimension color scattering vector  $v^{scat}$ . Second, we calculate the cosine similarity between vectors of two images as the color-scattering-based similarity  $s = \cos(v_1^{scat}, v_2^{scat})$ .

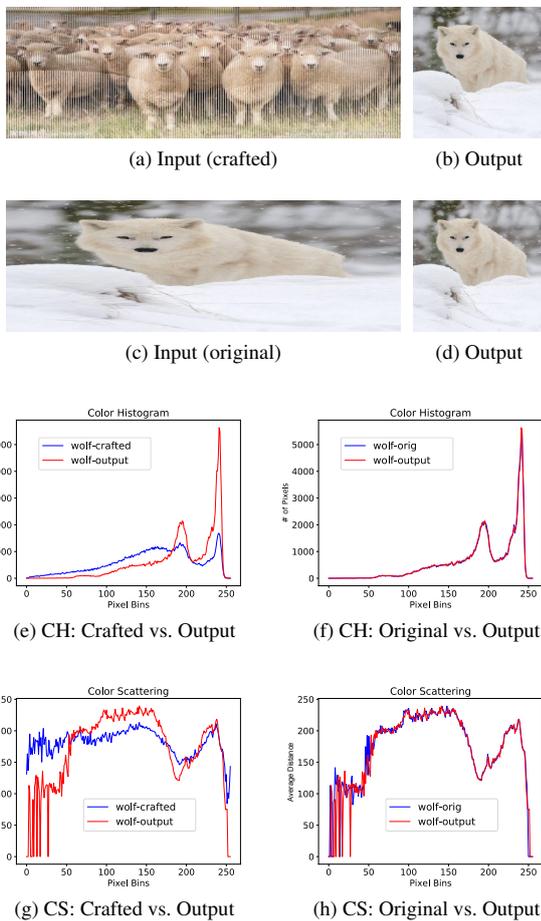

Figure 8: The color histograms and color scattering detection results of the scaling attack in the *wolf-in-sheep* example. (CH: color histogram, CS:color scattering)

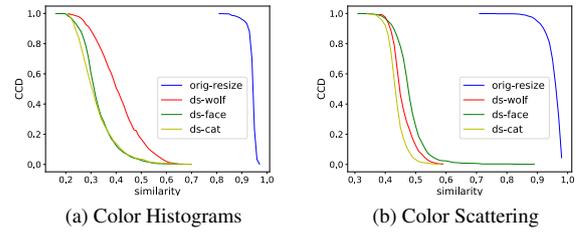

Figure 9: The CCD of color histogram similarity and color scattering similarity detection.

### 7.2.3 Evaluation

To evaluate the performance of two attack detection strategies, we have crafted three attack images for each *sourceImg* in the dataset established in Section 6.2, with three 224\*224 target images belong to the *wolf*, *human face* and *cat* category. Before the similarity comparison, we resize the output to the same size with the input, in order to eliminate the difference in pixel amount. Fig.8 exhibits the detecting result of a *wolf-in-sheep* attack image.

Fig.8e and Fig.8f present the comparison of grayscale histograms between the input images and their scaled output. The x-axis refers to pixel values ranging from 0 to 255, while the y-axis refers to the number of pixels with the same value. From Fig.8f, we can see that the two curves of the original input and its scaling output almost coincide, where the similarity is 0.96. In the meanwhile, we can see an obvious difference between the color distribution of the attack image and its scaling output, where the similarity is 0.50.

Fig.8g and Fig.8h present the comparison of grayscale color scattering measurement. The x-axis refers to pixel values ranging from 0 to 255, while the y-axis refers to the average distance between the image center and pixels with the same value. Similarly, we can see an obvious difference in the color scattering measurement of the attack image and its scaling output.

Fig.9 reports the complementary cumulative distribution (CCD) of the detection results of our test set. The legend “original-resize”, “ds-wolf”, “ds-face” and “ds-cat” refer to the original-image, wolf-as-target, human-face-as-target and cat-as-target case, respectively. We can observe that for both two detection metrics, the similarity between original images and their scaling outputs is obviously higher than that between attack images and their scaling outputs. The result indicates the two attack detection strategies work well in most cases.

## 8 Conclusion

This paper presents a camouflage attack on image scaling algorithms, which is a potential threat to computer vision ap-

plications. By crafting attack images, the attack can cause the visual semantics of images change significantly during scaling. We studied popular deep learning frameworks and showed that most of their default scaling functions are vulnerable to such attack. Our results also exhibit that even though cloud services (such as Microsoft Azure, Baidu, Aliyun and Tencent) hide the scaling algorithms and input scales, attackers can still achieve the deceiving effect. The purpose of this work is to raise awareness of the security threats buried in the data processing pipeline in computer vision applications. Compared to the intense interests in adversarial examples, we believe that the scaling attack is more effective in creating misclassification because of the deceiving effect it can create.

## Acknowledgments

## A Proof of Concept of the Scaling Attack

### A.1 Software Version and Model Information for Attack Demonstration

Here we present the software setup for the attack demonstration. Although the example used here targets applications with Caffe, the risk is not limited to Caffe. We have tested the scaling functions in Caffe, TensorFlow and Torch. All of them are vulnerable to scaling attacks.

The Caffe package and the corresponding image classification examples were checked out directly from the official GitHub on October 25, 2017, and the OpenCV used was the latest stable version from the following URL: <https://github.com/opencv/opencv/archive/2.4.13.4.zip>

We used the BAIR/BVLC CaffeNet Model in our proof of concept exploitation. The model is the result of training based on the instructions provided by the original Caffe package. To avoid any mistakes in model setup, we download the model file directly from BVLC’s official GitHub page. Detailed information about the model is provided in the list below.

Listing 1: Image classification model

## B Code Samples Containing Image Scaling

This appendix provides code snippets of using data scaling procedure examples, from popular deep learning frameworks' released demos without change.

Listing 4: Preprocessing in image demo of Tensorflow [28]

```
def read_tensor_from_image_file(file_name, input_height=299, input_width=299,
                               input_mean=0, input_std=255):
    input_name = "file_reader"
    output_name = "normalized"
    file_reader = tf.read_file(file_name, input_name)
    if file_name.endswith(".png"):
        image_reader = tf.image.decode_png(file_reader, channels = 3,
                                          name='png_reader')
    elif file_name.endswith(".gif"):
        image_reader = tf.squeeze(tf.image.decode_gif(file_reader,
                                                    name='gif_reader'))
    elif file_name.endswith(".bmp"):
        image_reader = tf.image.decode_bmp(file_reader, name='bmp_reader')
    else:
        image_reader = tf.image.decode_jpeg(file_reader, channels = 3,
                                          name='jpeg_reader')
    float_caster = tf.cast(image_reader, tf.float32)
    dims_expander = tf.expand_dims(float_caster, 0);
    resized = tf.image.resize_bilinear(dims_expander, [input_height, input_width])
    normalized = tf.divide(tf.subtract(resized, [input_mean]), [input_std])
    sess = tf.Session()
    result = sess.run(normalized)

    return result
```

  _imgs.push_back(ring);
  return 0;
}

```

## C Analysis and Examples of Popular Image Scaling Implementations

In this paper, we assume that the scaling algorithms first resize inputs horizontally and then vertically. This appendix provides examples of how we make our assumptions based on source code snippets of OpenCV and Pillow.

Here, Listing 9 shows one code snippet of OpenCV<sup>10</sup>, where lines 3607-3700 are the main part of the resizing function implementation. From the loop condition variables *dsize.width* (line 3607) and *dsize.height* (line 3674), we can infer that lines 3607-3662 present the horizontal scaling operation, and lines 3674-7300 show the vertical scaling operation.

Listing 9: Code snippet of OpenCV

```

...
3607 for( dx = 0; dx < dsize.width; dx++ )
3608 {
3609     if( !area_mode )
...
3662 }
3663
3664 for( dy = 0; dy < dsize.height; dy++ )
3665 {
3666     if( !area_mode )
...
3700 }
...

```

Listing 10 shows one code snippet of Pillow<sup>11</sup>, which follows the same procedure (lines 635-681). The scaling direction can be inferred from the variables *need\_horizontal* (line 636) and *need\_vertical* (line 662).

Listing 10: Code snippet of Pillow

```

...
635 /* two-pass resize, horizontal pass */
636 if (need_horizontal) {
637     // Shift bounds for vertical pass
638     for (i = 0; i < ysize; i++) {
639         bounds_vert[i * 2] -= ybox_first;
640     }
...
659 }
660
661 /* vertical pass */
662 if (need_vertical) {
663     imOut = ImagingNewDirty(imIn->mode, imIn->xsize, ysize);
664     if (imOut) {
665         /* imIn can be the original image or horizontally resampled one */
666         ResampleVertical(imOut, imIn, 0,
667                         ksize_vert, bounds_vert, kk_vert);
668     }
...
681 }

```

<sup>10</sup><https://github.com/opencv/opencv/blob/master/modules/imgproc/src/resize.cpp>

<sup>11</sup><https://github.com/python-pillow/Pillow/blob/master/src/libImaging/Resample.c>

## D Scaling Attack Examples

Table 5: Examples of two attack forms.

Style	Source Image	Target Image	Attack Image	Output Image
Strong Attack	 (328*438)	 (178*218)	 (328*438)	 (178*218)
Strong Attack	 (580*785)	 (128*128)	 (580*785)	 (128*128)
Strong Attack	 (580*785)	 (220*311)	 (580*785)	 (220*311)
Strong Attack <sup>◇</sup>	 (1280*720)	 (384*215)	 (1280*720)	 (384*215)
Strong Attack <sup>◆</sup>	 (922*692)	 (185*139)	 (922*692)	 (185*139)
Weak Attack	None (328*438)	 (109*145)	 (328*438)	 (109*145)

<sup>◇</sup>The car at the lower left corner of the attack image is removed after the attack image gets resized.

<sup>◆</sup>The "Prohibit left turn" sign in the attack image is changed into "Turn left" after the attack image gets resized.

# CT-GAN: Malicious Tampering of 3D Medical Imagery using Deep Learning

## Abstract

In 2018, clinics and hospitals were hit with numerous attacks leading to significant data breaches and interruptions in medical services. An attacker with access to medical records can do much more than hold the data for ransom or sell it on the black market.

In this paper, we show how an attacker can use deep-learning to add or remove evidence of medical conditions from volumetric (3D) medical scans. An attacker may perform this act in order to stop a political candidate, sabotage research, commit insurance fraud, perform an act of terrorism, or even commit murder. We implement the attack using a 3D conditional GAN and show how the framework (CT-GAN) can be automated. Although the body is complex and 3D medical scans are very large, CT-GAN achieves realistic results which can be executed in milliseconds.

To evaluate the attack, we focused on injecting and removing lung cancer from CT scans. We show how three expert radiologists and a state-of-the-art deep learning AI are highly susceptible to the attack. We also explore the attack surface of a modern radiology network and demonstrate one attack vector: we intercepted and manipulated CT scans in an active hospital network with a covert penetration test.

## 1 Introduction

Medical imaging is the non-invasive process of producing internal visuals of a body for the purpose of medical examination, analysis, and treatment. In some cases, volumetric (3D) scans are required to diagnose certain conditions. The two most common techniques for producing detailed 3D medical imagery are Magnetic Resonance Imaging (MRI), and CT (Computed Tomography). Both MRI and CT scanner are essential tools in the medical domain. In 2016, there were approximately 38 million MRI scans and 79 million CT scans performed in the United States [1].<sup>1</sup>

MRI and CT scanners are similar in that they both create 3D images by taking many 2D scans of the body over the axial plane (from front to back) along the body. The difference between the two is that MRIs use powerful magnetic fields

and CTs use X-Rays. As a result, the two modalities capture body tissues differently: MRIs are used to diagnose issues with bone, joint, ligament, cartilage, and herniated discs. CTs are used to diagnose cancer, heart disease, appendicitis, musculoskeletal disorders, trauma, and infectious diseases [2].

Today, CT and MRI scanners are managed through a picture archiving and communication system (PACS). A PACS is essentially an Ethernet-based network involving a central server which (1) receives scans from connected imaging devices, (2) stores the scans in a database for later retrieval, and (3) retrieves the scans for radiologists to analyze and annotate. The digital medical scans are sent and stored using the standardized DICOM format.<sup>2</sup>

### 1.1 The Vulnerability

The security of health-care systems has been lagging behind modern standards [3–6]. This is partially because health-care security policies mostly address data privacy (access-control) but not data security (availability/integrity) [7]. Some PACS are intentionally or accidentally exposed to the Internet via web access solutions. Some example products include Centricity PACS (GE Healthcare), IntelliSpace (Philips), Synapse Mobility (FujiFilm), and PowerServer (RamSoft). A quick search on Shodan.io reveals 1,849 medical image (DICOM) servers and 842 PACS servers exposed to the Internet. Recently, a researcher at McAfee demonstrated how these web portals can be exploited to view and modify a patient's 3D DICOM imagery [8]. PACS which are not directly connected to the Internet are indirectly connected via the facility's internal network [9]. They are also vulnerable to social engineering attacks, physical access, and insiders [10].

Therefore, a motivated attacker will likely be able to access a target PACS and the medical imagery within it. Later in section 4 we will discuss the attack vectors in greater detail.

### 1.2 The Threat

An attacker with access to medical imagery can alter the contents to cause a misdiagnosis. Concretely, the attacker can

<sup>1</sup>245 CT scans and 118 MRI scans per 1,000 inhabitants.

<sup>2</sup><https://www.dicomstandard.org/about/>

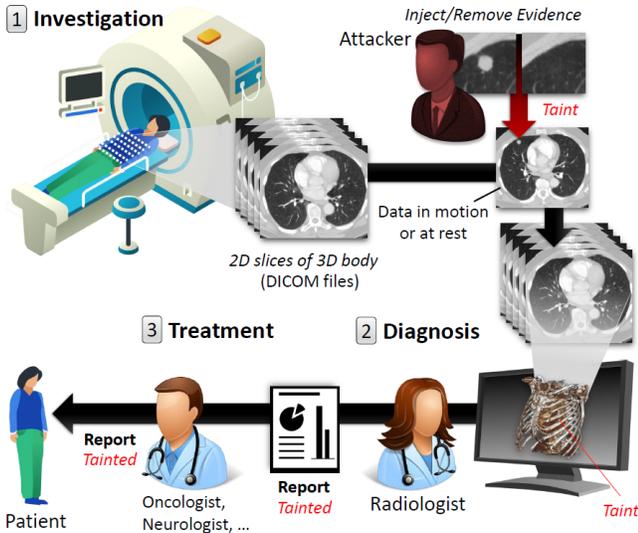

Figure 1: By tampering with the medical imagery between the investigation and diagnosis stages, both the radiologist and the reporting physician believe the fallacy set by the attacker.

add or remove evidence of some medical condition. Fig. 1 illustrates this process where an attacker injects/removes lung cancer from a scan.

Volumetric medical scans provide strong evidence of medical conditions. In many cases, a patient may be treated based on this evidence without the need to consider other medical tests. For example, some lesions are obvious or require immediate surgery. Moreover, some lesions will legitimately not show up on other medical tests (e.g., meniscus trauma and some breast cancers). Regardless, even if other tests aren't usually negative, ultimately, the evidence in the scan will be used to diagnose and treat the patient. As a result, an attacker with access to a scan has the power to change the outcome of the patient's diagnosis. For example, an attacker can add or remove evidence of aneurysms, heart disease, blood clots, infections, arthritis, cartilage problems, torn ligaments or tendons, tumors in the brain, heart, or spine, and other cancers.

There are many reasons why an attacker would want to alter medical imagery. Consider the following scenario: An individual or state adversary wants to affect the outcome of an election. To do so, the attacker adds cancer to a CT scan performed on a political candidate (the appointment/referral can be pre-existing, setup via social engineering, or part of a lung cancer screening program). After learning of the cancer, the candidate steps-down from his or her position. The same scenario can be applied to existing leadership.

Another scenario to consider is that of ransomware: An attacker seeks out monetary gain by holding the integrity of the medical imagery hostage. The attacker achieves this by altering a few scans and then by demanding payment for revealing which scans have been affected.

Furthermore, consider the case of insurance fraud: Somebody alters his or her own medical records in order to receive money directly from his or her insurance company, or receive

Table 1: Summary of an attacker's motivations and goals for injecting/removing evidence in 3D medical imagery.

		Goal								
		Steal Job Position	Affect Elections	Remove Leader	Sabotage Research	Falsify Research	Hold Data Hostage	Insurance Fraud	Murder	Terrorize
+		Add Evidence								
-		Remove Evidence								
±		Either

	Payout	●		○		○		○		●
Attack Type	Untargeted				X	X	X			X
	Targeted	X	X	X	X	X		X	X	

handicap benefits (e.g., lower taxes etc.) In this case, there is no risk of physical injury to others, and the payout can be very large. For example, one can (1) sign up for disability/life insurance, then (2) fake a car accident or other incident, (3) complain of an inability to work, sense, or sleep, then (4) add a small brain hemorrhage or spinal fracture to his or her own scan during an investigation (this evidence is very hard to refute), and then (5) file a claim and receive cash from the insurance company.<sup>3</sup>

There are many more reasons why an attacker would want to tamper with the imagery. For example: falsifying research evidence, sabotaging another company's research, job theft, terrorism, assassination, and even murder.

Depending on the attacker's goal, the attack may be either untargeted or targeted:

**Untargeted Attacks** are where there is no specific target patient. In this case, the attacker targets a victim who is receiving a random voluntary cancer screening, is having an annual scan (e.g., BRACA patients, smokers...), or is being scanned due to an injury. These victims will either have an 'incidental finding' when the radiologist reviews the scan (injection) or are indeed sick but the evidence won't show (removal).

**Targeted Attacks** are where there is a specific target patient. In these attacks, the patient may be lured to the hospital for a scan. This can be accomplished by (1) adding an appointment in the system, (2) crafting a cancer screening invite, (3) spoofing the patient's doctor, or (4) tampering/appending the patient's routine lab tests. For

<sup>3</sup>For example, see products such as AIG's Quality of Life insurance.

example, high-PSA in blood indicates prostate cancer leading to an **abdominal MRI**, high thyrotropin in blood indicates a brain tumor leading to a **head MRI**, and metanephrine in urine of hypertensive patients indicates cancer/tumor leading to a **chest/abdominal CT**

In this paper we will focus on the injection and removal of lung cancer from CT scans. Table 1 summarizes attacker's motivations, goals, and effects by doing so. The reason we investigate this attack is because lung cancer is common and has the highest mortality rate [11]. Therefore, due its impact, an attacker is likely to manipulate lung cancer to achieve his or her goal. We note that the threat, attack, and countermeasures proposed in this paper also apply to MRIs and medical conditions other than those listed above.

### 1.3 The Attack

With the help of machine learning, the domain of image generation has advanced significantly over the last ten years [12]. In 2014, there was a breakthrough in the domain when Goodfellow et al. [13] introduced a special kind of deep neural network called a generative adversarial network (GAN). GANs consist of two neural networks which work against each other: the *generator* and the *discriminator*. The *generator* creates fake samples with the aim of fooling the *discriminator*, and the *discriminator* learns to differentiate between real and fake samples. When applied to images, the result of this game helps the *generator* create fake imagery which are photo realistic. While GANs have been used for positive tasks, researchers have also shown how they can be used for malicious tasks such as malware obfuscation [14, 15] and misinformation (e.g., deepfakes [16]).

In this paper, we show how an attacker can realistically inject and remove medical conditions with 3D CT scans. The framework, called CT-GAN, uses two conditional GANs (cGAN) to perform in-painting (image completion) [17] on 3D imagery. For injection, a cGAN is trained on unhealthy samples so that the *generator* will always complete the images accordingly. Conversely, for removal, another cGAN is trained on healthy samples only.

To make the process efficient and the output anatomically realistic, we perform the following steps: (1) locate where the evidence should be inject/removed, (2) cut out a rectangular cuboid from the location, (3) interpolate (scale) the cuboid, (4) modify the cuboid with the cGAN, (5) rescale, and (6) paste it back into the original scan. By dealing with a small portion of the scan, the problem complexity is reduced by focusing the GAN on the relevant area of the body (as opposed to the entire CT). Moreover, the algorithm complexity is reduced by processing fewer inputs<sup>4</sup> (pixels) and concepts (anatomical features). This results in fast execution and high anatomical realism. The interpolation step is necessary because the scale of a scan can be different between patients. To compensate for the resulting interpolation blur, we mask the relevant content

<sup>4</sup>A 3D CT scan can have over 157 million pixels whereas the latest advances in GANs can only handle about 2 million pixels (HD images).

according to water density in the tissue (Hounsfield units) and hide the smoothness by adding Gaussian white noise. In order to assist the GAN in generating realistic features, histogram equalization is performed on the input samples. We found that this transformation helps the 3D convolutional neural networks in the GAN learn how to generate the subtle features found in the human body. The entire process is automated, meanings that the attack can be deployed in an air gapped PACS.

To verify the threat of this attack, we trained CT-GAN to inject/remove lung cancer and hired three radiologists to diagnose a mix of 70 tampered and 30 authentic CT scans. The radiologists diagnosed 99% of the injected patients with malign cancer, and 94% of cancer removed patients as being healthy. After informing the radiologists of the attack, they still misdiagnosed 60% of those with injections, and 87% of those with removals. In addition to the radiologists, we also showed how CT-GAN is an effective adversarial machine learning attack. We found that the state-of-the-art lung cancer screening model misdiagnosed 100% of the tampered patients. Thus, cancer screening tools, used by some radiologists, are also vulnerable to this attack.

This attack is a concern because infiltration of healthcare networks has become common [3], and internal network security is often poor [18]. Moreover, for injection, the attacker is still likely to succeed even if medical treatment is not performed. This is because many goals rely on simply scaring the patient enough to affect his/her daily/professional life. For example, even if an immediate deletion surgery is not deemed necessary based on the scan and lab results, there will still be weekly/monthly follow-up scans to track the tumor's growth. This will affect the patient's life given the uncertainty of his or her future.

### 1.4 The Contribution

To the best of our knowledge, it has not been shown how an attacker can maliciously alter the content of a 3D medical image in a realistic and automated way. Therefore, this is the first comprehensive research which exposes, demonstrates, and verifies the threat of an attacker manipulating 3D medical imagery. In summary, the contributions of this paper are as follows:

**The Attack Model** We are the first to present how an attacker can infiltrate a PACS network and then use malware to autonomously tamper 3D medical imagery. We also provide a systematic overview of the attack, vulnerabilities, attack vectors, motivations, and attack goals. Finally, we demonstrate one possible attack vector through a penetration test performed on a hospital where we covertly connect a man-in-the-middle device to an actual CT scanner. By performing this pen-test, we provide insights into the security of a modern hospital's internal network.

**Attack Implementation** We are the first to demonstrate how GANs, with the proper preprocessing, can be used to efficiently, realistically, and automatically inject/remove lung cancer into/from large 3D CT scans. We also evaluate how well the algorithm can deceive both humans and

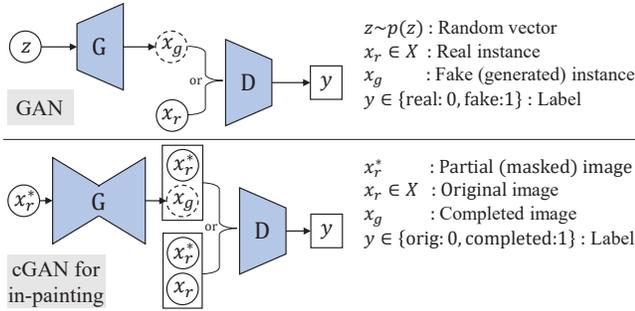

Figure 2: A schematic view of a classic GAN (top) and a cGAN setup for in-painting.

machines: radiologists and state-of-the-art AI. We also show how this implementation might be used by an attacker since it can be automated (in the case of an air gapped system) and is fast (in the case of an infected DICOM viewer).

**Countermeasures** We enumerate various countermeasures which can be used to mitigate the threat. We also provide the reader with best practices and configurations which can be implemented immediately to help prevent this attack.

For reproducibility and further investigation, we have published our tampered datasets and source code online<sup>5</sup> along with a pen-test video.<sup>6</sup>

The remainder of the paper is organized as follows: First we present a short background on GANs. Then, in section 3, we review related works and contrast them ours. In section 4 we present the attack model and demonstrate one of the attack vectors. In section 5, we present CT-GAN’s neural architecture, its attack process, and some samples. In section 6 we evaluate the quality of the manipulations and assess the threat of the attack. Finally, in sections 7 and 8 we present countermeasures and our conclusion.

## 2 Background: GANs

The most basic GAN consists of two neural networks: the *generator* ( $G$ ) and *discriminator* ( $D$ ). The objective of the GAN is to generate new images which are visually similar to real images found in a sample data distribution  $X$  (i.e., a set of images). The input to  $G$  is the random noise vector  $z$  drawn from the prior distribution  $p(z)$  (e.g., a Gaussian distribution). The output of  $G$ , denoted  $x_g$ , is an image which is expected to have visual similarity with those in  $X$ . Let the non-linear function learned by  $G$  parametrized by  $\theta_g$  be denoted as  $x_g = G(z; \theta_g)$ . The input to  $D$  is either a real image  $x_r \in X$  or a generated image  $x_g \in G(Z; \theta_g)$ . The output of  $D$  is the probability that  $x_g$  is real or fake. Let the non-linear function learned by  $D$  parametrized by  $\theta_d$  be denoted as  $x_d = D(x; \theta_d)$ . The top of Fig. 2 illustrates the configuration of a classic GAN.

It can be seen that  $D$  and  $G$  are playing a zero-sum game where  $G$  is trying to find better (more realistic) samples to fool

$D$ , while  $D$  is learning to catch every fake sample generated by  $G$ . After training,  $D$  is discarded and  $G$  is used to generate new samples.

A cGAN is a GAN which has a *generator* and *discriminator* conditioned on an additional input (e.g., class labels). This input extends the latent space  $z$  with further information thus assisting the network to generate and discriminate images better. In [17] the authors propose an image-to-image translation framework using cGANs (a.k.a. pix2pix). There the authors showed how deep convolutional cGANs can be used to translate images from one domain to another. For example, converting casual photos to a Van Gogh paintings.

One application of the pix2pix framework is in-painting; the process of completing a missing part of an image. When using pix2pix to perform in-painting, the *generator* tries to fill in a missing part of an image based on the surrounding context, and its past experience (other images seen during training). Meanwhile, the *discriminator* tries to differentiate between completed images and original images, given the surrounding context. Concretely, the input to  $G$  is a copy of  $x_r$  where missing regions of the image are replaced with zeros. We denote this masked input as  $x_r^*$ . The output of  $G$  is the completed image, visually similar to those in  $X$ . The input to  $D$  is either the concatenation  $(x_r^*, x_r)$  or  $(x_r^*, G(x_r^*; \theta_g))$ . The bottom of Fig. 2 illustrates the described cGAN. The process for training this kind of GAN is as follows:

### Training Procedure for cGAN In-painting

Repeat for  $k$  training iterations:

1. Pull a random batch of samples  $x_r \in X$ , and mask the samples with zeros to produce the respective  $x_r^*$ .
2. **Train  $D$ :**
  - 2.1. Forward propagate  $(x_r^*, x_r)$  through  $D$ , compute the error given the label  $y=0$ , and back propagate the error through  $D$  to update  $\theta_d$ .
  - 2.2. Forward propagate  $(x_r^*, G(x_r^*; \theta_g))$  through  $D$ , compute the error given the label  $y=1$ , and back propagate the error through  $D$  to update  $\theta_d$ .
3. **Train  $G$ :**
  - 3.1. Forward propagate  $x_r^*$  through  $G$  and then  $(x_r^*, G(x_r^*; \theta_g))$  through  $D$ , compute the error at the output of  $D$  given the label  $y=0$ , back propagate the error through  $D$  to  $G$  without updating  $\theta_d$ , and continue the back propagation through  $G$  while updating  $\theta_g$ .

Although pix2pix does not use a latent random input  $z$ , it avoids deterministic outputs by performing random dropouts in the generator during training. this forces the network to learn multiple representations of the data.

We note that there is a GAN called a CycleGAN [19] that can directly translate images between two domains (e.g., benign  $\leftrightarrow$  malign). However, we found that the CycleGAN was unable to inject realistic cancer into 3D samples. Therefore, we opted

<sup>5</sup><https://github.com/yimirsky/CT-GAN>

<sup>6</sup>[https://youtu.be/\\_mkRAArj-x0](https://youtu.be/_mkRAArj-x0)

to use the pix2pix model for in-painting because it produced much better results. This may be due to the complexity of the anatomy in the 3D samples and the fact that we had relatively few training samples. Since labeled datasets contain at most a few hundred scans, our approach is more likely to be used by an attacker. Another reason is that in-painting is arguably easier to perform than ‘style transfer’ when considering different bodies. Regardless, in-painting ensures that the final image can be seamlessly pasted back into the scan without border effects.

### 3 Related Work

The concept of tampering medical imagery, and the use of GANs on medical imagery, is not new. In this section we briefly review these subjects and compare prior results to our work.

#### 3.1 Tampering with Medical Images

Many works have proposed methods for detecting forgeries in medical images [20], but none have focused on the attack itself. The most common methods of image forgery are: copying content from one image to another (image splicing), duplicating content within the same image to cover up or add something (copy-move), and enhancing an image to give it a different feel (image retouching) [21].

Copy-move attacks can be used to cover up evidence or duplicate existing evidence (e.g., a tumor). However, duplicating evidence will raise suspicion because radiologists closely analyze each discovered instance. Image-splicing can be used to copy evidence from one scan to another. However, CT scanners have distinct local noise patterns which are visually noticeable [22, 23]. The copied patterns would not fit the local pattern and thus raise suspicion. More importantly, both copy-move and image-splicing techniques are performed using 2D image editing software such as Photoshop. These tools require a digital artist to manually edit the scan. Even if the attacker has a digital artist, it is hard to accurately inject and remove cancer realistically. This is because human bodies are complex and diverse. For example, cancers and tumors are usually attached to nearby anatomy (lung walls, bronchi, etc.) which may be hard to alter accurately under the scrutiny of expert radiologists. Another consideration is that CT scans are 3D and not 2D, which adds to the difficulty. It is also important to note that an attacker will likely need to automate the entire process in a malware since (1) many PACS are not directly connected to the Internet and (2) the diagnosis may occur immediately after the scan is performed.

In contrast to the Photoshopping approach, CT-GAN (1) works on 3D medical imagery, which provide stronger evidence than a 2D scans, (2) realistically alters the contents of a 3D scan while considering nearby anatomy, and (3) can be completely automated. The latter point is important because (1) some PACS are not directly connected to the Internet, (2) diagnosis can happen right after the actual scan, (3) the malware may be inside the radiologist’s viewing app.

#### 3.2 GANs in Medical Imagery

Since 2016, over 100 papers relating to GANs and medical imaging have been published [24]. These publications mostly relate image reconstruction, denoising, image generation (synthesis), segmentation, detection, classification, and registration. We will focus on the use of GANs to generate medical images.

Due to privacy laws, it is hard to acquire medical scans for training models and students. As a result, the main focus of GANs in this domain has been towards augmenting (expanding) datasets. One approach is to convert imagery from one modality to another. For example, in [25] the authors used cGANs to convert 2D slices of CT images to Positron Emission Tomography (PET) images. In [26, 27] the authors demonstrated a similar concept using a fully convolutional network with a cGAN architecture. In [28], the authors converted MRI images to CT images using domain adaptation. In [29], the authors converted MRI to CT images and vice versa using a CycleGAN.

Another approach to augmenting medical datasets is the generation of new instances. In [30], the authors use a deep convolutional GAN (DCGAN) to generate 2D brain MRI images with a resolution of 220x172. In [31], the authors used a DCGAN to generate 2D liver lesions with a resolution of 64x64. In [32], the authors generated 3D blood vessels using a Wasserstien (WGAN). In [33], the authors use a Laplace GAN (LAPGAN) to generate skin lesion images with 256x256 resolution. In [34], the authors train two DCGANs for generating 2D chest X-rays (one for malign and the other for benign). However, in [34], the generated samples were down sampled to 128x128 in resolution since this approach could not be scaled to the original resolution of 2000x3000. In [35] the authors generated 2D images of pulmonary lung nodules (lung cancer) with 56x56 resolution. The author’s motivation was to create realistic datasets for doctors to practice on. The samples were generated using a DCGAN and their realism was assessed with help of two radiologists. The authors found that the radiologists were unable to accurately differentiate between real and fake samples.

These works contrast to our work in the following ways:

1. We are the first to introduce the use of GANs as a way to tamper with 3D imagery. The other works focused on synthesizing cancer samples for boosting classifiers, experiments, and training students, but not for malicious attacks. We also provide an overview of how the attack can be accomplished in a modern medical system.
2. All of the above works either generate small regions of a scan without the context of a surrounding body or generate a full 2D scan with a very low resolution. Samples which are generated without a context cannot be realistically ‘pasted’ back into any arbitrary medical scan. We generate/remove content realistically within existing bodies. Moreover, very low-resolution images of full scans cannot replace existing ones without raising suspicion (especially if the body doesn’t match the actual person).

Our approach can modify full resolution 3D scans,<sup>7</sup> and the approach can be easily extended to 2D as well.

3. We are the first to evaluate how well a GAN can fool expert radiologists and state-of-the-art AI in full 3D lung cancer screening. Moreover, in our evaluation, the radiologists and AI were able to consider how the cancer was attached and placed within the surrounding anatomy.

## 4 The Attack Model

In this section we explore the attack surface by first presenting the network topology and then by discussing the possible vulnerabilities and attack vectors. We also demonstrate one of the attack vectors on an actual CT scanner.

### 4.1 Network Topology

In order to discuss the attack vectors we must first present the PACS network topology. Fig. 3 presents the common network configuration of PACS used in hospitals. The topology is based on PACS literature [9, 36–38], PACS enterprise solutions (e.g., Carestream), and our own surveys conducted on various hospitals. We note that, private medical clinics may have a much simpler topology and are sometimes directly connected to the Internet [8].

The basic elements of a PACS are as follows:

**PACS Server.** The heart of the PACS system. It is responsible for storing, organizing, and retrieving DICOM imagery and reports commonly via SQL. Although the most facilities use local servers, a few hospitals have transitioned to cloud storage [39].

**RIS Server.** The radiology information system (RIS) is responsible for managing medical imagery and associated data. Its primary use is for tracking radiology imaging orders and the reports of the radiologists. Doctors in the hospital's internal network can interface with the RIS to order scans, receive the resulting reports, and to obtain the DICOM scans [40].

**Modality Workstation.** A PC (typically Windows) which is used to control an imaging modality such as a CT scanner. During an appointment, the attending technician configures and captures the imagery via the workstation. The workstation sends all imagery in DICOM format to the PACS server for storage.

**Radiologist Workstation.** A radiologist can retrieve and view scans stored on the PACS server from various locations. The most common location is a viewing workstation within the department. Other locations include the radiologist's personal PC (local or remote via VPN), and sometimes a mobile device (via the Internet or within the local network).

<sup>7</sup>A CT scan can have a resolution from 512x512x600 to 1024x1024x600 and larger.

**Web Server.** An optional feature which enables radiologists to view of DICOM scans (in the PACS server) over the Internet. The content may be viewed through a web browser (e.g., medDream and Orthanc [41]), an app on a mobile device (e.g., FujiFilm's Synapse Mobility), or accessed via a web API (e.g., Dicoogle [42]).

**Administrative Assistant's PC.** This workstation has both Internet access (e.g., for emails) and access to the PACS network. Access to the PACS is enabled so that the assistant can maintain the devices' schedules: When a patient arrives at the imaging modality, for safety reasons, the technician confirms the patient's identity with the details sent to the modality's workstation (entered by the assistant). This ensures that the scans are not accidentally mixed up between the patients.

**Hospital Network.** Other departments within the hospital usually have access to the PACS network. For example, Oncology, Cardiology, Pathology, and OR/Surgery. In these cases, various workstations around the hospital can load DICOM files from the server given the right credentials. Furthermore, it is common for a hospital to deploy Wi-Fi access points, which are connected to the internal network, for employee access.

### 4.2 Attack Scenario

The attack scenario is as follows: An attacker wants to achieve one of the goals listed in Table 1 by injecting/removing medical evidence. In order to cause the target effect, the attacker will alter the contents of the target's CT scan(s) before the radiologist performs his or her diagnosis. The attacker will achieve this by either targeting the data-at-rest or data-in-motion.

The data-at-rest refers to the DICOM files stored on the PACS Server, or on the radiologist's personal computer (saved for later viewing). In some cases, DICOM files are stored on DVDs and then transferred to the hospital by the patient or an external doctor. Although the DVD may be swapped by the attacker, it is more likely the interaction will be via the network. The data-in-motion refers to DICOM files being transferred across the network or loaded into volatile memory by an application (e.g., a DICOM viewer).

We note that this scenario does not apply to the case where the goal is to falsify or sabotage research. Moreover, for insurance fraud, an attacker will have a much easier time targeting a small medical clinic. For simplicity, we will assume that the target PACS is in a hospital.

### 4.3 Target Assets

To capture/modify a medical scan, an attacker must compromise at least one of the assets numbered in Fig. 3. By compromising one of (1-4), the attacker gains access to every scan. By compromising (5) or (6), the attacker only gains access to a subset of scans. The RIS (3) can give the attacker full control over the PACS server (2), but only if the attacker can obtain the right

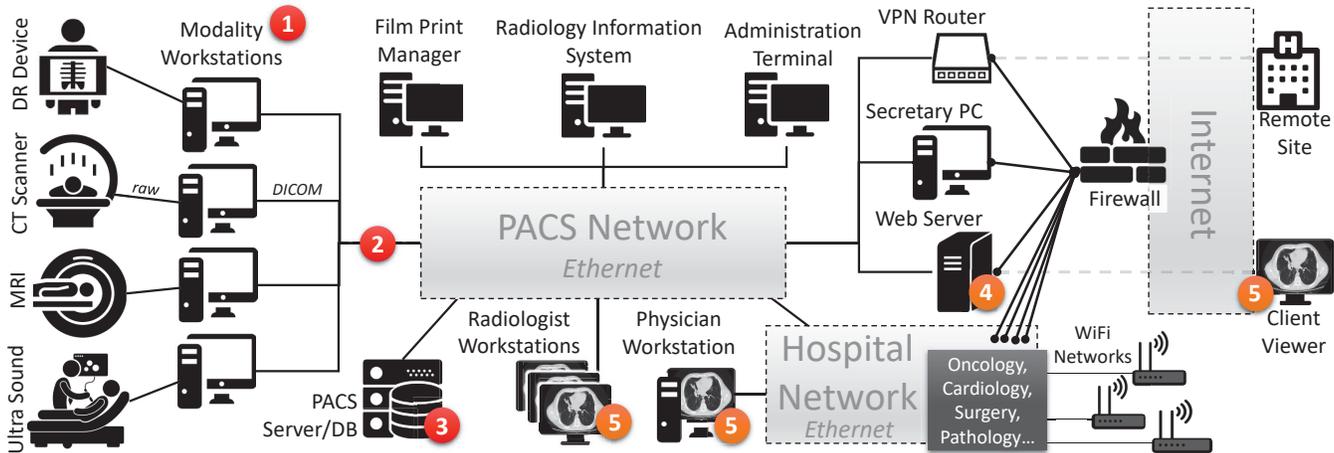

Figure 3: A network overview a PACS in a hospital. 1-3: points where an attacker can tamper with all scans. 4-5: points where an attacker can tamper with a subset of scans.

credentials or exploit the RIS software. The network wiring between the modalities and the PACS server (4) can be used to install a man-in-the-middle device. This device can modify data-in-motion if it is not encrypted (or if the protocol is flawed).

In all cases, it is likely that the attacker will infect the target asset with a custom malware, outlined in Fig. 4. This is because there may not be a direct route to the PACS via the Internet or because the diagnosis may take place immediately after the scan is taken.

#### 4.4 Attack Vectors

There are many ways in which an attacker can reach the assets marked in Fig. 3. In general, the attack vectors involve either remote or local infiltration of the facility’s network.

**Remote Infiltration.** The attacker may be able to exploit vulnerabilities in elements facing the Internet, providing the attacker with direct access to the PACS from the Internet (e.g., [8]). Another vector is to perform a social engineering attack. For example, a spear phishing attack on the department’s administrative assistant to infect his/her workstation with a backdoor, or a phishing attack on the technician to have him install fraudulent updates.

If the PACS is not directly connected to the Internet, an alternative vector is to (1) infiltrate the hospital’s internal network and then (2) perform lateral movement to the PACS. This is possible because PACS is usually connected to the internal network (using static routes and IPs), and the internal network is connected to the Internet (evident from the recent wave of

cyber-attacks on medical facilities [3, 43–45]). The bridge between the internal network and the PACS is to enable doctors to view scans/reports and to enable the administrative assistant to manage patient referrals [9]. Another vector from the Internet is to compromise a remote site (e.g., a partnered hospital or clinic) which is linked to the hospital’s internal network. Furthermore, the attacker may also try to infect a doctor’s laptop or phone with a malware which will open a back door into the hospital.

If the attacker knows that radiologist analyzes scans on his or her personal computer, then the attacker can infect the radiologist’s device or DICOM viewer remotely with the malware.

**Local Infiltration.** The attacker can gain physical access to the premises with a false pretext, such as being a technician from Philips who needs to run a diagnostic on the CT scanner. The attacker may also hire an insider or even be an insider. A recent report shows that 56% of cyber attacks on the healthcare industry come from internal threats [10].

Once inside, the attacker can plant the malware or a back door by (1) connecting a device to exposed network infrastructure (ports, wires, ...) [46] or (2) by accessing an unlocked workstation. Another vector which does not involve access to a restricted area, is to access to the internal network by hacking WiFi access points. This can be accomplished using existing vulnerabilities such as ‘Krack’ [47] or the more recent ‘Bleeding-Bit’ vulnerabilities which have affected many hospitals [48].

**Compromising the PACS.** Once access to the PACS has been achieved, there are numerous ways an attacker can compromise a target asset. Aside from exploiting misconfigurations or default credentials, the attacker can exploit known software vulnerabilities. With regards to PACS servers, some already disclose private information/credentials which can be exploited remotely to create of admin accounts, and have hard-coded credentials.<sup>8</sup> A quick search on [exploit-db.com](http://exploit-db.com) reveals seven implemented exploits for PACS servers in 2018 alone. With regards to modality workstations, they too have been found to have significant vulnerabilities [49]. In 2018

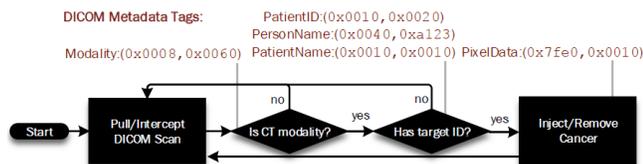

Figure 4: The tampering process of an autonomous malware.

<sup>8</sup>CVE-2017-14008 and CVE-2018-17906

Figure 5: Left: The CT scanner and the medical dummy used to validate the attack. Top-right: the Pi-bridge used to intercept the scans. Bottom-right: one of the dummy’s slices, sent by the CT scanner, and intercepted by the Pi-bridge.

the US Department of Homeland Security exposed ‘low skill’ vulnerabilities in Philips’ Brilliance CT scanners [50]. For example, improper authentication, OS command injection, and hard-coded credentials.<sup>9</sup> Other recent vulnerabilities include hard-coded credentials.<sup>10</sup>

Given the state of health-care security, and that systems such as CT scanners are rarely given software updates [51], it is likely that these vulnerabilities and many more exist. Once the target asset in the PACS has been compromised, the attacker will be able to install the malware and manipulate the scans of target patients.

## 4.5 Attack Demonstration

To demonstrate how an attacker can access and manipulate CT scans, we performed a penetration test on a hospital’s radiology department. The pen-test was performed with full permission of the participating hospital. To gain access to all CT scans, we performed a man-in-the-middle attack on the CT scanner using a Raspberry Pi 3B. The Pi was given a USB-to-Ethernet adapter, and was configured as a passive network bridge (without network identifiers). The Pi was also configured as a hidden Wi-Fi access point for backdoor access. We also printed a 3D logo of the CT scanner’s manufacturer and glued it to the Pi to make it less conspicuous. The pen-test was performed as follows: First we waited at night until the cleaning staff opened the doors. Then we found the CT scanner’s room and installed the Pi-bridge between the scanner’s workstation and the PACS network (location #2 in Fig. 3). Finally, we hid the Pi-bridge under an access panel in the floor. The entire installation process took 30 seconds to complete. We were able to connect to the Pi wirelessly from the waiting room (approximately 20m away) to monitor the device’s status, change the target identifier, etc.

At this point, an attacker could either intercept scans directly or perform lateral movement through the PACS to other subsystems and install the malware there. To verify that

we could intercept and manipulate the scans, we scanned a medical dummy (Fig. 5). We found that the scan of the dummy was sent over the network twice: once in cleartext over TCP to an internal web viewing service, and again to the PACS storage server using TLSv1.2. However, to our surprise, the payload of the TLS transmission was also in cleartext. Moreover, within 10 minutes, we obtained the usernames and passwords of over 27 staff members and doctors due to multicasted Ethernet traffic containing HTTP POST messages sent in cleartext. A video of the pen-test can be found online.<sup>11</sup>

These vulnerabilities were disclosed to the hospital’s IT staff and to their PACS software provider. Though inquiry, we found that it is not common practice for hospitals to encrypt their internal PACs traffic [52]. One reason is compatibility: hospitals often have old components (scanners, portals, databases, ...) which do not support encryption. Another reason is some PACS are not directly connected to the Internet, and thus it is erroneously thought that there is no need for encryption.

## 5 The CT-GAN Framework

In this section, we present the technique which an attacker can use to add/remove evidence in CT scans. First, we present the CT-GAN architecture and how to train it. Then, we will describe the entire tampering process and present some sample results. As a case study, we will focus on injecting/removing lung cancer.

It is important to note that there are many types of lung cancer. A common type of cancer forms a round mass of tissue called a solitary pulmonary nodule. Most nodules with a diameter less than 8mm are benign. However, nodules which are larger may indicate a malign cancerous growth. Moreover, if *numerous* nodules having a diameter  $> 8\text{mm}$  are found, then the patient has an increased risk of primary cancer [53]. For this attack, we will focus on injecting and removing multiple solitary pulmonary nodules.

### 5.1 The Neural Architecture

A single slice in a CT scan has a resolution of *at least*  $512 \times 512$  pixels. Each pixel in a slice measures the radiodensity at that location in Hounsfield units (HU). The CT scan of a human’s lungs can have over 157 million voxels<sup>12</sup> ( $512 \times 512 \times 600$ ). In order to train a GAN on an image of this size, we first locate a candidate location (voxel) and then cut out a small region around it (cuboid) for processing. The selected region is slightly larger than needed in order to provide the cGAN with context of the surrounding anatomy. This enables the cGAN to generate/remove lung cancers which connect to the body in a realistic manner.

To accurately capture the concepts of injection and removal, we use a framework consisting of two cGANs: one for injecting cancer ( $GAN_{inj}$ ) and one for removing cancer ( $GAN_{rem}$ ). Both  $GAN_{inj}$  and  $GAN_{rem}$  are deep 3D convolutional cGANs

<sup>9</sup>CVE-2018-8853, CVE-2018-8857, and CVE-2018-8861

<sup>10</sup>CVE-2017-9656

<sup>11</sup>[https://youtu.be/\\_mkRAArj-x0](https://youtu.be/_mkRAArj-x0)

<sup>12</sup>A voxel is the three dimensional equivalent of a pixel.

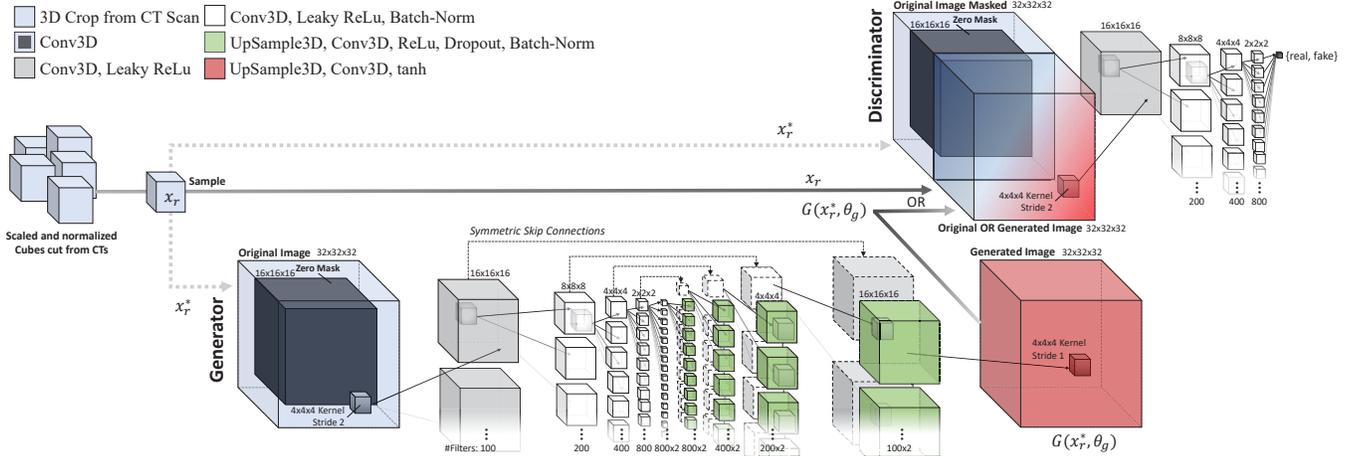

Figure 6: The network architecture, layers, and parameters used for both the injection ( $GAN_{inj}$ ) and removal ( $GAN_{rem}$ ) networks.

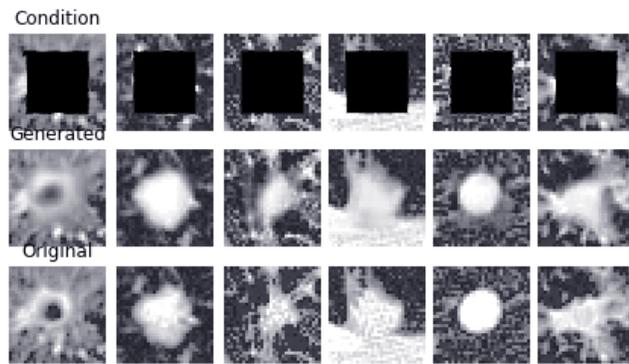

Figure 7: Training samples after 100 epochs showing the middle slice only. Top: the masked sample  $x_r^*$  given to both the generator  $G_{inj}$  and discriminator  $D_{inj}$ . Middle: The in-painted image  $x_g$  produced by the  $G_{inj}$ . Bottom: the ground-truth  $x_r$ . Note,  $D_{inj}$  sees either  $(x_r^*, x_r)$  or  $(x_r^*, x_g)$ .

trained to perform in-painting on samples which are  $32^3$  voxels in dimension. For the completion mask, we zero-out a  $16^3$  cube in the center of the input sample. To inject a large pulmonary nodule into a CT scan, we train  $GAN_{inj}$  on cancer samples which have a diameter of least 10mm. As a result, the trained generator completes sample cuboids with similar sized nodules. To remove cancer,  $GAN_{rem}$  is trained using the same architecture, but with samples containing benign lung nodules only (having a diameter  $< 3$ mm).

The model architecture (layers and configurations) used for both  $GAN_{inj}$  and  $GAN_{rem}$  is illustrated in Fig. 6. Overall,  $\theta_g$  and  $\theta_d$  had 162.6 million and 26.9 million trainable parameters respectively (189.5 million in total).

We note that follow up CT scans are usually ordered when a large nodule is found. This is because nodule growth is a strong indicator of cancer [53]. We found that an attacker is able to simulate this growth by conditioning each cancerous training sample on the nodule’s diameter. However, the objective of this paper is to show how GANS can add/remove evidence realistically. Therefore, for the sake of simplicity,

we have omitted this ‘feature’ from the above model.

## 5.2 Training CT-GAN

To train the GANs, we used a free dataset of 888 CT scans collected in the LIDC-IDRI lung cancer screening trial [54]. The dataset came with annotations from radiologists: the locations and diameters of pulmonary nodules having diameters greater than 3mm. In total there were 1186 nodules listed in the annotations.

To create the training set for  $GAN_{inj}$ , we extracted from the CT scans all nodules with a diameter between 10mm and 16mm (169 in total). To increase the number of training samples, we performed data augmentation: For each of the 169 cuboid samples, we (1) flipped the cuboid on the  $x$ ,  $y$ , and  $xy$  planes, (2) shifted the cuboid by 4 pixels in each direction on the  $xy$  plane, and (3) rotated the cuboid 360 degrees at 6 degree intervals. This produced an additional 66 instances for each sample. The final training set had 11,323 training samples.

To create the training set for  $GAN_{rem}$ , we first selected clean CT scans which had no nodules detected by the radiologists. On these scans, we used the nodule detection algorithm from [55] (also provided in the dataset’s annotations) to find benign micro nodules. Of the detected micro nodules, we selected 867 nodules at random and performed the same data augmentation as above. The final training set had 58,089 samples.

Prior to training the GANs, all of the samples were preprocessed with scaling, equalization, and normalization (described in the next section in detail). Both of the GANs were trained on their respective datasets for 200 epochs with a batch size of 50 samples. Each GAN took 26 hours to complete its training on an NVIDIA GeForce GTX TITAN X using all of the GPU’s memory. Fig. 7 shows how well  $GAN_{inj}$  was able to in-paint cancer patterns after 150 epochs.

## 5.3 Execution: The Tampering Process

In order to inject/remove lung cancer, pre/post-processing steps are required. The following describes the entire

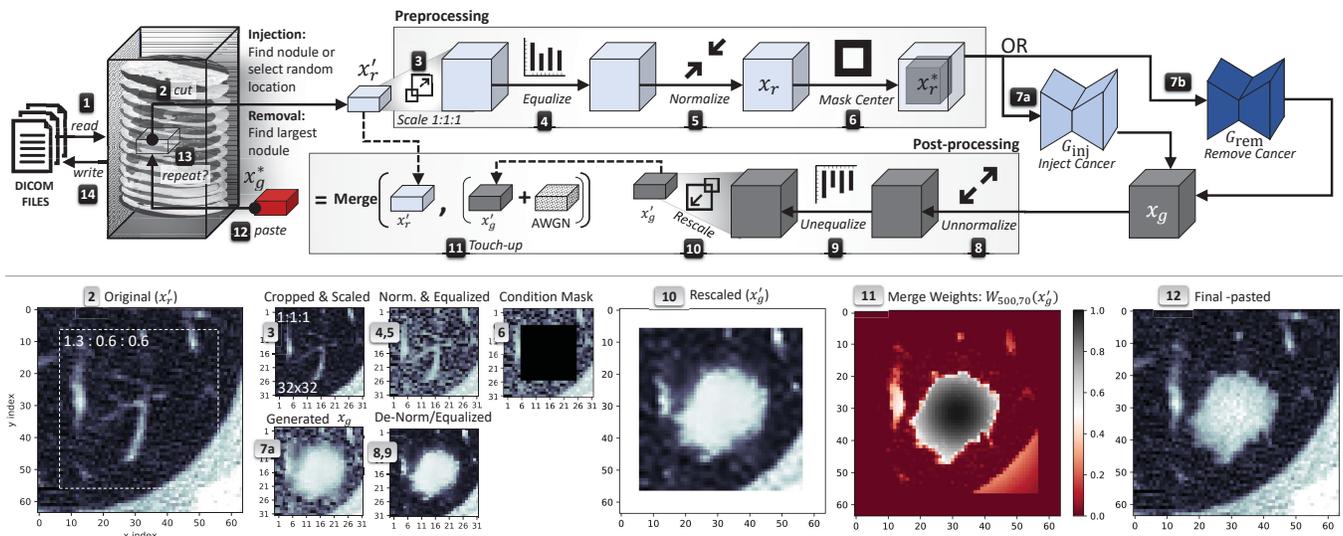

Figure 8: Top: the complete cancer injection/removal process. Bottom: sample images from the *injection* process. The grey numbers indicate from which step the image was taken. The sample 2D images are the middle slice of the respective 3D cuboid.

injection/removal process as illustrated in Fig. 8:

- 1. Capture Data.** The CT scan is captured (as data-at-rest or data-in-motion) in either raw or DICOM format using one of the attack vectors from section 4.
- 2. Localize & Cut.** A candidate location is selected where cancer will be injected/removed, and then the cuboid  $x'_r$  is cut out around it.

**Injection:** An injection location can be selected in one of two ways. The fastest way is to take one of the middle slices of the CT scan and select a random location near the middle of the left or right half (see Fig. 16 in the appendix). With 888 CT scans, this strategy gave us a 99.1% successes rate. A more precise way is to execute an existing nodule detection algorithm to find a random micro nodule. To improve speed, the algorithm can be given only a few slices and implemented with early stopping. In our evaluation, we used the algorithm in [55], though many other options are available.

**Removal:** A removal location can be found by selecting the largest nodule with [55], or by using a pre-trained deep learning cancer detection model.<sup>13</sup>

- 3. Scale.**  $x'_r$  is scaled to the original 1:1:1 ratio using 3D spline interpolation.<sup>14</sup> The ratio information is available in the DICOM meta data with the tags (0x0028,0x0030) and (0x0018,0x0050). Scaling is necessary because each scan is stored with a different aspect ratio, and a GAN needs consistent units to produce accurate results. To minimize the computations, the cuboid cut in step 2 is cut with the exact dimensions so that the result of the rescaling process produces a  $32^3$  cube.

<sup>13</sup>Pre-trained models are available here:

<https://concepttoclinic.drivendata.org/algorithms>

<sup>14</sup>In Python: `scipy.ndimage.interpolation.zoom`

- 4-5. Equalize & Normalize.** Histogram equalization is applied to the cube to increase contrast. This is a critical step since it enables the GAN to learn subtle features in the anatomy. Normalization is then applied using the formula  $X_n = 2 \frac{X - \min(X)}{\max(X) - \min(X)} - 1$ . This normalization ensures that all values fall on the range of  $[-1, 1]$  which helps the GAN learn the features better. The output of this process is the cube  $x_r$ .
- 6. Mask.** In the center of  $x_r$ , a  $16^3$  cube is masked with zeros to form  $x_r^*$ . The masked area will be in-painted (completed) by the *generator*, and the unmasked area is the context.
- 7. Inject/Remove.**  $x_r^*$  is passed through the chosen *discriminator* ( $G_{inj}$  or  $G_{rem}$ ) creating a new sample ( $x_g$ ) with new 3D generated content.
- 8-10. Reverse Preprocessing.**  $x_g$  is unnormalized, unequalized, and then rescaled with spline interpolation back to its original proportions, forming  $x'_g$ .
- 11. Touch-up.** The result of the interpolation usually blurs the imagery. In order to hide this artifact from the radiologists, we added Gaussian noise to the sample: we set  $\mu = 0$  and  $\sigma$  to the sampled standard deviation of  $x'_r$ . To get a clean sample of the noise, we only measured voxels with values less than  $-600$  HU. Moreover, to copy the relevant content into the scan, we merged the original cuboid ( $x'_r$ ) with the generated one ( $x'_g$ ) using a sigmoid weighted average.

Let  $W$  be the weight function defined as

$$W_{\alpha,\beta}(x) = \frac{1}{1 + e^{-(x+\alpha)/\beta}} * G(x) \quad (1)$$

where parameter  $\alpha$  is the HU threshold between wanted and unwanted tissue densities, and parameter  $\beta$  controls the smoothness of the cut edges. The function  $G(x)$  returns a 0-1 normalized Gaussian kernel with the dimensions of

$x$ .  $G(x)$  is used to decay the contribution of each voxel the further it is the cuboid's center.

With  $W$ , we define the merging function as

$$\text{merge}_{\alpha,\beta}(x,y) = W_{\alpha,\beta}(x) * x + (1 - W_{\alpha,\beta}(x)) * y \quad (2)$$

where  $x$  is source ( $x'_g$ ) and  $y$  is the destination ( $x'_r$ ). We found that setting  $\alpha = 500$  and  $\beta = 70$  worked best. By applying these touch-ups, the final cuboid  $x_g^*$  is produced.

12. **Paste.** The cuboid  $x_g^*$  is pasted back into the CT scan at the selected location. See Fig. 16 in the appendix for one slice of a complete scan.
13. **Repeat.** If the attacker is removing cancer, then return to step 2 until no more nodules with a diameter  $> 3\text{mm}$  are found. If the attacker is injecting cancer, then (optionally) return to step 2 until four injections have been performed. The reason for this is because the risk of a patient being diagnosed with cancer is statistically greater in the presence of exactly four solitary pulmonary nodules having a diameter  $> 8\text{mm}$  [53].
14. **Return Data.** The scan is converted back into the original format (e.g. DICOM) and returned back to the source.

The quality of the injection/removal process can be viewed in figures 9 and 10. Fig. 9 presents a variety of examples before and after tampering, and Fig. 10 provides a 3D visualization of a cancer being injected and removed. More visual samples can be found in the appendix (figures 19 and 20).

We note that although some steps involve image touch-ups, the entire process is automatic (unlike Photoshop) and thus can be deployed in an autonomous malware or inside a viewing application (real-time tampering). We note that the same neural architecture and tampering process works on other modalities and medical conditions. For example, Fig. 18 in the appendix shows CT-GAN successfully injecting brain tumors into MRI head scans.

## 6 Evaluation

In this section we present our evaluation on how well the CT-GAN attack can fool expert radiologists and state-of-the-art AI.

### 6.1 Experiment Setup

To evaluate the attack, we recruited three radiologists (denoted **R1**, **R2**, and **R3**) with 2, 5, and 7 years of experience respectively. We also used a trained lung cancer screening model (denoted **AI**), the same deep learning model which won the 2017 Kaggle Data Science Bowl (a \$1 million competition for diagnosing lung cancer).<sup>15</sup>

The experiment was performed in two trials: blind and open. In the blind trial, the radiologists were asked to diagnose 80 complete CT scans of lungs, but they were not told the purpose of the experiment or that some of the scans were manipulated.

<sup>15</sup>Source code and model available here: <https://github.com/lfz/DSB2017>

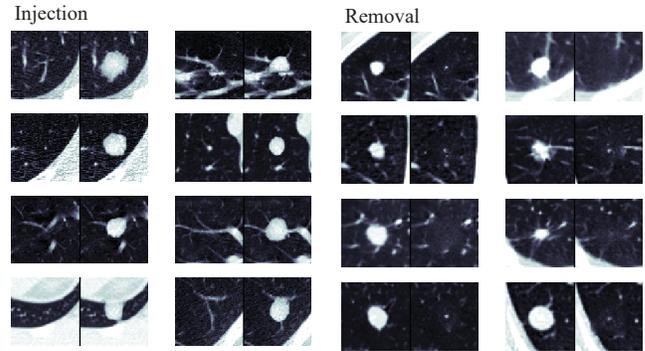

Figure 9: Sample injections (left) and removals (right). For each image, the left side is before tampering and the right side is after. Note that only the middle 2D slice is shown.

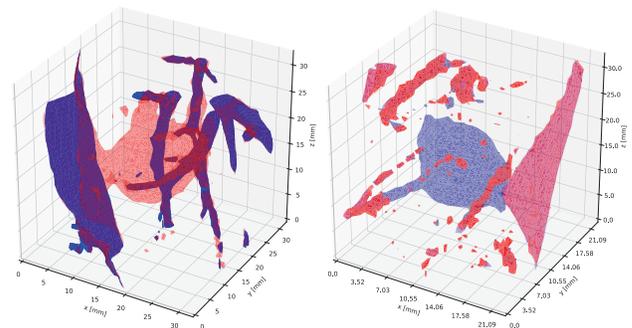

Figure 10: A 3D sample of injection (left) and removal (right) before (blue) and after (red) tampering with the CT scan.

Table 2: Summary of the scans and the relevant notations

	# Scans				# Slices	# Nodules		
	TB	TM	FB	FM		TM	FB	FM
Blind Trial	10	10	30	30	17,941	23	61	34
Open Trial	5	5	5	5	5,296	12	11	7

True-Benign (TB): an original instance with no cancer

True-Malign (TM): an original instance with cancer

False-Benign (FB): a tampered instance with cancer removed

False-Malign (FM): a tampered instance with cancer injected

In the open trial, the radiologists were told about the attack, and were asked to identify fake, real, and removed nodules in 20 CT scans. In addition, the radiologists were asked to rate the confidence of their decisions. After each trial, we gave the radiologists a questionnaire to assess how susceptible they were to the attacks. In all cases, the radiologists were asked to only detect and diagnose pulmonary nodules which have a diameter greater than 3mm.

The CT scans were taken from the LIDC-IDRI dataset [54]. The set of CT scans used in each trial and the notations used in this section are available in Table 2.

False benign (FB) and true malign (TM) scans truthfully contained at least one nodule with a diameter between 10mm and 16mm. FB scans were made by removing every nodule in the scan. FM scans were made by randomly injecting 1-4

Real Cancer: TM	2	6	3	6	2	4

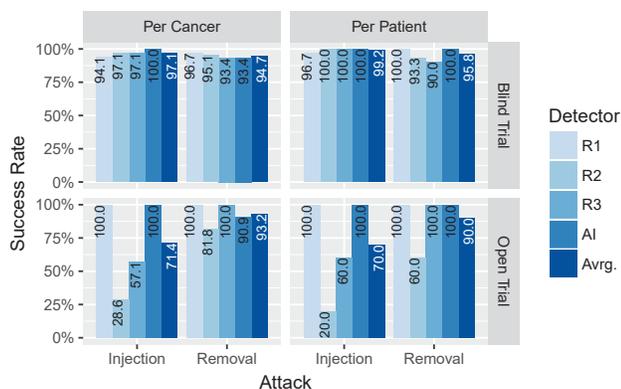

Figure 11: Attack success rates - Both Trials.

nodules into a benign scan, where the injected nodules had a diameter of 14.4mm on average. In total, there were 100 CT scans analyzed by each of the radiologists, and the radiologists spent approximately 10 minutes analyzing each of these scans.

We note that the use of three radiologists is common practice in medical research (e.g., [56]). Moreover, we found that radiologists (and AI) significantly agreed with each other's diagnosis per patient and per nodule. We verified this agreement by computing Fleiss' kappa [57] (a statistical interrater reliability measure) which produced an excellent kappa of 0.84 (p-value < 0.0001). Therefore, adding more radiologists will likely not affect the results.

## 6.2 Results: Blind Trial

In Table 3 we present the cancer detection performance of the radiologists and AI. The table lists the number of false-positives (FP - detected a non-existent cancer), true-positives

Figure 12: Malignancy of injected cancers (FM) - Blind Trial.

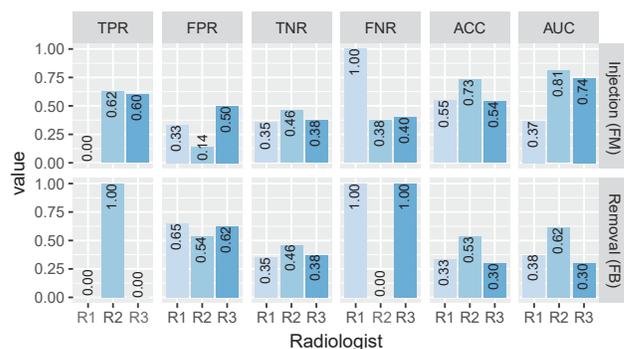

Figure 13: Attack detection performance - Open Trial.

(TP - detected a real cancer), false-negatives (FN - missed a real cancer), and their respective rates. The TCIA annotations (nodule locations) were used as our ground truth for measuring the performance on FB and TM scans. We evaluated these metrics per instance of cancer, and per patient as a whole. All four detectors performed well on the baseline (TB and TM) having an average TPR of 0.975 and a TNR of 1.0 in diagnosing the patients, meaning that we can rely on their diagnosis.

The top of Fig. 11 summarizes the attack success rates for the blind trial. In general, the attack had an average success rate of 99.2% for cancer injection and 95.8% for cancer removal. The AI was fooled completely which is an important aspect since some radiologists use AI tools to support their analysis (e.g. the Philips IntelliSite Pathology Solution). The radiologists were fooled less so, primarily due to human error (e.g., missing a nodule). When asked, none of the radiologists reported anything abnormal with the scans with the exception

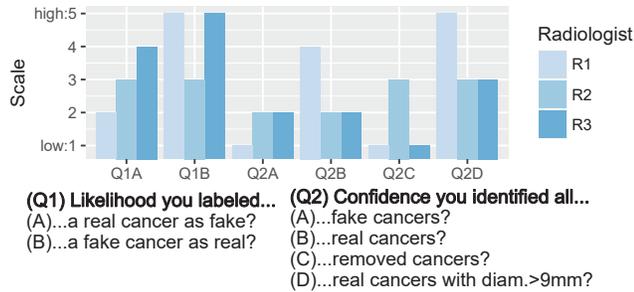

Figure 14: Confidence in detecting attacks - Open Trial.

of R2 who noted some noise in the area of one removal (FB). This may be attributed to “inattentive blindness,” where one may miss an obvious event (artifacts) while engaged in a different task (searching for large nodules). In [58], the authors showed that this phenomenon also affects radiologists.

With regards to the injected cancers (FM), the consensus among the radiologists was that one-third of the injections require an immediate surgery/biopsy, and that all of the injections require follow-up treatments/referrals. When asked to rate the overall malignancy of the FM patients, the radiologists said that nearly all cases were significantly malignant and pose a risk to the patient if left untreated. Fig. 12 summarizes radiologists’ ratings of the FM patients. One interesting observation is that the malignancy rating increased with the experience of the radiologist. Finally, we note that an attacker could increase the overall malignancy of the injections if CT-GAN were trained only on samples with high malignancy and/or a larger diameter.

### 6.3 Results: Open Trial

In Table 4 we present the radiologists’ attack detection performance with knowledge of the attack. Fig. 13 summarizes these results and provides the radiologists’ accuracy (ACC) and area under the curve (AUC). An AUC of 1.0 indicates a perfect binary classifier, whereas an AUC of 0.5 indicates random guessing. The results show that the radiologists could not consistently tell the difference between real and fake cancers or identify the locations of removed cancers.

With regards to the attack success rates (bottom of Fig. 11), knowledge of the attack did not significantly affect cancer removal (90% from 95.8%). However, the success of the cancer injection was affected (70% from 99.2%). Moreover, R2 also picked up on a particular pattern which gave away several instances. This is a promising result, since it indicates that a portion of CT-GAN’s attacks can be mitigated by educating radiologists. However, aside from low accuracy (61% for detecting an injection and 39% for detecting a removal), there was a significant number of false positives. With a high likelihood of making a mistake, a radiologist may choose not to report abnormalities. This is also apparent from the low confidence scores which the radiologists gave decisions (see Fig. 14).

In summary, both radiologists and AI are highly susceptible to CT-GAN’s image tampering attacks. Although knowledge of the attack can help mitigate some cases of cancer injection,

the error rates and confidence scores suggest that the attack may not be reported in most cases.

### 6.4 Baseline Analysis

As mentioned earlier, the attacker cannot use Photoshop on the images. This may be due to a time restriction: the radiologist may perform the diagnosis immediately after the scan has been taken, or the malware may be in the viewing application and operating in real-time. This may also be due to a connectivity restriction: many PACS do not have a direct connection to the Internet. Therefore, the attacker would need to infect the PACS with a malware that can perform the tampering autonomously.

However, for cancer injection, one may argue that there are simpler *automated* methods than using a GAN. For example, the malware could simply paste a pre-saved cropped image of cancer into a scan at a candidate location (found using steps 1 and 2 in Fig. 8). Therefore, to validate the use of a GAN, we evaluated this splice attack as a baseline comparison.

The experiment was setup as follows. To create our set of ‘pre-saved cancers’ we carefully cut out ten 32x32x32 cubes of real cancerous nodules from [54]. We then removed the irrelevant background tissue by producing transparency (alpha) channels using equation (1).

The evaluation dataset contained 20 scans in total: 10 FM and 10 TM. To create a FM scan, we took a random healthy scan and used steps 1 and 2 of Fig. 8 to select a candidate injection location. We then pasted one of the pre-saved cancers into the scan at that location using the transparency channel. To create the FM scans, we randomly selected 10 sick patients with exactly one nodule each.

To evaluate the baseline attack, we asked radiologist R2 to analyze the 20 scans and determine which of the scans were authentic (TM) and which were tampered (FM)—similar to the open trial. This task took the radiologist approximately two hours to perform.

In summary, R2 correctly labeled all of the tampered scans as fake. The only error was that R2 mislabeled three of the authentic scans as fake. These results indicate that the baseline cancer injection attack cannot trick a radiologist, in comparison to CT-GAN which succeeds nearly every time.

The reason the baseline attack failed to trick R2 is because the process of automatically pasting cancer creates obvious artifacts. This is because the pasted samples ignore the surrounding anatomy and may contain inconsistent noise patterns (textures). Fig. 15 illustrates some examples of these abnormalities such as cut bronchi, inconsistent noise patterns, and unaligned borders. CT-GAN does not produce these artifacts because it uses in-painting which considers the original content and surrounding anatomy.

## 7 Countermeasures

The tampering of DICOM medical files is a well-known concern. In the section we provide a brief overview of solutions for preventing and detecting this attack.

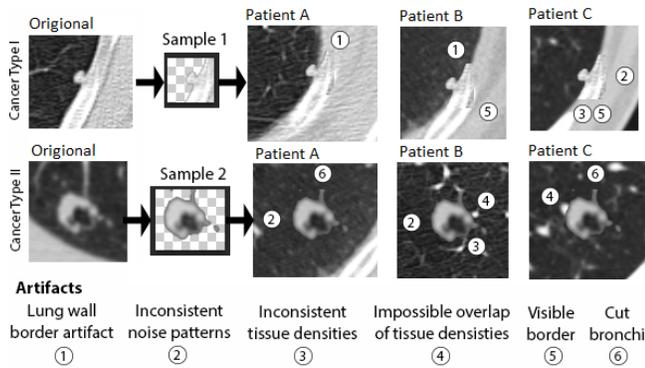

Figure 15: An illustration showing artifacts which can occur when using an *unsupervised* splice attack instead of CT-GAN. Only the middle slice is shown.

## 7.1 Prevention

To mitigate this threat, administrators should secure both the data-in-motion (DiM) and the data-at-rest (DaR). To secure data-in-motion, admins should enable encryption between the hosts in their PACS network using proper SSL certificates. This may seem trivial, but after discovering this flaw in the hospital we pen-tested, we turned to the PACS software provider for comment. The company, with over 2000 installations worldwide, confirmed to us that their hospitals do not enable encryption in their PACS because “it is not common practice”. We were also told that some of the PACS don’t support encryption at all.<sup>16</sup> To secure the DaR, servers and anti-virus software on modality and radiologist workstations should be kept up to date, and admins should also limit the exposure which their PACS server has to the Internet.

## 7.2 Detection

The best way to detect this attack is to have the scanner sign each scan with a digital signature. The DICOM image file standard already allows users to store signatures within the file’s data structure [59, 60]. However, although some PACS software providers offer this feature, we have not seen it in use within a PACS. If enabled, admins should check that valid certificates are being used and that the radiologists’ viewing applications are indeed verifying the signatures.

Another method for detecting this attack is digital watermarking (DW). A DW is a hidden signal embedded into an image such that tampering corrupts the signal and thus indicates a loss of integrity. For medical images, this subject has been researched in depth [20] and can provide a means for localizing changes in a tampered image. However, we did not find any medical devices or products which implement DW techniques. This may be due to the fact that they add noise to images which may harm the medical analysis.

Tampered images can also be detected with machine learning. In the supervised setting (where models are trained on examples of tampered images) the authors in [61] propose

<sup>16</sup>See [52] for further comments.

detection by (1) extracting a scan’s noise pattern using a Wiener filter, then (2) applying a multi-resolution regression filter on the noise, and then (3) executing an SVM and ELM together via a Bayesian Sum Rule model. Many domain specific methods exist for detecting images tampered by GANs (e.g., images/videos of faces [62–64]). However, the supervised approach in [65] is more suitable for detecting our attack since it is domain generic.

Several approaches have been proposed for unsupervised setting as well. These approaches attempt to detect anomalies (inconsistencies) within the tampered images. To detect these inconsistencies, researchers have considered JPEG blocks, signal processing, and compression/resampling artifacts [66]. For example, in a recent work the authors trained a Siamese network to predict the probability that a pair of patches from two images have the same EXIF metadata (e.g., focal length and shutter speed) [67]. In [67], the model is trained using a dataset of real images only. In [68], the authors proposed ‘noiseprint’ which uses a Siamese network to extract the camera’s unique noise pattern from an image (PRNU) to find inconsistent areas. In their evaluation, the authors show that they can detect GAN-based inpainting. In [69], the authors proposed three strategies for using PRNU-based tampering localization techniques with multi-scale analysis. Using this method, the authors were able to detect forgeries of all shapes and sizes.

While these countermeasures may apply to CT-GAN in some cases, they do admit some caveats; namely, that (1) medical scans are usually not compressed so compression methods are irrelevant, (2) these methods were tested on 2D images and not 3D volumetric imagery, and (3) CT/MR imaging systems produce very different noise patterns than standard cameras. For example, we found that the PRNU method in [69] does not work out-of-the-box on our tampered CT scans. This is because the noise patterns of CT images are altered by a radon transform used to construct the image. As future work, we plan to research how these techniques can be applied to detecting attacks such as CT-GAN.

## 8 Conclusion

In this paper we introduced the possibility of an attacker modifying 3D medical imagery using deep learning. We explained the motivations for this attack, discussed the attack vectors (demonstrating one of them), and presented a manipulation framework (CT-GAN) which can be executed by a malware autonomously. As a case study, we demonstrated how an attacker can use this approach to inject or remove lung cancer from full resolution 3D CT scans using free medical imagery from the Internet. We also evaluated the attack and found that CT-GAN can fool both humans and machines: radiologists and state-of-the-art AI. This paper also demonstrates how we should be wary of closed world assumptions: both human experts and advanced AI can be fooled if they fully trust their observations.

## Appendix

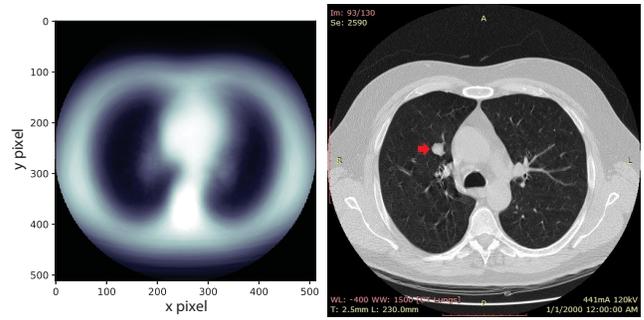

Figure 16: Left: the average of 888 CT scans’ middle slices before scaling to 1:1:1 ratio (black areas are candidate injection locations). Right: a full slice with an injected nodule.

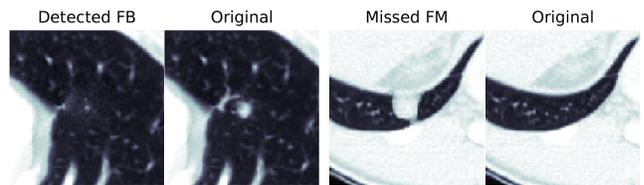

Figure 17: Examples of where the attack failed in the blind trial. Left: a removal (FB) detected as ‘ground-glass’ cancer due to too much additive noise. Right: an injection missed due to human error.

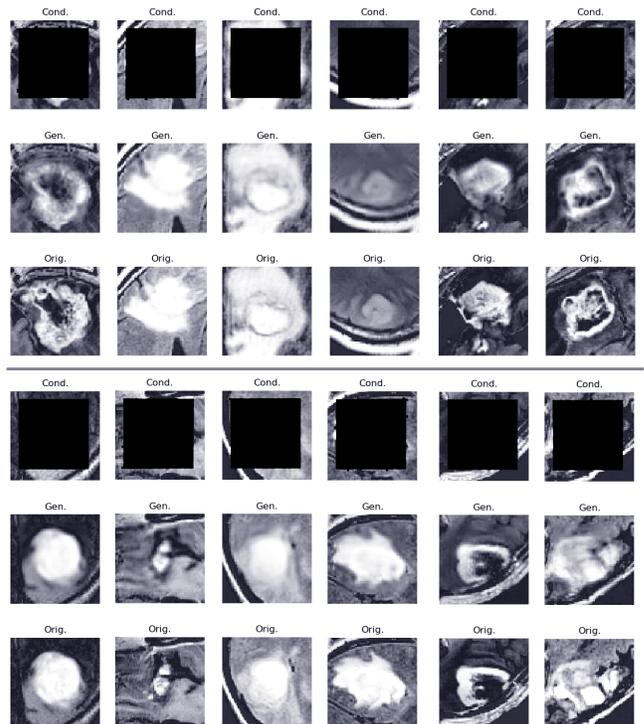

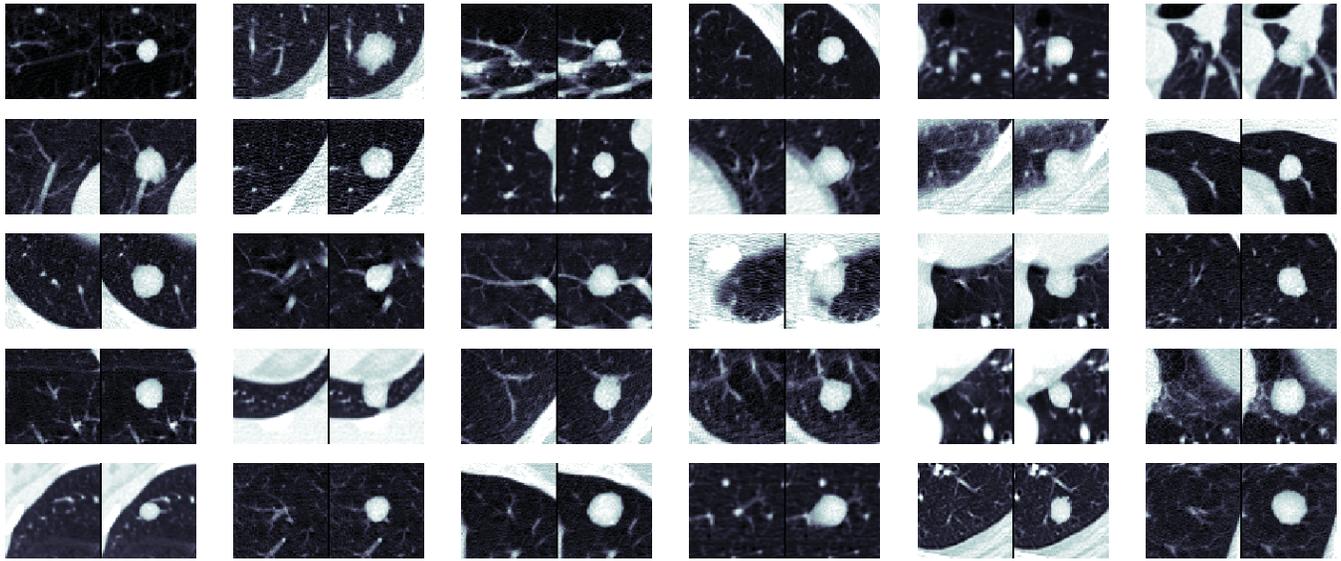

Figure 18: CT-GAN used to inject brain tumors into MRIs of healthy brains. Similar to Fig. 7, Top: context, middle: in-painted result, and bottom: ground-truth. Showing one slice in a 64x64x16 cuboid.

## Injection

## Removal

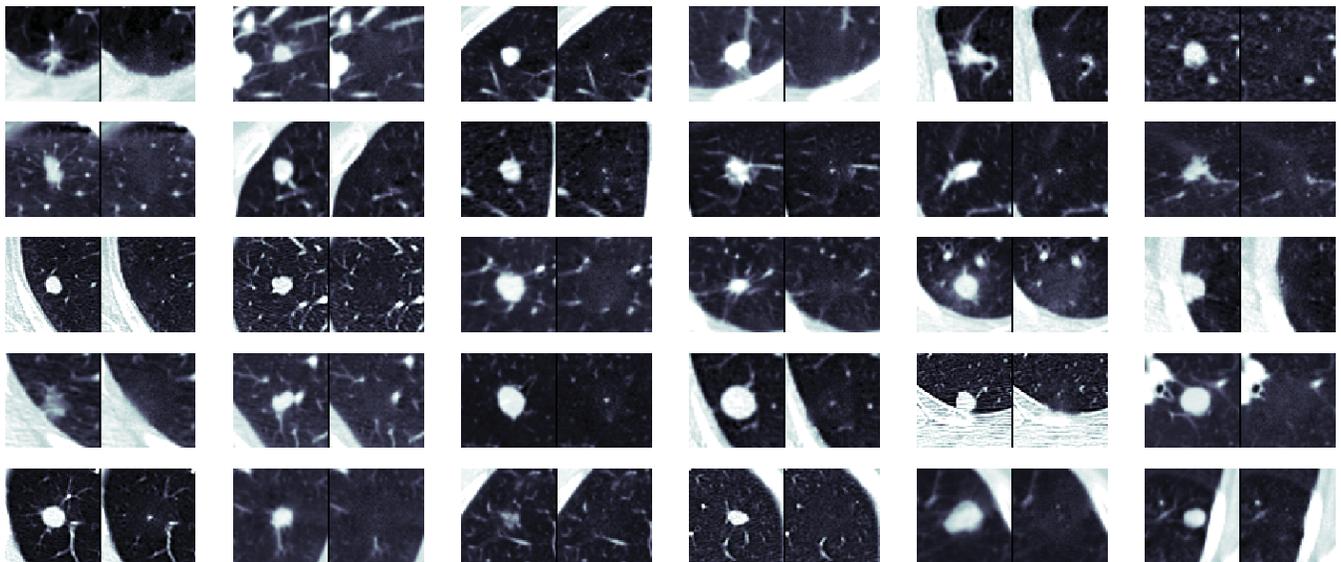

Figure 19: Samples of injected (top) and removed (bottom) pulmonary nodules. For each image, the left side is before tampering and the right side is after. Note, only the middle 2D slice is shown and the images are scaled to different ratios (the source scan).

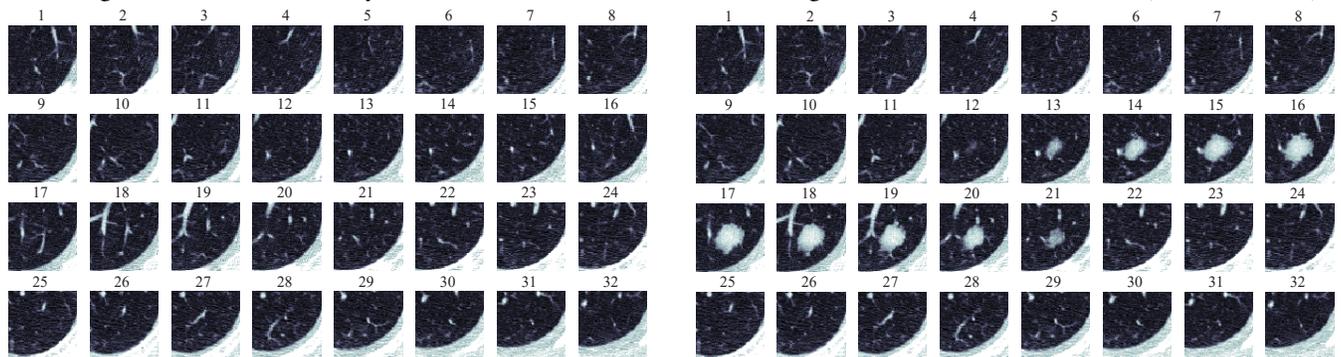

Figure 20: All 32 slices from a sample injection before (left) and after (right) tampering with the CT scan.

# Misleading Authorship Attribution of Source Code using Adversarial Learning

Erwin Quiring, Alwin Maier and Konrad Rieck

Technische Universität Braunschweig, Germany

## Abstract

In this paper, we present a novel attack against authorship attribution of source code. We exploit that recent attribution methods rest on machine learning and thus can be deceived by adversarial examples of source code. Our attack performs a series of semantics-preserving code transformations that mislead learning-based attribution but appear plausible to a developer. The attack is guided by Monte-Carlo tree search that enables us to operate in the discrete domain of source code. In an empirical evaluation with source code from 204 programmers, we demonstrate that our attack has a substantial effect on two recent attribution methods, whose accuracy drops from over 88% to 1% under attack. Furthermore, we show that our attack can imitate the coding style of developers with high accuracy and thereby induce false attributions. We conclude that current approaches for authorship attribution are inappropriate for practical application and there is a need for resilient analysis techniques.

## 1 Introduction

The source code of a program often contains peculiarities that reflect individual coding style and can be used for identifying the programmer. These peculiarities—or *stylistic patterns*—range from simple artifacts in comments and code layout to subtle habits in the use of syntax and control flow. A programmer might, for example, favor while-loops even though the use of for-loops would be more appropriate. The task of identifying a programmer based on these stylistic patterns is denoted as *authorship attribution*, and several methods have been proposed to recognize the authors of source code [1, 4, 9, 13] and compiled programs [3, 10, 17, 22].

While techniques for authorship attribution have made great progress in the last years, their robustness against attacks has received only little attention so far, and the majority of work has focused on achieving high accuracy. The recent study by Simko et al. [25], however, shows that developers can manually tamper with the attribution of source code and

thus it becomes necessary to reason about attacks that can forge stylistic patterns and mislead attribution methods.

In this paper, we present the first black-box attack against authorship attribution of source code. Our attack exploits that recent attribution methods employ machine learning and thus can be vulnerable to adversarial examples [see 20]. We combine concepts from adversarial learning and compiler engineering, and create adversarial examples in the space of semantically-equivalent programs.

Our attack proceeds by iteratively transforming the source code of a program, such that stylistic patterns are changed while the underlying semantics are preserved. To determine these transformations, we interpret the attack as a game against the attribution method and develop a variant of Monte-Carlo tree search [24] for constructing a sequence of adversarial but plausible transformations. This black-box strategy enables us to construct *untargeted attacks* that thwart a correct attribution as well as *targeted attacks* that imitate the stylistic patterns of a developer.

As an example, Figure 1 shows two transformations performed by our attack on a code snippet from the Google Code Jam competition. The first transformation changes the for-loop to a while-loop, while the second replaces the C++ operator `<<` with the C-style function `printf`. Note that the format string is automatically inferred from the variable type. Both transformations change the stylistic patterns of author A and, in combination, mislead the attribution to author B.

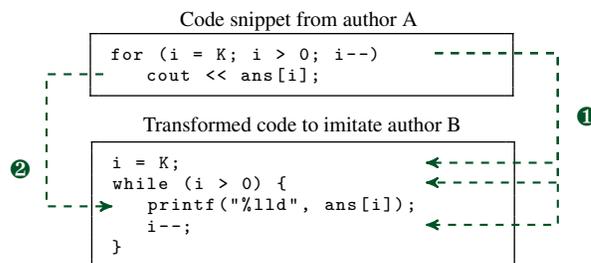

Figure 1: Two iterations of our attack: Transformation ① changes the control statement `for` → `while` and transformation ② manipulates the API usage `ostream` → `printf` to imitate the stylistic patterns of author B.

We conduct a series of experiments to evaluate the efficacy of our attack using the source code of 204 programmers from the Google Code Jam competition. As targets we consider the recent attribution methods by Caliskan et al. [9] and Abuhamad et al. [1], which provide superior performance compared to related approaches. In our first experiment, we demonstrate that our attack considerably affects both attribution methods [1, 9], whose accuracy drops from over 88% to 1% under attack, indicating that authorship attribution can be automatically thwarted at large scale. In our second experiment, we investigate the effect of targeted attacks. We show that in a group of programmers, each individual can be impersonated by 77% to 81% of the other developers on average. Finally, we demonstrate in a study with 15 participants that code transformed by our attack is plausible and hard to discriminate from unmodified source code.

Our work has implications on the applicability of authorship attribution in practice: We find that both, untargeted and targeted attacks, are effective, rendering the reliable identification of programmers questionable. Although our approach builds on a fixed set of code transformations, we conclude that features regularly manipulated by compilers, such as specific syntax and control flow, are not reliable for constructing attribution methods. As a consequence, we suggest to move away from these features and seek for more reliable means for identifying authors in source code.

**Contributions.** In summary, we make the following major contributions in this paper:

- *Adversarial learning on source code.* We present the first automatic attack against authorship attribution of source code. We consider targeted as well as untargeted attacks of the attribution method.
- *Monte-Carlo tree search.* We introduce Monte-Carlo tree search as a novel approach to guide the creation of adversarial examples, such that feasibility constraints in the domain of source code are satisfied.
- *Black-box attack strategy.* The devised attack does not require internal knowledge of the attribution method, so that it is applicable to any learning algorithm and suitable for evading a wide range of attribution methods.
- *Large-scale evaluation.* We empirically evaluate our attack on a dataset of 204 programmers and demonstrate that manipulating the attribution of source code is possible in the majority of the considered cases.

The remainder of this paper is organized as follows: We review the basics of program authorship attribution in Section 2. The design of our attack is lay out in Section 3, while Section 4 and 5 discuss technical details on code transformation and adversarial learning, respectively. An empirical evaluation of our attack is presented in Section 6 along with a discussion of limitations in Section 7. Section 8 discusses related work and Section 9 concludes the paper.

## 2 Authorship Attribution of Source Code

Before introducing our attack, we briefly review the design of methods for authorship attribution. To this end, we denote the source code of a program as  $x$  and refer to the set of all possible source codes by  $\mathcal{X}$ . Moreover, we define a finite set of authors  $\mathcal{Y}$ . Authorship attribution is then the task of identifying the author  $y \in \mathcal{Y}$  of a given source code  $x \in \mathcal{X}$  using a classification function  $f$  such that  $f(x) = y$ . In line with the majority of previous work, we assume that the programs in  $\mathcal{X}$  can be attributed to a single author, as the identification of multiple authors is an ongoing research effort [see 12, 17].

Equipped with this basic notation, we proceed to discuss the two main building blocks of current methods for authorship attribution: (a) the extraction of features from source code and (b) the application of machine learning for constructing the classification function.

### 2.1 Feature Extraction

The coding habits of a programmer can manifest in a variety of stylistic patterns. Consequently, methods for authorship attribution need to extract an expressive set of features from source code that serve as basis for inferring these patterns. In the following, we discuss the major types of these features and use the code sample in Figure 2 as a running example throughout the paper.

```
1 int foo(int a){
2     int b;
3     if (a < 2)      // base case
4         return 1;
5     b = foo(a - 1); // recursion
6     return a * b;
7 }
```

Figure 2: Exemplary code sample (see Figure 3, 5, and 6)

**Layout features.** Individual preferences of a programmer often manifest in the layout of the code and thus corresponding features are a simple tool for characterizing coding style. Examples for such features are the indentation, the form of comments and the use of brackets. In Figure 2, for instance, the indentation width is 2, comments are provided in C++ style, and curly braces are opened on the same line.

Layout features are trivial to forge, as they can be easily modified using tools for code formatting, such as GNU indent. Moreover, many integrated development editors automatically normalize source code, such that stylistic patterns in the layout are unified.

**Lexical features.** A more advanced type of features can be derived from the lexical analysis of source code. In this analysis stage, the source code is partitioned into so-called *lexems*, tokens that are matched against the terminal symbols of the language grammar. These lexems give rise to a strong

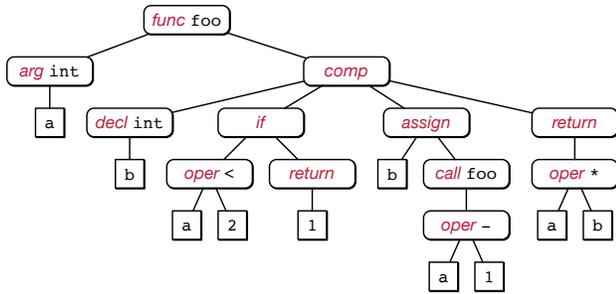

Figure 3: Abstract syntax tree (AST) for code sample in Figure 2.

set of string-based features jointly covering keywords and symbols. For example, in Figure 2, the frequency of the lexem `int` is 3, while it is 2 for the lexem `foo`.

In contrast to code layout, lexical features cannot be easily manipulated, as they implicitly describe the syntax and semantics of the source code. While the lexem `foo` in the running example could be easily replaced by another string, adapting the lexem `int` requires a more involved code transformation that introduces a semantically equivalent data type. We introduce such a transformation in Section 4.

**Syntactic features.** The use of syntax and control flow also reveals individual stylistic patterns of programmers. These patterns are typically accessed using the *abstract syntax tree* (AST), a basic data structure of compiler design [2]. As an example, Figure 3 shows a simplified AST of the code snippet from Figure 2. The AST provides the basis for constructing an extensive set of syntactic features. These features can range from the specific use of syntactic constructs, such as unary and ternary operators, to generic features characterizing the tree structure, such as the frequency of adjacent nodes. In Figure 3, there exist 21 pairs of adjacent nodes including, for example,  $(\text{func } \text{foo}) \rightarrow (\text{arg } \text{int})$  and  $(\text{return}) \rightarrow (1)$ .

Manipulating features derived from an AST is challenging, as even minor tweaks in the tree structure can fundamentally change the program semantics. As a consequence, transformations to the AST need to be carefully designed to preserve the original semantics and to avoid unintentional side effects. For example, removing the node pair  $(\text{decl } \text{int}) \rightarrow (b)$  from the AST in Figure 3 requires either replacing the type or the name of the variable without interfering with the remaining code. In practice, such transformations are often non-trivial and we discuss the details of manipulating the AST in Section 4.

## 2.2 Machine Learning

The three feature types (layout, lexical, syntactic) provide a broad view on the characteristics of source code and are used by many attribution methods as the basis for applying machine-learning techniques [e.g., 1, 4, 9, 21]

**From code to vectors.** Most learning algorithms are designed to operate on vectorial data and hence the first step for application of machine learning is the mapping of code to a vector space using the extracted features. Formally, this mapping can be expressed as  $\phi : \mathcal{X} \rightarrow \mathcal{F} = \mathbb{R}^d$  where  $\mathcal{F}$  is a  $d$  dimensional vector space describing properties of the extracted features. Different techniques can be applied for constructing this map, which may include the computation of specific metrics as well as generic embeddings of features and their relations, such as a TF-IDF weighting [1, 9].

Surprisingly, the feature map  $\phi$  introduces a non-trivial hurdle for the construction of attacks. The map  $\phi$  is usually not bijective, that is, we can map a given source code  $x$  to a feature space but are unable to automatically construct the source code  $x'$  for a given point  $\phi(x')$ . Similarly, it is difficult to predict how a code transformation  $x \mapsto x'$  changes the position in feature space  $\phi(x) \mapsto \phi(x')$ . We refer to this problem as the *problem-feature space dilemma* and discuss its implications in Section 3.

**Multiclass classification.** Using a feature map  $\phi$ , we can apply machine learning for identifying the author of a source code. Typically, this is done by training a *multiclass classifier*  $g : \mathcal{X} \rightarrow \mathbb{R}^{|\mathcal{Y}|}$  that returns scores for all authors  $\mathcal{Y}$ . An attribution is obtained by simply computing

$$f(x) = \arg \max_{y \in \mathcal{Y}} g_y(x).$$

This setting has different advantages: First, one can investigate all top-ranked authors. Second, one can interpret the returned scores for determining the confidence of an attribution. We make use of the latter property for guiding our attack strategy and generating adversarial examples of source code (see Section 5)

Different learning algorithms have been used for constructing the multiclass classifier  $g$ , as for example, support vector machines [21], random forests [9], and recurrent neural networks [1, 4]. Attacking each of these learning algorithms individually is a tedious task and thus we resort to a *black-box attack* for misleading authorship attribution. This attack does not require any knowledge of the employed learning algorithm and operates with the output  $g(x)$  only. Consequently, our approach is agnostic to the learning algorithm as we demonstrate in the evaluation in Section 6.

## 3 Misleading Authorship Attribution

With a basic understanding of authorship attribution, we are ready to investigate the robustness of attribution methods and to develop a corresponding black-box attack. To this end, we first define our threat model and attack scenario before discussing technical details in the following sections.

### 3.1 Threat Model

For our attack, we assume an adversary who has black-box access to an attribution method. That is, she can send an arbitrary source code  $x$  to the method and retrieve the corresponding prediction  $f(x)$  along with prediction scores  $g(x)$ . The training data, the extracted features, and the employed learning algorithm, however, are unknown to the adversary, and hence the attack can only be guided by iteratively probing the attribution method and analyzing the returned prediction scores. This setting resembles a classic *black-box attack* as studied by Tramèr et al. [26] and Papernot et al. [19]. As part of our threat model, we consider two types of attacks—*untargeted* and *targeted attacks*—that require different capabilities of the adversary and have distinct implications for the involved programmers.

**Untargeted attacks.** In this setting, the adversary tries to mislead the attribution of source code by changing the classification into *any* other programmer. This attack is also denoted as *dodging* [23] and impacts the correctness of the attribution. As an example, a benign programmer might use this attack strategy for concealing her identity before publishing the source code of a program.

**Targeted attacks.** The adversary tries to change the classification into a chosen *target* programmer. This attack resembles an *impersonation* and is technically more advanced, as we need to transfer the stylistic patterns from one developer to another. A targeted attack has more severe implications: A malware developer, for instance, could systematically change her source code to blame a benign developer.

Furthermore, we consider two scenarios for targeted attacks: In the first scenario, the adversary has no access to source code from the target programmer and thus certain features, such as variable names and custom types, can only be guessed. In the second scenario, we assume that the adversary has access to two files of source code from the target developer. Both files are not part of the training- or test set and act as external source for extracting template information, such as recurring custom variable names.

In addition, we test a scenario where the targeted attack solely rests on a separate training set, without access to the output of the original classifier. This might be the case, for instance, if the attribution method is secretly deployed, but code samples are available from public code repositories. In this scenario, the adversary can learn a substitute model with the aim that her adversarial example—calculated on the substitute—also transfers to the original classifier.

### 3.2 Attack Constraints

Misleading the attribution of an author can be achieved with different levels of sophistication. For example, an adversary

may simply copy code snippets from one developer for impersonation or heavily obfuscate source code for dodging. These trivial attacks, however, generate implausible code and are easy to detect. As a consequence, we define a set of constraints for our attack that should make it hard to identify manipulated source code.

**Preserved semantics.** We require that source code generated by our attack is semantically equivalent to the original code. That is, the two codes produce identical outputs given the same input. As it is undecidable whether two programs are semantically equivalent, we take care of this constraint during the design of our code transformations and ensure that each transformation is as semantics-preserving as possible.

**Plausible code.** We require that all transformations change the source code, such that the result is syntactically correct, readable and plausible. The latter constraint corresponds to the aspect of imperceptibility when adversarial examples are generated in the image domain [11]. In our context, plausibility is important whenever the adversary wants to hide the modification of a source file, for instance, when blaming another developer. For this reason, we do not include junk code or unusual syntax that normal developers would not use.

**No layout changes.** Layout features such as the tendency to start lines with spaces or tabs are trivial to change with tools for code formatting (see Section 6.4). Therefore, we restrict our attack to the forgery of lexical and syntactic features of source code. In this way, we examine our approach under a more difficult scenario for the attacker where no layout features are exploitable to mislead the attribution.

### 3.3 Problem-Feature Space Dilemma

The described threat model and attack constraints pose unique challenges to the design of our attack. Our attack jointly operates in two domains: On the one hand, we aim at attacking a classifier in the feature space  $\mathcal{F}$ . On the other hand, we require the source code to be semantically equivalent and plausible in the problem space  $\mathcal{X}$ . For most feature maps  $\phi$ , a one-to-one correspondence, however, does not exist between the two spaces and thus we encounter a dilemma.

**Problem space  $\rightsquigarrow$  feature space.** Each change in the source code  $x$  may impact a set of features in  $\phi(x)$ . The exact amount of change is generally not controllable. The correlation of features and post-processing steps in  $\phi$ , such as a TF-IDF weighting, may alter several features, even if only a single statement is changed in the source code. This renders target-oriented modification of the source code difficult.

For example, if the declaration of the variable `b` in line 2 of Figure 2 is moved to line 5, a series of lexical and syntactic features change, such as the frequency of the lexem `b` or the subtree under the node `assign` in Figure 3.

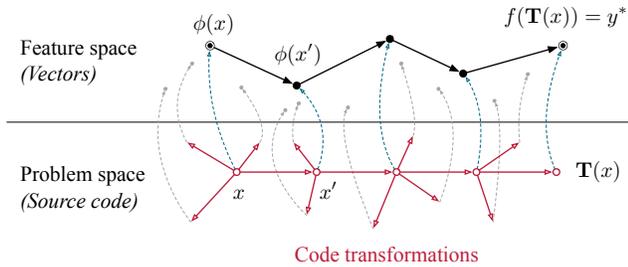

Figure 4: Schematic depiction of our approach. The attack is realized by moving in the problem space using code transformations while being guided by Monte-Carlo tree search in the feature space.

**Feature space  $\rightsquigarrow$  problem space.** Any change to a feature vector  $\phi(x)$  must ensure that there exists a plausible source code  $x$  in the problem space. Unfortunately, determining  $x$  from  $\phi(x)$  is not tractable for non-bijective feature maps, and it is impossible to directly apply techniques from adversarial learning that operate in the feature space.

For example, if we calculate the difference of two vectors  $\phi(z) = \phi(x) - \phi(x')$ , we have no means for determining the resulting source code  $z$ . Even worse, it might be impossible to construct  $z$ , as the features in  $\phi(z)$  can violate the underlying programming language specification, for example, due to feature combinations inducing impossible AST edges.

This dilemma has received little attention in the literature on adversarial learning so far, and it is often assumed that an adversary can change features almost arbitrarily [e.g. 6, 11, 18]. Consequently, our attack does not only pinpoint weaknesses in authorship attribution but also illustrates how adversarial learning can be conducted when the problem and feature space are disconnected.

### 3.4 Our Attack Strategy

To tackle this challenge, we adopt a mixed attack strategy that combines concepts from compiler engineering and adversarial learning. For the problem space, we develop code transformations (source-to-source compilations) that enable us to maneuver in the problem space and alter stylistic patterns without changing the semantics. For the feature space, we devise a variant of Monte-Carlo tree search that guides the transformations towards a target. This variant considers the attack as a game against the attribution method and aims at reaching a desired output with few transformations.

An overview of our attack strategy is illustrated in Figure 4. As the building blocks of our approach originate from different areas of computer science, we discuss their technical details in separate sections. First, we introduce the concept of semantics-preserving code transformations and present five families of source-to-source transformations (Section 4). Then, we introduce Monte-Carlo tree search as a generic black-box attack for chaining transformations together such that a target in the feature space is reached (Section 5).

## 4 Code Transformations

The automatic modification of code is a well-studied problem in compiler engineering and source-to-source compilation [2]. Consequently, we build our code transformations on top of the compiler frontend *Clang* [28], which provides all necessary primitives for parsing, transforming and synthesizing C/C++ source code. Note that we do *not* use code obfuscation methods, since their changes are (a) clearly visible, and (b) cannot mislead a classifier to a targeted author. Before presenting five families of transformations, we formally define the task of *code transformation* and introduce additional program representations.

**Definition 1.** A code transformation  $T : \mathcal{X} \rightarrow \mathcal{X}$ ,  $x \mapsto x'$  takes a source code  $x$  and generates a transformed version  $x'$ , such that  $x$  and  $x'$  are semantically equivalent.

While code transformations can serve various purposes in general [2], we focus on *targeted* transformations that modify only minimal aspects of source code. If multiple source locations are applicable for a transformation, we use a pseudo-random seed to select one location. To chain together targeted transformations, we define *transformation sequences* as follows:

**Definition 2.** A transformation sequence  $\mathbf{T} = T_1 \circ T_2 \circ \dots \circ T_n$  is the subsequent application of multiple code transformations to a source code  $x$ .

To efficiently perform transformations, we make use of different program representations, where the AST is the most important one. To ease the realization of involved transformations, however, we employ two additional program representations that augment our view on the source code.

**Control-flow graph with use-define chains.** The control flow of a program is typically represented by a *control-flow graph* (CFG) where nodes represent statements and edges the flow of control. Using the CFG, it is convenient to analyze the execution order of statements. We further extend the CFG provided by Clang with *use-define chains* (UDCs). These chains unveil dependencies between usages and the definitions of a variable. With the aid of UDCs, we can trace the flow of data through the program and identify data dependencies between local variables and function arguments. Figure 5 shows a CFG with use-define chains.

**Declaration-reference mapping.** We additionally introduce a declaration-reference mapping (DRM) that extends the AST and links each declaration to all usages of the declared variable. As an example, Figure 6 shows a part of the AST together with the respective DRM for the code sample from Figure 2. This code representation enables navigation between declarations and variables, which allows us to efficiently rename variables or check for the sound transformation of data types. Note the difference between use-define

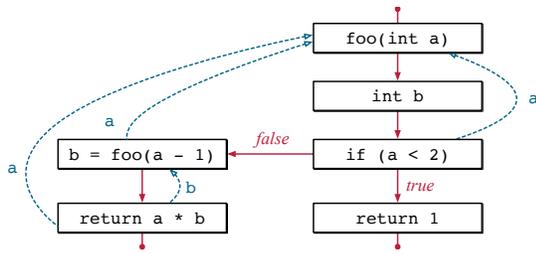

Figure 5: Control-flow graph with use-define chains for the code snippet from Figure 2. The control flow is shown in red (solid), use-define chains in blue (dashed).

Table 1: Implemented families of transformations.

Transformation family	#	AST	CFG	UDC	DRM
Control transformations	5	•	•	•	
Declaration transformations	14	•			•
API transformations	9	•	•		•
Template transformations	4	•			•
Miscellaneous transformations	4	•			

chains and declaration-reference mappings. The former connects variable usages to variable definitions, while the latter links variable usages to variable declarations.

Based on these program representations, we develop a set of generic code transformations that are suitable for changing different stylistic patterns. In particular, we implement 36 transformers that are organized into five families. Table 1 provides an overview of each family together with the program representation used by the contained transformers.

In the following, we briefly introduce each of the five families. For a detailed listing of all 36 transformations, we refer the reader to Table 8 in Appendix C.

**Control transformations.** The first family of source-to-source transformations rewrites control-flow statements or modifies the control flow between functions. In total, the family contains 5 transformations. For example, the control-flow statements `while` and `for` can be mutually interchanged by two transformers. These transformations address a developer’s preference to use a particular iteration type. As another example, Figure 7 shows the automatic creation of a function. The transformer moves the inner block of the `for`-statement to a newly created function. This transformation involves passing variables as function arguments, updating their values and changing the control flow of the caller and callee.

**Declaration transformations.** This family consists of 14 transformers that modify, add or remove declarations in source code. For example, in a widening conversion, the type of a variable is changed to a larger type, for example, `int` to `long`. This rewriting mimics a programmer’s preference for particular data types. Declaration transformations make it necessary to update all usages of variables which

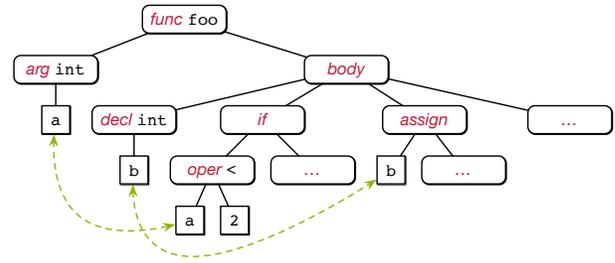

Figure 6: Abstract syntax tree with declaration-reference mapping for the code snippet from Figure 2. Declaration references are shown in green (dashed).

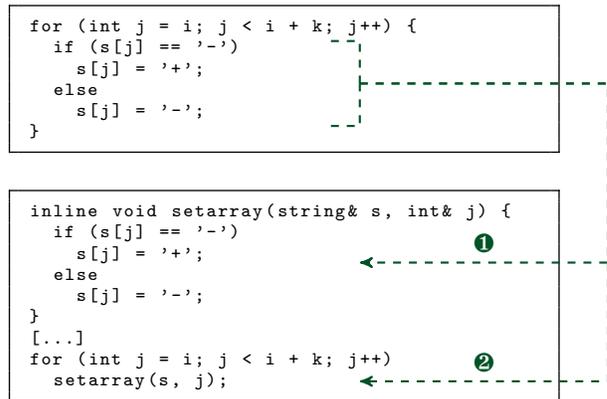

Figure 7: Example of a control transformation. 1 moves the compound statement into an own function and passes all variables defined outside the block as parameters. 2 calls the new function at the previous location.

can be elegantly carried out using the DRM representation. Replacing an entire data type is a more challenging transformation, as we need to adapt all usages to the type, including variables, functions and return values. Figure 8 shows the replacement of the C++ `string` object with a conventional `char` array, where the declaration and also API functions, such as `size`, are modified. Note that in our current implementation of the transformer the `char` array has a fixed size and thus is not strictly equivalent to the C++ `string` object.

**API transformations.** The third family contains 9 transformations and exploits the fact that various APIs can be used

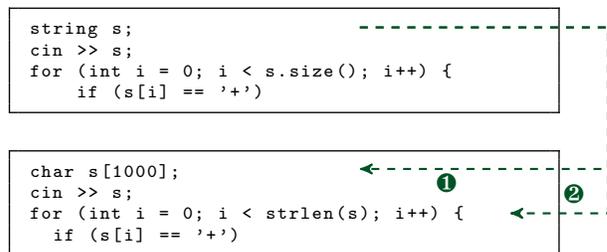

Figure 8: Example of a declaration transformation. 1 replaces the declaration of the C++ `string` object with a `char` array, 2 adapts all uses of the object.

```

cout << fixed << setprecision(10);
[...]
for (long long t = 0;
     t < (long long)(T); t++) {
  [...]
  cout << "Case #" << t + 1 << ": "
       << d / l << '\n';
}

for (long long t = 0;
     t < (long long)(T); t++) {
  [...]
  printf("Case #%lld: %.10f\n",
        t + 1, d / l);
}

```

Figure 9: Example of an API transformation. ❶ determines the current precision for output; ❷ replaces the C++ API with a C-style printf. The format specifier respects the precision and the data type of the variable.

to solve the same problem. Programmers are known to favor different APIs and thus tampering with API usage is an effective strategy for changing stylistic patterns. For instance, we can choose between various ways to output information in C++, such as `printf`, `cout`, or `ofstream`.

As an example, Figure 9 depicts the replacement of the object `cout` by a call to `printf`. To this end, the transformer first checks for the decimal precision of floating-point values that `cout` employs, that is, we use the CFG to find the last executed `fixed` and `setprecision` statement. Next, the transformer uses the AST to resolve the final data type of each `cout` entry and creates a respective format string for `printf`.

**Template transformations.** The fourth family contains 4 transformations that insert or change code patterns based on a give template. For example, authors tend to reuse specific variable names, constants, and type definitions. If a template file is given for a target developer, these information are extracted and used for transformations. Otherwise, default values that represent general style patterns are employed. For instance, variable names can be iteratively renamed into default names like `i`, `j`, or `k` until a developer’s tendency to declare control statement variables is lost (dodging attack) or gets matched (impersonation attack).

**Miscellaneous transformations.** The last family covers 4 transformations that conduct generic changes of code statements. For example, the use of curly braces around compound statements is a naive but effective stylistic pattern for identifying programmers. The compound statement transformer thus checks if the body of a control statement can be enclosed by curly braces or the other way round. In this way, we can add or remove a compound statement in the AST.

Another rather simple stylistic pattern is the use of return statements, where some programmers omit these statements in the `main` function and others differ in whether they return a constant, integer or variable. Consequently, we design a transformer that manipulates return statements.

## 5 Monte-Carlo Tree Search

Equipped with different code transformations for changing stylistic patterns, we are ready to determine a sequence of these transformations for untargeted and targeted attacks. We aim at a short sequence, which makes the attack less likely to be detected. Formally, our objective is to find a short transformation sequence  $\mathbf{T}$  that manipulates a source file  $x$ , such that the classifier  $f$  predicts the target label  $y^*$ :

$$f(\mathbf{T}(x)) = y^* . \quad (1)$$

In the case of an untargeted attack,  $y^*$  represents any other developer than the original author  $y^s$ , that is,  $y^* \neq y^s$ . In the case of a targeted attack,  $y^*$  is defined as a particular target author  $y^t$ .

As we are unable to control how a transformation  $T(x)$  moves the feature vector  $\phi(x)$ , several standard techniques for solving the problem in (1) are not applicable, such as gradient-based methods [e.g. 11]. Therefore, we require an algorithm that works over a search space of discrete objects such as the different transformations of the source code. As a single transformation does not necessarily change the score of the classifier, simple approximation techniques like Hill Climbing that only evaluate the neighborhood of a sample fail to provide appropriate solutions.

As a remedy, we construct our attack algorithm around the concept of *Monte-Carlo tree search* (MCTS)—a strong search algorithm that has proven effective in AI gaming with AlphaGo [24]. Similar to a game tree, our variant of MCTS creates a search tree for the attack, where each node represents a state of the source code and the edges correspond to transformations. By moving in this tree, we can evaluate the impact of different transformation sequences before deciding on the next move. Figure 10 depicts the four basic steps of our algorithm: selection, simulation, expansion and backpropagation.

**Selection.** As the number of possible paths in the search tree grows exponentially, we require a *selection policy* to identify the next node for expansion. This policy balances the tree’s exploration and exploitation by alternately selecting nodes that have not been evaluated much (exploration) and nodes that seem promising to obtain a better result (exploitation). Following this policy, we start at the root node and recursively select a child node until we find a node  $u$  which was not evaluated before. Appendix A gives more information about the used selection policy.

**Simulation & Expansion.** We continue by generating a set of unique transformation sequences with varying length that start at  $u$ . We bound the length of each sequence by a predefined value. In our experiments, we create sequences with up to 5 transformations. For each sequence, we determine the classifier score by providing the modified source code to the attribution method. The right plot in Figure 10 exemplifies

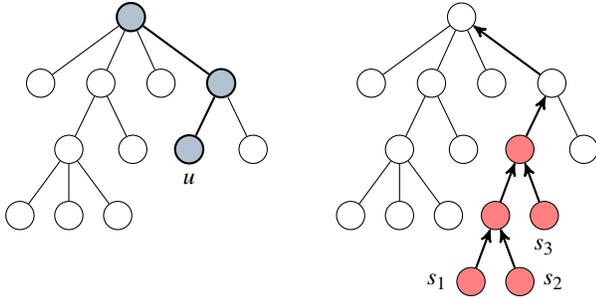

Figure 10: Basic steps of Monte-Carlo tree search. The left plot shows the selection step, the right plot the simulation, expansion and backpropagation.

the step: we create three sequences where two have the same first transformation. Next, we create the respective tree nodes. As two sequences start with the same transformation, they also share a node in the search tree.

**Backpropagation.** As the last step, we propagate the obtained classifier scores from the leaf node of each sequence back to the root. During this propagation, we update two statistics in each node on the path: First, we increment a counter that keeps track of how often a node has been part of a transformation sequence. In Figure 10, we increase the visit count of node  $u$  and the nodes above by 3. Second, we store the classifier scores in each node that have been observed in its subtree. For example, node  $u$  in Figure 10 stores the scores from  $s_1$ ,  $s_2$  and  $s_3$ . Both statistics are used by the selection policy and enable us to balance the exploration and exploitation of the tree in the next iterations.

**Iteration.** We repeat these four basic steps until a predefined iteration constraint is reached. After obtaining the resulting search tree, we identify the root's child node with the highest average classifier score and make it the novel root node of the tree. We then repeat the entire process again. The attack is stopped if we succeed, we reach a previously fixed number of iterations, or we do not obtain any improvement over multiple iterations.

Appendix A provides more implementation details on our variant of MCTS. We finally note that the algorithm resembles a black-box attack, as the inner working of the classifier  $f$  is not considered.

## 6 Evaluation

We proceed with an empirical evaluation of our attacks and investigate the robustness of source-code authorship attribution in a series of experiments. In particular, we investigate the impact of untargeted and targeted attacks on two recent attribution methods (Section 6.2 & 6.3). Finally, we verify in Section 6.4 that our initially imposed attack constraints are fulfilled.

## 6.1 Experimental Setup

Our empirical evaluation builds on the methods developed by Caliskan et al. [9] and Abuhamad et al. [1], two recent approaches that operate on a diverse set of features and provide superior performance in comparison to other attribution methods. For our evaluation, we follow the same experimental setup as the authors, re-implement their methods and make use of a similar dataset.

**Dataset & Setup.** We collect C++ files from the 2017 *Google Code Jam* (GCJ) programming competition [29]. This contest consists of various rounds where several participants solve the same programming challenges. This setting enables us to learn a classifier for attribution that separates stylistic patterns rather than artifacts of the different challenges. Moreover, for each challenge, a test input is available that we can use for checking the program semantics. Similar to previous work, we select eight challenges from the competition and collect the corresponding source codes from all authors who solved these challenges.

In contrast to prior work [1, 9], however, we set more stringent restrictions on the source code. We filter out files that contain incomplete or broken solutions. Furthermore, we format each source code using `clang-format` and expand macros, which removes artifacts that some authors introduce to write code more quickly during the contest. Our final dataset consists of 1,632 files of C++ code from 204 authors solving the same 8 programming challenges of the competition.

For the evaluation, we use a *stratified* and *grouped*  $k$ -fold cross-validation where we split the dataset into  $k - 1$  challenges for training and 1 challenge for testing. In this way, we ensure that training is conducted on different challenges than testing. For each of the  $k$  folds, we perform feature selection on the extracted features and then train the respective classifier as described in the original publications. We report results averaged over all 8 folds.

**Implementation.** We implement the attribution methods and our attack on top of Clang [28], an open-source C/C++ frontend for the LLVM compiler framework. For the method of Caliskan et al. [9], we re-implement the AST extraction and use the proposed random forest classifier for attributing programmers. The approach by Abuhamad et al. [1] uses lexical features that are passed to a long short-term memory (LSTM) neural network for attribution. Table 2 provides an overview of both methods. For further details on the fea-

Method	Lex	Syn	Classifier	Accuracy
Caliskan et al. [9]	•	•	RF	90.4% ± 1.7%
Abuhamad et al. [1]	•		LSTM	88.4% ± 3.7%

Table 2: Implemented attribution methods and their reproduced accuracy. (Lex = Lexical features, Syn = Syntactic features)

Method	Success rate of our attack		
	Untargeted	Targeted T+	Targeted T-
Caliskan et al. [9]	99.2%	77.3%	71.2%
Abuhamad et al. [1]	99.1%	81.3%	69.1%

Table 3: Performance of our attack as average success rate. The targeted attack is conducted with template (T+) and without template (T-).

ture extraction and learning process, we refer the reader to the respective publications [1, 9].

As a sanity check, we reproduce the experiments conducted by Caliskan et al. [9] and Abuhamad et al. [1] on our dataset. Table 2 shows the average attribution accuracy and standard deviation over the 8 folds. Our re-implementation enables us to differentiate the 204 developers with an accuracy of 90% and 88% on average, respectively. Both accuracies come close to the reported results with a difference of less than 6%, which we attribute to omitted layout features and the stricter dataset.

## 6.2 Untargeted Attack

In our first experiment, we investigate whether an adversary can manipulate source code such that the original author is not identified. To this end, we apply our untargeted attack to each correctly classified developer from the 204 authors. We repeat the attack for all 8 challenges and aggregate the results.

**Attack performance.** Table 3 presents the performance of the attack as the ratio of successful evasion attempts. Our attack has a strong impact on both methods and misleads the attribution in 99% of the cases, irrespective of the considered features and learning algorithm. As a result, the source code of almost all authors can be manipulated such that the attribution fails.

**Attack analysis.** To investigate the effect of our attack in more detail, we compute the ratio of changed features per adversarial sample. Figure 11 depicts the distribution over all samples. The method by Caliskan et al. [9] exhibits a bimodal distribution. The left peak shows that a few changes, such as the addition of include statements, are often sufficient to mislead attribution. For the majority of samples, however, the attack alters 50% of the features, which indicates the tight correlation between different features (see Section 3.3). A key factor to this correlation is the TF-IDF weighting that distributes minor changes over a large set of features.

In comparison, less features are necessary to evade the approach by Abuhamad et al. [1], possibly due to the higher sparsity of the feature vectors. Each author has 12.11% non-zero features on average, while 53.12% are set for the method by Caliskan et al. [9]. Thus, less features need to be changed and in consequence each changed feature impacts fewer other features that remain zero.

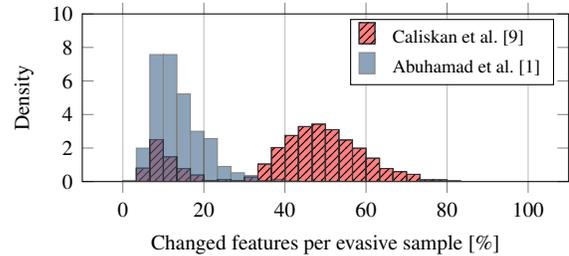

Figure 11: Untargeted attack: Histogram over the number of changed features per successful evasive sample for both attribution methods.

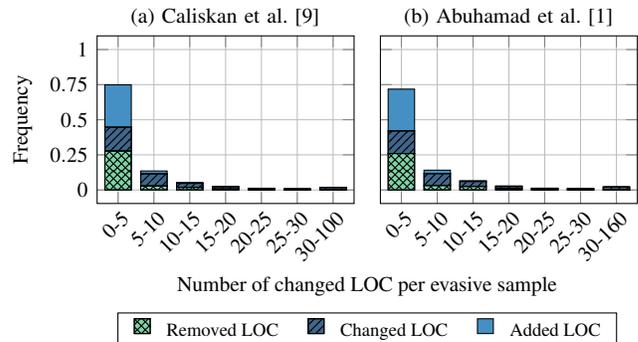

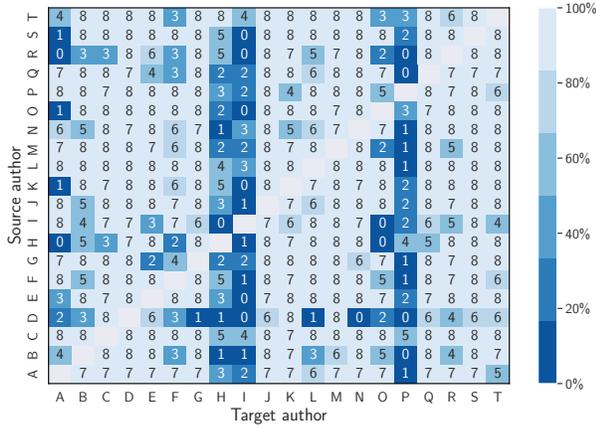

Figure 12: Untargeted attack: Stacked histogram over the number of changed lines of code (LOC) per successful evasive sample for both attribution methods. The original source files have 74 lines on average (std: 38.44).

Although we observe a high number of changed features, the corresponding changes to the source code are minimal. Figure 12 shows the number of added, changed and removed lines of code (LOC) determined by a context-diff with difflib for each source file before and after the attack. For the majority of cases in both attribution methods, less than 5 lines of code are added, removed or changed. This low number exemplifies the targeted design of our code transformations that selectively alter characteristics of stylistic patterns.

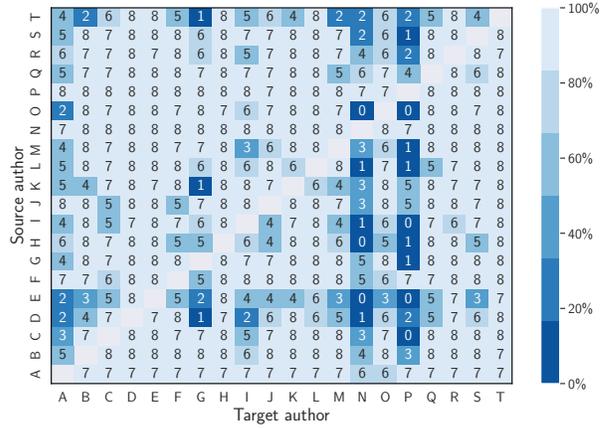

**Summary.** Based on the results from this experiment, we summarize that our untargeted attack severely impacts the performance of the methods by Caliskan et al. [9] and Abuhamad et al. [1]. We conclude that other attribution methods employing similar features and learning algorithms also suffer from this problem and hence cannot provide a reliable attribution in presence of an adversary.

## 6.3 Targeted Attack

We proceed to study the targeted variant of our attack. We consider pairs of programmers, where the code of the source author is transformed until it is attributed to the target author. Due to the quadratic number of pairs, we perform this experiment on a random sample of 20 programmers. This results in 380 source-target pairs each covering the source code of 8 challenges. Table 7 in Appendix B provides a list of the

(a) Caliskan et al. [9]

(b) Abuhamad et al. [1]

Figure 13: Impersonation matrix for both attribution methods. Each cell indicates the number of successful attack attempts for the 8 challenges.

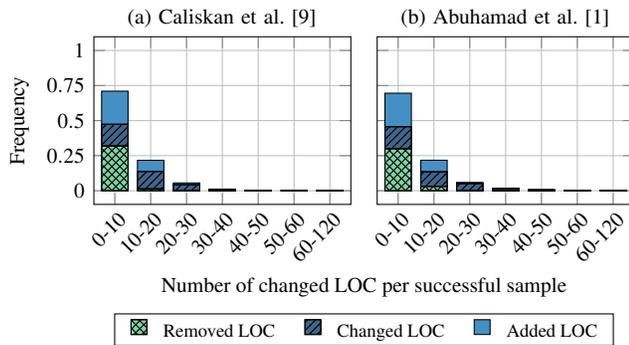

Figure 14: Targeted attack: Stacked histogram over the number of changed lines of code (LOC) per successful impersonation for both attribution methods. The original source files have 74 lines on average (std: 38.44).

selected authors. We start with the scenario where we retrieve two samples of source code for each of the 20 programmers from various GCJ challenges—not part of the fixed 8 train-test challenges—to support the template transformations.

**Attack performance.** Table 3 depicts the success rate of our attack for both attribution methods. We can transfer the prediction from one to another developer in 77% and 81% of all cases, respectively, indicating that more than three out of four programmers can be successfully impersonated.

In addition, Figure 13 presents the results as a matrix, where the number of successful impersonations is visually depicted. Note that the value in each cell indicates the absolute number of successful impersonations for the 8 challenges associated with each author pair. We find that a large set of developers can be imitated by almost every other developer. Their stylistic patterns are well reflected by our transformers and thus can be easily forged. By contrast, only the developers I and P have a small impersonation rate for Caliskan et al. [9], yet 68% and 79% of the developers can still imitate the style of I and P in at least one challenge.

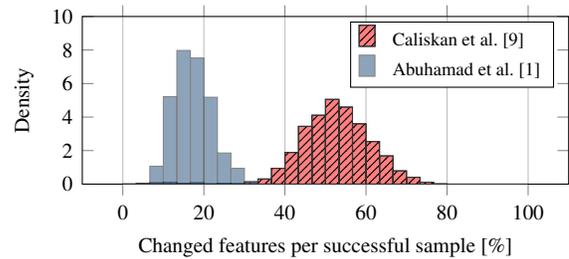

Figure 15: Targeted attack: Histogram over the number of changed features per successful impersonation for both attribution methods.

**Attack analysis.** The number of altered lines of code also remains small for the targeted attacks. Figure 14 shows that in most cases only 0 to 10 lines of code are affected. At the same time, the feature space is substantially changed. Figure 15 depicts that both attribution methods exhibit a similar distribution as before in the untargeted attack—except that the left peak vanishes for the method of Caliskan et al. [9]. This means that each source file requires more than a few targeted changes to achieve an impersonation.

Table 4: Usage of transformation families for impersonation

Transformation Family	Cal. [9]	Abu. [1]
Control Transformers	8.43%	9.72%
Declaration Transformers	14.11%	17.88%
API Transformers	29.90%	19.60%
Miscellaneous Transformers	9.15%	4.76%
Template Transformers	38.42%	48.04%

Table 4 shows the contribution of each transformation family to the impersonation success. All transformations are necessary to achieve the reported attack rates. A closer look reveals that the method by Abuhamad et al. [1] strongly rests on the usage of template transformers, while the families are more balanced for the approach by Caliskan et al. [9]. This

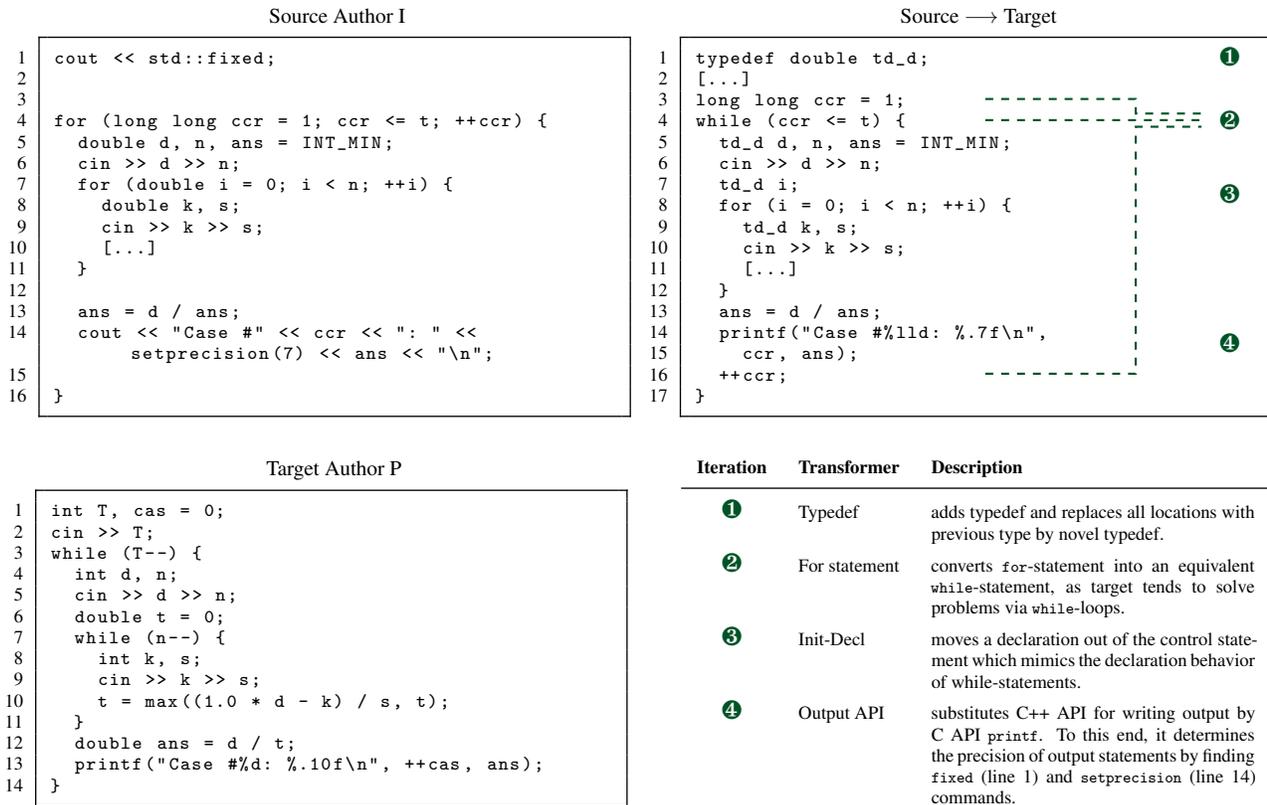

Figure 16: Impersonation example from our evaluation for the GCJ problem *Steed 2: Cruise Control*. The upper left listing shows the original source file, the upper right its modified version such that it is classified as the target author. For comparison, the lower left listing shows the original source file from the target author (which was not available for the attacker). The table lists the necessary transformations.

difference can be attributed to the feature sets, where the former method relies on simple lexical features only and the latter extracts more involved features from the AST.

**Case Study.** To provide further intuition for a successful impersonation, Figure 16 shows a case study from our evaluation. The upper two panels present the code from the source author in original and transformed form. The lower left panel depicts the original source text from the target author for the same challenge. Note that the attack has no access to this file. The table lists four conducted transformations. For instance, the target author has the stylistic pattern to use `while` statements, C functions for the output, and particular typedefs. By changing these patterns, our attack succeeds in misleading the attribution method.

**Attack without template.** We additionally examine the scenario when the adversary has no access to a template file of the target developer. In this case, our template transformers can only try common patterns, such as the iteration variables `i`, `j`, `...`, `k` or typedef `ll` for the type `long long`. Table 3 shows the results of this experiment as well. Still, we achieve an impersonation rate of 71% and 69%—solely by relying on the feedback from the classifier. The number of altered lines of code and features correspond to Figures 14 and 15.

Contrary to expectation, without a template, the approach by Abuhamad et al. [1] is harder to fool than the method by Caliskan et al. [9]. As the lexical features rest more on simple declaration names and included libraries, they are harder to guess without a template file. However, if a template file is available, this approach is considerably easier to evade.

**Attack with substitute model.** We finally demonstrate that an impersonation is even possible without access to the prediction of the original classifier, only relying on a substitute model trained from separate data. We split our training set into disjoint sets with three files per author to train the original and substitute model, respectively. We test the attack on the method by Caliskan et al. [9], which is the more robust attribution under attack. By the nature of this scenario, the adversary can use two files to support the template transformations.

Adversarial examples—generated with the substitute model—transfer in 79% of the cases to the original model, that is, attacks successful against the substitute model are also effective against the original in the majority of the cases. This indicates that our attack successfully changes indicative features for a target developer across models. The success rate of our attack on the original model is 52%. Due to the reduced number of training files in this experiment, the attack

is harder, as the coding habits are less precisely covered by the original and substitute models. Still, we are able to impersonate every second developer with no access to the original classifier.

**Summary.** Our findings show that an adversary can automatically impersonate a large set of developers without and with access to a template file. We conclude that both considered attribution methods can be abused to trigger false allegations—rendering a real-world application dangerous.

## 6.4 Preserved Semantics and Plausibility

In the last experiment, we verify that our adversarial code samples comply with the attack constraints specified in Section 3.2. That is, we empirically check that (a) the semantics of the transformed source code are preserved, (b) the generated code is plausible to a human analyst, and (c) layout features can be trivially evaded.

**Preserved semantics.** We begin by verifying the semantics of the transformed source code. In particular, we use the test file from each challenge of the GCJ competition to check that the transformed source code provides the same solution as the original code. In all our experiments, we can verify that the output remains unchanged for each manipulated source code sample before and after our attack.

**Plausible code.** Next, we check that our transformations lead to plausible code and conduct a discrimination test with 15 human subjects. The group consists of 4 undergraduate students, 6 graduate students and 5 professional computer scientists. The structure of the test follows an *AXY-test*: Every participant obtains 9 files of source code—each from a different author but for the same GCJ challenge. These 9 files consists of 3 unmodified source codes as reference (A) and 6 sources codes (XY) that need to be classified as either *original* or *modified*. The participants are informed that 3 of the samples are modified. We then ask each participant to identify the unknown samples and to provide a short justification.

The results of this empirical study are provided in Table 5. On average, the participants are able to correctly classify 60% of the provided files which is only marginally higher than random guessing. This result highlights that it is hard to decide whether source code has been modified by our attack or not. In several cases, the participants falsely assume that unused `typedef` statements or an inconsistent usage of operators are modifications.

**Evasion of layout features.** Finally, we demonstrate that layout features can be trivially manipulated, so that it is valid to restrict our approach to the forgery of lexical and syntactic features. To this end, we train a random forest classifier *only* on layout features as extracted by Caliskan et al. [9]. We then compare the attribution accuracy of the classifier on the test

Table 5: Study on plausibility of transformed source code.

Participant Group	Accuracy	Std
Undergraduate students	66.7%	23.6%
Graduate students	55.6%	15.7%
Professionals	60.0%	24.9%
Total	60.0%	21.8%
Random guessing	50.0%	—

set with and without the application of the formatting tool `clang-format`, which normalizes the layout of the code.

While the attribution method can identify 27.5% of the programmers based on layout features if the code is not formatted, the performance decreases to 4.5% if we apply the formatting tool to the source code. We thus conclude that it is trivial to mislead an attribution based on layout features.

## 7 Limitations

Our previous experiments demonstrate the impact of our attack on program authorship attribution. Nonetheless, our approach has limitations which we discuss in the following.

**Adversarial examples  $\neq$  anonymization.** Our attack enables a programmer to hide their identity in source code by misleading an attribution. While such an attack protects the privacy of the programmer, it is not sufficient for achieving anonymity. Note that  $k$ -anonymity would require a set of  $k$  developers that are equally likely to be attributed to the source code. In our setting, the code of the programmer is transformed to match a different author and an anonymity set of sufficient size is not guaranteed to exist. Still, we consider anonymization as promising direction for further research, which can build on the concepts of code transformations developed in this paper.

**Verification of semantics.** Finally, we consider two programs to be semantically equivalent if they return the same output for a given input. In particular, we verify that the transformed source code is semantically equivalent by applying the test cases provided by the GCJ competition. Although this approach is reasonable in our setting, it cannot guarantee strict semantic equivalence in all possible cases. Some of the exchanged API functions, for example, provide the same functionality but differ in corner cases, such as when the memory is exhausted. We acknowledge this limitation, yet it does not impact the general validity of our results.

## 8 Related Work

The automatic attack of source-code authorship attribution touches different areas of security research. In this section, we review related methods and concepts.

**Authorship attribution of source code.** Identifying the author of a program is a challenging task of computer security that has attracted a large body of work in the last years. Starting from early approaches experimenting with hand-crafted features [14, 16], the techniques for examining source code have constantly advanced, for example, by incorporating expressive features, such as n-grams [e.g., 1, 8, 13] and abstract syntax trees [e.g., 4, 9, 21]. Similarly, techniques for analyzing native code and identifying authors of compiled programs have advanced in the last years [e.g., 3, 10, 17, 22].

Two notable examples for source code are the approach by Caliskan et al. [9] and by Abuhamad et al. [1]. The former inspects features derived from code layout, lexical analysis and syntactic analysis. Regarding comprehensiveness, this work can be considered as the current state of the art. The work by Abuhamad et al. [1] focuses on lexical features as input for recurrent neural networks. Their work covers the largest set of authors so far and makes use of recent advances in deep learning. Table 6 shows the related approaches.

Method	Lay	Lex	Syn	Authors	Results
*Abuhamad et al. [1]		•		8903	92%
*Caliskan et al. [9]	•	•	•	250	95%
Alsulami et al. [4]			•	70	89%
Frantzeskou et al. [13]	•	•		30	97%
Krsul and Spafford [14]	•	•	•	29	73%
Burrows et al. [8]	•	•		10	77%

Table 6: Comparison of approaches for source code authorship attribution. Lay = Layout features, Lex = Lexical features, Syn = Syntactic features. \*Attacked in this paper.

Previous work, however, has mostly ignored the problem of untargeted and targeted attacks. Only the empirical study by Simko et al. [25] examines how programmers can mislead the attribution by Caliskan et al. [9] by mimicking the style of other developers. While this study provides valuable insights into the risk of forgeries, it does not consider automatic attacks and thus is limited to manipulations by humans. In this paper, we demonstrate that such attacks can be fully automated. Our generated forgeries even provide a higher success rate than the handcrafted samples in the study. Moreover, we evaluate the impact of different feature sets and learning algorithms by evaluating two attribution methods.

**Adversarial machine learning.** The security of machine learning techniques has also attracted a lot of research recently. A significant fraction of work on attacks has focused on scenarios where the problem and feature space are mainly identical [see 6, 11, 18]. In these scenarios, changes in the problem space, such as the modification of an image pixel, have a one-to-one effect on the feature space, such that sophisticated attack strategies can be applied. By contrast, a one-to-one mapping between source code and the extracted features cannot be constructed and thus we are required to introduce a mixed attack strategy (see Section 3).

Creating evasive PDF malware samples [27, 31] and adversarial examples for text classifiers [e.g., 5, 15] represent two similar scenarios, where the practical feasibility needs to be ensured. These works typically operate in the problem space, where search algorithms such as hill climbing or genetic programming are guided by information from the feature space. MCTS represents a novel concept in the portfolio of creating adversarial examples under feasibility constraints, previously examined by Wicker et al. [30] in the image context only.

Also related is the approach by Sharif et al. [23] for misleading face recognition systems using painted eyeglasses. The proposed attack operates in the feature space but ensures practical feasibility by refining the optimization problem. In particular, the calculated adversarial perturbations are required to match the form of eyeglasses, to be printable, and to be invariant to slight head movements. In our attack scenario, such refinements of the optimization problem are not sufficient for obtaining valid source code, and thus we resort to applying code transformations in the problem space.

## 9 Conclusion

Authorship attribution of source code can be a powerful tool if an accurate and robust identification of programmers is possible. In this paper, however, we show that the current state of the art is insufficient for achieving a robust attribution. We present a black-box attack that seeks adversarial examples in the domain of source code by combining Monte-Carlo tree search with concepts from source-to-source compilation. Our empirical evaluation shows that automatic untargeted and targeted attacks are technically feasible and successfully mislead recent attribution methods.

Our findings indicate a need for alternative techniques for constructing attribution methods. These techniques should be designed with robustness in mind, such that it becomes harder to transfer stylistic patterns from one source code to another. A promising direction are generative approaches of machine learning, such as generative adversarial networks, that learn a decision function while actively searching for its weak spots. Similarly, it would help to systematically seek for stylistic patterns that are inherently hard to manipulate, either due to their complexity or due to their tight coupling with program semantics.

**Public dataset and implementation.** To encourage further research on program authorship attribution and, in particular, the development of robust methods, we make our dataset and implementation publicly available.<sup>1</sup> The attribution methods, the code transformers as well as our attack algorithm are all implemented as individual modules, such that they can be easily combined and extended.

## A Monte-Carlo Tree Search

In this section, we provide further details about our variant of *Monte-Carlo tree search*. Algorithm 1 gives an overview of the attack. The procedure `ATTACK` starts with the root node  $r_0$  that represents the original source code  $x$ . The algorithm then works in two nested loops:

- The outer loop in lines 3–5 repetitively builds a search tree for the current state of source code  $r$ , and takes a single move (i.e. a single transformation). To do so, in each iteration, we choose the child node with the highest average classifier score. This process is repeated until the attack succeeds or a stop criterion is fulfilled (we reach a fixed number of outer iterations or we do not observe any improvement over multiple iterations) (line 3).
- The procedure `MCTS` represents the inner loop. It iteratively builds and extends the search tree under the current root node  $r$ . As this procedure is the main building block of our attack, we discuss the individual steps in more detail in the following.

---

### Algorithm 1 Monte-Carlo Tree Search

---

```

1: procedure ATTACK( $r_0$ )
2:    $r \leftarrow r_0$ 
3:   while not SUCCESS( $r$ ) and not STOPCRITERION( $r$ ) do
4:     MCTS( $r$ ) ▷ Extend the search tree under  $r$ 
5:      $r \leftarrow$  CHILDWITHBESTSCORE( $r$ ) ▷ Perform next move
6: procedure MCTS( $r$ )
7:   for  $i \leftarrow 1, N$  do
8:      $u \leftarrow$  SELECTION( $r, i$ )
9:      $\mathcal{T} \leftarrow$  SIMULATIONS( $u$ )
10:    EXPANSION( $u, \mathcal{T}$ )
11:    BACKPROPAGATION( $\mathcal{T}$ )

```

---

**Selection.** Algorithm 2 shows the pseudocode to find the next node which is evaluated. The procedure recursively selects a child node according to a selection policy. We stop if the current node has no child nodes or if we have not marked it before in the current procedure `SELECTION`. The procedure finally returns the node that will be evaluated next.

As the number of possible paths grows exponentially (we have up to 36 transformations as choice at each node), we cannot evaluate all possible paths. The tree creation thus crucially depends on a selection policy. We use a simple heuristic to approximate the *Upper Confidence Bound for Trees* algorithm that is often used as selection policy (see [7]). Depending on the current iteration index  $i$  of `SELECTION`, the procedure `SELECTIONPOLICY` alternately returns the decision rule to choose the child with the highest average score, the lowest visit count or the highest score standard deviation. This step balances the *exploration* of less-visited nodes and the *exploitation* of promising nodes with a high average score.

**Simulations.** Equipped with the node  $u$  that needs to be evaluated, the next step generates a set of transformation

---

**Algorithm 2** Selection Procedure of MCTS

---

```
1: procedure SELECTION( $r, i$ )
2:    $D \leftarrow$  SELECTIONPOLICY( $i$ )
3:    $u \leftarrow r$ 
4:   while  $u$  has child nodes do
5:      $v \leftarrow$  SELECTCHILD( $u, D$ )            $\triangleright$  Child of  $u$  w.r.t. to  $D$ 
6:     if  $v$  not marked as visited then
7:       Mark  $v$  as visited
8:     return  $v$ 
9:   else
10:     $u \leftarrow v$ 
```

---

sequences  $\mathcal{T}$  that start at  $u$ :

$$\mathcal{T} = \{\mathbf{T}_j \mid j = 1, \dots, k \text{ and } |\mathbf{T}_j| \leq M\}, \quad (2)$$

where  $|\mathbf{T}_j|$  is the number of transformations in  $\mathbf{T}_j$ . The sequences are created randomly and have a varying length which is, however, limited by  $M$ . In our experiments, we set  $M = 5$  to reduce the number of possible branches.

In contrast to the classic game use-case, we can use the returned scores  $g(x)$  as early feedback and thus we do not need to play out a full game. In other words, it is not necessary to evaluate the complete path to obtain feedback. For each sequence, we determine the classifier score by passing the modified source code at the end of each sequence to the attribution method. We further pinpoint a difference to the general MCTS algorithm. Instead of evaluating only one path, we create a batch of sequences that can be efficiently executed in parallel. In this way, we reduce the computation time and obtain the scores for various paths.

**Expansion.** We continue by inserting the respective transformations from the sequences as novel tree nodes under  $u$  (see Algorithm 3). For each sequence, we start with  $u$  and the first transformation. We check if a child node with the same transformation already exists under  $u$ . If not, a new node  $v$  is created and added as child under  $u$ . Otherwise, we use the already existing node  $v$ . We repeat this step with  $v$  and the next transformation. Figure 10 from Section 5 exemplifies this expansion step.

---

**Algorithm 3** Expansion Procedure of MCTS

---

```
1: procedure EXPANSION( $u, \mathcal{T}$ )
2:   for  $\mathbf{T}$  in  $\mathcal{T}$  do            $\triangleright$  For each sequence
3:      $z \leftarrow u$ 
4:     for  $T$  in  $\mathbf{T}$  do          $\triangleright$  For each transformer
5:       if  $z$  has no child with  $T$  then
6:          $v \leftarrow$  CREATENEWNODE( $T$ )
7:          $z.add\_child(v)$ 
8:       else
9:          $v \leftarrow z.GETCHILDWITH(T)$ 
10:       $z \leftarrow v$ 
```

---

**Backpropagation.** Algorithm 4 shows the last step that backpropagates the classifier scores to the root. For each sequence, the procedure first determines the last node  $n$  of the

current sequence and the observed classifier score  $s$  at node  $n$ . Next, all nodes on the path from  $n$  to the root node of the search tree are updated. First, the visit count of each path node is incremented. Second, the final classifier score  $s$  is added to the score list of each path node. Both statistics are used by SELECTCHILD to choose the next promising node for evaluation. Furthermore, CHILDWITHBESTSCORE uses the score list to obtain the child node with the highest average score.

---

**Algorithm 4** Backpropagation Procedure of MCTS

---

```
1: procedure BACKPROPAGATION( $\mathcal{T}$ )
2:   for  $\mathbf{T}$  in  $\mathcal{T}$  do
3:      $s \leftarrow$  GETSCORE( $\mathbf{T}$ )
4:     get  $n$  as tree leaf of current sequence
5:     while  $n$  is not None do            $\triangleright$  Backpropagate to root
6:        $n.visitCount \leftarrow n.visitCount + 1$     $\triangleright$  Increase visit count
7:        $n.scores = n.scores \cup s$                   $\triangleright$  Append score
8:        $n \leftarrow n.parent$                       $\triangleright$  Will be None for root node
```

---

We finally note a slight variation for the scenario with a substitute model (see Section 3.1). To improve the transferability rate from the substitute to the original model, we do not terminate at the first successful adversarial example. Instead, we collect all successful samples and stop the outer loop after a predefined number of iterations. We choose the sample with the highest score on the substitute to be tested on the original classifier.

## B List of Developers For Impersonation

Table 7 maps the letters to the 20 randomly selected programmers from the 2017 GCJ contest.

Table 7: List of developers for impersonation

Letter	Author	Letter	Author
A	4yn	K	chocimir

## C List of Code Transformations

A list of all 36 developed code transformations is presented in Table 8. The transformers are grouped accordingly to the family of their implemented transformations, i.e, transformations altering the control flow, transformations of declarations, transformations replacing the used API, template transformations, and miscellaneous transformations.

Table 8: List of Code Transformations

<b>Control Transformations</b>	
<b>Transformer</b>	<b>Description of Transformations</b>
For statement transformer	Replaces a <code>for</code> -statement by an equivalent <code>while</code> -statement.
While statement transformer	Replaces a <code>while</code> -statement by an equivalent <code>for</code> -statement.
Function creator	Moves a whole block of code to a standalone function and creates a call to the new function at the respective position. The transformer identifies and passes all parameters required by the new function. It also adapts statements that change the control flow (e.g. the block contains a <code>return</code> statement that also needs to be back propagated over the caller).
Deepest block transformer	Moves the deepest block in the AST to a standalone function.
If statement transformer	Split the condition of a single <code>if</code> -statement at logical operands (e.g., <code>&amp;&amp;</code> or <code>  </code> ) to create a cascade or a sequence of two <code>if</code> -statements depending on the logical operand.
<b>Declaration Transformations</b>	
<b>Transformer</b>	<b>Description of Transformation</b>
Array transformer	Converts a static or dynamically allocated array into a C++ vector object.
String transformer	<i>Array option:</i> Converts a char array (C-style string) into a C++ string object. The transformer adapts all usages in the respective scope, for instance, it replaces all calls to <code>strlen</code> by calling the instance methods <code>size</code> . <i>String option:</i> Converts a C++ string object into a char array (C-style string). The transformer adapts all usages in the respective scope, for instance, it deletes all calls to <code>c_str()</code> .
Integral type transformer	Promotes integral types ( <code>char</code> , <code>short</code> , <code>int</code> , <code>long</code> , <code>long long</code> ) to the next higher type, e.g., <code>int</code> is replaced by <code>long</code> .
Floating-point type transformer	Converts <code>float</code> to <code>double</code> as next higher type.
Boolean transformer	<i>Bool option:</i> Converts true or false by an integer representation to exploit the implicit casting. <i>Int option:</i> Converts an integer type into a boolean type if the integer is used as boolean value only.
Typedef transformer	<i>Convert option:</i> Convert a type from source file to a new type via <code>typedef</code> , and adapt all locations where the new type can be used. <i>Delete option:</i> Deletes a type definition ( <code>typedef</code> ) and replace all usages by the original data type.
Include-Remove transformer	Removes includes from source file that are not needed.
Unused code transformer	<i>Function option:</i> Removes functions that are never called. <i>Variable option:</i> Removes global variables that are never used.
Init-Decl transformer	<i>Move into option:</i> Moves a declaration for a control statement if defined outside into the control statement. For instance, <code>int i; ...; for(i = 0; i &lt; N; i++)</code> becomes <code>for(int i = 0; i &lt; N; i++)</code> . <i>Move out option:</i> Moves the declaration of a control statement's initialization variable out of the control statement.
<b>API Transformations</b>	
<b>Transformer</b>	<b>Description of Transformations</b>
Input interface transformer	<i>Stdin option:</i> Instead of reading the input from a file (e.g. by using the API <code>ifstream</code> or <code>freopen</code> ), the input to the program is read from <code>stdin</code> directly (e.g. <code>cin</code> or <code>scanf</code> ). <i>File option:</i> Instead of reading the input from <code>stdin</code> , the input is retrieved from a file.
Output interface transformer	<i>Stdout option:</i> Instead of printing the output to a file (e.g. by <code>ofstream</code> or <code>freopen</code> ), the output is written directly to <code>stdout</code> (e.g. <code>cout</code> or <code>printf</code> ). <i>File option:</i> Instead of writing the output directly to <code>stdout</code> , the output is written to a file.
Input API transformer	<i>C++-Style option:</i> Substitutes C APIs used for reading input (e.g., <code>scanf</code> ) by C++ APIs (e.g., usage of <code>cin</code> ). <i>C-Style option:</i> Substitutes C++ APIs used for reading input (e.g., usage of <code>cin</code> ) by C APIs (e.g., <code>scanf</code> ).
Output API transformer	<i>C++-Style option:</i> Substitutes C APIs used for writing output (e.g., <code>printf</code> ) by C++ APIs (e.g., usage of <code>cout</code> ). <i>C-Style option:</i> Substitutes C++ APIs used for writing output (e.g., usage <code>cout</code> ) by C APIs (e.g., <code>printf</code> ).
Sync-with-stdio transformer	Enable or remove the synchronization of C++ streams and C streams if possible.

Table 8: List of Code Transformations (continued)

<b>Template Transformers</b>	
<b>Transformer</b>	<b>Description of Transformations</b>
Identifier transformer	Renames an identifier, i.e., the name of a variable or function. If no template is given, default values are extracted from the 2016 Code Jam Competition set that was used by Caliskan et al. [9] and that is not part of the training- and test set. We test default values such as <code>T</code> , <code>t</code> , <code>...</code> , <code>i</code> .
Include transformer	Adds includes at the beginning of the source file. If no template is given, the most common includes from the 2016 Code Jam Competition are used as defaults.
Global declaration transformer	Adds global declarations to the source file. Defaults are extracted from the 2016 Code Jam Competition.
Include-typedef transformer	Inserts a type using <code>typedef</code> , and updates all locations where the new type can be used. Defaults are extracted from the 2016 Code Jam Competition.
<b>Miscellaneous Transformers</b>	
<b>Transformer</b>	<b>Description of Transformations</b>
Compound statement transformer	<i>Insert option:</i> Adds a compound statement ( <code>{ . . }</code> ). The transformer adds a new compound statement to a control statement ( <code>if</code> , <code>while</code> , etc.) given their body is not already wrapped in a compound statement. <i>Delete option:</i> Deletes a compound statement ( <code>{ . . }</code> ). The transformer deletes compound statements that have no effect, i.e., compound statements containing only a single statement.
Return statement transformer	Adds a return statement. The transformer adds a return statement to the main function to explicitly return 0 (meaning success). Note that <code>main</code> is a non-void function and is required to return an exit code. If the execution reaches the end of <code>main</code> without encountering a return statement, zero is returned implicitly.
Literal transformer	Substitutes a return statement returning an integer literal, by a statement that returns a variable. The new variable is declared by the transformer and initialized accordingly.

# Terminal Brain Damage: Exposing the Graceless Degradation in Deep Neural Networks Under Hardware Fault Attacks

## Abstract

Deep neural networks (DNNs) have been shown to tolerate “brain damage”: cumulative changes to the network’s parameters (e.g., pruning, numerical perturbations) typically result in a graceful degradation of classification accuracy. However, the limits of this natural resilience are not well understood in the presence of small adversarial changes to the DNN parameters’ underlying memory representation, such as bit-flips that may be induced by hardware fault attacks. We study the effects of bitwise corruptions on 19 DNN models—six architectures on three image classification tasks—and we show that most models have at least one parameter that, after a *specific bit-flip in their bitwise representation*, causes an accuracy loss of over 90%. For large models, we employ simple heuristics to identify the parameters likely to be vulnerable and estimate that 40–50% of the parameters in a model might lead to an accuracy drop greater than 10% when individually subjected to such single-bit perturbations. To demonstrate how an adversary could take advantage of this vulnerability, we study the impact of an exemplary hardware fault attack, *Rowhammer*, on DNNs. Specifically, we show that a Rowhammer-enabled attacker co-located in the same physical machine can inflict significant accuracy drops (up to 99%) even with single bit-flip corruptions and no knowledge of the model. Our results expose the limits of DNNs’ resilience against parameter perturbations induced by real-world fault attacks. We conclude by discussing possible mitigations and future research directions towards fault attack-resilient DNNs.

## 1 Introduction

Deep neural networks (DNNs) are known to be resilient to “brain damage” [32]: typically, cumulative changes to the network’s parameters result in a graceful degradation of classification accuracy. This property has been harnessed in a broad range of techniques, such as network pruning [35], which significantly reduces the number of parameters in the network and leads to improved inference times. Besides structural re-

silience, DNN models can tolerate slight noise in their parameters with minimal accuracy degradation [2]. Researchers have proposed utilizing this property in defensive techniques, such as adding Gaussian noise to model parameters to strengthen DNN models against adversarial examples [69]. As a result, this natural resilience is believed to make it difficult for attackers to significantly degrade the overall accuracy by corrupting network parameters.

Recent work has explored the impact of *hardware faults* on DNN models [34, 42, 45]. Such faults can corrupt the memory storing the victim model’s parameters, stress-testing DNNs’ resilience to bitwise corruptions. For example, Qin et al. [42], confirming speculation from previous studies [34, 35], showed that a DNN model for CIFAR10 image classification does not lose more than 5% accuracy when as many as 2,600 parameters out of 2.5 million are corrupted by *random errors*. However, this analysis is limited to a specific scenario and only considers accidental errors rather than attacker-induced corruptions by means of fault attacks. The widespread usage of DNNs in many mission-critical systems, such as self-driving cars or aviation [12, 51], requires a comprehensive understanding of the security implications of such adversarial bitwise errors.

In this paper, we explore the security properties of DNNs under bitwise errors that can be induced by practical hardware fault attacks. Specifically, we ask the question: *How vulnerable are DNNs to the atomic corruption that a hardware fault attacker can induce?* This paper focuses on single bit-flip attacks that are realistic as they well-approximate the constrained memory corruption primitive of practical hardware fault attacks such as Rowhammer [48]. To answer this question, we conduct a comprehensive study that characterizes the DNN model’s responses to single-bit corruptions in each of its parameters.

First, we implement a systematic vulnerability analysis framework that flips each bit in a given model’s parameters and measures the misclassification rates on a validation set. Using our framework, we analyze 19 DNN models composed of six different architectures and their variants on three pop-

ular image classification tasks: MNIST, CIFAR10, and ImageNet. Our experiments show that, on average,  $\sim 50\%$  of model parameters are vulnerable to single bit-flip corruptions, causing relative accuracy drops above 10%, and that all 19 DNN models include parameters that can cause an accuracy drop of over 90%<sup>1</sup>. The results expose the limits of the DNN’s resilience to numerical changes, as adversarial bitwise errors can lead to a *graceless degradation* of classification accuracy.

Our framework also allows us to characterize the vulnerability by examining the impact of various factors: the bit position, bit-flip direction, parameter sign, layer width, activation function, normalization, and model architecture. Our key findings include: 1) the vulnerability is caused by drastic spikes in a parameter value; 2) the spikes in positive parameters are more threatening, however, an activation function that allows negative outputs renders the negative parameters vulnerable as well; 3) the number of vulnerable parameters increases proportionally as the DNN’s layers get wider; 4) two common training techniques, e.g., dropout [52] and batch normalization [24], are ineffective in preventing the massive spikes bit-flips cause; and 5) the ratio of vulnerable parameters is almost constant across different architectures (e.g., AlexNet, VGG16, and so on). Further, building on these findings, we propose heuristics for speeding up the analysis of vulnerable parameters in large models.

Second, to understand the practical impact of this vulnerability, we use Rowhammer [26] as an exemplary hardware fault attack. While a variety of hardware fault attacks are documented in literature [11, 26, 38, 57], Rowhammer is particularly amenable to practical, real-world exploitation. Rowhammer takes advantage of a widespread vulnerability in modern DRAM modules and provides an attacker with the ability to trigger controlled memory corruptions directly from unprivileged software execution. As a result, even a constrained Rowhammer-enabled attacker, who only needs to perform a specific memory access pattern, can mount practical attacks in a variety of real-world environments, including cloud [44, 67], browsers [9, 15, 19, 48], mobile [15, 62], and servers [36, 60].

We analyze the feasibility of Rowhammer attacks on DNNs by simulating a Machine-Learning-as-a-Service (MLaaS) scenario, where the victim and attacker VMs are co-located on the same host machine in the cloud. The co-location leads the victim and the attacker to share the same physical memory, enabling the attacker to trigger Rowhammer bit-flips in the victim’s data [44, 67]. We focus our analysis to models with an applicable memory footprint, which can realistically be targeted by hardware fault attacks such as Rowhammer.

Our Rowhammer results show that in a *surgical* attack scenario, with the capability of flipping specific bits, the attacker can reliably cause severe accuracy drops in practical settings. Further, even in a *blind* attack scenario, the attacker can still

mount successful attacks without any control over the locations of bit-flips landed in memory. Moreover, we also reveal a potential vulnerability in the *transfer learning* scenario; in which a surgical attack targets the parameters in the layers victim model contains in common with a public one.

Lastly, we discuss directions for viable protection mechanisms, such as reducing the number of vulnerable parameters by preventing significant changes in a parameter value. In particular, this can be done by 1) restricting activation magnitudes and 2) using low-precision numbers for model parameters via quantization or binarization. We show that, when we restrict the activations using the ReLU-6 activation function, the ratio of vulnerable parameters decreases from 47% to 3% in AlexNet, and also, the accuracy drops are largely contained within 10%. Moreover, quantization and binarization reduce the vulnerable parameter ratio from 50% to 1-2% in MNIST. While promising, such solutions cannot deter practical hardware fault attacks in the general case, and often require training the victim model from scratch; hinting that more research is required towards fault attack-resilient DNNs.

**Contributions.** We make three contributions:

- We show DNN models are more vulnerable to bit-flip corruptions than previously assumed. In particular, we show adversarial bitwise corruptions induced by hardware fault attacks can easily inflict severe *indiscriminate damages* by drastically increasing or decreasing the value of a model parameter.
- We conduct the first comprehensive analysis of DNN models’ behavior against single bit-flips and characterize the vulnerability that a hardware fault attack can trigger.
- Based on our analysis, we study the impact of practical hardware fault attacks in a representative DL scenario. Our analysis shows that a Rowhammer-enabled attacker can inflict significant accuracy drops (up to 99%) on a victim model even with constrained bit-flip corruptions and no knowledge of the model.

## 2 Preliminaries

Here, we provide an overview of the required background knowledge.

**Deep neural networks.** A DNN can be conceptualized as a function that takes an input and returns a prediction, i.e., the inferred *label* of the input instance. The network is composed of a sequence of layers that is individually parameterized by a set of matrices, or *weights*. Our work focuses on feed-forward DNNs—specifically on convolutional neural networks (CNNs)—in the supervised learning setting, i.e., the weights that minimize the inference error are learned from

<sup>1</sup>The vulnerability of a parameter requires a *specific* bit in its bitwise representation to be flipped. There also might be multiple such bits in the representation that, when flipped separately, trigger the vulnerability.

a labeled *training set*. In a feed-forward network, each layer applies a linear transformation, defined by its weight matrix, to its input—the output of the previous layer—and a bias parameter is added optionally. After the linear transformation, a non-linear *activation function* is applied; as well as other optional layer structures, such as dropout, pooling or batch normalization. During training, the DNN’s *parameters*, i.e., the weights in each layer and in other optional structures, are updated iteratively by *backpropagating* the error on the training data. Once the network converges to an acceptable error rate or when it goes through sufficient iterations, training stops and the network, along with all its parameters, is stored as a trained network. During testing (or inference), we load the full model into the memory and produce the prediction for a given input instance, usually not in the training data.

**Single precision floating point numbers.** The parameters of a DNN model are usually represented as IEEE754 32-bit single-precision floating-point numbers. This format leverages the exponential notation and trades off the large range of possible values for reduced precision. For instance, the number 0.15625 in exponential notation is represented as  $1.25 \times 2^{-3}$ . Here, 1.25 expresses the *mantissa*; whereas  $-3$  is the *exponent*. The IEEE754 single-precision floating-point format defines 23 bits to store the mantissa, 8 bits for the exponent, and one bit for the sign of the value. The fact that different bits have different influence on the represented value makes this format interesting from an adversarial perspective. For instance, continuing our example, flipping the 16th bit in the mantissa increases the value from 0.15625 to 0.15625828; hence, a usually negligible perturbation. On the other hand, a flipping the highest exponent bit would turn the value into  $1.25 \times 2^{125}$ . Although both of these rely on the same bit corruption primitive, they yield vastly different results. In Sec 4, we analyze how this might lead to a vulnerability when a DNN’s parameters are corrupted via single bit-flips.

**Rowhammer attacks.** Rowhammer is the most common instance of software-induced fault attacks [9, 15, 19, 44, 48, 60, 62, 67]. This vulnerability provides an aggressor with a single-bit corruption primitive at DRAM level; thus, it is an ideal attack for the purpose of our analysis. Rowhammer is a remarkably versatile fault attack since it only requires an attacker to be able to access content in DRAM; an ubiquitous feature of every modern system. By simply carrying out specific memory access patterns—which we explain in Sec 5—the attacker is able to cause extreme stress on other memory locations triggering faults on other stored data.

### 3 Threat Model

Prior research has extensively validated a DNN’s resilience to parameter changes [2, 32, 34, 35, 42, 69], by considering

random or deliberate perturbations. However, from a security perspective, these results provide only limited insights as they study a network’s expected performance under cumulative changes. In contrast, towards a successful and feasible attack, an adversary is usually interested in inflicting the worst-case damage under minimal changes.

We consider a class of modifications that an adversary, using hardware fault attacks, can induce in practice. We assume a cloud environment where the victim’s deep learning system is deployed inside a VM—or a container—to serve the requests of external users. For making test-time inferences, the trained DNN model and its parameters are loaded into the system’s (shared) memory and remain constant in normal operation. Recent studies describe this as a typical scenario in MLaaS [61].

To understand the DNNs’ vulnerability in this setting, we consider the atomic change that an adversary may induce—the single bit-flip—and we, in Sec 4, systematically characterize the damage such change may cause. We then, in Sec 5, investigate the feasibility of inducing this damage in practice, by considering adversaries with different capabilities and levels of knowledge.

**Capabilities.** We consider an attacker *co-located* in the same physical host machine as the victim’s deep learning system. The attacker, due to co-location, can take advantage of a well-known software-induced fault attack, Rowhammer [44, 67], for corrupting the victim model stored in DRAM. We take into account two possible scenarios: 1) a *surgical* attack scenario where the attacker can cause a bit-flip at an intended location in the victim’s process memory by leveraging advanced memory massaging primitives [44, 62] to obtain more precise results; and 2) a *blind* attack where the attacker lacks fine-grained control over the bit-flips; thus, is completely unaware of where a bit-flip lands in the layout of the model.

**Knowledge.** Using the existing terminology, we consider two levels for the attacker’s knowledge of the victim model, e.g., the model’s architecture and its parameters as well as their placement in memory: 1) a *black-box* setting where the attacker has no knowledge of the victim model. Here, both the surgical and blind attackers only hope to trigger an accuracy drop as they cannot anticipate what the impact of their bit-flips would be; and 2) a *white-box* setting where the attacker knows the victim model, at least partially. Here, the surgical attacker can deliberately tune the attack’s inflicted accuracy drop—from minor to catastrophic damage. Optionally, the attacker can force the victim model to misclassify a specific input sample without significantly damaging the overall accuracy. However, the blind attacker gains no significant advantage over the black-box scenario as the lack of capability prevents the attacker from acting on the knowledge.

## 4 Single-Bit Corruptions on DNNs

In this section, we expose DNNs' vulnerability to single bit-flips. We start with an overview of our experimental setup and methodology. We then present our findings of DNNs' vulnerability to single bit corruptions. For characterizing the vulnerability, we analyze the impact of 1) the bitwise representation of the corrupted parameter, and 2) various DNN properties; on the resulting *indiscriminate damage*<sup>2</sup>. We also discuss the broader implications of the vulnerability for both the blind and surgical attackers. Finally, we turn our attention to two distinct attack scenarios single bit-flips lead to.

### 4.1 Experimental Setup and Methodology

Our vulnerability analysis framework systematically flips the bits in a model, individually, and quantifies the impact using the metrics we define. We implement the framework using Python 3.7<sup>3</sup> and PyTorch 1.0<sup>4</sup> that supports CUDA 9.0 for accelerating computations by using GPUs. Our experiments run on the high performance computing cluster that has 488 nodes, where each is equipped with Intel E5-2680v2 2.8GHz 20-core processors, 180 GB of RAM, and 40 of which have 2 Nvidia Tesla K20m GPUs. We achieve a significant amount of speed-up by leveraging a parameter-level parallelism.

**Datasets.** We use three popular image classification datasets: MNIST [31], CIFAR10 [29], and ImageNet [47]. MNIST is a grayscale image dataset used for handwritten digits (zero to nine) recognition, containing 60,000 training and 10,000 validation images of 28x28 pixels. CIFAR10 and ImageNet are colored image datasets used for object recognition. CIFAR10 includes 32x32 pixels, colored natural images of 10 classes, containing 50,000 training and 10,000 validation images. For ImageNet, we use the ILSVRC-2012 subset [46], resized at 224x224 pixels, composed of 1,281,167 training and 50,000 validation images from 1,000 classes.

**Models.** We conduct our analysis on 19 different DNN models. For MNIST, we define a baseline architecture, Base (B), and generate four variants with different layer configurations: B-Wide, B-PReLU, B-Dropout, and B-DP-Norm. We also examine well-known LeNet5 (L5) [31] and test two variants of it: L5-Dropout and L5-D-Norm. For CIFAR10, we employ the architecture from [55] as a baseline and experiment on its three variants: B-Slim, B-Dropout and B-D-Norm. In the following sections, we discuss why we generate these variants. In Appendix A, we describe the details of these custom architectures; in Appendix C, we present the hyper-parameters. For CIFAR10, we also employ two off-the-shelf

network architectures: AlexNet [30] and VGG16 [50]. For ImageNet, we use five well-known DNNs to understand the vulnerability of large models: AlexNet, VGG16, ResNet50 [22], DenseNet161 [23] and InceptionV3 [56]<sup>5</sup>.

**Metrics.** To quantify the indiscriminate damage of single bit-flips, we define the Relative Accuracy Drop as  $RAD = (Acc_{pristine} - Acc_{corrupted}) / Acc_{pristine}$ ; where  $Acc_{pristine}$  and  $Acc_{corrupted}$  denote the classification accuracies of the pristine and the corrupted models, respectively. In our experiments, we use  $[RAD > 0.1]$  as the criterion for indiscriminate damage on the model. We also measure the accuracy of each class in the validation set to analyze whether a single bit-flip causes a subset of classes to dominate the rest. In MNIST and CIFAR10, we simply compute the Top-1 accuracy on the test data (as a percentage) and use the accuracy for analysis. For ImageNet, we consider both the Top-1 and Top-5 accuracy; however, for the sake of comparability, we report only Top-1 accuracy in Table 1. We consider a parameter as *vulnerable* if it, in its bitwise representation, contains at least one bit that triggers severe indiscriminate damage when flipped. For quantifying the vulnerability of a model, we simply count the number of these vulnerable parameters.

**Methodology.** On our 8 MNIST models, we carry out a complete analysis: we flip each bit in all parameters of a model, in both directions—(0→1) and (1→0)—and compute the RAD over the entire validation. However, a complete analysis of the larger models requires infeasible computational time—the VGG16 model for ImageNet with 138M parameters would take  $\approx 942$  days on our setup. Therefore, based on our initial results, we devise three speed-up heuristics that aid the analysis of CIFAR10 and ImageNet models.

**Speed-up techniques.** The following three heuristics allow us to feasibly and accurately estimate the vulnerability in larger models:

- *Sampled validation set (SV).* After a bit-flip, deciding whether the bit-flip leads to a vulnerability  $[RAD > 0.1]$  requires testing the corrupted model on the validation set; which might be cost prohibitive. This heuristic says that we can still estimate the model accuracy—and the RAD—on a sizable subset of the validation set. Thus, we randomly sample 10% the instances from each class in the respective validation sets, in both CIFAR10 and ImageNet experiments.
- *Inspect only specific bits (SB).* In Sec 2, we showed how flipping different bits of a IEEE754 floating-point number results in vastly different outcomes. Our the initial MNIST analysis in Sec 4.3 shows that mainly the exponent bits lead to perturbations strong enough to cause indiscriminate damage.

<sup>2</sup>We use this term to indicate the severe overall accuracy drop in the model.

SV = Sampled Validation set    SB = Specific Bits    SP = Sampled Parameters set

Table 1: Indiscriminate damages to 19 DNN models caused by single bit-flips.

This observation is the basis of our *SB* heuristic that tells us to examine the effects of flipping only the exponent bits for CIFAR10 models. For ImageNet models, we use a stronger *SB* heuristic and only inspect the most significant exponent bit of a parameter to achieve a greater speed-up. This heuristic causes us to miss the vulnerability the remaining bits might lead to, therefore, its results can be interpreted as a conservative estimate of the actual number of vulnerable parameters.

- *Sampled parameters (SP) set.* Our MNIST analysis also reveals that almost 50% of all parameters are vulnerable to bit-flips. This leads to our third heuristic: uniformly sampling from the parameters of a model would still yield an accurate estimation of the vulnerability. We utilize the *SP* heuristic for ImageNet models and uniformly sample a fixed number of parameters—20,000—from all parameters in a model. In our experiments, we perform this sampling five times and report the average vulnerability across all runs. Uniform sampling also reflects the fact that a black-box attacker has a uniform probability of corrupting any parameter.

## 4.2 Quantifying the Vulnerability That Leads to Indiscriminate Damage

Table 1 presents the results of our experiments on single-bit corruptions, for 19 different DNN models. We reveal that an attacker, armed with a single bit-flip attack primitive, can successfully cause indiscriminate damage [ $RAD > 0.1$ ] and that the ratio of vulnerable parameters in a model varies be-

tween 40% to 99%; depending on the model. The consistency between MNIST experiments, in which we examine every possible bit-flip, and the rest, in which we heuristically examine only a subset, shows that, in a DNN model, approximately half of the parameters are vulnerable to single bit-flips. Our experiments also show small variability in the chances of a successful attack—indicated by the ratio of vulnerable parameters. With 40% vulnerable parameters, the InceptionV3 model is the most apparent outlier among the other ImageNet models; compared to 42-49% for the rest. We define the vulnerability based on [ $RAD > 0.1$ ] and, in Appendix B, we also give how vulnerability changes within the range [ $0.1 \leq RAD \leq 1$ ]. In the following subsections, we characterize the vulnerability in relation to various factors and discuss our results in more detail.

## 4.3 Characterizing the Vulnerability: Bitwise Representation

Here, we characterize the interaction how the features of a parameter’s bitwise representation govern its vulnerability.

**Impact of the bit-flip position.** To examine how much change in a parameter’s value leads to indiscriminate damage, we focus on the position of the corrupted bits. In Figure 1, for each bit position, we present the number of bits—in the log-scale—that cause indiscriminate damage when flipped, on MNIST-L5 and CIFAR10-AlexNet models. In our MNIST

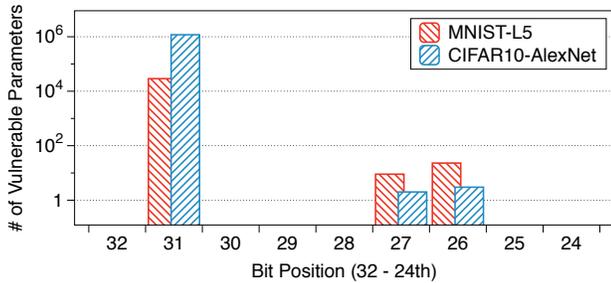

Figure 1: **The impact of the bit position.** The number of vulnerable parameters in bit positions 32nd to 24th.

experiments, we examine all bit positions and we observe that bit positions other than the exponents mostly do not lead to significant damage; therefore, we only consider the exponent bits. We find that *the exponent bits, especially the 31st-bit, lead to indiscriminate damage.* The reason is that a bit-flip in the exponents causes to a drastic change of a parameter value, whereas a flip in the mantissa only increases or decreases the value by a small amount— $[0, 1]$ . We also observe that flipping the 30th to 28th bits is mostly inconsequential as these bits, in the IEEE754 representation, are already set to one for most values a DNN parameter usually takes— $[3.0517 \times 10^{-5}, 2]$ .

**Impact of the flip direction.** We answer which direction of the bit-flip,  $(0 \rightarrow 1)$  or  $(1 \rightarrow 0)$ , leads to greater indiscriminate damage. In Table 2, we report the number of effective bit-flips, i.e., those that inflict  $[\text{RAD} > 0.1]$  for each direction, on 3 MNIST and 2 CIFAR10 models. We observe that *only  $(0 \rightarrow 1)$  flips cause indiscriminate damage and no  $(1 \rightarrow 0)$  flip leads to vulnerability.* The reason is that a  $(1 \rightarrow 0)$  flip can only decrease a parameter’s value, unlike a  $(0 \rightarrow 1)$  flip. The values of model parameters are usually normally distributed— $N(0, 1)$ —that places most of the values within  $[-1, 1]$  range. Therefore, a  $(1 \rightarrow 0)$  flip, in the exponents, can decrease the magnitude of a typical parameter at most by one; which is not a strong enough change to inflict critical damage. Similarly, in the sign bit, both  $(0 \rightarrow 1)$  and  $(1 \rightarrow 0)$  flips cannot cause severe damage because they change the magnitude of a parameter at most by two. On the other hand, a  $(0 \rightarrow 1)$  flip, in the exponents, can increase the parameter value significantly; thus, during the forward-pass, the extreme neuron activation caused by the corrupted parameter overrides the rest of the activations.

Direction (32-24th bits)	Models (M: MNIST, C: CIFAR10)				
	M-B	M-PreLU	M-L5	C-B	C-AlexNet
0→1	11,019	21,711	28,902	314,768	1,185,964
1→0	0	0	0	0	0
Total	11,019	21,711	28,902	314,768	1,185,964

Table 2: **The impact of the flip direction.** The number of effective bit-flips in 3 MNIST and 2 CIFAR10 models.

**Impact of the parameter sign.** As our third feature, we investigate whether the sign—positive or negative—of the corrupted parameter impacts the vulnerability. In Figure 2, we examine the MNIST-L5 model and present the number of vulnerable positive and negative parameters in each layer—in the log-scale. Our results suggest that *positive parameters are more vulnerable to single bit-flips than negative parameters.* We identify the common ReLU activation function as the reason: ReLU immediately zeroes out the negative activation values, which are usually caused by the negative parameters. As a result, the detrimental effects of corrupting a negative parameter fail to propagate further in the model. Moreover, we observe that *in the first and last layers, the negative parameters, as well as the positive ones, are vulnerable.* We hypothesize that, in the first convolutional layer, changes in the parameters yield a similar effect to corrupting the model inputs directly. On the other hand, in their last layers, DNNs usually have the Softmax function that does not have the same zeroing-out effect as ReLU.

#### 4.4 Characterizing the Vulnerability: DNN Properties

We continue our analysis by investigating how various properties of a DNN model affect the model’s vulnerability to single bit-flips.

**Impact of the layer width.** We start our analysis by asking whether increasing the width of a DNN affects the number of vulnerable parameters. In Table 1, in terms of the number of vulnerable parameters, we compare the MNIST-B model with the MNIST-B-Wide model. In the wide model, all the convolutional and fully-connected layers are twice as wide as the corresponding layer in the base model. We see that the ratio of vulnerable parameters is almost the same for both models: 50.2% vs 50.0%. Further, experiments on the CIFAR10-B-Slim and CIFAR10-B—twice as wide as the slim model—produce consistent results: 46.7% and 46.8%. We conclude that *the number of vulnerable parameters grows proportionally with the DNN’s width and, as a result, the ratio of vulnerable parameters remains constant at around 50%.*

**Impact of the activation function.** Next, we explore whether the choice of activation function affects the vulnerability. Previously, we showed that ReLU can neutralize the effects of large negative parameters caused by a bit-flip; thus, we experiment on different activation functions that allow negative outputs, e.g., PReLU [21], LeakyReLU, or RReLU [68]. These ReLU variants have been shown to improve the training performance and the accuracy of a DNN. In this experiment, we train the MNIST-B-PReLU model; which is exactly the same as the MNIST-B model, except that it replaces ReLU with PReLU. Figure 3 presents the layer-wise number of

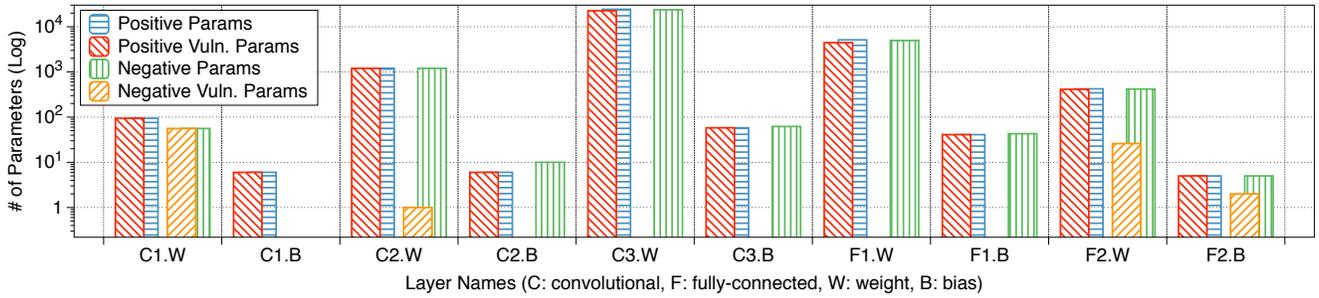

Figure 2: **The impact of the parameter sign.** The number of vulnerable positive and negative parameters, in each layer of MNIST-L5.

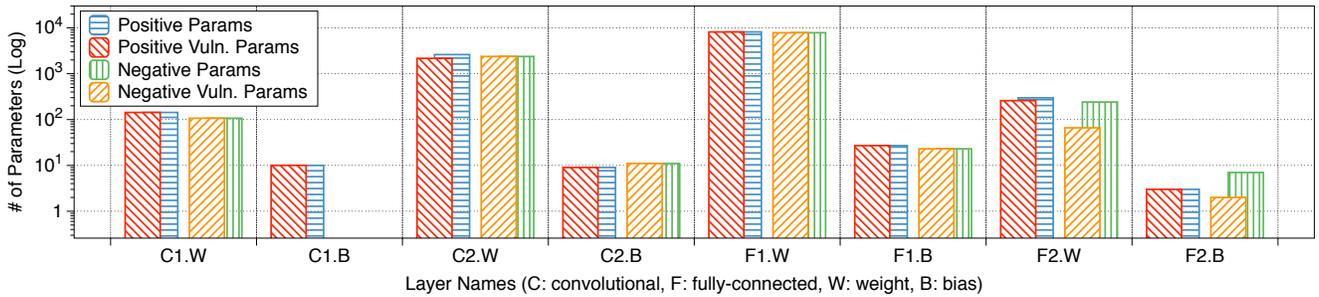

Figure 3: **The impact of the activation function.** The number of vulnerable positive and negative parameters, in each layer of MNIST-PReLU.

vulnerable positive and negative parameters in MNIST-B-PReLU. We observe that using PReLU causes the negative parameters to become vulnerable and, as a result, leads to a DNN approximately twice as vulnerable as the one that uses ReLU—50.2% vs. 99.2% vulnerable parameters.

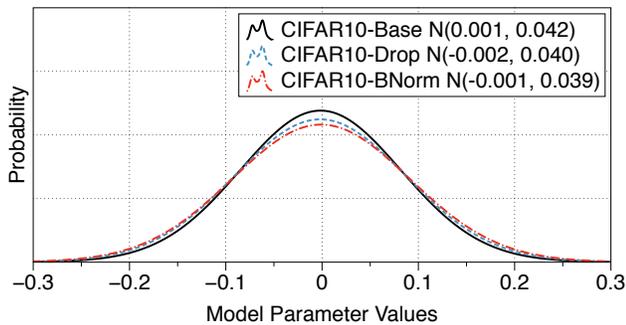

Figure 4: **The impact of the dropout and batch normalization.** The distributions of the parameter values of three CIFAR10 models variants.

**Impact of dropout and batch normalization.** We confirmed that successful bit-flip attacks increase a parameter’s value drastically to cause indiscriminate damage. In consequence, we hypothesize that common techniques that tend to constrain the model parameter values to improve the performance, e.g., dropout [52] or batch normalization [24], would

result in a model more resilient to single bit-flips. Besides the base CIFAR10 and MNIST models, we train the B-Dropout and B-DNorm models for comparison. In B-Dropout models, we apply dropout before and after the first fully-connected layers; in B-DNorm models, in addition to dropout, we also apply batch normalization after each convolutional layer. In Figure 4, we compare our three CIFAR10 models and show how dropout and batch normalization have the effect of reducing the parameter values. However, when we look into the vulnerability of these models, we surprisingly find that the vulnerability is mostly persistent regardless of dropout or batch normalization—with at most 6.3% reduction in vulnerable parameter ratio over the base network.

**Impact of the model architecture.** Table 1 shows that the vulnerable parameter ratio is mostly consistent across different DNN architectures. However, we see that the InceptionV3 model for ImageNet has a relatively lower ratio—40.8%—compared to the other models—between 42.1% and 48.9%. We hypothesize that the reason is the auxiliary classifiers in the InceptionV3 architecture that have no function at test-time. To confirm our hypothesis, we simply remove the parameters in the auxiliary classifiers; which bring the vulnerability ratio closer to the other models—46.5%. Interestingly, we also observe that the parameters in batch normalization layers are resilient to a bit-flip: corrupting `running_mean` and `running_var` cause negligible damage. In consequence, ex-

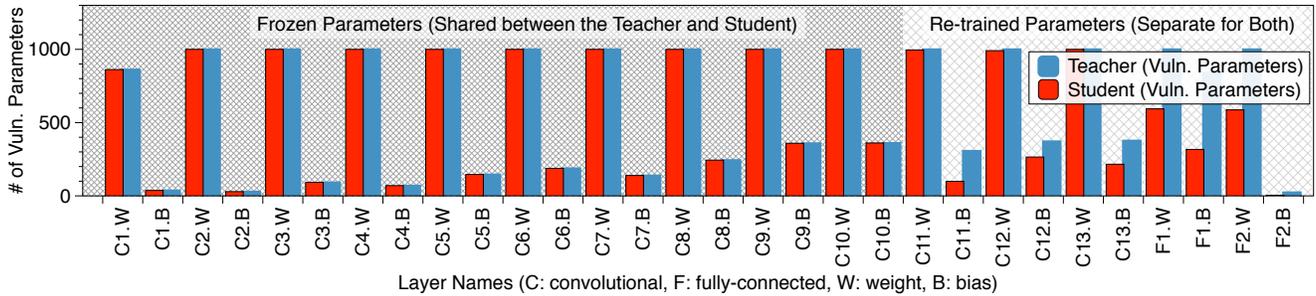

Figure 5: **The security threat in a transfer learning scenario.** The victim model—student—that is trained by transfer learning is vulnerable to the surgical attacker, who can see the parameters the victim has in common with the teacher model.

cluding the parameters in InceptionV3’s multiple batch normalization layers leads to a slight increase in vulnerability—by 0.02%.

#### 4.5 Implications for the Adversaries

In Sec 3, we defined four attack scenarios: the blind and surgical attackers, in the black-box and white-box settings. First, we consider the strongest attacker: the surgical, who can flip a bit at a specific memory location, white-box, with the model knowledge for anticipating the impact of flipping the said bit. To carry out the attack, this attacker identifies: 1) how much indiscriminate damage, the RAD goal, she intends to inflict, 2) a vulnerable parameter that can lead to the RAD goal, 3) in this parameter, the bit location, e.g., 31st-bit, and the flip direction, e.g., (0→1), for inflicting the damage. Based on our [RAD > 0.1] criterion, approximately 50% of the parameters are vulnerable in all models; thus, for this goal, the attacker can easily achieve 100% success rate. For more severe goals [0.1 ≤ RAD ≤ 0.9], our results in Appendix B suggest that the attacker can still find vulnerable parameters. In Sec 5.1, we discuss the necessary primitives, in a practical setting, for this attacker.

For a black-box surgical attacker, on the other hand, the best course of action is to target the 31st-bit of a parameter. This strategy maximizes the attacker’s chance of causing indiscriminate damage, even without knowing what, or where, the corrupted parameter is. Considering, the VGG16 model for ImageNet, the attack’s success rate is 42.1% as we report in Table 1; which is an upper-bound for the black-box attackers. For the weakest—black-box blind—attacker that cannot specifically target the 31st-bit, we conservatively estimate the lower-bound as 42.1% / 32-bits = 1.32%; assuming only the 31st-bits lead to indiscriminate damage. Note that the success rate for the white-box blind attacker is still 1.32% as acting upon the knowledge of the vulnerable parameters requires an attacker to target specific parameters. In Sec 5.2, we evaluate the practical success rate of a blind attacker.

#### 4.6 Distinct Attack Scenarios

In this section, other than causing indiscriminate damage, we discuss two distinct attack scenarios single bit-flips might enable: transfer learning and targeted misclassification.

**Transfer learning scenario.** Transfer learning is a common technique for *transferring* the knowledge in a pre-trained *teacher* model to a *student* model; which, in many cases, outperforms training a model from scratch. In a practical scenario, a service provider might rely on publicly available teacher as a starting point to train commercial student models. The teacher’s knowledge is transferred by *freezing* some of its layers and embedding them into the student model; which, then, trains the remaining layers for its own task. The security risk is that, for an attacker who knows the teacher but not the student, a black-box attack on the student might escalate into a white-box attack on the teacher’s frozen layers. The attacker first downloads the pre-trained teacher from the Internet. She then loads the teacher into the memory and waits for the *deduplication* [66] to happen. During deduplication, the memory pages with the same contents—the frozen layers—are merged into the shared pages between the victim and attacker. In consequence, a bit-flip in the attacker’s pages can also affect the student model in the victim’s memory. We hypothesize that a surgical attacker, who can identify the teacher’s vulnerable parameters and trigger bit-flips in these parameters, can cause indiscriminate damage to the student model. In our experiments, we examine two transfer learning tasks in [63]: the traffic sign (GTSRB) [53] and flower recognition (Flower102) [41]. We initialize the student model by transferring first ten frozen layers of the teacher—VGG16 or ResNet50 on ImageNet. We then append a new classification layer and train the resulting student network for its respective task by only updating the new unfrozen layer. We corrupt the 1,000 parameters sampled from each layer in the teacher and monitor the damage to the student model. Figure 5 reports our results: we find that *all vulnerable parameters in the frozen layers and more than a half in the re-trained layers are shared by the teacher and the student.*

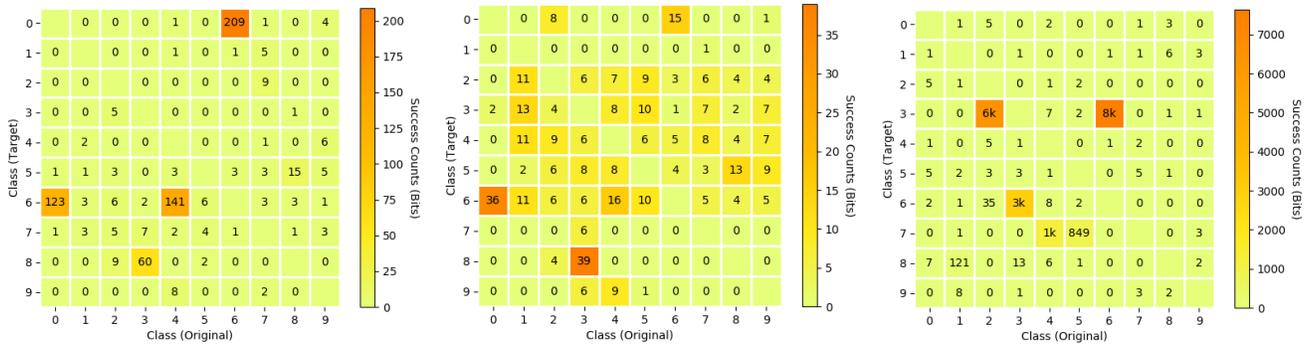

Figure 6: **The vulnerable parameters for a targeted attack in 3 DNN models.** Each cell reports the number of bits that lead to the misclassification of a target sample, whose original class is given by the x-axis, as the target class, which is given by the y-axis. From left to right, the models are MNIST-B, MNIST-L5 and CIFAR10-AlexNet.

**Targeted misclassification.** Although our main focus is showing DNNs’ graceless degradation, we conduct an additional experiment to see whether a single bit-flip primitive could be used in the context of *targeted misclassification* attacks. A targeted attack aims to preserve the victim model’s overall accuracy while causing the network to misclassify a specific target sample into the target class. We experiment with a target sample from each class in MNIST or CIFAR10—we use MNIST-B, MNIST-L5, and CIFAR10-AlexNet models. Our white-box surgical attacker also preserves the accuracy by limiting the  $[RAD < 0.05]$  as in [55]. We find that *the number of vulnerable parameters for targeted misclassifications is lower than that of for causing indiscriminate damage*. In Figure 6, we also see that for some (*original–target class*) pairs, the vulnerability is more evident. For example, in MNIST-B, there are 141 vulnerable parameters for (class 4–class 6) and 209 parameters for (class 6–class 0). Similarly, in CIFAR10-AlexNet, there are 6,000 parameters for (class 2–class 3); 3,000 parameters for (class 3–class 6); and 8,000 parameters for (class 6–class 3).

## 5 Exploiting Using Rowhammer

In order to corroborate the analysis made in Sec 4 and prove the viability of hardware fault attacks against DNN, we test the resiliency of these models against Rowhammer. At a high level, Rowhammer is a software-induced fault attack that provides the attacker with a single-bit write primitive to specific physical memory locations. That is, an attacker capable of performing specific memory access patterns (at DRAM-level) can induce persistent and repeatable bit corruptions from software. Given that we focus on single-bit perturbations on DNN’s parameters in practical settings, Rowhammer represents the perfect candidate for the task.

**DRAM internals.** In Figure 7, we show the internals of a DRAM *bank*. A bank is a bi-dimensional array of memory

*cells* connected to a *row buffer*. Every DRAM chip contains multiple banks. The cells are the actual storage of one’s data. They contain a capacitor whose charge determines the value of a specific bit in memory. When a read is issued to a specific row, this row gets *activated*, which means that its content gets transferred to the row buffer before being sent to the CPU. Activation is often requested to recharge a row’s capacitors (i.e., *refresh* operation) since they leak charge over time.

**Rowhammer mechanism.** Rowhammer is a DRAM disturbance error that causes spurious bit-flips in DRAM cells generated by frequent activations of a neighboring row. Here, we focus on double-sided Rowhammer, the most common and effective Rowhammer variant used in practical attacks [15, 44, 62]. Figure 8 exemplifies a typical double-sided Rowhammer attack. The victim’s data is stored in a row enclosed between two aggressor rows that are repeatedly accessed by the attacker. Due to the continuous activations of the neighboring rows, the victim’s data is under intense duress. Thus, there is a large probability of bit-flips on its content.

To implement such attack variant, the attacker usually needs some knowledge or control over the physical memory layout. Depending on the attack scenario, a Rowhammer-enabled attacker can rely on a different set of primitives for this purpose. In our analysis, we consider two possible scenarios: 1) we

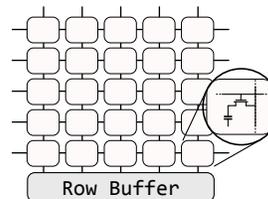

Figure 7: **DRAM bank structure.** Zoom-in on a cell containing the capacitor storing data.

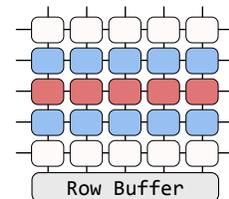

Figure 8: **Double-sided Rowhammer.** Aggressor rows (blue) and a victim row (red).

DRAM	# (0→1) flips	DRAM	# (0→1) flips
A_2	21,538	A_4	5,577
E_2	16,320	I_1	4,781
H_1	10,608	J_1	4,725
G_1	7,851	E_1	4,175
A_1	4,367	A_3	1,541
F_1	5,927	C_1	1,365

Table 3: **Hammertime database [58]**. We report the number of (0→1) bit-flips in 12 different DRAM setups. (The rows in gray are used for the experiments in Figure 9.)

initially consider the *surgical* attacker; that is, an attacker with the capability of causing bit-flips at the specific locations, and we demonstrate how, under these assumptions, she can induce indiscriminate damage to a co-located DNN application. 2) We then deprive the attacker of this ability to analyze the outcome of a *blind* attacker and we demonstrate that, even in a more restricted environment, the attacker can still cause indiscriminate damage by causing bitwise corruptions.

**Experimental setup.** For our analysis, we constructed a simulated environment<sup>6</sup> relying on a database of the Rowhammer vulnerability in 12 DRAM chips, provided by Tatar et al [58]. Different memory chips have a different degree of susceptibility to the Rowhammer vulnerability, enabling us to study the impact of Rowhammer attacks on DNNs in different real-world scenarios. Table 3 reports the susceptibility of the different memory chips to Rowhammer. Here, we only include the numbers for (0→1) bit-flips since these are the more interesting ones for the attacker targeting a DNN model according to our earlier analysis in Sec 4.3 and Sec 4.4.

We perform our analysis on an exemplary deep learning application implemented in PyTorch, constantly querying an ImageNet model. We use ImageNet models since we focus on a scenario where the victim has a relevant memory footprint that can be realistically be targeted by hardware fault attacks such as Rowhammer in practical settings. While small models are also potential targets, the number of interesting locations to corrupt is typically limited to draw general conclusions on the practical effectiveness of the attack.

## 5.1 Surgical Attack Using Rowhammer

We start our analysis by discussing a surgical attacker, who has the capability of causing a bit-flip at the specific location in memory. The two surgical attackers are available: the attacker with the knowledge of the victim model (white-

<sup>6</sup>We first implemented all the steps described in our paper on a physical system, considering using end-to-end attacks for our analysis. After preliminary testing of this strategy on our own DRAMs, we concluded it would be hard to generalize the findings of such an analysis and decided against it—in line with observations from prior work [59].

Network	Vuln. Objects (Vuln./Total)	Vuln. Params (in 20k params)	#Hammer Attempts (min/med/max)
AlexNet	7/16	9,522	4/64/4,679
VGG16	12/32	8,140	4/64/4,679
ResNet50	9/102	3,466	4/64/4,679
DenseNet161	63/806	5,117	4/64/4,679
InceptionV3	53/483	6,711	4/64/4,679

Table 4: **Effectiveness of surgical attacks.** We examine five different ImageNet models analyzed in Sec 4.

box) and without (black-box). However, in this subsection, we assume that the strongest attacker knows the parameters to compromise and is capable of triggering bit-flips on its corresponding memory location. Then, this attacker can take advantage of accurate memory massing primitives (e.g., memory deduplication) to achieve 100% attack success rate.

**Memory templating.** Since a surgical attacker knows the location of vulnerable parameters, she can *template* the memory up front [44]. That is, the attacker scans the memory by inducing Rowhammer bit-flips in her own allocated chunks and looking for exploitable bit-flips. A surgical attacker aims at specific bit-flips. Hence, while templating the memory, the attacker simplifies the scan by looking for bit-flips located at specific offsets from the start address of a memory *page* (i.e., 4 KB)—the smallest possible chunk allocated from the OS. This allows the attacker to find memory pages vulnerable to Rowhammer bit-flips at a given page offset (i.e., *vulnerable templates*), which they can later use to predictably attack the victim data stored at that location.

**Vulnerable templates.** To locate the parameters of the attacker’s interest (i.e., vulnerable parameters) within the memory page, she needs to find *page-aligned* data in the victim model. Modern memory allocators improve performances by storing large objects (usually multiples of the page size) page-aligned whereas smaller objects are not. Thus, we first analyzed the allocations performed by the PyTorch framework running on Python to understand if it performs such optimized page-aligned allocations for large objects similar to other programs [16, 39]. We discovered this to be the case for all the objects larger than 1 MB—i.e., our attacker needs to target the parameters such as weight, bias, and so on, stored as tensor objects in layers, larger than 1 MB.

Then, again focusing on the ImageNet models, we analyzed them to identify the objects that satisfy this condition. Even if the ratio between the total number of objects and target objects may seem often unbalanced in favor of the small ones<sup>7</sup>, we found that the number of vulnerable parameters in the target objects is still significant (see Table 4). Furthermore, it is

<sup>7</sup>The bias in convolutional or dense layers, and the `running_mean` and `running_var` in batch-norms are usually the small objects (< 1 MB).

important to note that when considering a surgical attacker, she only needs one single vulnerable template to compromise the victim model, and there is only 1,024 possible offsets where we can store a 4-byte parameter within a 4 KB page.

**Memory massaging.** After finding a vulnerable template, the attacker needs to *massage* the memory to land the victim’s data on the vulnerable template. This can be achieved, for instance, by exploiting memory deduplication [9, 44, 67]. Memory deduplication is a system-level memory optimization that merges read-only pages for different processes or VMs when they contain the same data. These pages re-split when a write is issued to them. However, Rowhammer behaves as invisible bit-wise writes that do not trigger the split, breaking the process boundaries. If the attacker knows (even if partially) the content of the victim model can take advantage of this merging primitive to compromise the victim service.

**Experimental results.** Based on the results of the experiments in Sec 4.3 and Sec 4.4, we analyzed the requirements for a surgical (white-box) attacker to carry out a successful attack. Here, we used one set of the five sampled parameters for each model. In Table 4, we report *min*, *median*, and *max* values of the number of rows that an attacker needs to hammer to find the first vulnerable template on the 12 different DRAM setups for each model. This provides a meaningful metric to understand the success rate of a surgical attack. As you can see in Table 4, the results remain unchanged among all the different models. That is, for every model we tested in the best case, it required us to hammer only 4 rows (*A\_2* DRAM setup) to find a vulnerable template all the way up to 4,679 in the worst case scenario (*C\_1*). The reason why the results are equal among the different models is *due to the number of vulnerable parameters which largely exceeds the number of possible offsets within a page that can store such parameters* (i.e., 1024). Since every vulnerable parameter yields indiscriminate damage [ $RAD > 0.1$ ], we simply need to identify a template that could match any given vulnerable parameter. This means that an attacker can find a vulnerable template at best in a matter of few seconds<sup>8</sup> and at worst still within minutes. Once the vulnerable template is found, the attacker can leverage memory deduplication to mount an effective attack against the DNN model—with no interference with the rest of the system.

## 5.2 Blind Attack Using Rowhammer

While in Sec 5.1 we analyzed the outcome of a surgical attack, here we abstract some of the assumptions made above and study the effectiveness of a blind attacker oblivious of the bit-flip location in memory. To bound the time of the lengthy

blind Rowhammer attack analysis, we specifically focus our experiments on the ImageNet-VGG16 model.

We run our PyTorch application under the pressure of Rowhammer bit-flips indiscriminately targeting both code and data regions of the process’s memory. Our goal is twofold: 1) to understand the effectiveness of such attack vector in a less controlled environment and 2) to examine the robustness of a running DNN application to Rowhammer bit-flips by measuring the number of failures (i.e., crashes) that our blind attacker may inadvertently induce.

**Attacker’s capabilities.** We consider a blind attacker who cannot control the bit-flips caused by Rowhammer. As a result, the attacker may corrupt bits in the DNN’s parameters as well as the code blocks in the victim process’s memory. In principle, since Rowhammer bit-flips propagate at the DRAM level, a fully blind Rowhammer attacker may also inadvertently flip bits in other system memory locations. In practice, even an attacker with limited knowledge of the system memory allocator, can heavily influence the physical memory layout by means of specially crafted memory allocations [17, 18]. Since this strategy allows attackers to achieve co-location with the victim memory and avoid unnecessary fault propagation in practical settings, we restrict our analysis to a scenario where bit-flips can only (blindly) corrupt memory of the victim deep learning process. This also generalizes our analysis to arbitrary deployment scenarios, since the effectiveness of blind attacks targeting arbitrary system memory is inherently environment-specific.

**Methods.** For every one of the 12 vulnerable DRAM setups available in the database, we carried out 25 experiments where we performed at most 300 “hammering” attempts—value chosen after the surgical attack analysis where a median of 64 attempts was required. The experiment has three possible outcomes: 1) we trigger one(or more) effective bit-flip(s) that compromise the model, and we record the relative accuracy drop when performing our testing queries; 2) we trigger one(or more) effective bit-flip(s) in other victim memory locations that result in a crash of the deep learning process; 3) we reach the “timeout” value of 300 hammering attempts. We set such “timeout” value to bound our experimental analysis which would otherwise result too lengthy.

**Experimental results.** In Figure 9, we present the results for three sampled DRAM setups. We picked *A\_2*, *I\_1*, and *C\_1* as representative samples since they are the most, least, and moderately vulnerable DRAM chips (see Table 3). Depending on the DRAM setup, we obtain fairly different results. We found *A\_2* obtains successful indiscriminate damages to the model in 24 out of 25 experiments while, in less vulnerable environments such as *C\_1*, the number of successes decreases to only one while the other 24 times out. However, it is im-

<sup>8</sup>We assume 200ms to hammer a row.

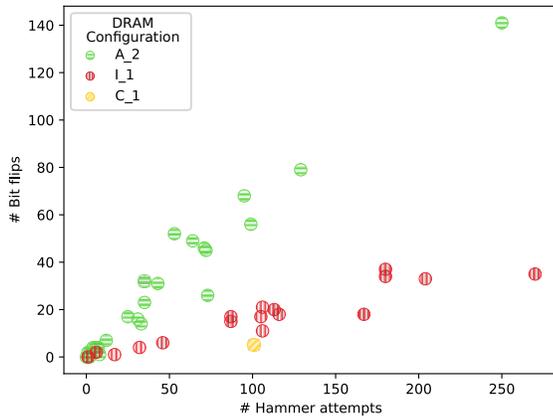

Figure 9: **The successful runs of a blind attack execution over three different DRAM setups (A\_2-most, I\_1-least, and C\_1-moderately vulnerable).** We report the success in terms of *#flips* and *#hammer attempts* required to obtain an indiscriminate damage to the victim model. We observe the successes within few hammering attempts.

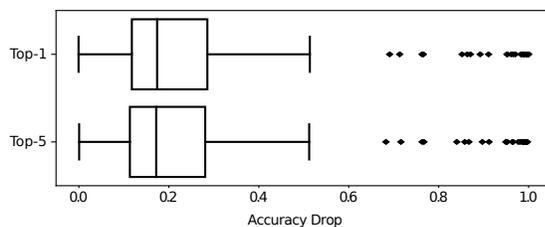

Figure 10: **The distribution of relative accuracy drop for Top-1 and Top-5.** We compute them over the effective *#flips* in our experiments on the ImageNet-VGG16 model.

portant to note that a timeout does not represent a negative result—a crash. Contrarily, while *C\_1* only had a single successful attack, it also represents a peculiar case corroborating the analysis presented in Sec 4. The corruption generated in this single successful experiment was induced by a single bit-flip, which caused one of the most significant RADs detected in the entire experiment, i.e., 0.9992 and 0.9959 in Top-1 and Top-5. Regardless of this edge case, we report a mean of 15.6 out of 25 effective attacks for this Rowhammer variant over the different DRAM setups. Moreover, we report the distribution of accuracy drops for Top-1 and Top-5 in Figure 10. In particular, the median drop for Top-1 and Top-5 confirms the claims made in the previous sections, i.e., the blind attacker can expect  $[RAD > 0.1]$  on average.

Interestingly, when studying the robustness of the victim process to Rowhammer, we discovered it to be quite resilient to spurious bit-flips. We registered only 6 crashes over all the different DRAM configurations and experiments—300

in total. This shows that the model effectively dominates the memory footprint of the victim process and confirms findings from our earlier analysis that bit-flips in non-vulnerable model elements have essentially no noticeable impact.

### 5.3 Synopsis

Throughout the section, we analyzed the outcome of surgical and blind attacks against large DNN models and demonstrated how Rowhammer can be deployed as a feasible attack vector against these models. These results corroborate our findings in Sec 4 where we estimated at least 40% of a model’s parameters to be vulnerable to single-bit corruptions. Due to this large attack surface, in Sec 5.1, we showed that a Rowhammer-enabled attacker armed with knowledge of the network’s parameters and powerful memory massaging primitives [44, 62, 67] can carry out precise and effective indiscriminate attacks in a matter of, at most, few minutes in our simulated environment. Furthermore, this property, combined with the resiliency to spurious bit-flips of the (perhaps idle) code regions, allowed us to build successful blind attacks against the ImageNet-VGG16 model and inflict “terminal brain damage” even when hiding the model from the attacker.

## 6 Discussion

In this section, we discuss and evaluate some potential mitigations to protect against single-bit attacks on DNN models. We discuss two research directions towards making DNN models resilient to bit-flips: *to restrict activation magnitudes* and *to use low-precision numbers*. Prior work on defenses against Rowhammer attacks suggest system-level defenses [10, 27] that often even require specific hardware support [6, 26]. Yet they have not been widely deployed since they require infrastructure-wide changes from cloud host providers. Moreover, even though the infrastructure is robust to Rowhammer attacks, an adversary can leverage other vectors to exploit bit-flips attacks to corrupt a model. Thus, we focus on the solutions that our victim can apply to his models.

### 6.1 Restricting Activation Magnitudes

In Sec 4.3, we found that the vulnerable parameter ratio changes based on inherent properties of a DNN; for instance, using PReLU activation function allows a model to propagate negative extreme activations. Hence, if we opt for an activation function that always bounds the output within a specific range, a bit-flip is hard to cause indiscriminate damage. There are several functions, such as Tanh or HardTanh [25], that suppresses the activations; however, using ReLU-6 [28] function provides two key advantages over the others: 1) the victim only needs to substitute the existing activation functions from ReLU to ReLU-6 without re-training, and 2) ReLU-6 allows

Network	Train	Base acc.	# Params	Vulnerability
Base (ReLU)	Scr	98.13		10,972 (50.2%)
Base (ReLU6)	Scr	98.16	21,840	313 (1.4%)
Base (Tanh)	Scr	97.25		507 (2.3%)
Base (ReLU6)	Sub	95.71		542 (2.4%)
AlexNet (ReLU)	-	56.52 / 79.07	20,000	9,467 (47.34%)
AlexNet (ReLU6)	Sub	39.80 / 65.82	(61M)	560 (2.8%)
AlexNet (ReLU-A)	Sub	56.52 / 79.07		1,063 (5.32%)
VGG16 (ReLU)	-	64.28 / 86.56	20,000	8,227 (41.13%)
VGG16 (ReLU6)	Sub	38.58 / 64.84	(138M)	2,339 (11.67%)
VGG16 (ReLU-A)	Sub	64.28 / 86.56		2,427 (12.14%)

Table 5: Effectiveness of restricting activation.

the victim to control the level of permitted activation by modifying the bounds, e.g., using other limits instead of 6, which minimizes the performance loss by bounding the activation. What the victim can do is to monitor the activation values over the validation set and to decide the limits that only suppresses the abnormal activation by bit-flips. For example, in our experiments with ImageNet-AlexNet, we set the limits to  $[0, max]$ , where  $max$  is defined adaptively by looking at the maximum activation from each layer (ReLU-A).

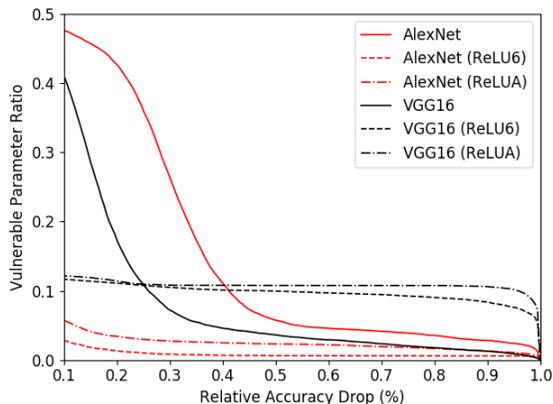

Figure 11: The vulnerability of DNN models using different criteria. We illustrate the ImageNet-AlexNet (red lines) and -VGG16 (black lines) cases with ReLU-6 and ReLU-A.

**Experiments.** We use three DNN models in Sec 4: the MNIST-B, ImageNet-AlexNet, and ImageNet-VGG16 models. We evaluate four activation functions: ReLU (default), Tanh, ReLU-6, and ReLU-A (only for AlexNet and VGG16), and two training methods: training a model from scratch (Scr) or substituting the existing activation into another (Sub). We use the notation as the network names with the activation in parenthesis, e.g., AlexNet (ReLU-6). For larger models, we use the same speed-up heuristics in Sec 4.2; SV, SB, and SP.

Table 5 shows the effectiveness of our proposal. For each network (Column 1), we list the training method, the base

Network	Method	Base acc.	# Params	Vulnerability
L5	-	99.24	62,598	30,686 (49.0%)
L5	8-bit Quantized	99.03	62,600	0 (0.0%)
L5	XNOR Binarized	98.39	62,286	623 (1.0%)

Table 6: Effectiveness of using low-precision.

accuracy, the number of examined parameters, and the vulnerability (Column 2-5). We found that restricting activation magnitudes with Tanh and ReLU-6 in some instances can reduce the vulnerability; For instance, in the MNIST models, we observed that the number of vulnerable parameters is reduced from 50% to 1.4-2.4% without incurring in significant performance loss. Further, we discovered that ReLU-6 achieves a similar effect without re-training of a model like Tanh. However, there are the vulnerable parameters after the restrictions since we cannot apply the ReLU-6 function to the last layer. In AlexNet and VGG16, the decrease in the number of vulnerable parameters is also generally significant, namely from 47.34% to 2.8% and 41.13% to 11.67%. However, we observe the models suffer from large accuracy drops caused by restricting the activation. To minimize the loss, we control the bounds of activation in AlexNet (ReLU-A) and VGG16 (ReLU-A) by choosing the maximum activation from each layer. With the ReLU-A, we can trade accuracy for the number of vulnerable parameters as we show in Table 5. Nevertheless, it is interesting to see that by employing ReLU-A, while the number of vulnerable parameters remains significant, the RAD also suffers from the new activation function limiting the possible effects of the corruption. In Figure 11, the dashed lines are for ReLU-6, the dashed-dot lines are for ReLU-A, and the straight lines are for ReLU. We found the ReLU-A lines are between the ReLU and ReLU-6 in AlexNet.

**Takeaways.** Our experimental results with restricting activation magnitudes suggest that: this mechanism 1) allows a defender to control the trade-off between the relative accuracy drop and reducing the vulnerable parameters and 2) enables ad-hoc defenses to DNN models, which does not require training the network from scratch. However, the remaining number of vulnerable parameters shows that the Rowhammer attacker still could inflict damage, with a reduced success rate.

## 6.2 Using Low-precision Numbers

Another direction is to represent the model parameters as low-precision numbers by using quantization and binarization. In Sec 4.3, we found that the vulnerability exploits the bit-wise representation of the corrupted parameter to induce the dramatic changes in the parameter value. Our intuition is to use low-precision numbers hard to be increased dramatically by a bit-flip; for example, an integer expressed as the 8-bit quantized format can be increased at most 128 by a flip in the

MSB (8th bit). Thus, the attacker only can increase a model parameter with such a restricted bound. Training models using low-precision numbers are supported by the popular deep learning frameworks such as TensorFlow<sup>9</sup>. The victim can train and deploy the model with the quantized or binarized parameters by utilizing the frameworks.

**Experiments.** To validate our intuition, we use 3 DNN models: the MNIST-L5 (baseline) and its quantized and binarized models. When we quantize the MNIST-L5 model, we use the 8-bit quantization in [7, 64] which converts the model parameters in all layers into integers between 0 and 255. For the binarization, we employ the method in XNOR-Net [43] which converts the model parameters to -1 and 1, except the first convolutional layer. Using the trained models, we evaluate the vulnerability to single bit-flips, and report the accuracy, total parameters, and vulnerability, without the speed-up heuristics.

Table 6 shows the effectiveness of using low-precision parameters. For each network (Column 1), we note the quantization method, the accuracy, the number of vulnerable parameters, and their percentage (Column 2-5). We found that *using low-precision parameters reduces the vulnerability*; in all cases, the percentage of vulnerable parameters are reduced from 49% (Baseline) to 0-2% (surprisingly 0% with the quantization). We focus on analyzing which layer has vulnerable parameters in the binarization model. We found that mostly the parameters in the first convolutional (150 parameters) and classification (last) layers (420 parameters) are vulnerable to a bit-flip, which corroborates what observed in Sec 4.3.

**Takeaways.** Even though we showed the elimination of the vulnerability through 8-bit quantization, in a real-world, training the large model such as [65] from scratch can take a week on a supercomputing cluster.

## 7 Related Work

**DNN's resilience to perturbations.** Prior work has utilized the *graceful degradation* of DNN models under parameter perturbations in a wide range of applications. For example, network quantization [3, 5], by quantizing a DNN model's high-precision parameter into low-precision, reduces the size and inference time of a model with negligible performance penalty. This property has also been used as a primitive for improving the security of DNNs. For example, modifying the parameter slightly to inject a watermark to allow model owners to prove ownership [1]; adding Gaussian noise to model parameter for reducing the reliability of test-time adversarial attacks on DNNs [69]; and fine-tuning the parameters for mitigating the malicious backdoors in a model [37]. Further,

the resilience to structural changes has led to pruning techniques [4, 20, 35] which improve the efficiency of a DNN model by removing unimportant neurons along with their parameters. In our work, we study the *graceless degradation* of DNNs under hardware fault attacks that induce single bit-flips to individual parameters.

**Indiscriminate poisoning attacks on DNNs.** Recent work on adversarial machine learning has demonstrated many attack scenarios to inflict indiscriminate damage on a model. One of the well-studied vectors is *indiscriminate poisoning attacks* [8] in which the adversary, by injecting malicious data in the victim's training set, aims to hurt the model. Previous studies suggest that such attack might require significant amount of poisonous instances [40]. For example, Steinhardt et al. [54] shows that, with IMDB dataset, an attacker needs to craft 3% of the total training instances to achieve 11% of accuracy drop compared to the pristine model. Further, the defenses based on robust outlier removal techniques could render poison injection ineffective by filtering it out [14, 54]. Moreover, to achieve targeted damages without harming the model's overall accuracy, *targeted poisoning attacks* [49, 55] have been studied. In this paper, we analyze a test-time vulnerability that does not require the adversary's contact to the victim model during its training. This vulnerability inflicts indiscriminate damage, similar to indiscriminate poisoning attacks, through a different attack medium.

**Hardware fault injection attacks.** Hardware fault injection is a class of attacks that rely on hardware glitches on the system to corrupt victim's data. These glitches generally provide a single-bit write primitive at the physical memory; which could potentially lead to privilege escalation [67]. While in the past these attacks required physical access to the victim's system [11, 38], recently they have gained more momentum since the software-based version of these attacks were demonstrated [26, 57]. Instances of these attacks are 1) the CLKSCREW attack [57] that leverages dynamic voltage and frequency scaling on mobile processors generate faults on instructions; or 2) the well-known Rowhammer vulnerability that triggers bitwise corruptions in DRAM. Rowhammer has been used in the context of cloud VMs [44, 67], on desktops [48] and mobile [62] and even to compromise browsers from JavaScript [9, 15, 19]. In the context of DNNs, fault attacks have been proposed as an alternative for inflicting indiscriminate damages. Instead of injecting poisonous instances, fault attacks directly induce perturbations to the models running on hardware [11, 13, 34, 38, 45]. These studies have considered the adversaries with direct access to the victim hardware [11, 13] and adversaries who randomly corrupt parameters [34, 38, 45]. We utilize Rowhammer as an established fault attack to demonstrate practical implications of the graceless degradation of DNNs. Our threat model follows the realistic single bit-flip capability of a fault attack and modern

<sup>9</sup>[https://www.tensorflow.org/lite/performance/post\\_training\\_quantization](https://www.tensorflow.org/lite/performance/post_training_quantization)

application of DNNs in a cloud environment, where physical access to the hardware is impractical.

## 8 Conclusions

This work exposes the limits of DNN’s resilience against the parameter perturbations. We study the vulnerability of DNN models to single bit-flips. We evaluated 19 DNN models with six architectures on three image classification tasks and showed that: we can easily find 40-50% vulnerable parameters where an attacker can cause indiscriminate damage [RAD > 0.1] by a bit-flip. We further characterize this vulnerability based on the impact of various factors: the bit position, bit-flip direction, parameter sign, layer width, activation function, training techniques, and model architecture. Understanding this emerging threat, we leverage the software-induced fault injection, Rowhammer, to demonstrate the feasibility of the bit-flip attacks in practice. In experiments with RowHammer, we found that, without knowing the victim’s deep learning system, the attacker can inflict indiscriminate damage without system crashes. Lastly, motivated by the attacks, we discuss two potential directions of mitigation: restricting activation magnitudes and using low-precision numbers.

## Appendix

### A Network Architectures

We use 19 DNN models in our experiments: six architecture and their variants. Table 7 describes two architectures and their six variations for MNIST. For CIFAR10, we employ the base architecture from [55] that has four convolutional layers and a fully-connected layer, and we make three variations of it. CIFAR10-AlexNet<sup>11</sup> and CIFAR10-VGG16<sup>12</sup> are from the community. For ImageNet, we use the DNN architectures available from the Internet<sup>13</sup>. In Sec 6.2, we employ two networks (8-bit quantized<sup>14</sup> and binarized versions of MNIST-L5) from the community<sup>15</sup> with adjustments.

### B The Vulnerability Using Different Criterion

We examine the vulnerable parameter ratio (vulnerability) using the different RAD criterion with 15 DNN models. Our results are in Figure 12. Each figure describe the vulnerable parameter ratio on a specific RAD criterion; for instance, in MNIST-L5, the model has 40% of vulnerable parameters that cause [RAD > 0.5], which estimates the upper bound of the blind attacker. In MNIST, CIFAR10, and two ImageNet models, the vulnerability decreases as the attacker aims to inflict the severe damage; however, in ImageNet, ResNet50, DenseNet161, and InceptionV3 have almost the same vulnerability (~50%) with the high criterion [RAD > 0.8].

### C Hyper-parameters for Training

In our experiments, we use these hyper-parameters:

- **MNISTs.** For MNIST models, we use: SGD, 40 epochs, 0.01 learning rate (lr), 64 batch, 0.1 momentum, and adjust learning rate by 0.1, in every 10 epochs.
- **CIFAR10s.** For Base models we use: SGD, 50 epochs, 0.02 lr, 32 batch, 0.1 momentum, and adjust lr by 0.5, in every 10 epochs. For AlexNet, we use: 300 epochs,

## Abstract

Machine learning has become mainstream across industries. Numerous examples prove the validity of it for security applications. In this work, we investigate how to reverse engineer a neural network by using side-channel information such as timing and electromagnetic (EM) emanations. To this end, we consider multilayer perceptron and convolutional neural networks as the machine learning architectures of choice and assume a non-invasive and passive attacker capable of measuring those kinds of leakages.

We conduct all experiments on real data and commonly used neural network architectures in order to properly assess the applicability and extendability of those attacks. Practical results are shown on an ARM Cortex-M3 microcontroller, which is a platform often used in pervasive applications using neural networks such as wearables, surveillance cameras, etc. Our experiments show that a side-channel attacker is capable of obtaining the following information: the activation functions used in the architecture, the number of layers and neurons in the layers, the number of output classes, and weights in the neural network. Thus, the attacker can effectively reverse engineer the network using merely side-channel information such as timing or EM.

## 1 Introduction

Machine learning, and more recently deep learning, have become hard to ignore for research in distinct areas, such as image recognition [25], robotics [21], natural language processing [47], and also security [53, 26] mainly due to its unquestionable practicality and effectiveness. Ever increasing computational capabilities of the computers of today and huge amounts of data available are resulting in much more complex machine learning architectures than it was envisioned before. As an example, AlexNet architecture consisting of 8 layers was the best performing algorithm in image classification task ILSVRC2012 (<http://www.image-net.org/challenges/LSVRC/2012/>). In 2015, the best performing

architecture for the same task was ResNet consisting of 152 layers [15]. This trend is not expected to stagnate any time soon, so it is prime time to consider machine/deep learning from a novel perspective and in new use cases. Also, deep learning algorithms are gaining popularity in IoT edge devices such as sensors or actuators, as they are indispensable in many tasks, like image classification or speech recognition. As a consequence, there is an increasing interest in deploying neural networks on low-power processors found in always-on systems, e.g., ARM Cortex-M microcontrollers.

In this work, we focus on two neural network algorithms: multilayer perceptron (MLP) and convolutional neural networks (CNNs). We consider feed-forward neural networks and consequently, our analysis is conducted on such networks only.

With the increasing number of design strategies and elements to use, fine-tuning of hyper-parameters of those algorithms is emerging as one of the main challenges. When considering distinct industries, we are witnessing an increase in intellectual property (IP) models strategies. Basically, in cases when optimized networks are of commercial interest, their details are kept undisclosed. For example, EMVCo (formed by MasterCard and Visa to manage specifications for payment systems and to facilitate worldwide interoperability) nowadays requires deep learning techniques for security evaluations [43]. This has an obvious consequence in: 1) security labs generating (and using) neural networks for evaluation of security products and 2) they treat them as IP, exclusively for their customers.

There are also other reasons for keeping the neural network architectures secret. Often, these pre-trained models might provide additional information regarding the training data, which can be very sensitive. For example, if the model is trained based on a medical record of a patient [9], confidential information could be encoded into the network during the training phase. Also, machine learning models that are used for guiding medical treatments are often based on a patient's genotype making this extremely sensitive from the privacy perspective [10]. Even if we disregard privacy issues,

obtaining useful information from neural network architectures can help acquiring trade secrets from the competition, which could lead to competitive products without violating intellectual property rights [3]. Hence, determining the layout of the network with trained weights is a desirable target for the attacker. One could ask the following question: Why would an attacker want to reverse engineer the neural network architecture instead of just training the same network on its own? There are several reasons that are complicating this approach. First, the attacker might not have access to the same training set in order to train his own neural network. Although this is admittedly a valid point, recent work shows how to solve those limitations [49]. Second, as the architectures have become more complex, there are more and more parameters to tune and it could be extremely difficult for the attacker to pinpoint the same values for the parameters as in the architecture of interest.

After motivating our use case, the main question that remains is on the feasibility of reverse engineering such architectures. Physical access to a device could allow readily reverse engineering based on the binary analysis. However, in a confidential IP setting, standard protections like blocking binary readback, blocking JTAG access [20], code obfuscation, etc. are expected to be in place and preventing such attacks. Nevertheless, even when this is the case, a viable alternative is to exploit side-channel leakages.

Side-channel analysis attacks have been widely studied in the community of information security and cryptography, due to its potentially devastating impact on otherwise (theoretically) secure algorithms. Practically, the observation that various physical leakages such as timing delay, power consumption, and electromagnetic emanation (EM) become available during the computation with the (secret) data has led to a whole new research area. By statistically combining this physical observation of a specific internal state and hypothesis on the data being manipulated, it is possible to recover the intermediate state processed by the device.

In this study, our aim is to highlight the potential vulnerabilities of standard (perhaps still naive from the security perspective) implementations of neural networks. At the same time, we are unaware of any neural network implementation in the public domain that includes side-channel protection. For this reason, we do not just pinpoint to the problem but also suggest some protection measures for neural networks against side-channel attacks. Here, we start by considering some of the basic building blocks of neural networks: the number of hidden layers, the basic multiplication operation, and the activation functions.

For instance, the complex structure of the activation function often leads to conditional branching due to the necessary exponentiation and division operations. Conditional branching typically introduces input-dependent timing differences resulting in different timing behavior for different activation function, thus allowing the function identification. Also, we

notice that by observing side-channel leakage, it is possible to deduce the number of nodes and the number of layers in the networks.

In this work, we show it is possible to recover the layout of unknown networks by exploiting the side-channel information. Our approach does not need access to training data and allows for network recovery by feeding known random inputs to the network. By using the known divide-and-conquer approach for side-channel analysis, (i.e., the attacker's ability to work with a feasible number of hypotheses due to, e.g., the architectural specifics), the information at each layer could be recovered. Consequently, the recovered information can be used as input for recovering the subsequent layers.

We note that there exists somewhat parallel research to ours also on reverse engineering by "simply" observing the outputs of the network and training a substitute model. Yet, this task is not so simple since one needs to know what kind of architecture is used (e.g., convolutional neural network or multilayer perceptron, the number of layers, the activation functions, access to training data, etc.) while limiting the number of queries to ensure the approach is realistic [39]. Some more recent works have tried to overcome a few of the highlighted limitations [49, 18].

To our best knowledge, this kind of observation has never been used before in this context, at least not for leveraging on (power/EM) side-channel leakages with reverse engineering the neural networks architecture as the main goal. We position our results in the following sections in more detail. To summarize, our main motivation comes from the ever more pervasive use of neural networks in security-critical applications and the fact that the architectures are becoming proprietary knowledge for the security evaluation industry. Hence, reverse engineering a neural network has become a new target for the adversaries and we need a better understanding of the vulnerabilities to side-channel leakages in those cases to be able to protect the users' rights and data.

## 1.1 Related Work

There are many papers considering machine learning and more recently, deep learning for improving the effectiveness of side-channel attacks. For instance, a number of works have compared the effectiveness of classical profiled side-channel attacks, so-called template attacks, against various machine learning techniques [30, 19]. Lately, several works explored the power of deep learning in the context of side-channel analysis [32]. However, this line of work is using machine learning to derive a new side-channel distinguisher, i.e., the selection function leading to the key recovery.

On the other hand, using side-channel analysis to attack machine learning architectures has been much less investigated. Shokri et al. investigate the leakage of sensitive information from machine learning models about individual

data records on which they were trained [44]. They show that such models are vulnerable to membership inference attacks and they also evaluate some mitigation strategies. Song et al. show how a machine learning model from a malicious machine learning provider can be used to obtain information about the training set of a model [45]. Hua et al. were first to reverse engineer two convolutional neural networks, namely AlexNet and SqueezeNet through memory and timing side-channel leaks [17]. The authors measure side-channel through an artificially introduced hardware trojan. They also need access to the original training data set for the attack, which might not always be available. Lastly, in order to obtain the weights of neural networks, they attack a very specific operation, i.e., zero pruning [40]. Wei et al. have also performed an attack on an FPGA-based convolutional neural network accelerator [52]. They recovered the input image from the collected power consumption traces. The proposed attack exploits a specific design choice, i.e., the line buffer in a convolution layer of a CNN.

In a nutshell, both previous reverse engineering efforts using side-channel information were performed on very special designs of neural networks and the attacks had very specific and different goals. Our work is more generic than those two as it assumes just a passive adversary able to measure physical leakages and our strategy remains valid for a range of architectures and devices. Although we show the results on the chips that were depackaged prior to experiments in order to demonstrate the leakage available to powerful adversaries, our findings remain valid even without depackaging. Basically, having EM as an available source of side-channel leakage, it comes down to using properly designed antennas and more advanced setups, which is beyond the scope of this work.

Several other works doing somewhat related research are given as follows. Ohrimenko et al. used a secure implementation of MapReduce jobs and analyzed intermediate traffic between reducers and mappers [37]. They showed how an adversary observing the runs of typical jobs can infer precise information about the inputs. In a follow-up work they discuss how machine learning algorithms can be exploited by various side-channels [38]. Consequently, they propose data-oblivious machine learning algorithms that prevent exploitation of side channels induced by memory, disk, and network accesses. They note that side-channel attacks based on power and timing leakages are out of the scope of their work. Xu et al. introduced controlled-channel attacks, which is a type of side-channel attack allowing an untrusted operating system to extract large amounts of sensitive information from protected applications [54]. Wang and Gong investigated both theoretically and experimentally how to steal hyper-parameters of machine learning algorithms [51]. In order to mount the attack in practice, they estimate the error between the true hyper-parameter and the estimated one.

In this work, we further explore the problem of reverse en-

gineering of neural networks from a more generic perspective. The closest previous works to ours have reverse engineered neural networks by using cache attacks that work on distinct CPUs and are basically micro-architectural attacks (albeit using timing side-channel). Our approach utilizes EM side-channel on small embedded devices and it is supported by practical results obtained on a real-world architecture. Finally, our attack is able to recover both the hyper-parameters (parameter external to the model, e.g., the number of layers) and parameters (parameter internal to the model, like weights) of neural networks.

## 1.2 Contribution and Organization

The main contributions of this paper are:

1. We describe full reverse engineering of neural network parameters based on side-channel analysis. We are able to recover the key parameters such as activation function, pre-trained weights, number of hidden layers and neurons in each layer. The proposed technique does not need any information on the (sensitive) training data as that information is often not even available to the attacker. We emphasize that, for our attack to work, we require the knowledge of some inputs/outputs and side-channel measurements, which is a standard assumption for side-channel attacks.
2. All the proposed attacks are practically implemented and demonstrated on two distinct microcontrollers (i.e., 8-bit AVR and 32-bit ARM).
3. We highlight some interesting aspects of side-channel attacks when dealing with real numbers, unlike in everyday cryptography. For example, we show that even a side-channel attack that failed can provide sensitive information about the target due to the precision error.
4. Finally, we propose a number of mitigation techniques rendering the attacks more difficult.

We emphasize that the simplicity of our attack is its strongest point, as it minimizes the assumption on the adversary (no pre-processing, chosen-plaintext messages, etc.)

## 2 Background

In this section, we give details about artificial neural networks we consider in this paper and their building blocks. Next, we discuss the concepts of side-channel analysis and several types of attacks we use in this paper.

### 2.1 Artificial Neural Networks

Artificial neural networks (ANNs) is an umbrella notion for all computer systems loosely inspired by biological neural networks. Such systems are able to “learn” from examples, which makes them a strong (and very popular) paradigm in

the machine learning domain. Any ANN is built from a number of nodes called artificial neurons. The nodes are connected in order to transmit a signal. Usually, in an ANN, the signal at the connection between artificial neurons is a real number and the output of each neuron is calculated as a nonlinear function of the sum of its inputs. Neurons and connections have weights that are adjusted as the learning progresses. Those weights are used to increase or decrease the strength of a signal at a connection. In the rest of this paper, we use the notions of an artificial neural network, neural network, and network interchangeably.

### 2.1.1 Multilayer Perceptron

A very simple type of a neural network is called perceptron. A perceptron is a linear binary classifier applied to the feature vector as a function that decides whether or not an input belongs to some specific class. Each vector component has an associated weight  $w_i$  and each perceptron has a threshold value  $\theta$ . The output of a perceptron equals “1” if the direct sum between the feature vector and the weight vector is larger than zero and “-1” otherwise. A perceptron classifier works only for data that are linearly separable, i.e., if there is some hyperplane that separates all the positive points from all the negative points [34].

By adding more layers to a perceptron, we obtain a multilayer perceptron algorithm. Multilayer perceptron (MLP) is a feed-forward neural network that maps sets of inputs onto sets of appropriate outputs. It consists of multiple layers of nodes in a directed graph, where each layer is fully connected to the next one. Consequently, each node in one layer connects with a certain weight  $w$  to every node in the following layer. Multilayer perceptron algorithm consists of at least three layers: one input layer, one output layer, and one hidden layer. Those layers must consist of nonlinearly activating nodes [7]. We depict a model of a multilayer perceptron in Figure 1. Note, if there is more than one hidden layer, then it can be considered a deep learning architecture. Differing from linear perceptron, MLP can distinguish data that are not linearly separable. To train the network, the backpropagation algorithm is used, which is a generalization of the least mean squares algorithm in the linear perceptron. Backpropagation is used by the gradient descent optimization algorithm to adjust the weight of neurons by calculating the gradient of the loss function [34].

### 2.1.2 Convolutional Neural Network

CNNs represent a type of neural networks which were first designed for 2-dimensional convolutions as it was inspired by the biological processes of animals’ visual cortex [28]. From the operational perspective, CNNs are similar to ordinary neural networks (e.g., multilayer perceptron): they consist of a number of layers where each layer is made up of

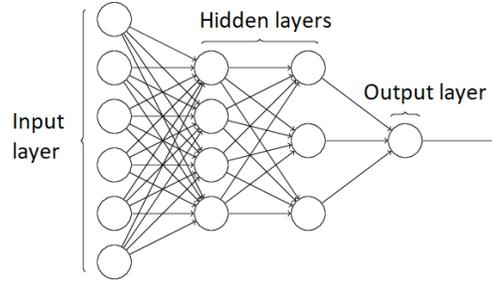

Figure 1: Multilayer perceptron.

neurons. CNNs use three main types of layers: convolutional layers, pooling layers, and fully-connected layers. Convolutional layers are linear layers that share weights across space. Pooling layers are non-linear layers that reduce the spatial size in order to limit the number of neurons. Fully-connected layers are layers where every neuron is connected with all the neurons in the neighborhood layer. For additional information about CNNs, we refer interested readers to [12].

### 2.1.3 Activation Functions

An activation function of a node is a function  $f$  defining the output of a node given an input or set of inputs, see Eq. (1). To enable calculations of nontrivial functions for ANN using a small number of nodes, one needs nonlinear activation functions as follows.

$$y = \text{Activation}(\sum(\text{weight} \cdot \text{input}) + \text{bias}). \quad (1)$$

In this paper, we consider the logistic (sigmoid) function, tanh function, softmax function, and Rectified Linear Unit (ReLU) function. The logistic function is a nonlinear function giving smooth and continuously differentiable results [14]. The range of a logistic function is  $[0, 1]$ , which means that all the values going to the next neuron will have the same sign.

$$f(x) = \frac{1}{1 + e^{-x}}. \quad (2)$$

The tanh function is a scaled version of the logistic function where the main difference is that it is symmetric over the origin. The tanh function ranges in  $[-1, 1]$ .

$$f(x) = \tanh(x) = \frac{2}{1 + e^{-2x}} - 1. \quad (3)$$

The softmax function is a type of sigmoid function able to map values into multiple outputs (e.g., classes). The softmax function is ideally used in the output layer of the classifier in order to obtain the probabilities defining a class for each input [5]. To denote a vector, we represent it in bold style.

$$f(\mathbf{x})_j = \frac{e^{x_j}}{\sum_{k=1}^K e^{x_k}}, \text{ for } j = 1, \dots, K. \quad (4)$$

The Rectified Linear Unit (ReLU) is a nonlinear function that is differing from the previous two activation functions as it does not activate all the neurons at the same time [35]. By activating only a subset of neurons at any time, we make the network sparse and easier to compute [2]. Consequently, such properties make ReLU probably the most widely used activation function in ANNs today.

$$f(x) = \max(0, x). \quad (5)$$

## 2.2 Side-channel Analysis

Side-channel Analysis (SCA) exploits weaknesses on the implementation level [33]. More specifically, all computations running on a certain platform result in unintentional physical leakages as a sort of physical signatures from the reaction time, power consumption, and Electromagnetic (EM) emanations released while the device is manipulating data. SCA exploits those physical signatures aiming at the key (secret data) recovery. In its basic form, SCA was proposed to perform key recovery attacks on the implementation of cryptography [23, 22]. One advantage of SCA over traditional cryptanalysis is that SCA can apply a divide-and-conquer approach. This means that SCA is typically recovering small parts of the key (sub-keys) one by one, which is reducing the attack complexity.

Based on the analysis technique used, different variants of SCA are known. In the following, we recall a few techniques used later in the paper. Although the original terms suggest power consumption as the source of leakage, the techniques apply to other side channels as well. In particular, in this work, we are using the EM side channel and the corresponding terms are adapted to reflect this.

**Simple Power (or Electromagnetic) Analysis (SPA or SEMA).** Simple power (or EM) analysis, as the name suggests, is the most basic form of SCA [22]. It targets information from the sensitive computation that can be recovered from a single or a few traces. As a common example, SPA can be used against a straightforward implementation of the RSA algorithm to distinguish square from multiply operation, leading to the key recovery. In this work, we apply SPA, or actually SEMA to reverse engineer the architecture of the neural network.

**Differential Power (or Electromagnetic) Analysis (DPA or DEMA).** DPA or DEMA is an advanced form of SCA, which applies statistical techniques to recover secret information from physical signatures. The attack normally tests for dependencies between actual physical signature (or measurements) and hypothetical physical signature, i.e., predictions on intermediate data. The hypothetical signature is based on a leakage model and key hypothesis. Small parts of the secret key (e.g., one byte) can be tested independently. The knowledge of the leakage model comes from the adversary's intuition and expertise. Some commonly used leakage

models for representative devices are the Hamming weight for microcontrollers and the Hamming distance in FPGA, ASIC, and GPU [4, 31] platforms. As the measurements can be noisy, the adversary often needs many measurements, sometimes millions. Next, statistical tests like correlation [6] are applied to distinguish the correct key hypothesis from other wrong guesses. In the following, DPA (DEMA) is used to recover secret weights from a pre-trained network.

## 3 Side-channel Based Reverse Engineering of Neural Networks

In this section, we discuss the threat model we use, the experimental setup and reverse engineering of various elements of neural networks.

### 3.1 Threat Model

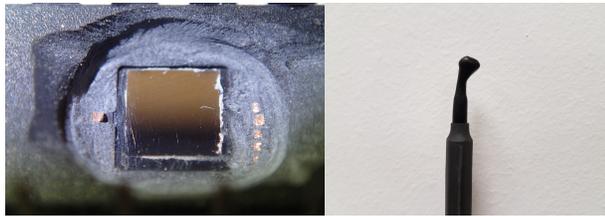

The main goal of this work is to recover the neural network architecture using only side-channel information.

**Scenario.** We select to work with MLP and CNNs since: 1) they are commonly used machine learning algorithms in modern applications, see e.g., [16, 11, 36, 48, 25, 21]; 2) they consist of different types of layers that are also occurring in other architectures like recurrent neural networks; and 3) in the case of MLP, the layers are all identical, which makes it more difficult for SCA and could be consequently considered as the worst-case scenario.

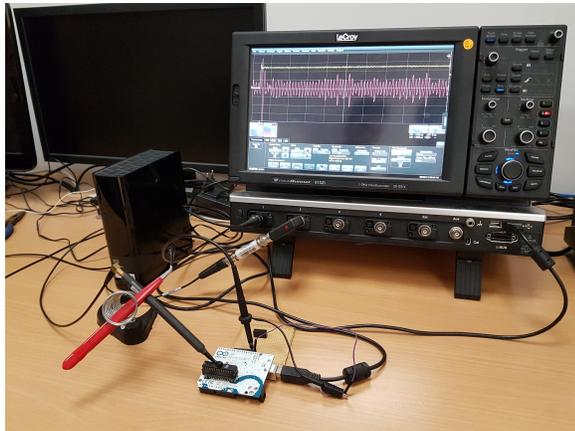

We choose our attack to be as generic as possible. For instance, we have no assumption on the type of inputs or its source, as we work with real numbers. If the inputs are in the form of integers (like the MNIST database), the attack becomes easier, since we would not need to recover mantissa bytes and deal with precision. We also assume that the implementation of the machine learning algorithm does not include any side-channel countermeasures.

**Attacker's capability.** The attacker in consideration is a passive one. This implies him/her acquiring measurements of the device while operating "normally" and not interfering with its internal operations by evoking faulty computations and behavior by e.g., glitching the device, etc. More in details, we consider the following setting:

1. **Attacker does not know the architecture of the used network but can feed random (and hence known) inputs to the architecture. We note that the attacks and analysis presented in our work do not rely on any assumptions on the distributions of the inputs, although a common assumption in SCA is that they are chosen uniformly at random.** Basically, we assume that the attacker has physical access to the device (can be remote, via EM signals) and he/she knows that the device runs some neural net. The attacker only controls the execution of it through selecting the inputs, but

(a) Target 8-bit microcontroller mechanically decapsulated (b) Langer RF-U 5-2 Near Field Electromagnetic passive Probe

(c) The complete measurement setup

Figure 2: Experimental Setup

he/she can observe the outputs and side-channel information (but not individual intermediate values). The attack scenario is often referred to as *known-plaintext attack*. An adequate use case would be when the attacker legally acquires a copy of the network with API access to it and aims at recovering its internal details e.g. for IP theft.

2. **Attacker is capable of measuring side-channel information leaked from the implementation of the targeted architecture.** The attacker can collect multiple side-channel measurements while processing the data and use different side-channel techniques for her analysis. In this work, we focus on timing and EM side channels.

### 3.2 Experimental Setup

Here we describe the attack methodology, which is first validated on Atmel ATmega328P. Later, we also demonstrate the proposed methodology on ARM Cortex-M3.

The side-channel activity is captured using the Lecroy WaveRunner 610zi oscilloscope. For each known input, the attacker gets one measurement (or trace) from the oscilloscope. In the following, nr. of inputs or nr. of traces are used interchangeably. Each measurement is composed of

many samples (or points). The number of samples (or length of the trace) depends on sampling frequency and execution time. As shown later, depending on the target, nr. of samples can vary from thousands (for multiplication) to millions (for a whole CNN network). The measurements are synchronized with the operations by common handshaking signals like start and stop of computation. To further improve the quality of measurements, we opened the chip package mechanically (see Figure 2a). An RF-U 5-2 near-field electromagnetic (EM) probe from Langer is used to collect the EM measurements (see Figure 2b). The setup is depicted in Figure 2c. We use the probe as an antenna for spying on the EM side-channel leakage from the underlying processor running ML. Note that EM measurements also allow to observe the timing of all the operations and thus the setup allows for timing side-channels analysis as well. Our choice of the target platform is motivated by the following considerations:

- Atmel ATmega328P: This processor typically allows for high quality measurements. We are able to achieve a high signal-to-noise ratio (SNR) measurements, making this a perfect tuning phase to develop the methodology of our attacks.
- ARM Cortex-M3: This is a modern 32-bit microcontroller architecture featuring multiple stages of the pipeline, on-chip co-processors, low SNR measurements, and wide application. We show that the developed methodology is indeed versatile across targets with a relevant update of measurement capability.

In addition, real-world use cases also justify our platforms of choice. Similar micro-controllers are often used in wearables like Fitbit (ARM Cortex-M4), several hardware crypto wallets, smart home devices, etc. Additionally, SCA on a GPU or an FPGA platform is practically demonstrated in several instances, thus our methodology can be directly adapted for those cases as well. For different platforms, the leakage model could change, but this would not limit our approach and methodology. In fact, adequate leakage models are known for platforms like FPGA [4] and GPU [31]. Moreover, as for ARM Cortex-M3, low SNR of the measurement might force the adversary to increase the number of measurements and apply signal pre-processing techniques, but the main principles behind the analysis remain valid.

As already stated above, the exploited leakage model of the target device is the Hamming weight (HW) model. A microcontroller loads sensitive data to a data bus to perform indicated instructions. This data bus is pre-charged to all '0's' before every instruction. Note that data bus being pre-charged is a natural behavior of microcontrollers and not a vulnerability introduced by the attacker. Thus, the power consumption (or EM radiation) assigned to the value of the data being loaded is modeled as the number of bits equal to '1'. In other words, the power consumption of loading data

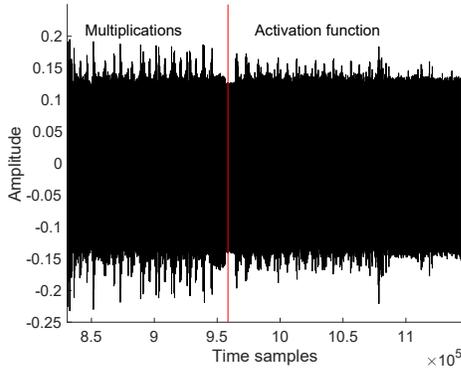

Figure 3: Observing pattern and timing of multiplication and activation function

$x$  is:

$$HW(x) = \sum_{i=1}^n x_i, \quad (6)$$

where  $x_i$  represents the  $i^{th}$  bit of  $x$ . In our case, it is the secret pre-trained weight which is regularly loaded from memory for processing and results in the HW leakage. To conduct the side-channel analysis, we perform the divide-and-conquer approach, where we target each operation separately. The full recovery process is described in Section 3.6.

Several pre-trained networks are implemented on the board. The training phase is conducted offline, and the trained network is then implemented in C language and compiled on the microcontroller. In these experiments, we consider multilayer perceptron architectures consisting of a different number of layers and nodes in those layers. Note that, with our approach, there is no limit in the number of layers or nodes we can attack, as the attack scales linearly with the size of the network. The methodology is developed to demonstrate that the key parameters of the network, namely the weights and activation functions can be reverse engineered. Further experiments are conducted on deep neural networks with three hidden layers but the method remains valid for larger networks as well.

### 3.3 Reverse Engineering the Activation Function

We remind the reader that nonlinear activation functions are necessary in order to represent nonlinear functions with a small number of nodes in a network. As such, they are elements used in virtually any neural network architecture today [25, 15]. If the attacker is able to deduce the information on the type of used activation functions, he/she can use that knowledge together with information about input values to deduce the behavior of the whole network.

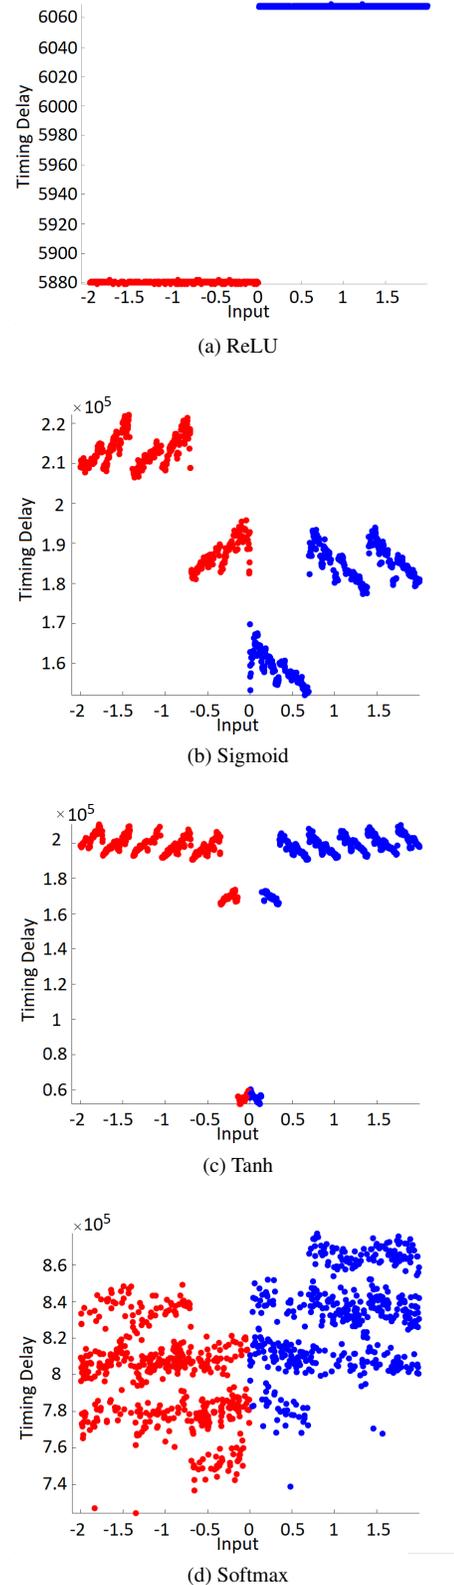

Figure 4: Timing behavior for different activation functions

Table 1: Minimum, Maximum, and Mean computation time (in ns) for different activation functions

Activation Function	Minimum	Maximum	Mean
ReLU	5 879	6 069	5 975
Sigmoid	152 155	222 102	189 144
Tanh	51 909	210 663	184 864
Softmax	724 366	877 194	813 712

We analyze the side-channel leakage from different activation functions. We consider the most commonly used activation functions, namely ReLU, sigmoid, tanh, and softmax [14, 35]. The timing behavior can be observed directly on the EM trace. For instance, as shown later in Figure 8a, a multiplication is followed by activation with individual signatures. For a similar architecture, we test different variants with each activation function. We collect EM traces and measure the timing of the activation function computation from the measurements. The measurements are taken when the network is processing random inputs in the range, i.e.,  $x \in \{-2, 2\}$ . A total of 2000 EM measurements are captured for each activation function. As shown in Figure 3, the timing behavior of the four tested activation functions have distinct signatures allowing easy characterization.

Different inputs result in different processing times. Moreover, the timing behavior for the same inputs largely varies depending on the activation function. For example, we can observe that ReLU will require the shortest amount of time, due to its simplicity (see Figure 4a). On the other hand, tanh and sigmoid might have similar timing delays, but with different pattern considering the input (see Figure 4b and Figure 4b), where tanh is more symmetric in pattern compared to sigmoid, for both positive and negative inputs. We can observe that softmax function will require most of the processing time, since it requires the exponentiation operation which also depends on the number of neurons in the output layer. As neural network algorithms are often optimized for performance, the presence of such timing side-channels is often ignored. A function such as tanh or sigmoid requires computation of  $e^x$  and division and it is known that such functions are difficult to implement in constant time. In addition, constant time implementations might lead to substantial performance degradation. Other activation functions can be characterized similarly. Table 1 presents the minimum, maximum, and mean computation time for each activation function over 2000 captured measurements. While ReLU is the fastest one, the timing difference for other functions stands out sufficiently, to allow for a straightforward recovery. To distinguish them, one can also do some pattern matching to determine which type of function is used, if necessary. Note, although Sigmoid and Tanh have similar Maximum and mean values, the Minimum value differs significantly. Moreover, the attacker can sometimes pre-characterize (or

profile) the timing behavior of the target activation function independently for better precision, especially when common libraries are used for standard functions like multiplication, activation function, etc.

### 3.4 Reverse Engineering the Multiplication Operation

A well-trained network can be of significant value. Main distinguishing factors for a well trained network against a poorly trained one, for a given architecture, are the weights. With fine-tuned weights, we can improve the accuracy of the network. In the following, we demonstrate a way to recover those weights by using SCA.

For the recovery of the weights, we use the Correlation Power Analysis (CPA) i.e., a variant of DPA using the Pearson’s correlation as a statistical test.<sup>1</sup> CPA targets the multiplication  $m = x \cdot w$  of a known input  $x$  with a secret weight  $w$ . Using the HW model, the adversary correlates the activity of the predicted output  $m$  for all hypothesis of the weight. Thus, the attack computes  $\rho(t, w)$ , for all hypothesis of the weight  $w$ , where  $\rho$  is the Pearson correlation coefficient and  $t$  is the side-channel measurement. The correct value of the weight  $w$  will result in a higher correlation standing out from all other wrong hypotheses  $w^*$ , given enough measurements. Although the attack concept is the same as when attacking cryptographic algorithms, the actual attack used here is quite different. Namely, while cryptographic operations are always performed on fixed length integers, in ANN we are dealing with real numbers.

We start by analyzing the way the compiler is handling floating-point operations for our target. The generated assembly is shown in Table 2, which confirms the usage of IEEE 754 compatible representation as stated above. The knowledge of the representation allows one to better estimate the leakage behavior. Since the target device is an 8-bit microcontroller, the representation follows a 32-bit pattern ( $b_{31} \dots b_0$ ), being stored in 4 registers. The 32-bit consist of: 1 sign bit ( $b_{31}$ ), 8 biased exponent bits ( $b_{30} \dots b_{23}$ ) and 23 mantissa (fractional) bits ( $b_{22} \dots b_0$ ). It can be formulated as:

$$(-1)^{b_{31}} \times 2^{(b_{30} \dots b_{23})_2 - 127} \times (1.b_{22} \dots b_0)_2.$$

For example, the value 2.43 can be expressed as  $(-1)^0 \times 2^{(1000000)_2 - 127} \times (1.00110111000010100011111)_2$ . The measurement  $t$  is considered when the computed result  $m$  is stored back to the memory, leaking in the HW model i.e.,  $HW(m)$ . Since 32-bit  $m$  is split into individual 8-bits, each byte of  $m$  is recovered individually. Hence, by recovering this representation, it is enough to recover the estimation of the real number value.

To implement the attack two different approaches can be considered. The first approach is to build the hypothesis on

<sup>1</sup> It is called CEMA in case of EM side channel.

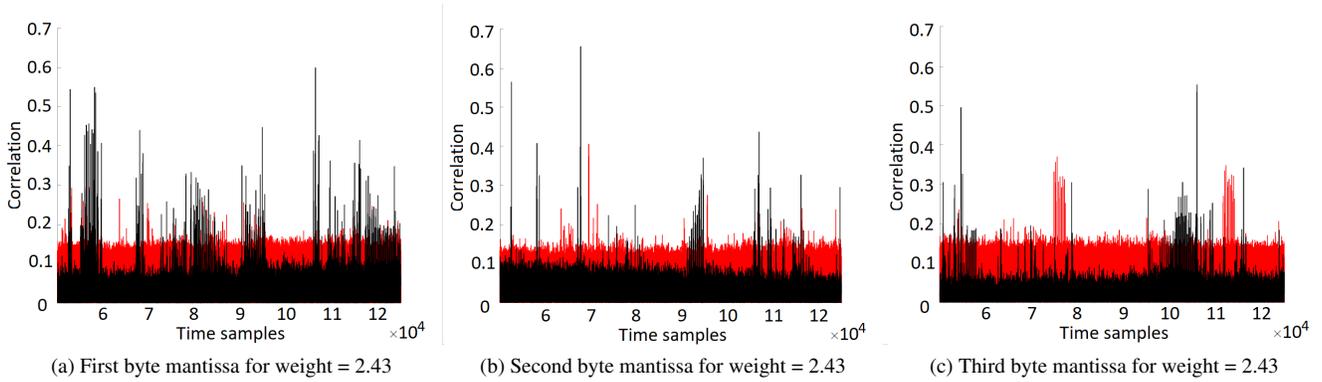

Figure 5: Correlation of different weights candidate on multiplication operation

Table 2: Code snippet of the returned assembly for multiplication:  $x = x \cdot w$  ( $w = 2.36$  or  $0x3D0A1740$  in IEEE 754 representation). The multiplication itself is not shown here, but from the registers assignment, our leakage model assumption holds.

the weight directly. For this experiment, we target the result of the multiplication  $m$  of known input values  $x$  and unknown weight  $w$ . For every input, we assume different possibilities for weight values. We then perform the multiplication and estimate the IEEE 754 binary representation of the output. To deal with the growing number of possible candidates for the unknown weight  $w$ , we assume that the weight will be bounded in a range  $[-N, N]$ , where  $N$  is a parameter chosen by the adversary, and the size of possible candidates is denoted as  $s = 2N/p$ , where  $p$  is the precision when dealing with floating-point numbers.

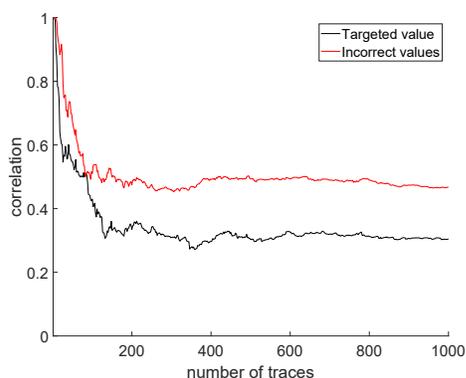

Then, we perform the recovery of the 23-bit mantissa of the weight. The sign and exponent could be recovered separately. Thus, we are observing the leakage of 3 registers, and based on the best CPA results for each register, we can reconstruct the mantissa. Note that the recovered mantissa does not directly relate to the weight, but with the recovery of the

sign and exponent, we could obtain the unique weight value. The traces are measured when the microcontroller performs secret weight multiplication with uniformly random values between -1 and 1 ( $x \in \{-1, 1\}$ ) to emulate normalized input values. We set  $N = 5$  and to reduce the number of possible candidates, we assume that each floating-point value will have a precision of 2 decimal points,  $p = 0.01$ . Since we are dealing with mantissa only, we can then only check the weight candidates in the range  $[0, N]$ , thus reducing the number of possible candidates. We note here that this range  $[-5, 5]$  is based on the previous experiments with MLP. Although, in the later phase of the experiment, we targeted the floating point and fixed-point representation ( $2^{32}$  in the worst case scenario on a 32-bit microcontroller, but could be less if the value is for example normalized), instead of the real value, which could in principle cover all possible floating values.

In Figure 5, we show the result of the correlation for each byte with the measured traces. The horizontal axis shows the time of execution and vertical axis correlation. The experiments were conducted on 1 000 traces for each case. In the figure, the black plot denotes the correlation of the “correct” mantissa weight ( $|m(\hat{w}) - m(w)| < 0.01$ ), whereas the red plots are from all other weight candidates in the range described earlier. Since we are only attacking mantissa in this phase, several weight candidates might have similar correlation peaks. After the recovery of the mantissa, the sign bit and exponent can be recovered similarly, which narrows down the list candidate to a unique weight. Another observation is that the correlation value is not very high and scattered across different clock cycles. This is due to the reason that the measurements are noisy and since the operation is not constant-time, the interesting time samples are distributed across multiple clock cycles. Nevertheless, it is shown that the side-channel leakage can be exploited to recover the weight up to certain precision. Multivariate side channel analysis [42] can be considered if distributed samples hinder recovery.

(a) weight = 1.635

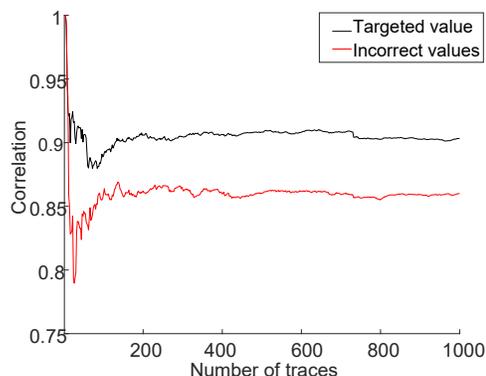

(b) weight = 0.890

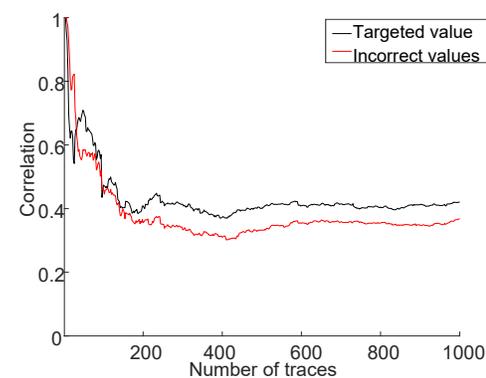

Figure 6: Correlation comparison between the correct and incorrect mantissa of the weights. (a) Correct mantissa can be recovered (correct values/black line has a higher value compared to max incorrect values/red line). (b) A special case where the incorrect value of mantissa has a higher correlation, recovering 0.896025 (1100100000..00) instead of 0.89 (1100011110...10), still within precision error limits resulting in attack success

We emphasize that attacking real numbers as in the case of weights of ANN can be easier than attacking cryptographic implementations. This is because cryptography typically works on fixed-length integers and exact values must be recovered. When attacking real numbers, small precision errors due to rounding off the intermediate values still result in useful information.

To deal with more precise values, we can target the mantissa multiplication operation directly. In this case, the search space can either be  $[0, 2^{23} - 1]$  to cover all possible values for the mantissa (hence, more computational resources will be required) or we can focus only on the most significant bits of the mantissa (lesser candidates but also with lesser precision). Since the 7 most significant bits of the mantissa are processed in the same register, we can aim to tar-

(a) First byte recovery (sign and 7-bit exponent)

(b) Second byte recovery (lsb exponent and mantissa)

Figure 7: Recovery of the weight

get only those bits, assigning the rest to 0. Thus, our search space is now  $[0, 2^7 - 1]$ . The mantissa multiplication can be performed as  $1.mantissa_x \times 1.mantissa_w$ , then taking the 23 most significant bits after the leading 1, and normalization (updating the exponent if the result overflows) if necessary.

In Figure 6, we show the result of the correlation between the HW of the first 7-bit mantissa of the weight with the traces. Except for Figure 6b, the other results show that the correct mantissa can be recovered. Although the correlation is not increasing, it is important that the difference becomes stable after a sufficient amount of traces is used and eventually distinguishing correct weight from wrong weight hypotheses. The most interesting result is shown in Figure 6b, which at first glance looks like a failure of the attack. Here, the target value of the mantissa is **1100011110...10**, while the attack recovers **1100100000..00**. Considering the sign and exponents, the attack recovers 0.890625 instead of 0.89, i.e., a precision error at 4<sup>th</sup> place after decimal point. Thus, in both cases, we have shown that we can recover the weights from the SCA leakage.

In Figure 7, we show the composite recovery of 2 bytes of the weight representation i.e., a low precision setting where

we recover sign, exponent, and most significant part of mantissa. Again, the targeted (correct) weight can be easily distinguished from the other candidates. Hence, once all the necessary information has been recovered, the weight can be reconstructed accordingly.

### 3.5 Reverse Engineering the Number of Neurons and Layers

After the recovery of the weights and the activation functions, now we use SCA to determine the structure of the network. Mainly, we are interested to see if we can recover the number of hidden layers and the number of neurons for each layer. To perform the reverse engineering of the network structure, we first use SPA (SEMA). SPA is the simplest form of SCA which allows information recovery in a single (or a few) traces with methods as simple as a visual inspection. The analysis is performed on three networks with different layouts.

The first analyzed network is an MLP with one hidden layer with 6 neurons. The EM trace corresponding to the processing of a randomly chosen input is shown in Figure 8a. By looking at the EM trace, the number of neurons can be easily counted. The observability arises from the fact that multiplication operation and the activation function (in this case, it is the Sigmoid function) have completely different leakage signatures. Similarly, the structures of deeper networks are also shown in Figure 8b and Figure 8c. The recovery of output layer then provides information on the number of output classes. However, distinguishing different layers might be difficult, since the leakage pattern is only dependent on multiplication and activation function, which are usually present in most of the layers. We observe minor features allowing identification of layer boundaries but only with low confidence. Hence, we develop a different approach based on CPA to identify layer boundaries.

The experiments follow a similar methodology as in the previous experiments. To determine if the targeted neuron is in the same layer as previously attacked neurons, or in the next layer, we perform a weight recovery using two sets of data.

Let us assume that we are targeting the first hidden layer (the same approach can be done on different layers as well). Assume that the input is a vector of length  $N_0$ , so the input  $x$  can be represented  $x = \{x_1, \dots, x_{N_0}\}$ . For the targeted neuron  $y_n$  in the hidden layer, perform the weight recovery on 2 different hypotheses. For the first hypothesis, assume that the  $y_n$  is in the first hidden layer. Perform weight recovery individually using  $x_i$ , for  $1 \leq i \leq N_0$ . For the second hypothesis, assume that  $y_n$  is in the next hidden layer (the second hidden layer). Perform weight recovery individually using  $y_i$ , for  $1 \leq i \leq (n - i)$ . For each hypothesis, record the maximum (absolute) correlation value, and compare both. Since the correlation depends on both inputs to the multi-

plication operation, the incorrect hypothesis will result in a lower correlation value. Thus, this can be used to identify layer boundaries.

### 3.6 Recovery of the Full Network Layout

The combination of previously developed individual techniques can thereafter result in full reverse engineering of the network. The full network recovery is performed layer by layer, and for each layer, the weights for each neuron have to be recovered one at a time. Let us consider a network consisting of  $N$  layers,  $L_0, L_1, \dots, L_{N-1}$ , with  $L_0$  being the input layer and  $L_{N-1}$  being the output layer. Reverse engineering is performed with the following steps:

1. The first step is to recover the weight  $w_{L_0}$  of each connection from the input layer ( $L_0$ ) and the first hidden layer ( $L_1$ ). Since the dimension of the input layer is known, the CPA/CEMA can be performed  $n_{L_0}$  times (the size of  $L_0$ ). The correlation is computed for  $2^d$  hypotheses ( $d$  is the number of bits in IEEE 754 representation, normally it is 32 bits, but to simplify, 16 bits can be used with lesser precision for the mantissa). After the weights have been recovered, the output of the sum of multiplication can be calculated. This information provides us with input to the activation function.
2. In order to determine the output of the sum of the multiplications, the number of neurons in the layer must be known. This can be recovered by the combination of SPA/SEMA and DPA/DEMA technique described in the previous subsection (2 times CPA for each weight candidate  $w$ , so in total  $2n_{L_0}2^d$  CPA required), in parallel with the weight recovery. When all the weights of the first hidden layer are recovered, the following steps are executed.
3. Using the same set of traces, timing patterns for different inputs to the activation function can be built, similar to Figure 4. Timing patterns or average timing can then be compared with the profile of each function to determine the activation function (a comparison can be based on simple statistical tools like correlation, distance metric, etc). Afterward, the output of the activation function can be computed, which provides the input to the next layer.
4. The same steps are repeated in the subsequent layers ( $L_1, \dots, L_{N-1}$ , so in total at most  $2Nn_L2^d$ , where  $n_L$  is  $\max(n_{L_0}, \dots, n_{L_{N-1}})$ ) until the structure of the full network is recovered.

The whole procedure is depicted in Figure 9. In general, it can be seen that the attack scales linearly with the size of the network. Moreover, the same set of traces can be reused for various steps of the attack and attacking different layers, thus reducing measurement effort.

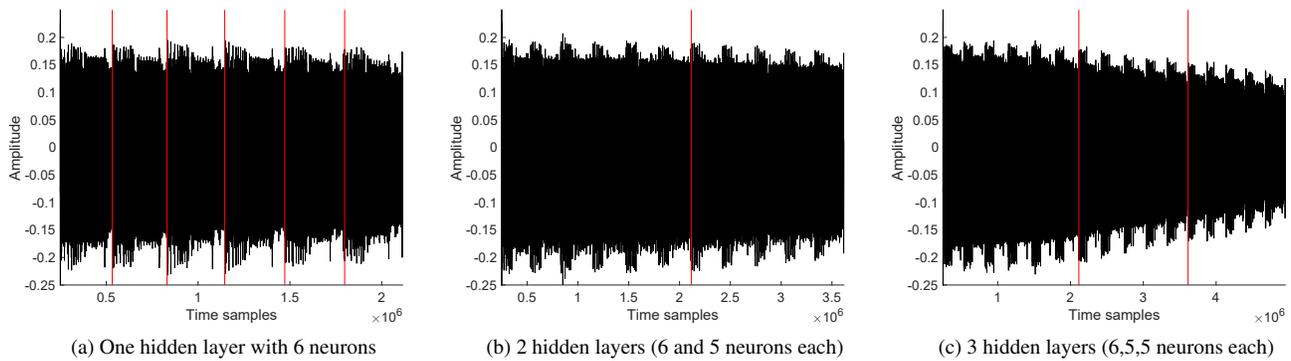

Figure 8: SEMA on hidden layers

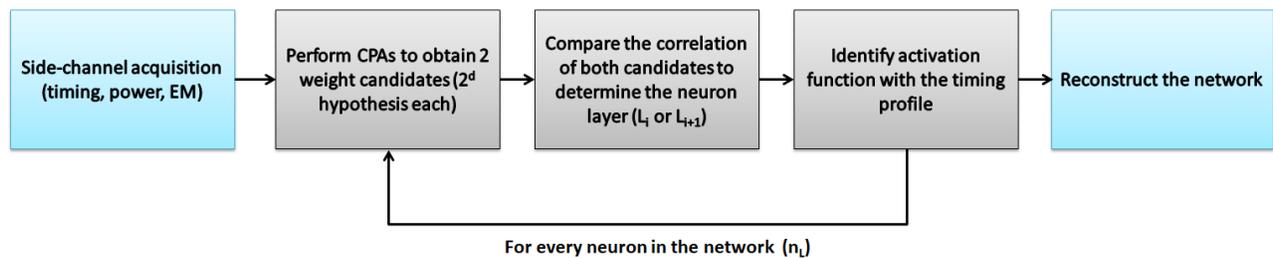

Figure 9: Methodology to reverse engineer the target neural network

## 4 Experiments with ARM Cortex-M3

In the previous section, we propose a methodology to reverse engineer sensitive parameters of a neural network, which we practically validated on an 8-bit AVR (Atmel ATmega328P). In this section, we extend the presented attack on a 32-bit ARM microcontroller. ARM microcontrollers form a fair share of the current market with huge dominance in mobile applications, but also seeing rapid adoption in markets like IoT, automotive, virtual and augmented reality, etc. Our target platform is the widely available *Arduino due* development board which contains an *Atmel SAM3X8E ARM Cortex-M3* CPU with a 3-stage pipeline, operating at 84 MHz. The measurement setup is similar to previous experiments (Lecroy WaveRunner 610zi oscilloscope and RF-U 5-2 near-field EM probe from Langer). The point of measurements was determined by a benchmarking code running AES encryption. After capturing the measurements for the target neural network, one can perform reverse engineering. Note that ARM Cortex-M3 (as well as M4 and M7) have support for deep learning in the form of CMSIS-NN implementation [27].

The timing behavior of various activation functions is shown in Figure 10. The results, though different from previous experiments on AVR, have unique timing signatures, allowing identification of each activation function. Here, sigmoid and tanh activation functions have similar minimal

computation time but the average and maximum values are higher for tanh function. To distinguish, one can obtain multiple inputs to the function, build patterns and do pattern matching to determine which type of function is used. The activity of a single neuron is shown in Figure 11a, which uses sigmoid as an activation function (the multiplication operation is shown separated by a vertical red line).

A known input attack is mounted on the multiplication to recover the secret weight. One practical consideration in attacking multiplication is that different compilers will compile it differently for different targets. Modern microcontrollers also have dedicated floating point units for handling operations like multiplication of real numbers. To avoid the discrepancy of the difference of multiplication operation, we target the output of multiplication. In other words, we target the point when multiplication operation with secret weight is completed and the resultant product is updated in general purpose registers or memory. Figure 11b shows the success of attack recovering secret weight of 2.453, with a known input. As stated before, side-channel measurements on modern 32-bit ARM Cortex-M3 may have lower SNR thus making attack slightly harder. Still, the attack is shown to be practical even on ARM with  $2\times$  more measurements. In our setup, getting 200 extra measurements takes less than a minute. Similarly, the setup and number of measurements can be updated for other targets like FPGA, GPU, etc.

Finally, the full network layout is recovered. The activity

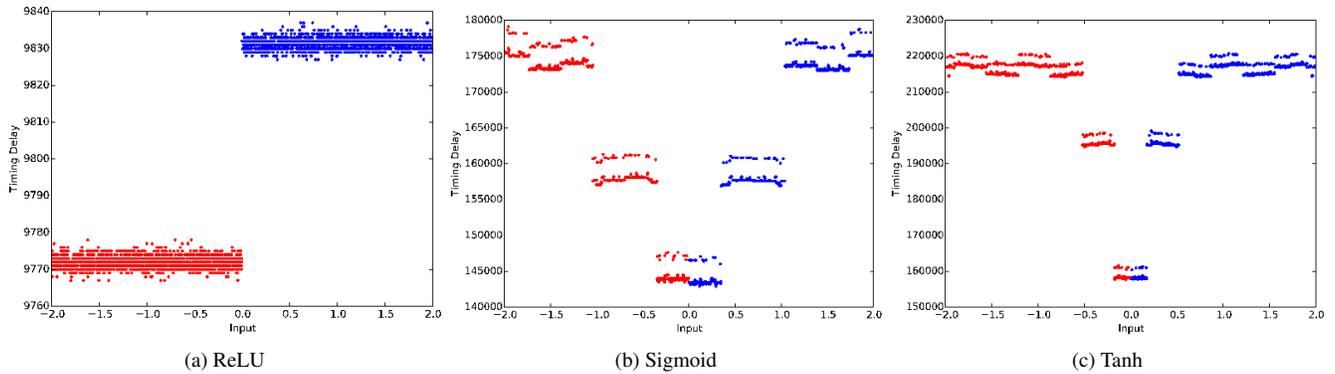

Figure 10: Timing behavior for different activation functions

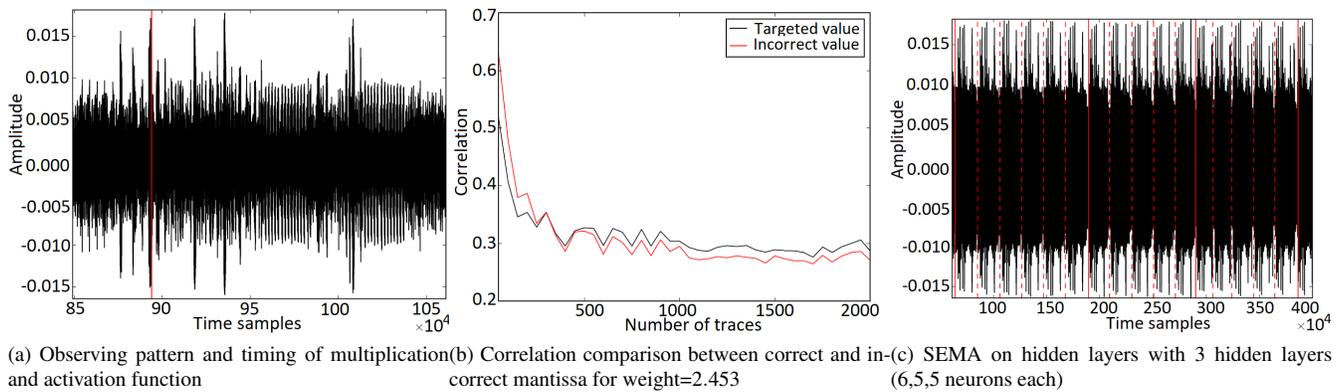

Figure 11: Analysis of an (6,5,5) neural network

of a full network with 3 hidden layers composed of 6, 5, and 5 neurons each is shown in Figure 11c. All the neurons are observable by visual inspection. The determination of layer boundaries (shown by a solid red line) can be determined by attacking the multiplication operation and following the approach discussed in Section 3.6.

#### 4.1 Reverse Engineering MLP

The migration of our testbed to ARM Cortex-M3 allowed us to test bigger networks, which are used in some relevant case-studies. First, we consider an MLP that is used in profiling side-channel analysis [41]. Our network of choice comes from the domain of side-channel analysis which has seen the adoption of deep learning methods in the past. With this network, a state-of-the-art profiled SCA was conducted when considering several datasets where some even contain implemented countermeasures. Since the certification labs use machine learning to evaluate the resilience of cryptographic implementations to profiled attacks, an attacker being able to reverse engineer that machine learning would be able to use it to attack implementations on his own. The MLP we inves-

tigate has 4 hidden layers with dimensions (50,30,20,50), it uses ReLU activation function and has Softmax at the output. The whole measurement trace is shown in Figure 12(a) with a zoom on 1 neurons in the third layer in Figure 12(b). When measuring at 500 *MSamples/s*, each trace had  $\sim 4.6$  million samples. The dataset is DPAcontest v4 with 50 samples and 75 000 measurements [46]. The first 50 000 measurements are used for training and the rest for testing. We experiment with the Hamming weight model (meaning there are 9 output classes). The original accuracy equals 60.9% and the accuracy of the reverse engineered network is 60.87%. While the previously developed techniques are directly available, there are a few practical issues.

- As the average run time is 9.8 *ms*, each measurement would take long considering the measurement and data saving time. To boost up the SNR, averaging is recommended. We could use the oscilloscope in-built feature for averaging. Overall, the measurement time per trace was slightly over one second after averaging 10 times.
- The measurement period was too big to measure the whole period easily at a reasonable resolution. This was resolved by measuring two consecutive layers at a time

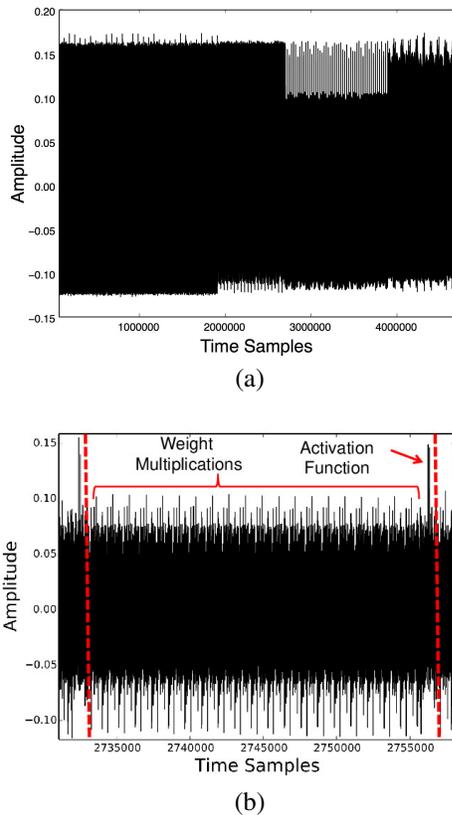

Figure 12: (a) Full EM trace of the MLP network from [41], (b) zoom on one neuron in the third hidden layer showing 20 multiplications, followed by a ReLU activation function. 50 such patterns can be seen in (a) identifying third layer in (50,30,20,50) MLP

in independent measurements. It is important to always measure two consecutive layers and not individual layer to determine layer boundaries. This issue otherwise can be solved with a high-end oscilloscope.

- We had to resynchronize traces each time according to the target neuron which is a standard pre-processing in side-channel attacks.

Next, we experiment with an MLP consisting of 4 hidden layers, where each layer has 200 nodes. We use the MNIST database as input to the MLP [29]. The MNIST database contains 60 000 training images and 10 000 testing images where each image has  $28 \times 28$  pixel size. The number of classes equals 10. The accuracy of the original network is equal to 98.16% while the accuracy of the reverse engineered network equals 98.15%, with an average weight error converging to 0.0025.

We emphasize that both attacks (on DPAcontest v4 and MNIST) were performed following exactly the same procedure as in previous sections leading to a successful recovery of the network parameters. Finally, in accordance with the

conclusions that our attack scales linearly with the size of the network, we did not experience additional difficulties when compared to attacking smaller networks.

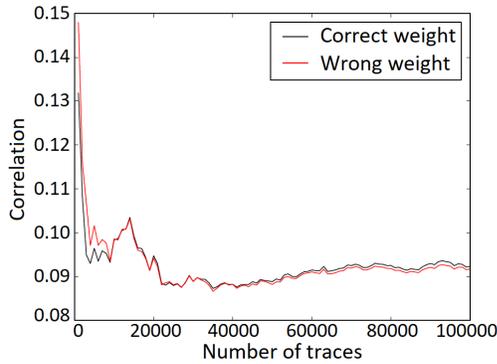

## 4.2 Reverse Engineering CNN

When considering CNN, the target is the CMSIS-NN implementation [27] on ARM Cortex-M3 with measurement setup same as in previous experiments. Here, as input, we target the CIFAR-10 dataset [24]. This dataset consists of 60 000  $32 \times 32$  color images in 10 classes. Each class has 6 000 images and there are in total 50 000 training images and 10 000 test images. The CNN we investigate is the same as in [27] and it consists of 3 convolutional layers, 3 max pooling layers, and one fully-connected layer (in total 7 layers).

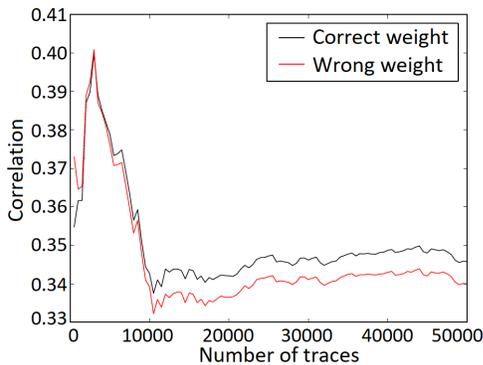

We choose as target the multiplication operation from the input with the weight, similar as in previous experiments. Differing from previous experiments, the operations on real values are here performed using fixed-point arithmetic. Nevertheless, the idea of the attack remains the same. In this example, numbers are stored using 8-bit data type – `int8` (q7). The resulting multiplication is stored in temporary `int` variable. This can also be easily extended to `int16` or `int32` for more precision. Since we are working with integer values, we use the Hamming weight model of the hypothetical outputs (since the Hamming weight model is more straightforward in this case).

If the storing of temporary variable is targeted, as can be seen from Figure 13(a), around 50 000 traces will be required before the correct weight can be distinguished from the wrong weights. This is based on 0.01 precision (the absolute difference from the actual weight in floating number). However, in this case, it can be observed that the correlation value is quite low ( $\sim 0.1$ ). In the case that the conversion to `int8` is performed after the multiplication, this can be also targeted. In Figure 13(b), it can be seen that after 10 000 traces, the correct weight candidate can be distinguished, and the correlation is slightly higher ( $\sim 0.34$ ).

Next, for pooling layer, once the weights in the convolution part are recovered, the output can be calculated. Most CNNs use max pooling layers, which makes it also possible to simply guess the pooling layer type. Still, because the max pooling layer is based on the following conditional instruction, *conditional*(if( $a > \max$ ) $\max = a$ ), it is straightforward to differentiate it from the average pooling that has summation and division operations. This technique is then repeated to reverse engineer any number of convolutional and pooling layers. Finally, the CNN considered here uses ReLU activation function and has one fully-connected layer, which are reverse engineered as discussed in previous sections. In our experiment, the original accuracy of the CNN equals 78.47% and the accuracy of the recovered CNN is 78.11%. As it can be seen, by using sufficient measurements (e.g.,  $\sim 50000$ ), we are able to reverse engineer CNN architecture as well.

(a) int scenario

(b) int8 scenario

## 5 Mitigation

As demonstrated, various side-channel attacks can be applied to reverse engineer certain components of a pre-trained network. To mitigate such a recovery, several countermeasures can be deployed:

1. Hidden layers of an MLP must be executed in sequence but the multiplication operation in individual neurons within a layer can be executed independently. An example is shuffling [50] as a well-studied side-channel countermeasure. It involves shuffling/permuting the order of execution of independent sub-operations. For example, given  $N$  sub-operations  $(1, \dots, N)$  and a random permutation  $\sigma$ , the order of execution becomes  $(\sigma(1), \dots, \sigma(N))$  instead. We propose to shuffle the order of multiplications of individual neurons within a hidden layer during every classification step. Shuffling modifies the time window of operations from one execution to another, mitigating a classical DPA/DEMA attack.

2. Weight recovery can benefit from the application of masking countermeasures [8, 42]. Masking is another widely studied side-channel countermeasure that is even accompanied by a formal proof of security. It involves assuring that sensitive computations are with random values to remove the dependencies between actual data and side-channel signatures, thus preventing the attack. Every computation of  $f(x, w)$  is transformed into  $f_m(x \oplus m_1, w \oplus m_2) = f(x, w) \oplus m$ , where  $m_1, m_2$  are uniformly drawn random masks, and  $f_m$  is the masked function which applies mask  $m$  at the output of  $f$ , given masked inputs  $x \oplus m_1$  and  $w \oplus m_2$ . If each neuron is individually masked with an independently drawn uniformly random mask for every iteration and every neuron, the proposed attacks can be prevented. However, this might result in a substantial performance penalty.
3. The proposed attack on activation functions is possible due to the non-constant timing behavior. Mostly considered activation functions perform exponentiation operation. Implementation of constant time exponentiation has been widely studied in the domain of public key cryptography [13]. Such ideas can be adjusted to implement constant time activation function processing.

Note, the techniques we discuss here represent well-explored methods of protecting against side-channel attacks. As such, they are generic and can be applied to any implementation. Unfortunately, all those countermeasures also come with an area and performance cost. Shuffling and masking require a true random number generator that is typically very expensive in terms of area and performance. Constant time implementations of exponentiation [1] also come at performance efficiency degradation. Thus, the optimal choice of protection mechanism should be done after a systematic resource and performance evaluation study.

## 6 Further Discussions and Conclusions

Neural networks are widely used machine learning family of algorithms due to its versatility across domains. Their effectiveness depends on the chosen architecture and fine-tuned parameters along with the trained weights, which can be proprietary information. In this work, we practically demonstrate reverse engineering of neural networks using side-channel analysis techniques. Concrete attacks are performed on measured data corresponding to implementations of chosen networks. To make our setting even more general, we do not assume any specific form of the input data (except that inputs are real values).

We conclude that using an appropriate combination of SEMA and DEMA techniques, all sensitive parameters of the network can be recovered. The proposed methodology is demonstrated on two different modern controllers, a classic 8-bit AVR and a 32-bit ARM Cortex-M3 microcontroller. As also shown in this work, the attacks on modern devices are

typically somewhat harder to mount, due to lower SNR for side-channel attacks, but remain practical. In the presented experiments, the attack took twice as many measurements, requiring roughly 20 seconds extra time. Overall, the attack methodology scales linearly with the size of the network. The attack might be easier in some setting where a new network is derived from well known network like VGG-16, Alexnet, etc. by tuning hyper-parameters or transfer learning. In such cases, the side-channel based approach can reveal the remaining secrets. However, analysis of such partial cases is currently out of scope.

The proposed attacks are both generic in nature and more powerful than the previous works in this direction. Finally, suggestions on countermeasures are provided to help the designer mitigate such threats. The proposed countermeasures are borrowed mainly from side-channel literature and can incur huge overheads. Still, we believe that they could motivate further research on optimized and effective countermeasures for neural networks. Besides continuing working on countermeasures, as the main future research goal, we plan to look into more complex CNNs. Naturally, this will require stepping aside from low power ARM devices and using for instance, FPGAs. Additionally, in this work, we considered only feed-forward networks. It would be interesting to extend our work to other types of networks like recurrent neural networks. Since such architectures have many same elements like MLP and CNNs, we believe our attack should be (relatively) easily extendable to such neural networks.

## Abstract

Trusted Platform Modules are valuable building blocks for security solutions and have also been recognized as beneficial for security on mobile platforms, like smartphones and tablets. However, strict space, cost, and power constraints of mobile devices prohibit an implementation as dedicated on-board chip and the incumbent implementations are software TPMs protected by Trusted Execution Environments.

In this paper, we present simTPM, an alternative implementation of a mobile TPM based on the SIM card available in mobile platforms. We solve the technical challenge of implementing a TPM2.0 in the resource-constrained SIM card environment and integrate our simTPM into the secure boot chain of the ARM Trusted Firmware on a HiKey960 reference board. Most notably, we address the challenge of how a removable TPM can be bound to the host device's root of trust for measurement. As such, our solution not only provides a mobile TPM that avoids additional hardware while using a dedicated, strongly protected environment, but also offers promising synergies with co-existing TEE-based TPMs. In particular, simTPM offers a user-centric trusted module. Using performance benchmarks, we show that our simTPM has competitive speed with a reported TEE-based TPM and a hardware-based TPM.

## 1 Introduction

Trusted computing technology has become a valuable building block for security solutions. The most widely deployed form of trusted computing on end-consumer devices is the Trusted Platform Module (TPM), a dedicated hardware chip that offers facilities for crypto co-processing, protected credentials, secure storage, or even the attestation of its host platform's state. By today, software and system vendors have built various security solutions on top of TPM. For instance, Microsoft's BitLocker uses it to release disk-encryption credentials only to a trustworthy bootloader [49]; or Google's Chromium uses the TPM for a range of objectives [60], such

as preventing software version rollback, protecting RSA keys, or attesting protected keys.

TPM is also of interest for the different stakeholders on mobile devices. However, the particular benefits that the TPM offers have historically hung on the TPM's implementation as a dedicated security chip that can act as a "local trusted third party" on devices. Mobile devices are, however, constrained in space, cost, and power consumption, which prohibits a classical deployment of TPM. To address the particular problems of the mobile domain, the Trusted Computing Group (TCG) introduced the Mobile Trusted Module (MTM) specifications [61]. Although the MTM concept has never left the prototype status, its ideas influenced the latest TPM2.0 specification [64]. The TPM2.0 mobile reference architecture [63] proposed different alternatives for implementing a TPM on a mobile device, including virtualization, dedicated cores, or hardware-based isolation. The de-facto implementation of mobile TPMs today are protected environments through hardware-based trusted execution environment (TEE) [23, 24, 32, 45, 46, 54], like ARM TrustZone that is available on virtually all mobile platforms today, where the TPM is implemented as protected software application inside the TEE.

Given the different proposals for realizing TPMs on mobile platforms, we conduct a systematic comparison of the different solutions in terms of security of the TPM itself, their applicability in current systems, and deploy-ability in the specific setting of mobile devices. While the solutions naturally differ in their security guarantees for the TPM (i.e., TPM state or execution) due to differences in the underlying technology (e.g., dedicated hardware chip vs. virtual machine), we see particularly shortcomings of the current solutions in terms of applicability and deploy-ability. In particular, the currently incumbent fTPM (firmware TPM) is strictly bound to the platform vendors and serves their purposes (e.g., securing vendor credentials), but is not or only very limited available to other stakeholders in the system, such as the user. Moreover, an fTPM [54] that is based on a TEE falls short on providing a fully measured boot by itself. The availability of an fTPM

depends on the availability of the TEE during boot, which is one of the last steps in the long boot-chain. In light of recent attacks against mobile bootloaders [55] and trusted software in TEE [3, 8, 18, 39, 41, 51, 56–58], this lacking support to attest the entire, early boot-chain, including the software in the TEE, is unsatisfactory.

To put a new perspective on solving those issues of fTPM, we add in this paper an alternative implementation of a hardware TPM called *simTPM* to the landscape of mobile TPM implementations by using the subscriber identity module (SIM) card. We have implemented a prototype of our solution on a Hikey960 reference board [1] and using a Gemalto Multos card as SIM card. Our *simTPM* solves the technical challenge of implementing TPM2.0 compliant functionality on the SIM card, which does not require any additional hardware for the TPM. This approach keeps the costs down and leverages dormant hardware capabilities of mobile devices. Through performance tests, we show that *simTPM* is competitively fast to reported fTPM implementations. A particular challenge of this design is the lack of the usual physical binding between the TPM and its host platform’s root of trust for measurement (RTM), that is, a SIM card can be moved to another platform. We discuss two strategies in the particular setting of mobile devices on how to bind the *simTPM* to a device’s RTM, either through an extended secure boot and TEE proxy or through a distance bounding protocol. Once bound to the device’s RTM, we also integrated *simTPM* with the ARM Trusted Firmware (ATF) boot chain to augment the ATF secure boot with an authenticated boot. Our solution not only fills the gap of TEE-based TPMs for measured boots, but the co-existence of a fTPM and *simTPM* on a mobile device creates also promising synergies between the two TPMs (e.g., to support multiple stakeholders). Our contribution can be summarized as follows:

1. A systematic comparison of existing solutions for mobile TPMs and their enabling technologies. We discover that incumbent solutions fall short on applicability and deploy-ability aspects.
2. We implemented the first SIM card based TPM2.0 for mobile devices by developing a *simTPM*, which can be executed in this constrained environment. Our solution enables a user-centric trusted module offering a portable sealed storage.
3. We propose an integration with the on-board TEE to solve the problem of binding the *simTPM* to the RTM and discuss an alternative solution based on distance bounding. As a result of this binding, a fully measured boot on the ARM Trusted Firmware (ATF) secure boot chain is possible.
4. The performance of our *simTPM* is competitively fast to a reported fTPM implementation and is comparable with existing hardware TPMs.

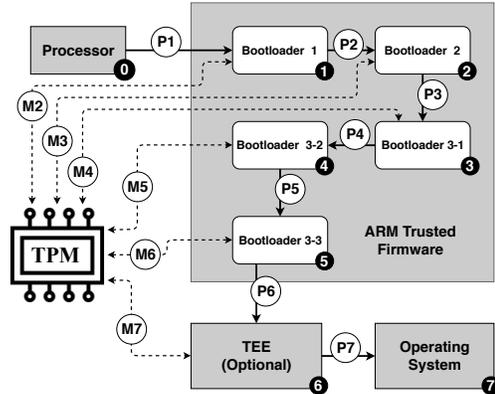

Figure 1: Trusted Boot Process with TPM; P(#) = boot chain path; M(#) = measurement of component #

## 2 Background

We briefly introduce necessary background information about ARM Trusted Firmware, TPM, and SIM cards.

### 2.1 ARM Trusted Firmware (ATF)

ATF implements a subset of the trusted board boot requirements for ARM reference platform [5]. Figure 1 illustrates the bootloader settings and boot chain. ATF is triggered when the platform is powered on. After the primary CPU and all other CPU cores are initialized successfully, the primary core triggers the ATF (P1). ATF is divided in five steps depending on modularity: 1 BootLoader stage 1 (BL1) for AP trusted boot ROM, 2 BootLoader stage 2 (BL2) for Trusted Boot Firmware, 3 BootLoader stage 3-1 (BL3-1) for EL3 Runtime Firmware, 4 BootLoader stage 3-2 (BL3-2) for Secure-EL1 Payload (optional), 5 BootLoader stage 3-3 (BL3-3) for Non-trusted Firmware.

**Secure boot:** ATF implements a secure boot in which every component along the boot chain (P#) verifies the authenticity and integrity of the next component. Since BL1 does not have a preceding component, it has to be axiomatically trusted. Thus, BL1 verifies BL2, BL2 verifies BL3.x, and so forth. Verification is usually based on certificates, where a hash of a trusted (vendor) public key is fused into the hardware and is available to BL1 to ensure a trustworthy signature of BL2. At the end of a successful secure boot, every component in the boot chain has been checked for integrity and authenticity before handing control to it. If any verification fails, the boot aborts.

### 2.2 Trusted Platform Module (TPM)

TPM by the Trusted Computing Group is the most widespread trusted computing technology on end-user devices. By today, the TPM specification is in its version 2.0, addressing

many of the security issues and practical concerns of previous versions 1.0–1.2. According to this specification, a TPM provides a number of desirable hardware and security features. It is equipped with secure non-volatile memory, a set of platform configuration register (PCR) banks, a processor to run TPM code in isolation, co-processors for common cryptographic primitives (e.g., RSA, ECC, SHA-1, SHA-256), a clock, and a random number generator. By default, a TPM is deployed as a hardware chip soldered onto a platform's motherboard. Besides acting as a cryptographic co-processor, a TPM provides the facilities to securely store measurement about the host platform's configuration (e.g., software state) in its PCRs and to reliably report those measurements to a remote verifier (remote attestation based on a pre-installed endorsement key), as well as creating secure storage through TPM protected credentials and data sealing with extended authorization policies. Further, the TPM non-volatile memory, including secure monotonic counters, can be attractive for building security solutions, e.g., version rollback prevention for software updates.

By now, a number of real world applications make use of TPM. For instance, IBM's password manager uses it for storing keys, Microsoft windows management instrumentation uses TPM for cryptographic co-processing, Intel's Trusted eXecution Technology or AMD's Secure Technology rely on a hardware TPM, several VPN apps can make use of it, TPM is used in full disk encryption (e.g., Microsoft Bitlocker, dm-crypt), and even browsers like Chrome make use of TPM for different purposes.

**Measured boot:** Of particular relevance for this paper is measured (or authenticated) boot based on TPM (see Figure 1). During a measured boot, every component in the boot chain (P#) measures the next component—a cryptographic hash of the component—and then stores this measurement in the PCR of the TPM (M#) before passing on control. Since BL1 does not have a preceding component, it is not measured and acts as the *Root of Trust for Measurement*, which starts the measurement chain. In contrast to a secure boot, the components are not verified and the boot is not aborted, however, after a measured boot the software configuration of the boot components can be attested by the TPM or used to seal storage to this configuration (i.e., values in the PCR).

## 2.3 Subscriber Identification Module (SIM)

SIM card is the module that authenticates the mobile device in the network. The primary job of the SIM card is to prove the identity of the owner of subscription to the cellular carrier to enable services like calling, Internet, and various others.

Through physically separated pins, a SIM module can achieve the same degree of independence from power supply, reset capability, clock signal, and separated I/O communication with the host platform like a TPM.

Since SIM cards are smart cards, they use command-

response communication and the application protocol data unit (APDU) to communicate with their reader. The Android radio interface layer can be extended to send specialized APDU commands to the SIM card, which we use in simTPM. It is worth noting, that this APDU command sent by the Android radio interface has to go through the baseband processor. The structure of the APDU commands are defined in the ISO/IEC 7816-4 standard and are recalled later on in Section 4.

## 3 Requirement Analysis & Systematization of Existing Solutions

There exists many approaches to realize TPM in a way different than using a dedicated hardware TPM. In this section, we systematically compare different solutions of trusted computing procedures using both hardware and software that are representative for the different implementation options. For comparison, we first re-enumerate the objectives a secure and practical TPM implementation needs to fulfill (Section 3.1) and then discuss the existing solutions (Sections 3.2 through 3.4). In particular, this systematization should help to understand the trade-off of the proposed solutions in comparison to the default hardware TPM and where our simTPM solution fits into. Table 1 summarizes the discussion in the remainder of this section.

### 3.1 Objectives

We start by briefly formulating the objectives a trusted module, in particular for mobile devices, should fulfill. We group them into security of the TPM itself, the applicability of the implementation, and desirable deploy-ability objectives.

#### 3.1.1 Security of TPM

These are objectives that should be fulfilled to ensure the security of the TPM state, its execution and trustworthiness, and secure operations.

**S1 Confidentiality and integrity of TPM state:** The TPM state should be confidential and protected against untrusted code (e.g., host platform, non-TEE apps) and only be available to authorized entities. We assign ✓ if the confidentiality and integrity of the state is protected through strong security means (e.g., physical isolation), ✨ if they depend on software integrity (e.g., of the OS), and ✗ in other cases.

**S2 Rollback Protection:** Reverting the TPM state back to a former version must be prevented or at least be detectable. We assign ✓ if rollback protection is guaranteed through hardware means (e.g., hardware counters), ✨ if there is a dependency on untrusted OS but rollbacks can be detected, ✗ if no rollback protection or detection is provided.

**S3 Trustworthy Endorsement:** A TPM should be carrying an asymmetric encryption key called Endorsement key (EK) that can live as long as the TPM and for which credentials exist that verify the authenticity of the TPM and allow a verifier to recognize a genuine TPM. We assign ✓ if endorsement credentials are available to the TPM (e.g., pre-installed at manufacturing time or derived from other verifiable credentials), ✨ if the TPM has to create an EK and prove it is genuine through a remote verification, ✗ otherwise.

**S4 Secure Counter:** TPM has to provide secure, persistent monotonic counters, e.g., for its clients or extended authorization policies. We assign ✓ if the TPM provides such counters backed by hardware support or NV-storage of the TPM software state that is protected (i.e., S1, S2 both ✓). We assign ✨ if the security of the counter depends on software integrity (e.g., of the OS or hypervisor). Otherwise ✗.

**S5 Secure Clock:** A clock is needed for attestation, for generation of timed attestation keys, and for authorization policies with lock-out time. If a secure clock is available to the TPM (e.g., its own hardware clock), we assign ✓; if the clock depends on shared resources but manipulation can be detected we assign ✨, otherwise ✗.

**S6 Security of TPM Execution:** The execution of the TPM code or firmware has to be protected against compromise. We assign ✓ if a strong security boundary exists between untrusted code and the TPM execution environment (e.g., dedicated physical chip). If the execution environment shares hardware resources (e.g., CPU or RAM) with untrusted code and the shared resources provide isolation (e.g., modes of operation of CPU and separate memory regions), we assign ✨, since the shared resources open an attack surface. If the security of the TPM execution environment is based purely on software means (e.g., hypervisor or OS), we assign ✗ for this weakest form of isolation.

### 3.1.2 Applicability

These are objectives related to the application of TPM, such as authenticated boot or providing secure storage to clients.

**A1 Secure Persistent Storage:** TPM provides a persistent storage to securely store limited amounts of data (e.g., certificates). We assign ✓ if the TPM provides such storage (e.g., NV-RAM in a dedicated chip) and ✨ if the persistent storage is part of an outsourced TPM state that is protected (i.e., S1, S2 both ✓). We assign ✗ in other cases.

**A2 Early Availability:** A main use-case for TPM is storing the measurement of loaded software components, i.e., measured boot. To be able to attest the entire software stack, the TPM has to be early available during the boot sequence. If the trusted module is available as soon as the platform has power, we assign ✓. Otherwise, if the TPM becomes available at late

stage during boot (e.g., after initializing a separate execution environment), we assign ✗.

**A3 Multiple Stakeholders:** Computer systems, in particular mobile platforms and enterprise devices, usually have multiple stakeholders co-existing with an interest in protecting credentials and software on the platform (e.g., end-user, administrator, network operator, software vendor). If the TPM was designed to support both platform software and users (e.g., distinct hierarchies), we assign ✓. If the TPM primarily supports the platform but offers limited functionality to the end-user, we give ✨. If the TPM was designed solely as support for the platform vendor, we give ✗.

### 3.1.3 Deploy-ability

Objectives related to the deployment of TPM, in particular if deployment complies with the requirements of mobile devices or if it is bound to a specific platform.

**D1 Mobile Availability:** We want to have the TPM available for mobile devices. This imposes strict constraints, such as not changing the current architecture by adding a new on-board chip. If the TPM implementation adheres to this constraints, we assign ✓, otherwise ✗.

**D2 Movability:** The TCG specification has introduced the TPM as being bound to its host platform (e.g., fixed part of the motherboard). However, depending on the context, the movability of the TPM to another platform is desirable, e.g., if an associated virtual machine migrates to another platform. If the TPM is generally easily moved to another platform, we assign ✓, if it is bound to a specific platform, we assign ✗.

**D3 Bound RTM:** The measurements during a measured boot are given to the TPM by the host platform, starting with the Root of Trust for Measurement (RTM). To ensure that the provided measurements indeed describe the TPM's host platform's configuration, TPM and RTM must be bound together on the same platform. If this binding is achieved via physical means (e.g., TPM and RTM are fixed parts of the same motherboard), we assign ✓. If the TPM receives those measurements from another trusted entity (e.g., another, bound TPM, or a secure boot anchored at the RTM), we assign ✨. If the TPM cannot establish trust into the RTM, we assign ✗.

In Section 2.2, while introducing the hardware TPM, we explained all its properties, which allow the TPM to achieve the objectives we defined in Section 3.1 and summarized in Table 1. Objectives S1 to S6 and A1 to A3 are our interpretation of properties derived from TCG's mobile TPM [61, 63] and standard TPM specification [62, 64]. We define *Deploy-ability* as added objectives that simTPM should achieve. The current TCG specifications do not stipulate a removable TPM. We will use the standard hardware TPM as the baseline that simTPM should achieve.

Table 1: Comparison of existing TPM implementations

Category	Objective	fTPM [54]	vTPM <sup>†</sup> [9]	Intel SGX [19]	simTPM	Hardware TPM
Security of TPM	S1. Confidentiality and integrity	✓	✓/✱	✱	✓	✓
	Security of TPM state					
	S2. Rollback protection	✓	✓/✱	✓	✓	✓
	S3. Trustworthy Endorsement	✓	✱/✱	✓	✓	✓
	S4. Secure counter	✓	✓/✱	✓	✓	✓
	S5. Secure clock	✱	✓/✗	✗	✓	✓
Applicability	S6. Security of TPM execution	✱	✓/✗	✱	✓	✓
	A1. Secure persistent storage	✱	✓/✗	✱	✓	✓
	A2. Early availability	✗	✓/✓	✗	✓	✓
Deploy-ability	A3. Multiple stake holder	✗	✓/✓	✓	✓	✓
	D1. Mobile availability	✓	✗/✗	✗	✓	✗

### 3.2 fTPM

Specifically for the mobile domain, a number of past implementations [25, 54, 66] leveraged trusted execution environments (TEE) to realize a software-based TPM. We use Microsoft’s fTPM [54] as a representative for those implementations, since it is one of the most recent solutions. The fTPM implementation is widely deployed in Microsoft mobile devices using a TEE on top of ARM TrustZone (D1: ✓). TrustZone creates a memory and process isolation between the protected environment ("secure world") running inside the TEE and the "normal world" (i.e., Android or similar), and allows the execution to switch contexts between those two worlds via a secure monitor.

fTPM provides confidentiality, integrity (S1: ✓), and rollback protection (S2: ✓) for fTPM states by creating a trusted storage through a combination of encryption with fused keys, device UUID, and Replay Protected Memory Block (RPMB) with authenticated writes and write counter. Any form of secure persistent storage the fTPM offers to clients is based on this securely outsourced state (A1: ✱), which is also used to provide secure counters to clients (S4: ✓).

Due to ARM TrustZone, the execution of the fTPM environment is isolated from the normal world, however, both worlds still share the CPU and RAM (S6: ✱), which has opened TrustZone TEEs to attacks (e.g., [41]).

fTPM does not have a separate secure clock. It uses the clock of the system in cooperation with the untrusted OS (S5: ✱). To handle the shared clock situation, fTPM implements *fate sharing*, where fTPM refuses to provide any func-

tionality if the OS does not cooperate.

fTPM is primarily designed to provide TPM support to the platform vendor (A3: ✗). The fTPM is a software implementation and bound to one device (D2: ✗), since it derives many of its credentials from device-specific keys or UUIDs, including its endorsement credentials (S3: ✓).

Since the fTPM is implemented as software in the TEE on top of ARM TrustZone, the fTPM becomes only available once the TEE has been initialized during the boot sequence (see also Section 2). That means the fTPM (or any TEE-based TPM) is not early enough available to store measurements of the early boot stages (A2: ✗). But this can be alleviated by introducing shared memory between the bootloaders and TEE for measurement storage. We will discuss this solution in more details in Section 4.3.

Although the fTPM is only available after the bootchain has created the TEE, the secure boot transitively extends the trust put into the RTM (BL1) to the remainder of the secure bootchain on the same platform as the TEE. Thus, fTPM can assume that the measurements are done as if by the RTM on the same platform (D3: ✓) if the measurements comes from a component of the secure bootchain.

### 3.3 vTPM

Another way of implementing a software TPM is by creating virtual instances over a physical TPM [9]. This, in particular, targets cloud environments in which virtual machines need a TPM, but sharing a single physical TPM (or providing an array

of physical TPM) is not an option. The representative work for virtual TPM, or vTPM, is based on the Xen hypervisor and proposes two different implementation options: 1) a software only implementation with vTPM instances running inside a privileged VM, and 2) a secure co-processor (SCoP) to run all vTPM instances with better isolation at the cost of additional hardware. Both options are not feasible for mobile TPMs (**D1: ✗**), since virtualization is not sufficiently supported or effective, and adding a secure co-processor is too costly in terms of space and power. However, by design vTPMs must be movable to different platforms to support migration of associated VMs between platforms (**D2: ✓**).

In both deployment options, a vTPM has to create its endorsement key at creation time. To establish trust into the EK for a remote verifier, a genuine, primary TPM on the platform (hardware TPM) must attest the trustworthiness of the vTPM's EK (**S3: ✨**).

In case of SCoP-vTPM, the TPM logic and vTPM instances are executed inside the secure co-processor (**S6|SCoP-vTPM: ✓**). Further, the secure co-processor used in [9] (an IBM PCIXCC) provides CMOS RAM backed persistent storage. We assume it provides the confidentiality, integrity, and rollback protection of the vTPM states as well as sufficient secure persistent storage to the vTPM clients (**S1, S2, A1|SCoP-vTPM: ✓**). The same co-processor also offers facilities for secure counters (**S4|SCoP-vTPM: ✓**) and a secure clock (**S5|SCoP-vTPM: ✓**).

For SW-only-vTPM the vTPM instances reside in Xen's privileged *dom0*. Thus, their execution is protected from untrusted VMs by only the Xen hypervisor (**S6|SW-only-vTPM: ✗**), and their state, when stored in persistent storage in *dom0*, is also protected by only the access control and isolation of the hypervisor and *dom0* (**S1, S2|SW-only-vTPM: ✨**). Similar, the protection of any persistent storage offered to vTPM clients depends on the integrity and trustworthiness of *dom0* (**A1|SW-only-vTPM: ✗**) as does any counter stored in the vTPM state (**S4|SCoP-vTPM: ✨**). A vTPM relies on the platform's clock shared between all vTPMs including untrusted code and not specifically protected (**S5|SCoP-vTPM: ✗**). Although vTPM instances are created after the host platform has booted up, a vTPM receives the initial measurement from the underlying hardware TPM of its platform, which also attests the vTPM trustworthiness, and *dom0* protects the vTPM state from migrating to an untrusted platform (**D3|SW-only-vTPM: ✨**). Further, vTPM instances are created together with their associated VM, hence, allowing the VM to measure its entire bootchain and store the measurements in its vTPM (**A2: ✓**).

In case of SCoP-vTPM, the TPM resides entirely in the IBM PCIXCC, a removable peripheral. Thus, no physical binding to the RTM exists and no authenticity/trustworthiness of the RTM is being ensured (**D3|SCoP-vTPM: ✗**), hence, an attacker could move the TPM to an untrusted platform that feeds the TPM with arbitrary measurements. This situation

is very similar to our simTPM, which is also removable, and we discuss solutions to this challenge in Section 4.3, which might also be applicable to SCoP-vTPM.

The vTPM does not make any assumptions about which stakeholder—user or platform—within the associated VM uses the vTPM and supports, like a regular hardware TPM, multiple hierarchies (**A3: ✓**).

### 3.4 Intel SGX

Although Intel SGX is not an implementation of a TPM but a solution to allow applications to establish a TEE, *enclave* in SGX jargon (**S1, S7: ✖**), we include it here for comparison because it offers in many dimensions similar protections as a hardware TPM and shares a lot of a TPM's objectives (we mark non-applicable objectives with ✖ in Table 1). For this work we have only considered stock SGX implementations in Intel processor to keep the comparison on par with other candidates. SGX is currently only supported by desktop and server class Intel processors (**D1: ✗**) and binds any credentials, like generated and derived keys, and transitively sealed data strictly to the CPU (**D2: ✗**).

In SGX, *attestation* means verifying that a certain enclave code was initialized correctly and not tampered with by the untrusted host OS. For *remote attestation* in SGX an Intel-provided *Quoting Enclave* provides the facilities to enclaves to do direct anonymous attestation (DAA) using attestation keys endorsed by Intel (**S3: ✓**). The SGX extensions to the CPU measure the enclaves, hence, the enclaves are physically bound to their RTM (**D3: ✓**).

SGX supports enclaves in sealing data for storing it on untrusted persistent storage, since enclaves themselves do not have any persistent storage like NV-RAM (**A1: ✨**). In addition, Intel has added support for monotonic counters [30, 43] that allow rollback protection of sealed data (**S4, S2: ✓**).

It is a processor based technology, so it can fully utilize the clock of the system. But the current SGX implementation does not accommodate a trusted and fine grained clock for the user-level enclaves. There is an API provided by Intel, e.g., `get_trusted_time`, but this call can be arbitrarily modified by the untrusted OS, since it requires to make an *OCALL* [4, 6, 17, 31, 37]. Moreover, any timing mechanism must account for the fact that the OS can interrupt the enclave at any point in its execution, wait for an arbitrary period of time, and then resume the enclave using *ERESUME* (**S5: ✗**).

Both regular applications and system software can use enclaves and SGX is not restricted to particular stakeholders (**A3: ✓**). However, an early firmware initialized enclave is not possible, since the OS is needed for memory management of enclaves (**A2: ✗**).

### 3.5 Java-card based MTM

Dietrich and Winter proposed a way of implementing a mobile trusted module (MTM) in a Java-based smart-card for mobile devices [21, 26]. The implementation is for applications running on mobiles and the TPM communicates through NFC.

The TPM is installed as a set of applets in the Java-card, where a *master-applet* provides services to other applets, like TPM command handling and controls the access to the endorsement key. The actual processing of TPM commands is handled by specific applets implementing those commands.

Although this implementation seems like closest related work to our simTPM, their work described a proof-of-concept prototype and is unfortunately silent about many aspects, such as secure persistent storage, and some functionality is not available, such as attestation of the system or authenticated boot. The Java-card communicates with the system over NFC, so binding the card with the system is not possible and early availability of the trusted module is also not possible before the NFC driver is loaded.

Their implementation provides important insights on the implementation of MTM on mobile devices through a programmable TPM and presented pioneering work, but given the lack of documentation and also differences in engineering (see Section 4), we cannot provide a full and fair comparison with simTPM and exclude it from our systematization.

## 4 System Design and Security Analysis

The main component of simTPM is a smart card based implementation of a SIM TPM. However, to properly work it also requires changes in the bootloader and the operating system (i.e., Android). In this section, we describe the design and implementation of simTPM in more details. We also discuss how our solution solves the shortcomings described in Section 3 and argue about our design’s security. Along with the design descriptions, we indicate how the objectives shown in Table 1 are met by simTPM.

### 4.1 SIM TPM

Modern SIM cards are usually general purpose smart cards running an applet created by the mobile network provider. The two most prominent smart card technologies are Java Cards and Multos cards. Both introduce a custom OS (i.e., Java Card OS and Multos OS) and APIs that can be used by programmers for cryptographic (e.g., encryption, signing) and non-cryptographic (e.g., memory allocation and copy) operations that are implemented and executed directly on the microprocessor. Depending on the technology, applets can be programmed in C/C++ (e.g., Multos cards) or in Java (e.g., Java Card). Additional cryptographic algorithms, not provided by the API, can be implemented in software.

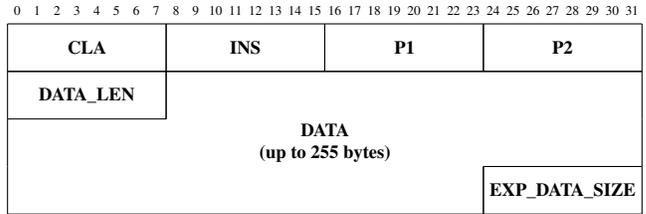

Figure 2: Generic APDU command structure

Both card technologies have support for multiple applets. To properly manage them, cards provide a specialized security manager that is responsible for installing and deleting of user defined applets. Once an applet is uploaded, the security manager creates its instance and allows the applet to create necessary objects and allocate memory.

#### 4.1.1 API Limitations of Smart Cards

As mentioned above, each Smart Card OS provides a card specific API that allows applets to perform extended operations. This forces the programmer to use only a predefined set of functions. For example, in case of Java cards the API supports only a subset of the standard Java language and is limited to high level cryptographic operations (e.g., encryption, hashing, signing). There is no support for mathematical functions like modular multiplication or elliptic curve point addition, which are one of the main building blocks of public key cryptography. In other words, the developer cannot use hardware support for those low-level operations and is limited to software implementations that are inefficient due to the overhead of the virtualization layer.

Obviously, those limitation do not directly concern TPM commands that only use basic cryptographic operations. Unfortunately, the TPM standard defines a remote attestation scheme that is not supported by the cards API, because it uses, e.g., zero-knowledge proofs. This constitutes an interesting engineering problem that we solve. In particular, we were able to implement simTPM on a Gemalto MultiApp Multos smart card with an Infineon SLE78CLX family microprocessor. This card also helped us achieving process isolation from the general-purpose processor (**S6: ✓**). It is worth noting, that in this paper we focused mainly on the Multos API [42], because it supports a broader range of functions than the Java card API. In particular, we were able to efficiently implement a remote attestation scheme on-card.

#### 4.1.2 Smart Cards and TPM Command Parsing

SIM cards are connected to the main processing unit over a separate bus and available for mobile telephony services (**D1: ✓**). Smart cards work in a command/response manner, i.e., given an input the card executes the code and returns a response. The input data is defined by an APDU command

(see Figure 2), which consists of a class byte (CLA), an instruction byte (INS), two bytes for parameters (P1, P2), one byte for the expected response length, one byte for the data length (DATA\_LEN), and DATA\_LEN bytes of data. The cards' response contains the response data and two bytes that constitute the status word (not shown in the figure). The data field is limited to 255 bytes. There exist an extended length APDU specification that allows for a larger data field but it is not widely implemented.

In a multi applet system, an APDU command will be forwarded to the currently selected applet. To select an applet, the SELECT APDU command with a unique applet identifier has to be sent to the card. This command is then recognized and executed by the OS. Once selected, the applet can parse incoming commands according to its work flow. In particular, this means that the developer can use the instruction and parameters bytes to program the behavior of the card.

The APDU data structure provides a convenient way to communicate with the card. We designed a custom APDU command that implements TPM commands. The data length size of up to 255 bytes is sufficient for the payload sizes of most TPM commands, and for TPM commands with larger payload sizes (e.g., sealed data blobs), we send the payload split across multiple APDU messages and use the parameter bytes to communicate the card if more data is to be expected.

**Changes to Android's radio interface:** The Android Radio interface layer (RIL) is responsible for communicating with the device's SIM card. To allow RIL to communicate with simTPM, we introduced a set of TPM commands. We implemented a custom RIL as a shared library, which sends APDU commands as bulk transfer to the simTPM and receives its responses.

### 4.1.3 TPM Commands

We now briefly discuss how we designed the card to handle basic TPM commands related to PCR banks and sealing. The former case is easy, the applet reserves enough non-volatile memory to store the PCRs. The number of banks is defined by the installation parameter of the TPM applet, which also defines the algorithm we use to extend the PCR (e.g., SHA1 or SHA256). In a standard setup we use 24 PCRs. For the TPM\_EXTEND and TPM\_READ commands we used two separate instruction bytes (respectively, 0x10 and 0x20) to form the APDU. In both cases the number of the PCRs is given using parameter P1.

To design (un-)sealing on a smart card was a bit harder. Due to the limited input data size, the card has to encrypt/decrypt the input in chunks, which are split across multiple APDU messages. The storage key for sealing is generated by the card after receiving the TPM\_INIT command. The key is stored in the non-volatile memory that is allocated during installation of the applet (see next Section 4.1.4).

It is worth noting that smart cards can be programmed to execute all TPM commands that require basic cryptographic algorithms, on-card key generation, key agreement, or storing data in volatile/non-volatile memory. Unfortunately, the privacy-preserving variant of remote attestation (i.e., direct anonymous attestation, DAA) requires zero-knowledge proofs and other unsupported crypto operations. What is more, in versions below TPM 2.0 the specification defined only one algorithm for anonymous attestation [14], which is based on groups with hidden order (i.e., using a RSA modulus) and Camenisch-Lysyanskaya signatures. The TPM 2.0 specification, however, allows for algorithm agility. We leveraged this fact and used a custom scheme. We present the full scheme and security proofs in the technical report of our paper [16]. Here, we only draft the idea behind the scheme, which follows the generic approach used by other DAA schemes: The TPM receives a signature/certificate under its secret DAA key from an authority. It then uses this secret key to certify its attestation key using a proof. In this zero-knowledge proof the TPM shows that it knows a certificate under a DAA key and a signature created using this key under an attestation key. The scheme uses Boneh and Boyen [11] signatures and an efficient zero-knowledge proof for the above statement that is made non-interactive using the Fiat-Shamir transformation [28]. The main advantage of the scheme is that it can be executed solely by the TPM (i.e., on-card) and does not require any involvement of the host platform. To further improve efficiency of our scheme, we decided to optimize the workload between commands, i.e., if the TPM\_CREATE command recognizes that the TPM is creating an attestation key, it already does some pre-computation for the DAA certification.

### 4.1.4 PCR and NV storage

All smart cards implement a small amount of non-volatile storage that can be used for various purposes. This memory of the smart card is by design tamper-resistant and therefore offers memory isolation from the rest of the system (S6: ✓). Modification of this memory is only possible by the applet that reserved it and we reserve some of the NV storage for the simTPM (A1: ✓). Smart cards are equipped with features preventing updates of its internal state by the outside world. To update stored content (e.g., applets), one has to issue an authorized command to the card manager to update storage or perform applet specific commands, e.g., PCR extension (S1: ✓). Our simTPM is equipped with PCR banks that are initialized when power cycling the device and, hence, the SIM card, and can only be changed between power cycles using PCR\_EXTEND.

System software or user level software can keep a counter containing the current version of the software inside the NV-storage and updates to the counter are only allowed via authorized commands. This provides an easy setup for secure counter and rollback protection (S4: ✓).

### 4.1.5 Trustworthy endorsement & Clock

Trustworthy endorsement of a TPM is very important. The standard solution is to use an asymmetric encryption key called endorsement key. This key is unique per TPM and should stay alive as long as the TPM is alive. This key differentiates a genuine from a rogue TPM. simTPM can achieve secure endorsement by putting a (vendor) certified endorsement key inside its NV-storage and implementing TPM logic that ensures that the private portion of the key is never released to the outside world (**S3**: ✓).

SIM cards are equipped with a clock pin connected to the baseband processor. Thus, they cannot be clocked higher or lower by an untrusted application or OS. This separate clock helps simTPM to work on a different clock frequency not under direct influence of the main processor. What is more, the baseband processor can be used as a secure external clock. In particular, since the baseband processor is by default isolated with a strong security boundary from untrusted code on the platform, it can prepend any APDU command with an APDU command containing the current time (this can also be limited to time-sensitive TPM commands only). This way simTPM can be provided with a secure clock (**S5**: ✓).

### 4.1.6 Mobility & Stakeholders

The other unique feature of the simTPM architecture is its movability (**D2**: ✓). simTPM implements the TPM inside the SIM card. So by design, simTPM can be transferred to a different device. This creates some interesting use-cases, which we discuss in more details in Section 6.2, but also challenges, which we discuss separately in Section 4.3. simTPM is not specifically bound to one particular stakeholder and supports the multiple stakeholder model proposed by TCG (**A3**: ✓), although we think the end-users and their apps are the primary beneficiaries of simTPM.

## 4.2 ATF boot-loader changes

In Section 2.1, we have briefly introduced ATF and its boot-loader chains. In this section we describe the changes we have implemented to enable communication between the boot-loader components and the simTPM. Figure 1 can be helpful as a visual aid for understanding.

After turning on the secondary cores on the cold boot path, the processor kicks in the first stage BL1 of the boot-loader (❶). Current bootloaders are not implemented such as to be able to communicate with a device like a SIM card and to run a command response protocol. Thus, we have extended all the boot-loaders with the capability to communicate with the SIM card via bus communication. This modification in ATF makes the simTPM already available to the early BL1 stage (**A2**: ✓). The boot-loader software is capable of translating TPM commands to APDU commands, sending them to simTPM, receiving responses, and translating them to a meaningful

response that can be used to make decisions (e.g., failed/successful PCR extension commands). One thing that needed to be addressed here is that except for BL3-3, all bootloaders are secure mode software (i.e., secure world in TrustZone). So during execution, simTPM has to be initialized as secure mode hardware to be available to the boot-loader. We initialize the simTPM as a secure mode hardware, but after a successful boot chain verification, we switch simTPM to normal mode (of TrustZone). This allows us to maintain normal efficiency in the normal world, since the SIM card functionality (e.g., calls or text messages) is accessed by Android and switching context from normal world to secure world every time before accessing the SIM card in Android can interrupt the normal world execution and would be highly inefficient.

## 4.3 Bootstrapping trust for movable simTPM

Parno [53] was first to identify the problem of how to bootstrap trust into a hardware TPM and the possibility of *cuckoo attacks*. A fundamental problem of TPM is that the verifier (e.g., local user) does not know if they are talking to the *intended* (e.g., local) TPM, just that they are talking to a *genuine* TPM. In a cuckoo attack, an attacker that compromised the local platform can exploit this problem and fool the verifier into trusting the compromised platform: the attacker simply relays the verifier's communication to another (remote) TPM on an attacker-controlled platform, which then can attest an arbitrary, trustworthy state to the verifier. The preferred solutions to prevent cuckoo attacks are hardwired channels via a special purpose hardware interface to the on-board TPM or, alternatively, a cryptographically secured verifier-TPM communication where the verifier has knowledge of the public key of the TPM on the intended platform.

However, those solutions make an implicit assumption: Historically TPMs are soldered onto the motherboard, eliminating the issue of ensuring proper binding to the device's root of trust of measurement (RTM), usually in form of an immutable piece of trusted code in the BIOS. Due to this static design a TPM is ensured that the very first received measurement in a chain-of-trust is coming from a trusted, local RTM. Only a sophisticated hardware attack can break this binding. A TPM that is by-design movable, such as our simTPM or the PCI-attached secure co-processor for vTPM [9], raises an interesting question about how to re-establish this bond between TPM and RTM.

**Lack of chain-of-trust:** Without binding the TPM to a trusted, local RTM, the measurements of any authenticated boot cannot be trusted. An adversary could simply plug the simTPM into an attacker-controlled platform and replay<sup>1</sup> any desired measurements sequence, i.e., create arbitrary PCR values akin to a TPM reset attack [29, 36]. This allows the

<sup>1</sup>The TPM is a passive device to which the measurements have to be provided by its caller.

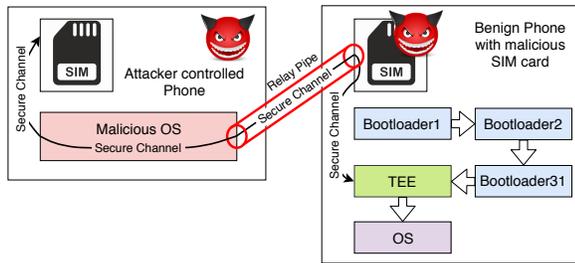

Figure 3: Using TEE as TPM proxy to bind simTPM with RTM and to mitigate the effects of relay attacks.

attacker to fool a remote verifier during remote attestation but also to gain access to sealed secrets, whose release is bound to the platform state (i.e., PCR values).

**Binding simTPM and RTM:** To create a binding between the simTPM and a trusted, local RTM, we need the simTPM to 1) authenticate the RTM to ensure its a trusted code (e.g., BL1 of ATF); and to 2) ensure policies (e.g., for data release) and commands (e.g., attestation) are only executed for exactly the platform for which the simTPM stores the measurements. To address those challenges, we identified two possible solutions, using the device’s TEE as a proxy to the simTPM (see below) or using distance bounding protocols (discussion deferred to the technical report of our implementation [16]).

*Using TEE as TPM proxy:* One way to bind the simTPM with the device’s RTM is by leveraging the platform security building blocks of mobile devices and using the TEE as a proxy to simTPM (see Figure 3). On a genuine device with secure boot in place, i.e., BL1 as a trusted RTM, the TEE has exclusive access to device-specific credentials that are certified by the device vendor. Using those credentials, the simTPM and TEE can establish a secure end-to-end channel. In this setup, simTPM will only respond to PCR extensions, attestation requests, or unsealing of encrypted data if the commands come via this secure channel. As a result, an attacker cannot forge arbitrary PCR values without compromising the device-specific key. Further, if the TPM enforces a particular device key, it can ensure that only the intended platform is using the simTPM; however, even without this strict set of device keys, this solution still ensures that any TPM commands, such as releasing data to the host platform, can only come from a genuine mobile platform with an intact secure boot from which it received the measurements. Considering previously mentioned software-based attacks against TEE (see Section 3.2), an attacker could compromise the TEE to steal the device-specific key and impersonate the TEE to the simTPM. This can be alleviated by using session keys instead of the long-term secret device-specific key for communication between TEE and simTPM, which could be setup during the bootstrapping and, hence, before untrusted code can attack the TEE. A drawback of this solution is that the simTPM

requires the TEE to be bootstrapped to become itself operational, which prevents an early availability of the simTPM. Since the simTPM is not early available in this setup, ATF’s secure boot has to be extended to store the measurements of verified software components and pass those measurements on to the TEE, which then can forward them to the simTPM via the secured channel (D3: ✨). It should be noted that while this extension to ATF would also provide a solution to the early availability of fTPM [54], simTPM gives a user-centric solution and additional interesting use-cases in comparison to fTPM (see Section 6). We discuss an alternative solution based on a distance bounding protocol in Appendix A.

#### 4.4 Security analysis

Lastly, we analyze the security of simTPM in comparison to the closest solutions fTPM and hardware TPM, specifically considering the deployment of our TPM on a SIM card.

**Off-chip protection:** As mentioned in Section 3, fTPM depends on the integrity of the secure world, which has been under attack recently [3, 8, 18, 41, 51, 55–57]. Our simTPM implements an off-board TPM on the SIM card and, like a discrete TPM, is physically isolated from untrusted code. This provides a stronger protection of the simTPM’s trusted computing base, however, we cannot fully exclude potential software attacks against the SIM card software. For instance, in the past smart cards have exhibited bugs [50] like hidden commands, buffer overflows, weaknesses of cryptographic protocols [52], or malicious applets [52]. Further, like a hardware TPM, simTPM is connected via a bus, which makes it prone to advanced bus attacks [12, 34, 36] that, however, are considered outside the attacker model for consumer grade hardware like the TPM.

**SIM card cloning:** Deployment on a SIM card also raises the concern of card cloning [65], which could easily enable impersonation attacks or theft of credentials. However, driven by the interests of telecommunication companies, modern SIM cards come with anti-cloning defenses that mitigate this attack vector [42].

**SIM swapping attack:** In SIM swap attack, an attacker obtains details about the victim and then tricks the telephony company to port the victim’s phone number to a fraudulent SIM card owned by the attacker, usually with the goal to receive all SMS including highly sensitive information, like OTP for online banking. In our design, the TPM is not dependent on the SIM telephony functionalities. simTPM works as a local co-processor with desirable attributes. An attacker can port the telephony services to a fraudulent SIM card, but not the TPM state, as it is bound to the local SIM-card and would require explicit migration policies to other (SIM)TPM.

**Side-channel attacks:** To be compliant with the TPM 2.0 specification, the hardware has to implement cryptographic functions that are resilient to timing-based side-channel attacks. There exists a similar requirement for smart cards, which are designed to be resistant against various types of side-channel attacks. Thus, simTPM immediately benefits from the security features of the underlying smart card.

However, a motivated attacker can easily move simTPM to a controlled environment and mount different active side-channel attacks, such as clock frequency, heat measurement, probing [33], fault injection [35], or power analysis [40,47,48]. While similar attacks have been shown against ARM TrustZone (e.g., [39,58]) and discrete TPM chips [59], deploying the TPM on a removable card might ease mounting those attacks. Nevertheless, it should be noted that such sophisticated hardware attacks are not only strenuous, exorbitant, and inconsistent, but also beyond the protection that a consumer grade security chip can offer.

## 5 Performance Evaluation

We evaluate the performance of simTPM on a HiKey960 board in comparison with a hardware TPM. We focus on the most frequent commands executed by a TPM, i.e., key generation, sealing/unsealing of data, extending/reading a PCR, generating random bytes, and computing a hash value of an input. Beside simTPM we prepared two test setups equipped with an Infineon SLB 9670 TPM chip. One of these two test benches is a plug-able TPM on a Raspberry-Pi (*piTPM*) and the other one is an embedded TPM on a standard Lenovo laptop (*embTPM*). More details about the setups is given in [16]. We have used a TSS implementation by IBM [2] to communicate with the Infineon TPM. The results of our benchmarks are summarized in Figure 4. All results come from 50 measurements per command per device. We report the 95% confidence intervals.

### 5.1 Test cases and results

**Key generation:** We measured the time to generate a 256-bit ECC key and output the public part of the key. Our implementation of simTPM creates the key on average in  $257 \pm 8.03ms$ , comparable to the piTPM performance ( $253 \pm 1.25ms$ ), but slower than the embTPM ( $172 \pm 0.61ms$ ).

**Create hash:** We measured the time it takes for the TPM to hash 256 bits of input data with SHA-256 and output the digest. piTPM ( $50 \pm 0.76ms$ ) and embTPM ( $21 \pm 0.16ms$ ) outperform the simTPM ( $72 \pm 10.13ms$ ) by a factor of 1.44 and 3.42, respectively.

**Extending and reading a PCR:** We evaluated the PCR extend and read commands. The former allows to extend the

PCR with a new value, while the latter command is used to read the current value of a PCR. We use SHA-256 as hash algorithm and a 128 bit string as input value. For PCR extension, simTPM ( $24 \pm 2.66ms$ ) is on par with embTPM ( $21 \pm 0.11ms$ ), however, exhibits a higher instability of the performance. For reading PCRs, simTPM ( $15 \pm 0.15ms$ ) is the fastest implementation, followed by embTPM ( $21 \pm 0.13ms$ ). piTPM is the slowest implementation in both cases ( $41 \pm 1.22ms$  and  $57 \pm 2.58ms$ ) and exhibits an unstable performance, too.

**Sealing and unsealing data:** The TPM seal command takes a byte array, attaches a policy, encrypts it with a TPM storage key, and returns a blob to the caller. When unsealing, the TPM takes an encrypted blob, checks the policy, and decrypts the blob if the policy is satisfied by the TPM state. For our performance measurement we used 128 bits input data, a 256-bit ECC sealing key with ECIES, and an empty policy. The embTPM is the fastest solution for sealing and unsealing ( $130 \pm 0.27ms$  and  $89 \pm 0.46ms$ ) and outperforms our simTPM ( $588 \pm 18.55ms$  and  $376 \pm 22.30ms$ ) by a factor of 4.52 and 4.22, respectively.

**Random number generation:** We use the TPM to generate a 64 bit random number. Our simTPM is the fastest solution ( $15 \pm 0.14ms$ ), followed by embTPM ( $21 \pm 0.17ms$ ) and then piTPM ( $63 \pm 1.63ms$ ).

### 5.2 Discussion of performance

Our test results show that there is no clear winner among our test systems. simTPM as well as embTPM excel for some commands and we would argue that our simTPM prototype shows a competitive performance. Unfortunately, the implementation of Infineon SLB 9670 TPM is not publicly available, thus commenting on the exact reasons for those differences would result in speculations. If we would venture to speculate, potential reasons for the differences could be the different communication buses. embTPM has a dedicated bus communication with the onboard processor and a faster processor, while piTPM is running on a Raspberry Pi and is connected over GPIO with lower bandwidth. On the other hand, simTPM is connected through the USB bus. Moreover, our simTPM implementation uses only the publicly available APIs of the smart card OS, which provide only an indirect access to hardware level commands. Hence, a vendor-supported implementation with direct access to the microprocessor would improve in efficiency.

The fTPM is unfortunately not available, precluding a direct comparison in our test suite; however, our observations for the embTPM speed are comparable to those reported by Raj et al. [54], although it is unclear which hardware TPM they evaluated. An fTPM, unsurprisingly, outperforms any other tested implementation here—e.g., slowest fTPM in [54]

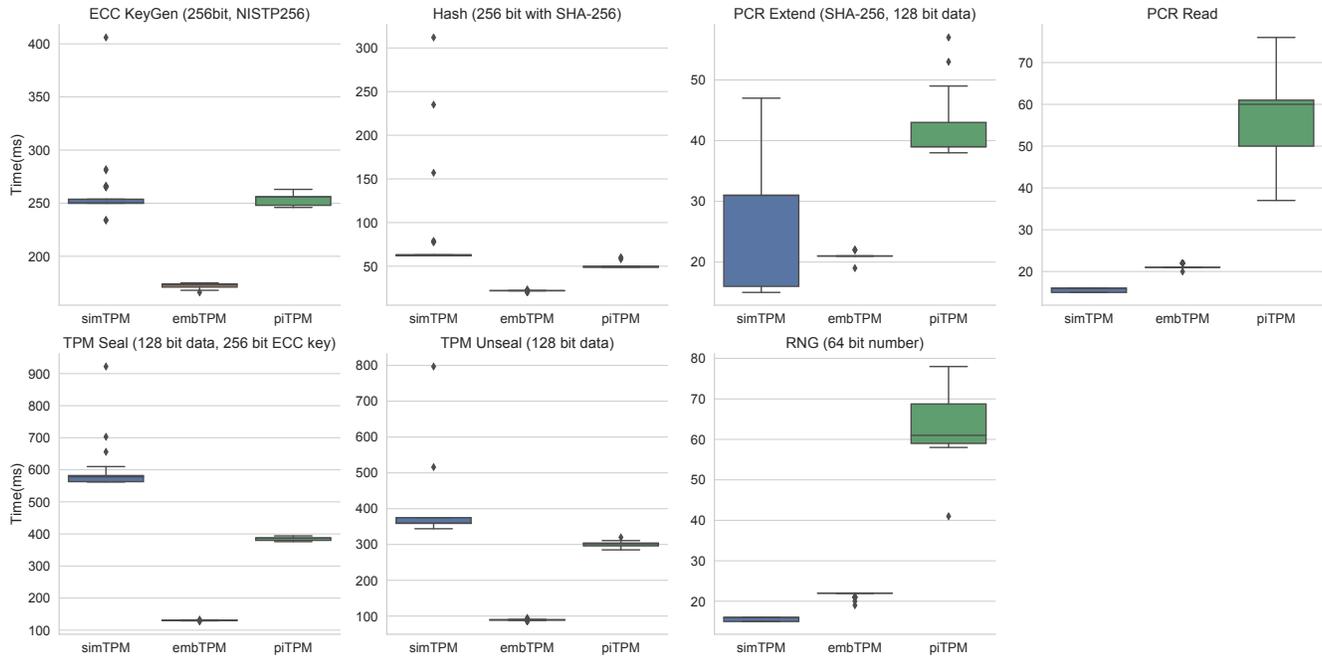

Figure 4: Performance comparison (in *ms*) of different TPM commands for simTPM and an Infineon SLB 9670 TPM2.0 on a Raspberry-Pi and Lenovo laptop.

was between 2.4–15.12 times faster than the fastest hardware TPM—since it is executed on the ARM Cortex main application processor, whereas discrete TPMs use slower microprocessors, as does our simTPM.

## 6 Use Cases

We discuss briefly how simTPM fits into the trusted computing landscape and explain scenarios that are of particular interest when simTPM and fTPM co-exist.

### 6.1 Multiple stakeholder model

The TPM specifications [64] as well as the obsolete Mobile Trusted Module (MTM) specifications [61] acknowledged the fact that a trusted platform might have multiple stakeholders. In particular, mobile platforms are not considered under the full management of the user, but critical mobile network management is the domain of the mobile carrier/network operator and the device vendor has high interest in keeping highest privileged operations (e.g., TEE and OS) under their control. The old and new TCG specifications define recommended capabilities and various implementation alternatives to allow multiple stakeholders to safely coexist. For instance, the MTM specification clearly differentiates between remote stakeholders and local stakeholders, each with their own TPM under their control. This concept is reflected in the recom-

mended capabilities for a mobile TPM2.0 [63], which advise the isolation between stakeholders and their resources and policy-based authorization of stakeholder sensitive data. To realize this multiple stakeholder model, the reference architecture outlines different implementation alternatives. For instance, multiple TPMs within a protected environment like TEE, or virtual TPMs supported by a hypervisor [9], where stakeholders are isolated from each other based on the compartmentalization provided by the TEE’s trusted OS or the hypervisor, respectively.

Our particular setting also fits well into the defined multiple stakeholder model: two distinct TPMs co-exist, each with a distinct affinity to a different stakeholder. The fTPM is by design designated to the platform stakeholder (i.e., device manufacturer) and it is bound to the device through the device-specific credentials within the TEE (e.g., eFuses) from which fTPM derives its endorsement key and to which it anchors its key/storage hierarchies. For instance, the fTPM described in [54] is designated entirely to the platform and its services. In contrast, the simTPM is designated to the end-user. This intuition is based on the observation that users use the SIM to authenticate themselves to the mobile network and rather stick to one SIM (i.e., phone number) while changing more frequently the device. Moreover, users have to explicitly authenticate themselves to the SIM card, i.e., their mobile carrier issued PIN. In this setting we are going beyond the initial proposals by the TCG reference architecture by actually as-

Table 2: Migrating user data when switching SIM card or device

	Data bound to device	Data <b>not</b> bound to device
New SIM card	Key duplication	Key duplication
New device	TPM_Authorize key policy	—

signing two distinct stakeholders to two *physically* separated TPM instances, SIM card versus TEE.

## 6.2 Switching SIM card or device

Since the SIM card is removable and exchangeable, two scenarios have to be considered: the user switches devices but keeps the SIM card, or the user keeps the device and switches to a new SIM card. How this affects migration of the user data protected with the simTPM is summarized in Table 2 and explained in the following.

**Switching device:** When switching the mobile device and migrating the user data to a new device, the complexity of the operation is dependent on whether the user bound any data to the device. For instance, during secure boot, BL1 has access to device-specific information like the `board_id` (or potentially values derived from the device-specific vendor key) that uniquely identifies the current platform. This `board_id` (like derived values) can be included in the measurements collected during secure boot (see Section 4.3) and allow the simTPM to bind data or keys to this particular platform.<sup>2</sup> If the user did not bind any data/keys to the platform, no further action is required beyond moving the SIM card to the new phone. The entire simTPM state including the key hierarchy is inherently migrated to the new device and can be used to decrypt the user data—i.e., a form of *portable sealed storage*. If the data is bound to the `board_id`, a new feature of TPM2.0 called `TPM_Authorize` has to be used to avoid the problem of *"brittle policies"*. Without `TPM_Authorize`, the user data would be bound to one particular `board_id` and could never be decrypted on another device. With `TPM_Authorize` different possible `board_id` values can be signed off as valid for a successful verification of the platform state and, hence, decryption of data migrated with the SIM card. The valid `board_id` values can be signed off by the user to endorse a new phone to which data should be migrated, or by another entity, like the mobile carrier or the employer in BYOD settings.

**Switching SIM card:** If the user switches the SIM card and hence moves to another simTPM, all user data has to be migrated to the new SIM card, i.e., the necessary simTPM

<sup>2</sup>Assuming a bond between the RTM and simTPM was established.

keys have to be moved to the new simTPM. Independent of whether the user data is bound to the device or not, switching the SIM card requires the simTPM keys used for securing the data to be duplicated to the new simTPM. This is an example scenario for TPM2.0 key duplication to migrate keys and associated data to another TPM and is supported by simTPM.

The bottom line of those two scenarios is that a user that wants to keep the option to migrate data secured with the simTPM to both new SIM cards and new devices should use duplicable keys with `TPM_Authorize`.

## 7 Discussion

The fTPM [54] is the incumbent deployment for a TPM on mobile devices and was part of the Windows Phone platform. However, it was designed primarily for vendor services and did not specifically target the end-user. In this work, we add to the landscape of mobile trusted computing and advocate using the dormant hardware capabilities of SIM cards to provide (additional) TPM support on mobile devices. Our systematization of related works shows that a simTPM can take a niche among the existing works and, in particular, inherently avoids problems of TEE-based deployments (e.g., protected state or secure clock) that currently require compromises and modifications to the TPM specification (e.g., "dark period" or cooperative checkpointing of fTPM) or that make additional hardware requirements (e.g., replay-protected memory blocks). On the other hand, a movable TPM raises the challenge of how to bind the TPM and the platform RTM. In this work, we proposed using the unique features of mobile devices—secure boot and TEE with device-specific, certified keys—to address this challenge. However, we find that this problem also affects prior solutions, like a vTPM based on a PCI-attached secure co-processor, and our solution might give insights into how to establish the TPM-RTM binding in those prior works.

Our simTPM implementation is based on a physical SIM card, thus it is currently not suitable for phones using eSIM (e.g., Apple iPhone). However, eSIM solutions are supported by separate hardware modules (such as JEDEC SON-8) and it might be worthwhile to investigate how those modules can be extended to implement a full TCG compliant TPM2.0.

Recently, Google introduced their Titan chip [67] as part of their Nexus 3 phones, which shows the need for hardware-backed security features in addition to TEE-based implementations on mobile end-user devices. Similar to the simTPM, Titan chip also provides hardware-backed security for system operations like verified booting as well as a hardware-implemented keystore for apps and users. But Titan is exclusive for Google devices, whereas our simTPM is portable between mobile devices and provides TPM2.0 compliant features. Since implementation details are yet unknown, we excluded the Titan chip from our systematization in Section 3.

## 8 Conclusion

In this paper we proposed simTPM, a hardware-based TPM implementation for mobile devices using the SIM card. Performance evaluation of our prototype shows that our implementation is comparable with an existing discrete TPM chip. Thus, we think simTPM is a practical solution to add user-centric trusted computing technology to mobile devices without the need to add hardware. A particular challenge of a movable TPM is the binding between TPM and the device RTM, which we addressed through a TEE-proxy or a distance bounding protocol. Future work includes a more detailed and formal write-up of the custom DAA scheme we used in our prototype, since it is particularly fitting for implementation on a smart card. Also future implementations of simTPM in industrial IoT or automotive settings for hardware based attestation could be worthwhile to pursue.

## 9 Acknowledgment

We are grateful to N. Asokan for his insightful suggestions. We are also thankful to the anonymous reviewers for their valuable comments.

## A Binding RTM with distance bounding

In Section 4.3 we discussed using the TEE as proxy in order to assert the authenticity of the RTM and mitigate the risks of a relay attack. Another way to bind the simTPM with its RTM is by using a distance bounding (DB) protocol [7, 10, 13]. Distance bounding is widely used for card-based payment systems. When a credit card is punched to the card reader, the reader runs a distance bounding protocol to check the proximity of the card to prevent a possible relay attack. We are facing the opposite scenario, in which the card is trying to

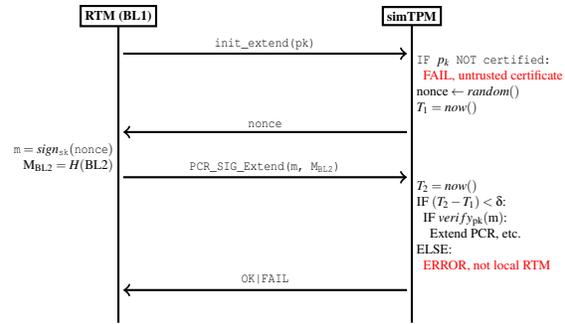

Figure 5: Prototypical distance bounding protocol for binding local RTM (BL1) and simTPM

assert the proximity of the device where the communication partner, here the RTM, resides.

**Prototypical distance bounding:** We assume the device vendors equipped the simTPM with certificates for their device-specific keys, which allows a verifier to distinguish trusted code with access to such secrets (e.g., early bootstages, like BL1 or the TEE) from untrusted code, like the host OS or apps. To assert the proximity of the RTM, only the very first measurement provided to the simTPM, i.e., the measurement by BL1 (RTM) of BL2, has to be checked for proximity. After that, the chain of trust of an authenticated boot will transitively extend this trust into the proximity of the RTM. Figure 5 illustrates a prototypical protocol for our scenario. We consider a two-step PCR extension by the RTM for verifying the proximity: (1) the RTM provides the public key  $pk$  of its device-specific key (or a key derived from it) to the TPM, which then can verify the authenticity of the RTM using the vendor-supplied certificate; (2) as in other distance bounding protocols, the simTPM (verifier) challenges the RTM (prover) with a nonce to which the RTM replies with the signed nonce value (using the authenticated private key) as well as the PCR extension arguments. If this reply of the signed nonce is received within a time threshold  $T$  and the signature verifies, simTPM assumes the RTM to be local and extends the PCR with the supplied measurement value  $M_{BL2}$ ; if either condition fails, the simTPM aborts. For robustness of the protocol, the challenge-response can be repeated  $N$  times to decrease the chances of a legitimate, local RTM failing the threshold.

**Prototypical setup:** In general, calculating the threshold for distance bounding is difficult, because various factors can influence the response time. For instance, jitters of the network over which the verifier and prover communicate, interrupts of the prover's computation, cache and memory delays, etc. might introduce a high uncertainty of the expectable response time. At first glance, our particular scenario seems very favorable for a distance bounding protocol, since the prover (RTM) is the BL1 that has exclusively control of the CPU without interrupts or interference of an OS; and the RTM is connected

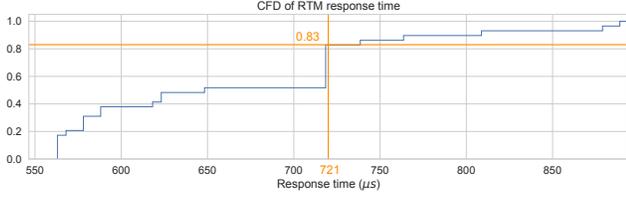

Figure 6: Cumulative frequency distribution of the RTM response time in our measurements ( $N = 30$ )

to the SIM card over a 480 mbps USB 2.0 bus, in modern devices even via a 5 gbps USB 3.0 bus, with no parallel transfers, providing favorable circumstances for a challenge-response protocol and small error-margin in which an attacker has to fall for a successful, undetected relay attack [20, 22, 44].

The SIM card is connected to the phone through a reader, which is directly connected to the baseband processor. The reader powers the smart card and provides it with the baseband’s clock. The clock duty cycle shall be between 40% and 60% of the period during stable operation [27]. Modern smart cards support clock stop to allow preservation of power, which an attacker could use to tamper with the verifier’s perception of time. However, this feature can be disabled by initializing the card as clock stop not allowed by setting the *VERIFY CHV* command to 0. Disabling this feature will increase the phone’s battery consumption, but not in a significant amount, since the maximum current consumption of an idle SIM card should not exceed  $200\mu\text{A}$ .

The SIM card and the reader connection are in a contact connection and generally interfaces within  $20\text{ns}$  [15, 38]. The reader connects to the baseband processor through Non-Level-Shifted bidirectional I/O. The connection in our test setup goes through an USB 2.0 bus with 480 mbps. Communication between SIM card and the CPU via this bus ranges between  $35\text{ns}$  to  $72\text{ns}$ .

**Measurements and threshold:** We conducted measurements on our test device to evaluate the feasibility of distance bounding to bind the RTM and simTPM. We measured 30 times<sup>3</sup> the speed of the prover (RTM) for calculating the response to the challenge (64 bits nonce) using ECC with the NIST P-256 curve. In our test, the responses took  $563\text{--}894\mu\text{s}$ , and the average response time was  $669.759 \pm 49.804\mu\text{s}$  for a confidence level of 99%. Figure 6 shows the CFD of the RTM response time, where 83% of all responses were  $\leq 721\mu\text{s}$  and 93% of all responses were  $\leq 812\mu\text{s}$ . The success chance of the distance bounding protocol  $P_{DB}$  for a single round is the cumulative probability sampled over the frequency distribution in Figure 6. If we were to set the threshold  $T$  for successful distance bounding to  $721\mu\text{s}$ :

<sup>3</sup>A single measurement requires  $\approx 5\text{min}$ , since only a single measurement per power-cycle is possible on our test device.

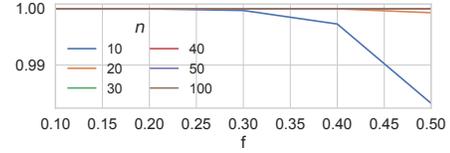

Figure 7: Success probability of local RTM for distance bounding depending on  $f$  and  $n$  for  $T = 721\mu\text{s}$  ( $p = 0.83$ )

$$P_{DB} = \Pr[x \leq 721] = \sum_{i=563}^{721} \Pr[x = i] \approx 0.83$$

where  $563\mu\text{s}$  is the lowest latency in our dataset. Going below  $721\mu\text{s}$  reduces the probability of a successful bounding protocol for legitimate devices, i.e., to 0.52 for a threshold of  $649\mu\text{s}$ . To increase the chances for local RTM to pass the distance bounding check, a successful verification usually requires that the response is below  $T$  for a sufficient fraction  $f$  of the responses, means at-least  $f \times n$  out of  $n$  responses should arrive within  $T$ . When modeling the challenge-response game as binomial distribution and requiring  $f \times n$  responses within  $721\mu\text{s}$  out of  $n$  responses (i.e., success probability  $P_{DB} = 0.83$ ), the cumulative probability distribution is:

$$\Pr[x \geq fn] = \sum_{i=fn}^n \binom{n}{i} (p)^i (1-p)^{n-i} \text{ where } p \in \{P_{DB}\}$$

Figure 7 shows the success probabilities for different choices of  $f$  and  $n$ . An optimal choice minimizes  $n$  (lower overall runtime overhead for the protocol) while maximizing  $\Pr[x \geq fn]$  and minimizing the chance of the attacker to successfully relay. We have observed from our dataset that setting  $f = 0.47$  for  $n = 30$  (i.e., 14 out of 30 runs) offers a success rate  $\Pr[x \geq fn] = 0.99999724049$  for local RTM.

**Attacker chances:** The APDU package for the challenge is 112 bits and for the response 304 bits, which are transferred virtually instantly between verifier and prover ( $\leq 1\mu\text{s}$ ). Thus, the response time measured in Figure 6 consists virtually only of the processing time of the RTM, which an attacker cannot speed up (see Figure 3). As a consequence, if an attacker requires more than  $721 - 563 = 158\mu\text{s}$  to relay the challenge and the response, the relay attack has no chance of winning, since the RTM in our tests required at least  $563\mu\text{s}$  to compute the response. Assuming a packet size of 55 bytes (minimal Ethernet frame size, IP header, and UDP package with 1 byte payload for the nonce/response), the attacker needs at least a relay bandwidth of  $\approx 5.87$  mbps to have *any* chance of winning, which is a very reasonable assumption. Hence, attacks against this distance bounding are feasible. From our measurements it is hard to concretely model the attacker, however, the attack chance is already 0.1% when relaying via Ethernet and an IP network (55 bytes datasize) with a bandwidth of  $\approx 49$  mbps, or when relaying only the APDU data of 14 bytes (e.g., via a custom build connection) with  $\approx 10$  mbps.

# The Betrayal At Cloud City: An Empirical Analysis Of Cloud-Based Mobile Backends

## Abstract

Cloud backends provide essential features to the mobile app ecosystem, such as content delivery, ad networks, analytics, and more. Unfortunately, app developers often disregard or have no control over prudent security practices when choosing or managing these services. Our preliminary study of the top 5,000 Google Play Store free apps identified 983 instances of N-day and 655 instances of 0-day vulnerabilities spanning across the software layers (OS, software services, communication, and web apps) of cloud backends. The mobile apps using these cloud backends represent between 1M and 500M installs each and can potentially affect hundreds of thousands of users. Further, due to the widespread use of third-party SDKs, app developers are often unaware of the backends affecting their apps and where to report vulnerabilities. This paper presents SkyWalker, a pipeline to automatically vet the backends that mobile apps contact and provide actionable remediation. For an input APK, SkyWalker extracts an enumeration of backend URLs, uses remote vetting techniques to identify software vulnerabilities and responsible parties, and reports mitigation strategies to the app developer. Our findings suggest that developers and cloud providers do not have a clear understanding of responsibilities and liabilities in regards to mobile app backends that leave many vulnerabilities exposed.

## 1 Introduction

Cloud-based mobile backends provide a wide array of features, such as ad networks, analytics, content delivery, and much more. These features are supported by multiple layers of software and multiple parties including content delivery networks (CDNs), hosting providers, and cloud providers who offer virtual/physical hardware, provisioned operating systems, and managed platforms. Due to the inherent complexity of cloud-based backends, deploying and maintaining them securely is challenging. Consequently,

mobile app developers often disregard prudent security practices when choosing cloud infrastructure, building, or renting these backends.

Recent backend breaches of the British Airways [1] app and Air Canada [2] app demonstrate how wide-spread these incidents are. More recently, the hijacking of the Fortnite mobile game [3] showed how incrementally-downloaded content from mobile backends can allow an attacker to install additional mobile apps without the user's consent. Additional cases [4] involving the exposure of 43TB of enterprise customer names, email addresses, phone numbers, PIN reset tokens, device information, and password lengths was due to *insecure mobile backends* and not the developer's mobile app code.

Even for security-conscious developers, it is not clear what backends their mobile app will interact with because of third-party libraries. Third-party libraries do not expose their backends to developers, instead, they offer an application program interface (API) that developers use. Many of these vulnerabilities can be identified ahead of time if developers have the right tools and resources to evaluate the security of their backends. Further, identifying vulnerable software layers and the responsible party can expedite remediation and therefore lower the risk of exposure.

To deal with the complexities in cloud infrastructure, the research community surveyed [5] and proposed several taxonomies [6], ontologies [7], assessment models [8], and threat classifications [9]. Unfortunately, these approaches provide few practical recommendations for mobile app developers. Recent works on server-side vulnerability discovery of mobile apps [10]–[12] have shown that a lack of security awareness among app developers is a growing problem. Yet, these works only scratch the surface by examining only the software service layer of mobile backends.

A systematic study is needed to identify the most pressing issues facing mobile backends. Moreover, to conduct such a study, the analysis must be reproducible, transparent, and easy to interpret for developers. The study should be done on a representative mobile app ecosystem to provide real in-

\*Authors contributed equally.

sight into the backend vulnerability landscape. Finally, the study should offer practical steps to guide and inform app developers on the security of their mobile backends.

To this end, this paper presents the design and implementation of SkyWalker, an analysis pipeline to study mobile backends. Using SkyWalker, we conducted an empirical analysis of the top 5,000 free mobile apps in the Google Play store from August 2018. Based on this study, we uncovered 655 0-day instances and 983 N-day instances affecting thousands of apps. We used Google Play Store metadata to measure the impact of our findings and estimate the number of affected users. We propose mitigation strategies for different types of vulnerabilities and guidelines for developers to follow. Lastly, we offer the SkyWalker analysis pipeline as a free public web-service to help developers identify what backends their mobile apps interact with, the security state of the backends, and recommendations to address any detected issues.

Our empirical study found 983 N-day instances of 52 vulnerabilities affecting hypervisors, operating systems, databases, mail servers, DNS servers, web servers, scripting language interpreters, and others. We found 655 0-day instances of SQL injection (SQLi), cross-site-scripting (XSS), and external XML entity (XXE). These affected thousands of mobile apps, with some apps having over 50M+ installs and more than 332,000 reviews. We present two case studies to demonstrate the vulnerabilities affecting a specific developer and vulnerabilities affecting a platform that is used by many developers.

We found these backends to be geographically distributed across the globe and hosted on 6,869 different networks. We notified all affected parties about the findings, and were careful to follow ethical and legal guidelines when conducting this study, additional details are in Section 8. We propose mitigation strategies for developers to follow based on the issues found and the types of backends. We conclude with recommendations for deploying and maintaining secure backends.

## 2 A Motivating Example

Mobile apps use cloud-based backend services to support extensive functions like ads, telemetry, content delivery, and analytics. Unfortunately, a mobile app developer who wants to audit the backends their app uses will quickly find that this is harder than it seems. The first thing the developer must do is simply enumerate those mobile backends. Consider the *Crime City Real Police Driver* (*com.vg.crazypoliceduty*) app, a mobile game with over 10M+ installs and 126,257 reviews. The mobile app uses several third-party SDK libraries including Amazon In-App Billing, SupersonicAds, Google AdMob, Unity3D, Nuance Speech Recognition Kit, and Xamarin Mono. The developer may not be aware of many of the backends that are invoked from imported native

or Java libraries, i.e., the Unity3D backends. In most cases, the developer will first have to employ static binary analysis tools or dynamically instrument the app to track multiple levels of SDK inclusion. SkyWalker automatically identified 13 unique backends from this app’s APK (shown in Table 1) and mapped them to the modules they were found in, i.e., library backends versus developer backends.

Party	Vendor	Backend	Purpose
Hybrid	Vasco Games	androidha.vascogames.com	Game Content
		api.uca.cloud.unity3d.com cdn-highwinds.unityads.unity3d.com config.uca.cloud.unity3d.com impact.applifier.com	Telemetry Ads Telemetry Telemetry
Third	Sizmek	bs.serving-sys.com secure-ds.serving-sys.com	Ads Ads
		Moat	px.moatads.com z.moatads.com
	Google		googleads.g.doubleclick.net pagead2.googlesyndication.com tpc.googlesyndication.com www.google-analytics.com

Table 1: Backends identified for *Crime City Real Police Drive* and their purpose. The red cells indicate vulnerable backends.

Backends have layers of software (components) that support the web application software (AS), including an operating system (OS), software services (SS), and communication services (CS). The developer now has to fingerprint the backends to inventory the software layers and identify the software type, version, and its purpose. Using this information, the developer can then check to see if any of their software is outdated or affected by a known vulnerability [13], a laborious and time-consuming task. SkyWalker identified that the game content backend runs *Debian 6* for the OS; *OpenSSH 6.5p1*, *Apache httpd 2.2.22*, *PHP/5.4.4-14*, and *Apache-Coyote/1.1* for the SS; and uses the HTTP protocol for CS. SkyWalker’s search of the national vulnerability database (NVD) [13] and correlation with the fingerprint results showed multiple common vulnerability exposure (CVE) entries affecting PHP 5.4.4-14. Further, the Debian version running on the backend is no longer supported and does not receive any updates from the vendor.

In addition to these issues, the developer’s AS can contain bugs that must be audited. The developer can check the AS by auditing the parameters passed to each API and testing for SQLi, XSS, XXE, or any other applicable vulnerabilities from OWASP’s top 10 common issues [14]. This task requires secure programming experience and security domain expertise to identify bugs in the source code. SkyWalker found that the game content backend interface is vulnerable to SQLi for some parameters passed by the mobile app, which is due to the AS not properly sanitizing the input.

The developer must now remediate or mitigate these risks, but each backend layer may be operated by different entities that provide hardware and software as a service. Therefore,

before fixing any issues, they must figure out what party is responsible for each component. SkyWalker fingerprinted the *Crime City Real Police Driver* game content backend, *androidha.vascogames.com*, as being hosted on a Google Compute Engine Flexible Environment instance (which provides virtual hardware, operating system, and PHP). We refer to this type of backend model as *hybrid* since Google is partially responsible for the virtual environment and the developer is responsible for the *AS* and *CS*.

The developer must come up with a remediation strategy to address these problems. Google advertises that they patch any vulnerable software affecting the *OS* and *SS*, but this is only applicable to non-deprecated versions. In the case of *Crime City Real Police Driver* app, the developer is responsible for all the software layers since the *OS* and *SS* versions are deprecated. The developer must upgrade to a supported *OS*, apply patches to the PHP interpreter (*SS*), patch the *AS* source code against SQLi, and support *HTTPS* for secure *CS*.

The Unity3D, Sizmek, and Moat backends shown in Table 1 are called *third-party*, since the developer has no control over them. This evaluation must also be carried out on third-party backends to identify additional vulnerabilities (potentially affecting all apps which use those shared services). SkyWalker found that the *Crime City Real Police Driver* app uses the *config.uca.cloud.unity3d.com* backend, which contains an XXE vulnerability, and the *bs.serving-sys.com* backend that contains an XSS vulnerability. Ideally, the developer could report those vulnerabilities to the platform through a bug bounty program or migrate their app to backends that are not vulnerable.

This manual assessment procedure is very involved and requires extensive security domain knowledge, which many app developers may not have. Instead, SkyWalker gives all mobile app developers the ability to identify the backends invoked by their app, assess their software layers, and suggest remediation strategies to improve the security for their mobile app backends.

### 3 Background

This section defines an abstraction to model mobile backends for our empirical study. We also define our labeling for backends and create a mapping between responsible stakeholders and resources. We outline how we count vulnerabilities and define them in the context of this work.

#### 3.1 Mobile App Backend Model

We follow the standard definition for mobile backends used by industry leaders [15]–[18], which encompass many cloud features, such as storage, user management, notifications, and APIs for various services, regardless of who maintains/owns them. We breakdown mobile backends into a stack representation that consists of five layers:

- **Hardware (HW)** refers to the physical or virtual hardware that hosts the backend.
- **Operating System (OS)** refers to the OS running on the hardware, i.e., Linux or Windows.
- **Software Services (SS)** refers to software services running in the OS, i.e., database service, web service, etc.
- **Application Software (AS)** refers to the custom application interface used by mobile apps to interact with the running services.
- **Communication Services (CS)** refers to the communication channel supported between the mobile app and the mobile backend.

Our approach does not consider the hardware layer because 1) we would need root-level access on the backend to evaluate the hardware and 2) mobile app developers have no direct way of addressing hardware vulnerabilities, i.e., manufacturers must issue firmware updates or replace the hardware. It is important to note that this work does not consider the mobile app security, instead we leverage the mobile app to study the backend.

We differentiate between mobile backends by ownership, which provides a granular mapping between stakeholders and resources. We define four labels for the mobile backends with respect to the app developer:

- **First-Party ( $B_{1st}$ )** refers to backends that are fully managed by the mobile app developers (i.e., full control over the backend).
- **Third-Party ( $B_{3rd}$ )** refers to backends that are fully managed by third-parties (i.e., no control over the backend).
- **Hybrid ( $B_{hyb}$ )** refers to backends that are co-managed by third-parties and developers such as cloud infrastructure (i.e., some control over the mobile backend).
- **Unknown ( $B_{unkn}$ )** refers to backends that ownership could not be established with high confidence.

In our model, there are two primary stakeholders, the app developers (*D*) and the cloud service providers (*SP*). There are additional stakeholders, like app users and internet service providers (ISP), but they do not have direct remediation oversight. We define a mapping between backends layers, labels, and ownership, shown in Table 2.

The final piece of the model is the mitigation component that maps vulnerable backends to the proper mitigation strategies. There are five mitigation strategies for developers:

- **Upgrade (*u*)** the software to vendor supported versions.
- **Patch (*p*)** vulnerable software with a vendor patch.

Label	<i>HW</i>	<i>OS</i>	<i>SS</i>	<i>AS</i>	<i>CS</i>
First-Party ( $B_{1st}$ )	○	○	○	○	○
Third-Party ( $B_{3rd}$ )	●	●	●	●	●
Hybrid ( $B_{hyb}$ )	●	◐	◐	○	○

Table 2: Backend labels (first-party -  $B_{1st}$ , third-party  $B_{3rd}$ , and hybrid -  $B_{hyb}$ ) and cloud layers (hardware -  $HW$ , operating system -  $OS$ , software services -  $SS$ , application software -  $AS$ , and communication services -  $CS$ ) mapping to stakeholders (developers - ○, service providers - ●, and shared - ◐)

- **Block** ( $b$ ) incoming internet traffic to exposed services.
- **Report** ( $r$ ) the vulnerability to the responsible party.
- **Migrate** ( $m$ ) the backend to secure infrastructure.

In many cases, the developer may not have control or authority to fix the issues but still has the option to report it ( $r$ ) or change service provider ( $m$ ).

### 3.2 Counting Vulnerabilities

This work considers vulnerabilities which are software bugs that exist in the backend software stack, including the operating system ( $OS$ ), services ( $SS$ ), application ( $AS$ ), and communication ( $CS$ ). We consider  $N$ -Day vulnerabilities to be those vulnerabilities which have an associated common vulnerabilities and exposure (CVE) number assigned by the national institute of standards and technology (NIST) and indexed in the national vulnerability database (NVD) [13]. In our findings, we count  $N$ -Day vulnerabilities by class and instance, where class refers to the CVE number of a particular vulnerability and an instance refers to the vulnerability affecting a specific interface or software component on a mobile backend. For example, Apache Struts vulnerability *CVE-2017-5638* that affects Apache Struts 2.3.x before 2.3.32 and 2.5.x before 2.5.10.1 is counted as a single vulnerability (class), but it can affect multiple backends that run different versions of Apache Struts (instances).

Some software versions are affected by multiple CVEs, in this case, we **do not** count every CVE as an instance. We generally assume patching the latest CVE should address all previous unpatched CVEs. We only consider the latest CVE affecting the vulnerable software and count it once. Further, a vulnerability instance is a tuple of the backend’s domain name, IP address, and the vulnerable software version. As for  $0$ -Day vulnerabilities, they are associated with the software application ( $AS$ ) running on the backend. This work looks at three classes of  $0$ -Day vulnerabilities, SQLi, XSS, and XXE and counts each instance per API interface endpoint on the mobile backend. The defined model, labels, mitigations, mappings, and vulnerabilities are the basis for our methodology, which we describe next.

## 4 Methodology

In this section, we provide an overview of our assessment and details about implementing SkyWalker. Figure 1 is an overview of SkyWalker’s internal components. We divide the implementation into four phases, namely binary analysis, labeling, fingerprinting, and vulnerability analysis. Each phase provides input to the next phase, starting from an input app APK to the final vulnerability/mitigation report.

### 4.1 Binary Analysis

SkyWalker leverages our prior work, Smartgen [19], to perform the binary analysis and extract query messages from an APK binary. SkyWalker dynamically executes the code paths to the network functions and extracts the native usage of the backend APIs. The native usage of an API includes the URI path and their parameter types/values.

### 4.2 Backend Labels

Backend labeling assigns one of the four labels defined in our model. The labels are used to map the responsible parties and the mitigation strategies needed (excluding unknown), shown in Table 2. Moreover, the labels are used to identify where the most common issues are found. To perform the labeling, we curate three unique lists using the ipcat [20] datacenter dataset. The first list is called  $CP$  and contains cloud providers, content delivery networks (CDNs), and mobile platform cloud services. The second list,  $Colo$ , contains a list of collocation centers. The third list is a list of  $SDK$  libraries that we extracted using LibScout [21] (Table 3), which help SkyWalker identify third-party backends. OS-SPolice [22] provides a more comprehensive list, including native libraries used by the mobile app, but our binary analysis technique only instruments Java code, therefore, we limit the third-party SDK identification to LibScout.

To perform the labeling we generate a tuple for each extracted backend  $B$  that contains the effective-second level domain  $d$ , IP address  $ip$ , a boolean flag  $lib$  indicating if the backend belongs to an SDK library, and the developer or vendor name  $v$ . We define a function  $owner()$  that parses WHOIS, MaxMind [23], and ASN records to extract ownership information. The  $owner()$  function uses text tokenization, normalization, and aliasing to consolidate varying records.

SkyWalker uses Algorithm 1 to assign labels to each backend. Algorithm 1 takes as input a list of backends,  $\beta$ , containing tuples  $B = \{d, ip, lib, v\}$  and returns a list of labeled backends  $\beta'$ . The algorithm uses the  $CP$  and  $Colo$  list to check membership for the domains and IPs to determine the appropriate label. The first check is to determine the origin of the backend (was it extracted from an SDK library?) then

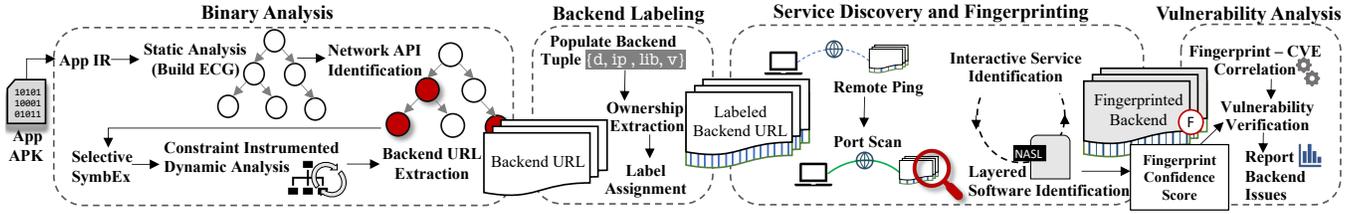

Figure 1: SkyWalker Overview. Phase 1 (Binary Analysis) extracts backend URLs through a dynamic binary instrumentation technique. Phase 2 labels backends into first-party, third-party, and hybrid. Phase 3 discovers and fingerprints the backend services to collect cloud layer information. Phase 4 (vulnerability analysis) uses the fingerprints and correlates them with public vulnerabilities to identify vulnerable backends.

### Algorithm 1: Assigning Labels to Backends

```

Input:  $\beta$  = List of backend tuple  $B = \{d, ip, lib, v\}$ 
Output:  $\beta'$  = Ownership labeled backend list
SDK: List of backend domains found in the SDK libraries;
CP: List of cloud and hosting providers (domains, net prefix, and ASNs);
Colo: List of collocation providers (domains, net prefix, and ASNs);
for  $\forall B \in \beta$  do
  if  $B.lib \vee B.d \in SDK$  then
    // Backend from Java lib
     $B.label \leftarrow$  "third-party";
    continue
  end
  if  $owner(B.d) \neq v \wedge owner(B.d) \notin CP$  then
    // Backend domain not owned by developer or CP
     $B.label \leftarrow$  "third-party";
    continue
  end
  if  $B.ip \in CP$  then
    // Backend IP hosted by cloud provider
     $B.label \leftarrow$  "hybrid";
    continue
  end
  if  $B.ip \in Colo$  then
    // Backend IP hosted by collocation center
     $B.label \leftarrow$  "first-party";
    continue
  end
   $B.label \leftarrow$  "unknown";
end

```

assigns “third-party” label if *lib*’s value is true or the backend domain belongs to the list of SDK backends.

If none of the previous statements are true about the domain, then SkyWalker checks the *IP* membership against the *CP* and *Colo* list. If the IP address belongs to a network on the *CP* list SkyWalker assigns “hybrid” label. If the IP address belongs to a network on the *Colo* list SkyWalker assigns “first-party” label. Otherwise, SkyWalker assigns an “unknown” label since it cannot be determined. It is important to note that SkyWalker’s labeling approach relies on LibScout [21] to identify third-party backends based on the SDK libraries. SkyWalker performs an additional check before setting the *lib* flag to exclude *SDK* libraries built by the same vendor (Google, Facebook, etc.).

### 4.3 Service Discovery and Fingerprinting

Service discovery identifies internet-facing services on backends and fingerprinting identifies the software type, version,

#### Third-Party SDKs

ACRA	CleverTap	InMobi	Supersonic

Table 3: A list of third-party SDKs extracted by LibScout from the top 5,000 apps, which is used to curate third-party backends.

and configuration of each service. Our approach is a multi-tier approach that starts by remotely pinging the backend, then port scanning it, then interacting with the discovered service, and finally collecting service configurations. For instance, the scan first checks to see if the host is reachable, then it scans for all ports to identify available services, then it tries to connect to the service to collect its banner, and finally, if the services use TLS/SSL, it would collect their configurations and supported ciphers. For each step, our scanner is configured to be non-intrusive, throttled (slow scan speed and a light load on the remote server), and conservative (using techniques that yield low to no false positives).

First, SkyWalker groups all IP addresses into their network prefixes and in a random order picks a prefix and a random IP from the selected prefix to scan. Prefixes are grouped by the autonomous system number (ASN) for each network. If a network spans multiple ASNs, SkyWalker keeps each ASN as a separate prefix to distribute the scanning uniformly across different IP segments. SkyWalker does a TCP ping against common service ports (FTP, SSH, HTTP/S, IMAP, SMTP, RDP, etc.) by sending out a SYN packet followed by

a RST packet. TCP ping scans are more reliable in detecting the availability of the remote server (backend) because they are not filtered by firewalls like ICMP scans.

Once SkyWalker establishes the host is reachable, SkyWalker conducts a TCP SYN scan (SYN-SYN/ACK-RST) across *all* ports. This process identifies candidate ports on the target backend that will be used for a more thorough scan (TCP connect). To be efficient, SkyWalker uses the list of ports identified in the TCP SYN scan to conduct a TCP connect scan (SYN-SYN/ACK-ACK) i.e., establish a complete connection. Based on the port/service identified, SkyWalker interactively grabs the banner, the header response, and any available configuration. The retrieved information varies per service type, for example, HTTP will have header information unlike SSH, nonetheless, both help fingerprint the host. Moreover, SkyWalker looks for TLS/SSL connections on all candidate ports because many services like HTTP and IMAP can run over TLS/SSL. Finally, to obtain the backend IP address fronted by CDNs, SkyWalker looks up the IP address in a manually curated CDN list and uses passive DNS to find historical records that existed just before the current records. When SkyWalker cannot locate such record, the backend is excluded from fingerprinting.

Once SkyWalker discovers all the services running on a backend, SkyWalker uses the result to fingerprint the backend. The fingerprint identifies the *OS*, *SS*, and *CS* type (Linux, Windows; PHP, .NET, Python, Perl; FTP, SFTP, HTTP, HTTPS, SSH, IMAP, etc.), version, and configuration information if available. The fingerprinting uses open source and commercial Nessus Attack Scripting Language (NASL) scripts to identify the different layers of software on the backend. For example, to identify the *OS*, the NASL script inspects the banner string, analyzes the SSL certificate, checks additional running services (SMB, RDP, SSH), performs structured ICMP pings, inspects HTTP headers, and uses TCP/IP fingerprinting algorithms [24]. Based on these signals a confidence score is provided based on matching a set of pre-profiled *OSes*. For example, if 90% of the signals match a *Windows Server 2008 R2 Service Pack 1* profile, we consider the *OS* layer for that backend in the vulnerability analysis. Any confidence level below 90% or ambiguity between the same *OS* but different versions will not be considered for the vulnerability analysis phase.

**Web Applications.** Web apps (*AS*) are generally tailored per mobile app, unlike *OS*, *SS*, and *CS* layers. The binary phase performs in-context analysis for each API interface on the backend, which provides API information used for fingerprinting. We reference the OWASP's top 10 vulnerability issues [14] that can be passively tested within the ethical and legal bounds discussed in Section 8. Specifically, SkyWalker uses side-channel SQLi through time delay, reflective XSS, and XXE callback to identify *candidate* issues in web apps. It is important to note that other vulnerabilities such as authentication bypass, broken access control, and sensitive data

exposure present a high risk that can violate legal obligations. Adding a module to SkyWalker to support additional vulnerabilities is trivial and can be easily implemented.

For each backend interface, a number of parameters ( $p$ ) are associated with each request. SkyWalker tests each interface  $p$  times to check every parameter for SQLi and XSS. The XXE check is performed on all interfaces because some *AS* can accept JSON or XML requests. As mentioned earlier, the scan is slow and randomly done to avoid congestion and degradation of service on production backends. SkyWalker creates two queues, a job queue and a processing queue. SkyWalker generates  $p$  requests for a given backend interface and stores them in the job queue. The job queue contains all backend requests, which are shuffled and loaded into the processing queue in batches (128 requests per batch). Batches that contain requests with the same domain or IP address are removed and replaced by non-overlapping domains and IP address requests. There are 32 workers that ingest from the processing queue and store the results for vulnerability analysis.

#### 4.4 Vulnerability Analysis

The vulnerability analysis is two parts, N-day analysis, and 0-day analysis. For the N-day analysis, SkyWalker correlates CVE entries with results from the fingerprinting to identify possible issues. The confidence level of the fingerprint results is also used to verify each vulnerability. SkyWalker uses NASL scripts that take the output of the service discovery, *OS* identification, *SS* identification, and *CS* identification as input and match them against known vulnerabilities (CVEs). The NASL results are considered if they have 90% confidence level or higher for *OS* detection, which provides high accuracy for vulnerability matching. Note, that the confidence level is calculated based on pre-profiled *OSes* by matching the fingerprint signals (collected from all layers) to the profile signals.

We manually verified all 983 N-days and found them to be all true positives. The zero false positive results are due to the Nessus configuration, which allows us to tune how the scans are done and how they should be reported. For example, we configure Nessus to perform the scan types described above, consider *OS* type and version detection of 90% or higher and consider *SS* that have banner information with version numbers. On the other hand, when we used UDP scanning techniques and consider generic service banner information we find over 6,500 candidate N-day instances with a large false positive rate. In theory, the backend can be configured to lie about the banner information, which would make it hard for us to verify.

For the 0-day analysis, SkyWalker carefully triggers the candidate vulnerability to verify the findings. For each vulnerable parameter, SkyWalker generates a pair of request messages, the original message and the vulnerable message.

For *SQLi*, SkyWalker baselines the original request message several times throughout the week and at different times of the day. Then SkyWalker performs the same measurement on the vulnerable message in the same week but in non-overlapping time intervals by triggering the vulnerable parameter through an *SQLi* sleep injection. SkyWalker calculates the response time deviation based on the sleep parameter passed in the SQL statement and the average response time of the message pairs. If the deviation is equal to the time delay parameter in the SQL statement, SkyWalker concludes that the interface and parameter pair is vulnerable.

Similarly for *XSS*, SkyWalker triggers the vulnerable parameter and includes JavaScript code to create a new *div* element with a unique *name* attribute. SkyWalker checks the returned content by parsing the document object model (DOM) to find the *div* element containing the unique *name* attribute. If the *div* element with the set *name* attribute exists SkyWalker concludes that the interface and parameter are vulnerable. Note that SkyWalker matches the returned content with parameters sent to ensure that the *XSS* candidate vulnerability is of type 2 (reflected). For *XXE*, SkyWalker generates a request message that contains an HTTP callback request to a server we operate. The request message is passed to the backend, which will parse the specially crafted XML document. If the parser is vulnerable to *XXE*, SkyWalker will log an HTTP request from the backend under analysis, which indicates the interface is vulnerable. In addition, we manually reviewed the request/return pairs for all 655 0-day instances and found no false positives.

## 4.5 Open Access for Developers

One of our primary goals for this work is to empower app developers with open access to SkyWalker via a free-to-use web-service. The service currently supports Android mobile apps but can be extended to support other mobile platforms, e.g., Apple iOS. The web-interface takes as input a link to an Android app in the Google Play store or a direct APK upload. SkyWalker then performs binary analysis to extract the backends, label them based on our curated dataset, fingerprint them, and identify vulnerabilities that affect them. In addition to the analysis, the output report provides guidelines on how to mitigate the identified issues using the strategies discussed earlier (upgrade, patch, block, report, and migrate).

SkyWalker summarizes vulnerability findings across all observed SDK and Java library backends, which developers can turn to *proactively* to make an informed decision when choosing third-party libraries to include in their future apps. It is important to note that attackers can abuse this system to attack mobile app backends. Therefore we require the developers to disclose their affiliation with the target app before the analysis results are provided. Once a user is manually vetted, they can only submit apps that they develop. We do not consider third-party *SDKs* in

this process. The SkyWalker service can be found at: <https://MobileBackend.vet>.

## 5 Assessment Findings

### 5.1 Experiment Setup

**Environmnet.** We use a local workstation running Ubuntu 14.04 with 24GB memory and 16 x 2.393GHz Intel Xeon CPUs and four Nexus phones to run and instrument the mobile apps. We use an Amazon Web Service (AWS) Elastic Compute (EC2) instance with a reserved IP address to conduct the fingerprinting and run a web server with information about our study along with an email address for backend hosts to contact us if they want to opt-out.

**Tools and Data Sets.** For the binary analysis tool implementation, we relied on Soot [25], FlowDroid [26], Z3-str [27], and Xposed [28] with custom code written in Java (7,000 lines of code) and Python (900 lines of code). For our backend labeling implementation, we relied on Team Cymru IP-to-ASN [29], MaxMind Geolocation [23], Alexa ranking [30], ipcat list [20], and Domaintools WHOIS [31] with custom code written in Python (480 lines of code). For fingerprinting, we relied on the Nessus scanner and commercial plugins [32], sqlmap [33], and Acunetix [34]. We used Nessus plugins and custom Python code (1010 lines of code) to perform the vulnerability analysis. For internet measurements, we utilized honeypot scanning activity from Greynoise [35].

### 5.2 Software Vulnerability Details

Table 4 shows the distribution of 0-day and N-day instances across the software layers. We categorize the apps using the Google Play store groups and present the number of vulnerabilities and backend labels. Overall, we analyzed 4,980 apps with cloud-based backends and successfully extracted backends for 4,740 mobile apps. The remaining 240 mobile apps crashed and did not complete the full binary analysis.

Interestingly, the *OS* component reports the least vulnerabilities, while the *AS* component reports the most vulnerabilities, across all mobile app categories. Recall from Section 3.2, vulnerabilities affecting *AS* components are all considered 0-day. The *OS*, *SS*, and *SC* components account for *N-day* vulnerabilities. Although the number of apps is not uniform across the categories, we use the *raw* vulnerability count for ranking. For 0-day vulnerabilities, the top three mobile app categories are tools, entertainment, and games. For *N-day* vulnerabilities, the top three mobile app categories are entertainment, tools, and games.

**Ownership.** Table 4 presents the labels for the backends used by mobile apps. The most common label is *hybrid*, where 3,336 backends use hybrid infrastructure. The second

Category	# Mob. Apps	Vulnerabilities					Labels				
		# OS	# SS	# AS	# CS	Total	# $B_{1st}$	# $B_{3rd}$	# $B_{hyb}$	# $B_{ukn}$	Total

Table 4: An overview of the vulnerable mobile apps per genre along with the *raw* counts of vulnerabilities and labels.

Party	Vulnerable Component				Total
	OS	SS	AS	CS	
$B_{1st}$	37	87	155	211	490
$B_{3rd}$	6	21	200	42	269
$B_{hyb}$	47	150	154	184	535
$B_{ukn}$	55	135	146	173	509

Table 5: Count of *apps* affected by vulnerabilities per cloud layer and their corresponding labels.

Comp.	Vulnerability (Top 3)	#Apps
OS	Expired Lifecycle for Linux OS (various)	124
	Windows Server RCE (MS15-034)	64
	Expired Lifecycle for Windows Server	9
SS	Vulnerable PHP Version	357
	Expired Lifecycle for Web Server (various)	181
	Vulnerable Apache Version	76
AS	XSS (various)	262
	SQLi (various)	160
	XXE (various)	86
CS	Support for Vulnerable SSL Version 2 and 3	997
	OpenSSH Bypass (CVE-2015-5600)	16
	Vulnerable OpenSSL (various)	15

Table 6: The top three vulnerabilities found per cloud layer along with the number of affected mobile apps.

largest is *first-party* with 2,492 backends followed by *third-party* with 1,089 backends. There are 2,506 backends that we were not able to label due to ambiguities, but we labeled approximately 73% of all backends we encountered.

More important is providing remediation guidance to the responsible party. Table 5 shows the mapping between the backend labels and the vulnerable apps. We cannot say much about the *Unknown* category since the vulnerabilities may belong to either *first-party* or *hybrid* categories. We observe that for first-party backends, the highest number of vulnerable apps are found in *AS* and *CS* components with 155 and 211 instances, respectively. Similarly, the hybrid backends have 154 0-day vulnerability instances and 184 N-day instances. In general, we observe that the components that app developers are responsible for (*AS* and *CS* in the  $B_{1st}$  and  $B_{hyb}$ ) have more vulnerabilities.

**Operating System (OS).** The *OS* component issues can be summarized into two categories: legacy unsupported *OS* or unpatched *OS*. The difference is that the legacy *OS* are no longer supported by the vendor, hence vulnerabilities will not be addressed. We see from Table 6 that both *Linux* (various flavors) and *Windows* backends use expired lifecycle versions and 133 apps use these backends. The second most common issue is the *Windows Server* vulnerability *MS15-034* affecting 64 apps, which have patches by the vendor. Overall, the top three *OS* vulnerabilities listed in Table 6 affect 197 mobile apps.

We found the *MS15-034* vulnerability affecting hybrid backends ( $B_{hyb}$ ) that run on *Amazon AWS*, *Akamai*, *OVH*, *Go Daddy*, *Digital Ocean*, and other smaller hosting providers. Further, some of the backends appear on CDN networks, like *Akamai*, *Fastly*, and *CloudFlare*, that offer “EdgeComputing” services [36] which provide web app accelerator services. This insight shows that some developers who deploy vanilla versions of *Windows Server OS* are not maintaining them. In Table 5 the first-party *OS* component has 37 vulnerable backends, which is much higher than third-party backends (6). App developers who run and maintain their own backends ( $B_{1st}$ ) have to be mindful of these bugs, which in some cases require provisioning new backends with newer OSes causing incompatibilities with existing services (*SS*) and applications (*AS*). SkyWalker can inform the developer of these issues and report mitigation strategies.

**Software Services (SS).** SkyWalker identified multiple vulnerabilities affecting a range of PHP versions, which can be used to cause denial of service (*CVE-2017-6004*), disclose memory content (*CVE-2017-7890*), disclose sensitive information (*CVE-2016-1903*), and execute arbitrary code (*CVE-2017-11145*). Backends of 357 mobile apps affected by PHP vulnerabilities, significantly higher than the other two vulnerabilities. Further, even though some mobile app backends had no 0-day vulnerabilities, an attacker can still craft special requests to trigger deep bugs within the interpreter to compromise the backend. Although this might be a difficult task, recent advancement in vulnerability fuzzing [37] can uncover these deep bugs.

The second most common *SS* vulnerability was unsupported versions of Apache web server (1.3.x and 2.0.x), Tomcat server (8.0.x), and Microsoft IIS web server (5.0). Similar to unsupported *OS*, web server vendors will not issue security patches for unsupported software, which affects backends of 181 mobile apps. For Apache web server versions less than 2.2.15, they are affected by several denial of service bugs (*CVE-2010-0408*, *CVE-2010-0434*) and TLS injection bug (*CVE-2009-3555*) affecting 76 mobile apps. Additionally, Apache servers that use Apache Struts versions 2.3.5 - 2.3.31 or 2.5.10.1 and lower are vulnerable to *CVE-2017-5638*, which allows remote code execution. The same Apache Struts vulnerability was reportedly used against Equifax’s hack [38]. In total, the top three *SS* vulnerabilities affect 614 mobile apps.

**Applications (AS).** Table 7 has a breakdown of the number of mobile apps, their number of install categories, and the instances of *0-day* bugs affecting them. Although *XSS* is the largest category with 503 instances followed by *SQLi* (215) and *XXE* (46), we note that not all of the bugs have the same impact and some affect the same backend. For instance, an *SQLi* can be limited to an isolated instance of the app (e.g., a container), which would limit the attack to disclosing information from the application database or modifying pre-existing records. Moreover, *XSS* vulnerabilities often have less impact than *SQLi* and *XXE*.

*XXE* vulnerabilities affect web apps that use XML for their API communication. The fundamental flaw that enables *XXE* vulnerabilities to exist is a faulty implementation of the XML parser. Based on our measurement, we found 1 *XXE* instance in the top 100M, 5 in the top 50M, 15 in the top 10M, 9 in the top 5M, and 17 in the top 1M. Table 7 shows the concentration of vulnerabilities found in lower ranking apps. For example: 1 *XXE* and 3 *XSS* vulnerabilities in the top 132 mobile apps; 4 *SQLi*, 10 *XSS*, and 5 *XXE* vulnerabilities in the next 131 mobile apps (though still representing over 50M+ installs each). However, *AS* vulnerabilities are not confined to lower ranking apps but do affect higher ranking apps.

# Installs	# Apps	# SQLi	# XSS	# XXE
1B	5	0	0	0
500M	11	0	0	0
100M	116	0	3	1
50M	131	4	10	5
10M	1,049	25	85	15
5M	1,047	54	89	9
1M	2,621	132	316	17

Table 7: The number of *0-day* vulnerabilities found per install category.

Table 8 shows the *AS* layer implementation language and associated vulnerabilities. *AS* implemented in *PHP* have the most *0-days* instances (284) affecting 108 different back-

Language	# Backends	# 0-Days
PHP	108	284
ASP.NET	13	33
PERL	4	9
JS	4	8
JSP	2	5
Unknown	72	316

Table 8: The number of identified languages associated with *0-day* vulnerable backends.

ends, followed by *ASP.NET* with 33 *0-day* instances affecting 13 different backends. We note that this trend does not mean causation. *PHP* is the most popular language used for web application development [39], hence it is expected to represent more vulnerabilities by being more popular. Furthermore, we found 9 *0-day* instances in *PERL*, 8 in *JavaScript (NodeJS)*, 5 in *JSP*, and the rest of the 316 could not be determined.

**Communication (CS).** All mobile apps rely on the HTTP/HTTPS protocol for communication with their backends. The binary analysis phase extracted a total of 17,725 request messages from the 4,740 mobile apps. The request messages are split into HTTP (8,118) request messages and HTTPS (9,607) request messages. There are 446 mobile apps that only use HTTP communication and another set of 147 mobile apps that only use HTTPS communication. The remaining set of 4,147 apps mix between HTTP and HTTPS communication.

Despite using HTTPS, over 20% of the backends (1,012) have issues with TLS/SSL configuration (e.g., insecure session renegotiation and resumption) or unpatched software versions (e.g., SSL version 2 and 3). These flaws can be exploited by an attacker to carry out a MITM attack by downgrading the protocol negotiation using the POODLE [40] attack. Additionally, the OpenSSH Bypass vulnerability exposes the backend to compromise via SSH credential guessing or secret key leak. The mobile apps using these vulnerable backends do not use the *SSH* service and to remediate one can turn off, patch, or block the incoming internet traffic to it.

Those backends which only use HTTP expose users to eavesdropping and MITM attacks because it does not offer integrity or confidentiality. We manually inspected the request messages sent from 3,253 apps that use HTTP and found personally identifiable information (PII) such as name, gender, birth year, user ID, password, username, and country. Additionally, we found device information like MAC, IMEI, SDK version, make/model, SSID, Wifi signal, cell signal, screen resolution, carrier, root access, IP Address, and coordinate location. Combining this information, a network attacker can identify individuals and attribute behavior profiles to them. Furthermore, 6 apps we investigated perform a password reset over HTTP. Interestingly, the Apple iOS App Store enforces strict use of HTTPS through their *App Trans-*

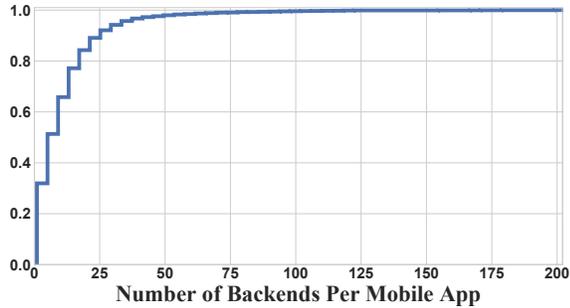

Figure 2: The figure shows the CDF of the number of backends per mobile app.

port Security [41] model. We recommend that the Android platform adopt the same restriction.

### 5.3 Impact on Mobile Application Users

The overall impact for each vulnerability varies based on the severity, the mobile app to backend usage, and the adversary capability/visibility. Although it is important to understand the impact of each vulnerability, it is not trivial to quantify the impact of each vulnerable backend on mobile apps. For N-day vulnerabilities, an attacker can perform an internet-wide scan to identify and attempt to compromise these backends. Even once identified, these N-days span many different components (*OS*, *SS*, and *CS*) that have varying impacts on the backend from basic information disclosure to a full system compromise. For 0-day vulnerabilities the attack impact varies based on the exploit type (*SQLi*, *XSS*, or *XXE*) and how the backend infrastructure is set up. Moreover, how the mobile app uses the backend directly impacts the severity of the vulnerability. For example, if a mobile app uses app slicing [3] or downloads additional libraries from the mobile backend, an attacker who compromises the backend can modify the content and attain code execution on the mobile device.

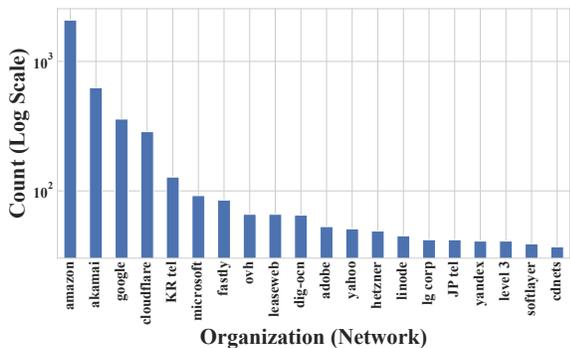

Figure 3: The figure shows the distribution of backends across internet networks.

In general, an attacker has a larger attack surface for apps that have many backends. Figure 2 shows a CDF of backends per mobile app. We can see that the majority of the 5,000 apps studied have between one and 25 different backends and in the worst case they have up to 203 different backends. We also observe that these backends reside in diverse networks as shown in Figure 3, which means the infrastructure set up for the backends will be different affecting the impact of the vulnerability.

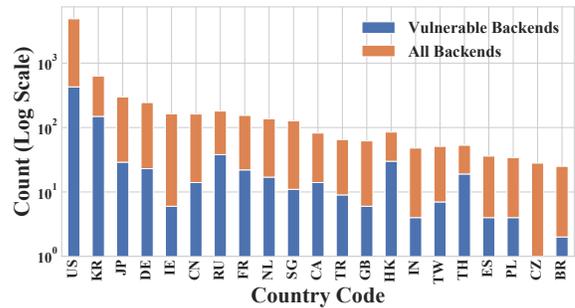

Figure 4: The figure shows the distribution of all mobile backends and vulnerable backends across the world.

Finally, the geographical distribution of the backends, shown in Figure 4, affect the impact on mobile apps. Many mobile apps deploy multiple backends that are geographically distributed to provide faster content for different user segments. In some cases, the different backends may not be fully synchronized in terms of the latest software patches for *OS*, *SS*, *AS*, and *CS* layers, which results in a vulnerable backend affecting only a segment of users for a particular mobile app. Directly quantifying the impact of each vulnerability is an involved task and depends on many variables such as the severity of the vulnerability, the mobile app to backend usage, the adversary capability, and other nuance factors (number of backends per app, network distribution, and geographical distribution). We plan to perform a comprehensive analysis to understand this impact as future work.

### 5.4 Vulnerability Disclosure, Bug Bounties, And In The Wild Threats

During our disclosure process, we identified two mobile platform vendors that have a bounty program, namely *Unity3D* [42] and *Simplifi* [43]. In addition, the top third-party platform providers, Google, Facebook, Crashlytics, and Flurry, all participate in or run their own bug bounty programs. Similarly, the cloud providers either run their own program or use a third-party bug bounty program like Bugcrowd [44] or Bounty Factory [45]. We submitted our vulnerability disclosures through their bounty management program (e.g., *HackerOne* [46]) and received confirmation of the bugs.

For smaller third-party and first-party developers, they did not have a formal way to contact them to report vulnerabilities. We followed a tiered approach in our notification by first notifying the app developer directly using the contact information in the Play Store. Our second attempt to report the vulnerability is by contacting the domain owner using the WHOIS information and following the mitigation strategy. Our third attempt to report the vulnerability is by contacting Google directly through their issue tracker portal. For parties that did not confirm or respond to our multiple attempts, we reported the vulnerabilities to US-CERT [47].

Component	# IP Scanners
Operating System ( <i>OS</i> )	341,521
Services ( <i>SS</i> )	445,908
Application ( <i>AS</i> )	206,533

Table 9: Number of IPs observed scanning the internet for vulnerabilities reported by Greynoise.io [35] over a period of a year (Sept 2017 to Sept 2018).

The *N*-day vulnerabilities we found are discoverable and easy to exploit due to the availability of fast internet scanners like ZMap [48] and MASSCAN [49]. We argue that it is a matter of time until these vulnerabilities are found and exploited. Table 9 shows the number of active scans detected on the internet through Greynoise [35] honeypots over a period of one year (Sept 2017 to Sept 2018). There are 341,521 unique IPs scanning for *OS* related vulnerabilities, 445,908 unique IPs scanning for *SS* vulnerabilities, and 206,533 unique IPs scanning for *AS* vulnerabilities. Many of these scans target *N*-day vulnerabilities, while scans for *0*-day vulnerabilities cannot be accounted for. Nonetheless, past events demonstrate that attackers are prone to scan for and exploit 0-day vulnerable web apps like Wordpress [50], Drupel [51], and PHPMyAdmin [52] when publicly disclosed. Furthermore, a recent report [53] also pointed out that the number of vulnerabilities in web apps increased in 2018 and that support for PHP version 5.x and 7.x will end in 2019, which means we can anticipate more unpatched and exposed backends in the future.

## 6 Case Studies

### 6.1 Case Study 1: Vulnerable Web App

The mobile app “Dailyhunt” has more than 50M+ installs and is part of the “Books & Reference” category. The mobile app interacts with nine different backends as shown in Table 10. The backends are split into two labels, hybrid and third-party. The hybrid backends are hosted on Akamai’s EdgeComputing [36] and run a custom web app to serve the mobile app. The hybrid backends are used for CDN, telemetry, and requesting app-specific data. Specifically, the

Label	Backend	Use	Vulns.	
			AS	CS
<i>B<sub>hyb</sub></i>	api-news.dailyhunt.in	App Data	0	1
	acq-news.dailyhunt.in	App Data & Telemetry	2	1
	bcdn.newshunt.com	CDN	0	1
	acdn.newshunt.com	CDN	0	1
<i>B<sub>3rd</sub></i>	fonts.gstatic.com	CDN	0	0
	e.crashlytics.com	Telemetry	0	0
	settings.crashlytics.com	Telemetry	0	0
	t.appsflyer.com	Ads	0	0
	api.appsflyer.com	Ads	0	0

Table 10: A list of backends and issues found for the mobile app Dailyhunt.

*api-news.\** domain registers the device and requests content, where the *acq-news.\** backend captures user behavior and offers promotion and the actual content is delivered by the two CDN domains *acdn.\** and *bcdn.\**.

We were not able to fingerprint the *OS* and the *SS* because the Akamai servers respond only to web app specific responses, i.e., minimal header and banner information. Nonetheless, we found two 0-day vulnerabilities in the *acq-news.\** backend on the same API interface. Since this web application is specific to this mobile app, we looked for other apps published by the same developer. We found that the *eBooks by Dailyhunt* app (which has over 500K installs but does not rank in the top 5,000 apps) also uses the same vulnerable API interface. Additionally, the mobile apps use HTTP to communicate with the hybrid backends and HTTPS to communicate with third-party services.

As for the third-party services, we did not find any vulnerabilities. The third-party backends serve requests on port 443 (HTTPS). The *appsflyer.com* backend is a service for ad analytics that provides different functions using the same interface. The *t.appsflyer.com* backend is a telemetry endpoint for the ad network and the *api.appsflyer.com* backend authenticates and associates the app with its profile.

**Takeaway.** This case highlights several challenges to securing mobile app backends. First, backends are heterogeneous and differ across their software stack, topology setup, configuration, and custom application. Second, outsourcing cloud management and provisioning (e.g., to cloud providers and CDNs) benefits security but comes with a lack of visibility, limited per-app customization, and unclear incident liability. Third, vulnerabilities can exist (and be scanned for) in any software layer of the cloud and API interface on the web app, which makes them challenging to identify and fix. Unfortunately, app developers do not have the resources, time, or personnel to fulfill this task. Using SkyWalker, we aim to provide guidance to where the most pressing issues exist and map them to responsible parties as shown in Table 2.

App Name	# Reviews	# Installs
com.icegame.fruitlink	332,907	50M+
com.unbrained.wifipasswordgenerator	151,518	10M+
com.magdalm.wifimasterpassword	148,355	10M+
com.unbrained.wifipassgen.app	43,824	1M+
com.magdalm.freewifipassword	35,552	1M+
apps.ignisamerica.gamebooster	23,725	500K+
com.icegame.crazyfruit	23,631	1M+
com.magdalm.wifipasswordpro	22,113	1M+
apps.ignisamerica.bluelight	16,659	500K+
com.icegame.fruitsplash2	15,193	1M+

Table 11: A list of the top 10 mobile apps using the *appnext* platform.

Label	Backend	Usage	Vulns.		
			OS	AS	CS
<i>B</i> <sub>3rd</sub>	admin.appnext.com	App Data	0	1	0
	global.appnext.com	App Data	0	0	0
	cdn.appnext.com	CDN	1	0	1
	cdn3.appnext.com	CDN	1	0	1

Table 12: List of backends and vulnerable layers found in the *appnext* platform.

## 6.2 Case Study 2: Vulnerable Platform

The *appnext* [54] platform integrates with mobile apps to ingest user behavior telemetry and provide predictive actions that users might perform. Developers use this to upsell subscription, ads, or recommend actions to app users. The *appnext* platform is used by 6 mobile apps from the top 5,000 free apps. We analyzed all apps by the same developers that are not in the top 5,000 and found 140 additional apps using the *appnext* platform. The top 10 most reviewed apps using the *appnext* platform can be found in Table 11. The top app has 332,907 reviews and over 50M+ installs. These numbers give us an indication of the the platform’s significant popularity and daily use.

The *appnext* platform backends (shown in Table 12) are labelled as third-party, because the backends are found in an SDK library. We found two CDN domains that point to the same server IP, which are hosted on *Limelight Networks*, a CDN provider. This CDN backend is vulnerable to an *OS* integer overflow in the HTTP protocol stack (MS15-034) that can be remotely exploited. Further, the *CS* still offers SSLv2 and SSLv3, which are vulnerable to insecure padding scheme for *CBC* cipher. *appnext*’s *admin.\** and *global.\** domains run on Amazon AWS and provide app-specific data, like authentication, telemetry ingestion, predictive actions, and configuration. The infrastructures run Microsoft Windows Server 2008 R2 for the *OS*, Microsoft-IIS/7.5 for its web server (*SS*), and the *CS* uses *HTTPS*. The application (*AS*) backend is a custom web application that is written in *ASP* and uses the *ASP.NET* framework. The *AS* has a vulnerability that allows an attacker to run arbitrary SQL queries.

We have notified the developers about these findings and awaiting remediation.

**Takeaway.** This case highlights multiple vulnerabilities, *0-day* and *N-day*, that affect three of the four software layers. This mobile platform collects sensitive information about user behavior, including PII and device information. Unfortunately, these backend vulnerabilities are inherited by multiple apps and developers, and the app developers cannot immediately remediate the vulnerabilities in third-party services. The mitigation strategy for the app developer is to report (*r*) these findings to *appnext* or migrate (*m*) their app to a different service. SkyWalker helps us label the backends, identify the vulnerability, and guide the developer to a clear action (report or migrate).

## 7 Mitigation

The goal of our empirical analysis was to bring attention to this overlooked problem in mobile backends, but also to provide guidance to app developers for building or choosing secure backends. In this section, we discuss the general mitigation strategies which SkyWalker recommends for app developers and to help improve the security posture of their app backends.

### 7.1 Remediation Strategies

App developers who rely on first-party backends have to **upgrade**, **patch**, and **block** as needed for each software layer on their backend. If they rely on third-party backends they can **report** the issue or **migrate** their backend to a more secure provider. Ambiguity arises when the backend is hosted by a cloud provider, a hybrid type backend. To resolve these issues we further generalize the hybrid backends into IaaS (cloud provider manages the virtual *HW*) and PaaS (cloud provider manages *HW*, *OS*, and *SS*).

Strategies	Hybrid				
	HW	OS	SS	AS	CS
Upgrade		✓	✓		✓✓
Patch		✓	✓	✓✓	✓✓
Block			✓		✓
Report	✓✓	✓	✓		
Migrate	✓✓	✓	✓		

Table 13: A mapping of mitigation strategies for developers hosting their hybrid backend on infrastructure (**IaaS**) or a platform (**PaaS**).

Table 13 provides developers with a guideline on how to mitigate vulnerable hybrid backends. For example: if the hybrid backend is using a cloud provider’s platform offering, developers should report and/or migrate their backend if the vulnerabilities are found in *HW*, *OS*, *SS* and upgrade or patch if the vulnerabilities *CS* or *AS* related, respectively.

This matrix provides a starting point for app developers to explore their options, i.e., migrate or wait for a fix. In some cases, the offering from cloud providers includes *HW* and *OS* (as in the motivating example which uses Google Compute Engine Flexible Environment). In this case, developers have to make sure they use the latest *OS* images supported by their cloud provider.

## 7.2 Recommendations

The empirical analysis provides insight not only about insecure mobile backends, but also secure practices that developers can learn from. For developers who decide to build their own first-party backends, we recommend the following: First, developers should **delegate** as much of the backend functionality to reputable third-party backends and minimize the number of features and functions their backend needs to support. Second, developers should **dedicate** personnel to manage and maintain their backends including the routine maintenance of *OS*, *SS* and *CS*, and timely fixes of known vulnerabilities affecting their cloud backends and mobile apps using patching tools [55]–[57]. Third, developers should **develop** an audit plan and a mitigation plan and be familiar with it to execute during an incident or vulnerability disclosure. Finally, developers should utilize **defense** tools like web app firewalls (WAF), DDoS mitigation, and crawler/scanner blockers to protect from internet scanners, DDoS threats, and web app attacks (SQLi, authentication bypass, etc.). We identified over 730 backends using defense services, all of which had smaller footprints when fingerprinted and no vulnerabilities were detected.

## 8 Measurement Considerations

**Ethical.** Because our work does not require or implicate human subjects, no IRB approval was required by our institute. Our study identified a large number of *0-day* and *N-day* vulnerabilities in active mobile app backends through scanning and probing. Our techniques include service scans, banner grabs, and side-channel probes. We emphasize that no active exploitation, disruption, or sensitive data access was attempted against the mobile backends. Although there are no set guidelines for vulnerability measurements in the community, several previous works (e.g., [48], [58]–[60]) have set some precedent. Our measurements followed the best practices used in previous work using the following approach:

- **Good Internet Citizenship:** Similar to the work of Li et al. [58], we provided an opt-out page for our scanner IP that gives targets an option to be removed from the study. Further, we signal our benign intention by setting the user-agent string in the scans and provide a reverse DNS record for our IP to give targets additional information about our study. We were contacted by one app

developer and requested that we remove their backends and related infrastructure from our study.

- **Non-Exploit Payloads:** Similar to the work of Durumeric et al. [59], our scanning and measurement techniques did not include any active exploits against the mobile app backends. We used side-channel measurements with time delay probes to infer vulnerabilities. The requests were carefully crafted to ensure that vulnerabilities are triggered for verification and not persistent or full system exploitation. Further, our scanning approach was throttled to ensure the availability of the backend is not affected by the additional load.
- **Responsible Disclosure:** Lastly, we notified affected mobile app developers and third-party mobile service providers through the appropriate channels. For developers and third-party service providers who did not respond to our communication, we reported the vulnerabilities through the US-CERT [47].

**Legal.** Similar to Ristenpart et al. [60], we operate within the legal bounds in conducting this study. In the US, the Computer Fraud and Abuse Act (CFAA) is the governing law that pertains to use and access of computer systems. The law states, in brief, that access to any computer system must be authorized, but does so in broad terms. The decision from the case of Moulton v VC3 (2000) sets a precedent that service discovery scanning does not cause damages or direct harm to target systems. Additionally, we assume any internet-facing service gives implicit permission to access the target computer system, in particular, we refer to how web crawlers and internet indexing services operate. As we outlined in our ethical section earlier, we provide subjects the option to opt-out, perform non-malicious measurement probes, and use responsible disclosure to notify affected parties.

## 9 Related Work

**Cloud Security.** Cloud security has been surveyed extensively [61]–[65]. Xiao et al. [9] performed a comprehensive analysis of the security issues in cloud services by surveying high-level *provider* and *tenant* issues for the cloud-based services in general. Singh et al. [66] presented a survey to identify common issues reported in third-party cloud services and summarize the work from the architecture framework, service and deployment, and cloud technologies perspective. Our work looks at “in-the-wild” deployment of cloud services from the *OS*, *SS*, *AS*, and *CS* perspectives to empirically study and uncover common issues in mobile backends.

**Measurement Studies.** Durumeric et al. [67] conducted a comprehensive internet-wide study of the HTTPS certificate ecosystem. Later, Durumeric et al. [59] carried out a similar internet-wide study for the Heartbleed vulnerability [68].

Perez-Botero et al. [69] presented an in-depth study characterizing hypervisor vulnerabilities in cloud services. Zuo et al. [19] proposed a system to identify mobile app URLs and examine their reputation with public blacklists to detect malicious apps. Our work differs from prior work by studying a range of vulnerabilities which may affect mobile app backends on the internet.

**Empirical Backend Analysis.** Zuo et al. [12] performed an assessment of mobile app backend services by investigating the cloud offerings of Google, Amazon, and Microsoft. Our work provides a wider analysis by going beyond just the third-party service backends and by examining a diverse set of cloud-based backends. Fernandes et al. [70] analyzed the top apps found in the Samsung SmartThings platform to identify permission issues. We follow a similar approach but focus on the mobile app integration with cloud services instead of IoT apps and cloud services. Alrawi et al. [71] presented a systematization security assessment of home-based IoT devices and their companion cloud and mobile apps. Our work encompasses a wider application, beyond only IoT mobile apps, and a more focused assessment by looking at the supporting backends provided by cloud services.

## 10 Conclusion

This paper presented SkyWalker, an analysis pipeline to study mobile app backends. We used SkyWalker to empirically analyze the top 5,000 mobile apps in the Google Play store and uncovered 655 0-days and 983 N-days instances affecting thousands of apps. Lastly, we offer SkyWalker as a public service to help app developers improve the security of their backends, give insight on what platforms are vulnerable, and guide developers to fix issues found in their backends: <https://MobileBackend.vet>.

## Abstract

Modern operating systems support a cooperating program abstraction that, instead of placing all functionality into a single program, allows diverse programs to cooperate to complete tasks requested by users. However, untrusted programs may exploit such interactions to spy on users through device sensors by causing privileged system services to misuse their permissions, or to forward user requests to malicious programs inadvertently. Researchers have previously explored methods to restrict access to device sensors based on the state of the user interface that elicited the user input or based on the set of cooperating programs, but the former approach does not consider cooperating programs and the latter approach has been found to be too restrictive for many cases. In this paper, we propose **ENTRUST**, an authorization system that tracks the processing of input events across programs for eliciting approvals from users for sensor operations. **ENTRUST** constructs *delegation graphs* by linking input events to cooperation events among programs that lead to sensor operation requests, then uses such *delegation graphs* for eliciting authorization decisions from users. To demonstrate this approach, we implement the **ENTRUST** authorization system for Android OS. In a laboratory study, we show that attacks can be prevented at a much higher rate (47-67% improvement) compared to the first-use approach. Our field study reveals that **ENTRUST** only requires a user effort comparable to the first-use approach while incurring negligible performance (<1% slowdown) and memory overheads (5.5 KB per program).

## 1 Introduction

Modern operating systems, such as Android OS, Apple iOS, Windows Phone OS, and Chrome OS, support a programming abstraction that enables programs to cooperate to perform user commands via input event delegations. Indeed, an emergent property of modern operating systems is that system services are relatively simple, provide a specific functionality, and often rely on the cooperation with other programs to perform tasks.

For instance, modern operating systems now ship with voice-controlled personal assistants that may enlist apps and other system services to fulfill user requests, reaching for a new horizon in human-computer interaction.

Unfortunately, system services are valuable targets for adversaries because they often have more permissions than normal apps. In particular, system services are automatically granted access to device sensors, such as the camera, microphone, and GPS. In one recent case reported by Gizmodo [1], a ride-sharing app took advantage of Apple iOS system services to track riders. In this incident, whenever users asked their voice assistant “Siri, I need a ride”, the assistant enlisted the ride-sharing app to process the request, which then leveraged other system services to record the users’ device screens, even while running in the background. Other online magazines have reported cases of real-world evidence that apps are maliciously colluding with one another to collect and share users’ personal data [2, 3, 4].

Such attacks are caused by system services being tricked into using their permissions on behalf of malicious apps (confused deputy attacks [5, 6]), or malicious apps exploiting their own privileges to steal data, and a combination of the two. Researchers have previously shown that such system services are prone to exploits that leverage permissions only available to system services [7]. Likewise, prior work has demonstrated that system services inadvertently or purposely (for functionality reasons) depend on untrusted and possibly malicious apps to help them complete tasks [8].

Such attacks are especially hard to prevent due to two information asymmetries. System services are being exploited when performing tasks on behalf of users, where: (1) users do not know what processing will result from their requests and (2) services do not know what processing users intended when making the request. Current systems employ methods to ask users to authorize program access to sensors, but to reduce users’ authorization effort they only ask on a program’s first use of that permission. However, once authorized, a program can utilize that permission at will, enabling programs

to spy on users as described above. To prevent such attacks, researchers have explored methods that bind input events, including facets of the user interface used to elicit those inputs, to permissions to perform sensor operations [9, 10, 12]. Such methods ask users to authorize permissions for those events and reuse those permissions when the same event is performed to reduce the user burden. Recent research extends the collection of program execution context (e.g., data flows and/or GUI flows between windows) more comprehensively to elicit user authorizations for sensitive operations [16, 11]. However, none of these methods addresses the challenge where an input event is delivered to one program and then a sensor operation, in response to that event, is requested by another program in a series of inter-process communications, a common occurrence in modern operating systems supporting the cooperating program abstraction.

Researchers have also explored methods to prevent unauthorized access by regulating inter-process communications (IPCs) and by reducing the permissions of programs that perform operations on behalf of other programs. First, prior work developed methods for blocking IPC communications that violate policies specified by app developers [8, 18, 19, 21, 22]. However, such methods may prevent programs from cooperating as expected. Decentralized information flow control [23, 24] methods overcome this problem by allowing programs with the authority to make security decisions and make IPCs that may otherwise be blocked. Second, DIFC methods, like capability-based systems in general [34], enable reduction of a program’s permissions (i.e., callee) when performing operations on behalf of other programs (i.e., callers). Initial proposals for reducing permissions simply intersected the parties’ permissions [7], which however was too restrictive because parties would have their permissions pruned after the interaction with less privileged parties. DIFC methods, instead, provide more flexibility [20], albeit with the added complexity of requiring programs to make non-trivial security decisions. Our insight to simplify the problem is that while DIFC methods govern information flows comprehensively to prevent the leakage of sensitive data available to programs, users instead want to prevent programs from abusing sensor access to obtain sensitive data in the first place.

In addition, prior work has also investigated the use of machine learning classifiers to analyze the contextuality behind user decisions to grant access to sensors automatically [14, 15]. Unfortunately, the effectiveness of the learning depends on the accuracy of the user decisions while training the learner. Therefore, we firmly believe that additional effort is necessary in improving user decision making before the user decisions can be used to train a classifier.

In this work, we propose the **ENTRUST** authorization system to prevent malicious programs from exploiting

cooperating system services to obtain unauthorized access to device sensors. At a high-level, our insight is to combine techniques that regulate IPC communications of programs of different privilege levels with techniques that enable users to be aware of the permissions associated with an input event and decide whether to grant such permissions for the identified flow context. The former techniques identify how a task is “delegated” among cooperating programs to restrict the permissions of the delegatee.<sup>1</sup> The latter techniques expose more contextual information to a user, which may be useful to make effective authorization decisions.

However, combining these two research threads results in several challenges. First, we must be able to associate input events with their resulting sensor operations in other programs to authorize such operations relative to the input events and sequence of cooperating programs. Prior work does not track how processing resulting from input events is delegated across programs [9, 10, 11, 12], but failing to do so results in attack vectors exploitable by an adversary. In **ENTRUST**, we construct *delegation graphs* that associate input events with their resulting sensor operations across IPCs to authorize operations in other programs.

Second, multiple, concurrent input events and IPCs may create ambiguity in tracking delegations across processes that must be resolved to ensure correct enforcement. Prior work either makes assumptions that are often too restrictive or require manual program annotations to express such security decisions. **ENTRUST** leverages the insights that input events are relatively infrequent, processed much more quickly than users can generate distinct events, and are higher priority than other processing. It uses these insights to ensure that an unambiguous *delegation path* can be found connecting each input event and sensor operation, if one exists, with little impact on processing overhead.

Third, we must develop a method to determine the permissions to be associated with an input event for other programs that may perform sensor operations. Past methods, including machine learning techniques [14, 15], depend on user decision making to select the permissions associated with input events, but we wonder whether the information asymmetries arising from delegation of requests across programs impair user decision making. In **ENTRUST**, we elicit authorization decisions from users by using delegation paths. We study the impact of using delegation paths on users’ decision making for both primed and unprimed user groups. Historically, there has been a debate on whether users should be considered a weak link in security [56, 57]. We examine this argument in a specific context by investigating if users can make informed security decisions given informative, yet precise, contextual information.

We implement and evaluate a prototype of the **ENTRUST** authorization system for Android OS. We find that **ENTRUST** significantly reduces exploits from three

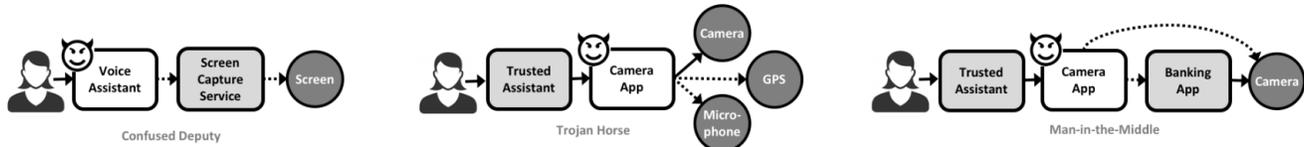

Figure 1: Possible attack vectors when diverse programs interact via input event delegations in a cooperating model. For consistency, we present the attack scenarios in terms of voice assistants receiving input events via voice commands; however, similar attack scenarios are possible for input events received by programs via Graphical User Interface (GUI) widgets rendered on the users’ device screen.

canonical types of attack vectors possible in systems supporting cooperating programs, requires little additional user effort, and has low overhead in app performance and memory consumption. In a laboratory study involving 60 human subjects, **ENTRUST** improves attack detection by 47-67% when compared to the first-use authorization approach. In a field study involving 9 human subjects, we found that - in the worst scenarios seen - programs required no more than four additional manual authorizations from users, compared to the less secure first-use authorization approach; which is far below the threshold that is considered at risk for user annoyance and habituation [33]. Lastly, we measured the overhead imposed by **ENTRUST** via benchmarks and found that programs operate effectively under **ENTRUST**, while incurring a negligible performance overhead (<1% slowdown) and a memory footprint of only 5.5 kilobytes, on average, per program.

In summary, we make the following contributions:

- We propose a method for authorizing sensor operations in response to input events performed by cooperating programs by building unambiguous *delegation graphs*. We track IPCs that delegate task processing to other programs without requiring system service or app code modifications.
- We propose **ENTRUST**, an authorization system that generates delegation paths to enable users to authorize sensor operations, resulting from input events, and reuse such authorizations for repeated requests.
- We implement the **ENTRUST** prototype and test its effectiveness with a laboratory study, the users’ authorization effort with a field study, and performance and memory overhead via benchmarks.

## 2 Problem Statement

In current operating systems, users interact with programs that initiate actions targeting sensors, but users do not have control over *which programs* are going to service their requests, or *how such programs access sensors* while servicing such requests. Unfortunately, three well-studied attack vectors become critical in operating systems supporting a cooperating program abstraction.

**Confused Deputy** — First, a malicious program may leverage an input event as an opportunity to confuse a more privileged program into performing a sensitive operation. For example, a malicious voice assis-

tant may invoke the screen capture service at each voice command (left side of Figure 1). The malicious voice assistant may therefore succeed in tricking the screen capture service into capturing and inadvertently leaking sensitive information (e.g., a credit card number written down in a note). In this scenario, the user only sees the new note created by the notes app, whereas the screen capture goes unnoticed. Currently, there are over 250 voice assistants available to the public on Google Play with over 1 million installs, *many by little known or unknown developers*.

**Trojan Horse** — Second, a program trusted by the user may delegate the processing of an input event to an untrusted program able to perform the requested task. For example, a trusted voice assistant may activate a camera app to serve the user request to take a selfie (middle of Figure 1). However, the camera app may be a Trojan horse app that takes a picture, but also records a short audio via the microphone, and the user location via GPS (e.g., a spy app<sup>2</sup> installed by a jealous boyfriend stalking on his girlfriend). Researchers reported over 3,500 apps available on Google Play Store that may be used as spyware apps for Intimate Partner Violence (IPV) [25]. In this scenario, the user only sees the picture being taken by the camera app, whereas the voice and location recordings go unnoticed, since a camera app is likely to be granted such permission. Also, the ride-sharing attack in the introduction is another example of this attack. Such attacks are possible because even trusted system services may inadvertently leverage malicious apps and/or rely on unknown apps by using implicit intents. An implicit intent enables any program registered to receive such intents to respond to IPCs when such intents are invoked. Researchers have reported several ways how programs can steal or spoof intents intended for other programs [26, 27, 28]. We performed an analysis of system services and applications distributed via the Android Open Source Project (AOSP), and found that 10 system programs out of a total of 69 (14%) use implicit intents.

**Man-In-The-Middle** — Third, a request generated by a program trusted by the user may be intercepted by a malicious program, which can behave as a man-in-the-middle in serving the input event in the attempt to obtain access to unauthorized data (right side of Figure 1). For example, a legitimate banking app may adopt the voice interaction intent mechanism to allow

customers to direct deposit a check via voice assistant with a simple voice command (e.g., “deposit check”).<sup>3</sup> A malicious program may exploit such a service by registering itself with a voice assistant as able to service a similar voice interaction, such as “deposit *bank* check.” Therefore, whenever the user instantiates the “deposit *bank* check” voice command, although the user expects the legitimate banking app to be activated, the malicious app is activated instead. The malicious app opens the camera, captures a frame with the check, and sends a spoofed intent to launch the legitimate banking app, all while running in the background. In this scenario, the user only sees the trusted banking app opening a camera preview to take a picture of the check. This is a realistic threat. We performed an analysis of 1,000 apps (among the top 2,000 most downloaded apps on Google Play Store) and found that 227 apps (23%) export at least a public service or a voice interaction intent. Apps were selected from the Google Play Store among those apps declaring at least one permission to access a sensitive sensor (e.g., camera, microphone, or GPS).

**Security Guarantee.** To mitigate such attack vectors, an authorization mechanism must provide the following guarantee, *for any sensor operation to be authorized, that operation must be: (1) initiated by an input event; (2) authorized for the input event to trigger the sensor operation; and (3) authorized for the sequence of programs receiving the input event directly or indirectly through IPCs leading to the program performing the sensor operation.* Such a guarantee ensures that any sensor operation must be initiated by an input event, the input event must imply authorization of the resultant sensor operation by the requesting program, and all programs associated with communicating the request for the sensor operation must be authorized to enable the sensitive data to be collected by the requesting program. To achieve the security guarantee above, we require a mechanism that accurately tracks the delegations leading from input events to resulting sensor operations, as well as a mechanism to authorize sensor operations to collect sensitive data given input events and delegations.

Regarding tracking delegations, a problem is that determining whether an IPC derives from an input event or receipt of a prior IPC depends on the data flows produced by the program implementations in general. Solving this problem requires data flow tracking, such as performed by taint tracking. However, taint tracking has downsides that we aim to avoid. Static taint tracking can be hard to use and be imprecise [30] and dynamic taint tracking has non-trivial overhead [29]. Instead, we aim to explore solutions that ensure all sensor operations resulting from an input event are detected (i.e., we overapproximate flows) without heavyweight analysis or program modifications.

Authorizing sensor operations to collect sensitive data, given an input event and one or more delegations, depends on determining the parties involved in the del-

egation as well as the user’s intent when generating the event. Methods that restrict the permissions of an operation to the intersection of permissions granted to the parties involved [7], have been found to be too restrictive in practice. Decentralized information flow control [23, 24] (DIFC) prevents information leakage while allowing some privileged programs to make flexible security decisions to determine when to permit communications that are normally unauthorized, which has been applied to mobile systems [20, 13]. However, these information flow control techniques focus on preventing the leakage of sensitive information available to programs, whereas the main goal here is to prevent programs from obtaining access to sensitive information in the first place by abusing sensor access. To address this problem more directly, researchers have explored techniques that enable users to express the intent of their input events to authorize sensor operations, binding this intent to the context in which the input event was elicited, such as the graphical user interface (GUI) context [9, 10, 11]. In IoT environments, researchers have similarly explored gathering program execution context (e.g., data flows) to enable users to authorize IoT operations more accurately [16]. However, none of these techniques account for delegations of tasks to other processes. We aim to explore methods for eliciting user authorizations for sensor operations using contextual information related to the tracking of input events and subsequent delegations.

Further, researchers have explored learning methods to predict permissions for sensor operation based on prior user decisions [14, 15]. However, accurate user decision making is vital for improving the accuracy of these learning techniques.

### 3 Security Model

**Trust Model** – We assume that the system (e.g., Linux kernel, operating system, system services, and device drivers) is booted securely, runs approved code from device vendors, and is free of malice; user-level programs (e.g., applications) are isolated from each other via the sandboxing mechanism using separated processes [35, 36]; and, by default, user-level programs have no direct access to sensors due to the use of a Mandatory Access Control (MAC) policy [37, 38] enforced from boot time. We assume the use of *trusted paths*, protected by MAC, allowing users to receive unforgeable communications from the system, and providing unforgeable input events to the system. Our assumptions are in line with existing research on trusted paths and trusted user interfaces for browsers [39], X window systems [40, 41], and mobile operating systems [42].

**Threat Model** – We assume that users may install programs from unknown sources that may be malicious, then grant such programs access to sensors at first use. Despite the default isolation via sandboxing, programs may communicate via IPC mechanisms (i.e., intents or

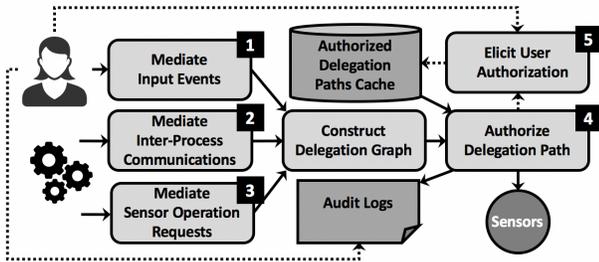

Figure 2: ENTRUST Authorization Method – Input events, handoff events, and sensor operations are linked via delegation graphs to compute unambiguous delegation paths for user authorization of sensor operations.

broadcast messages). Thus, user-level programs (e.g., apps) may leverage such communication to exploit the attack vectors described in Section 2. Our objective is to provide a mechanism that helps users control how cooperating programs access sensors. *How programs manage and share the data collected from sensors is outside the scope of our research.* Researchers have already examined solutions to prevent data leakage based on taint analysis [29, 30, 31, 18] and Decentralized Information Flow Control (DIFC) [20, 23, 24, 32].

## 4 ENTRUST Authorization Design

In this section, we describe our proposed framework, ENTRUST, designed to restrict when programs may perform sensor operations by requiring each sensor operation to be unambiguously associated with an input event, even if the sensor operation is performed by a program different from the one receiving the input event. Figure 2 provides an overview of the ENTRUST authorization system, which consists of five steps. In the first three steps, ENTRUST mediates and records input events, inter-process communication events (handoff events), and sensor operation requests, respectively, to construct a *delegation graph* connecting input events to their handoff events and sensor operation requests. In the fourth step, ENTRUST uses the constructed delegation graph to compute an unambiguous *delegation path* to a sensor operation request from its originating input event. Unless the authorization cache contains a user authorization for the constructed delegation path already, the fifth step elicits an authorization from the user for the delegation path, and caches the authorization for later use for the same delegation path. Optionally, users can review their prior decisions and correct them via an audit mechanism that logs past authorized and denied delegation graphs.

### 4.1 Building Delegation Graphs

The first challenge is to link input events to all the sensor operations that result from cooperating programs processing those events and then construct *delegation graphs* rooted at such input events.

Figure 3: Delegation graphs connect input events with operation requests for sensors via handoff events.

First, for each input event received via a sensor  $s$  for a program  $p_i$ , ENTRUST creates an *input event* tuple  $e = (c, s, p_i, t_0)$ , where  $c$  is the user interface context captured at the moment the input event occurred;  $s$  is the sensor through which the event was generated;  $p_i$  is the program displaying its graphical user interface on the screen and receiving the input event  $e$ ; and  $t_0$  is the time of the input event (step 1 in Figure 2). Note: ENTRUST is designed to mediate both input events coming from input sensors (e.g., touch events on widgets rendered on the screen) as well as voice commands captured via the microphone. Voice commands are translated into text by the Google Cloud Speech-to-Text service.

Second, after receiving the input event, program  $p_i$  may hand off the event to another program  $p_j$ . ENTRUST mediates handoff events by intercepting spawned intents and messages exchanged between programs [43] and models them as tuples  $h = (p_i, p_j, t_i)$ , where  $p_i$  is the program delegating the input event,  $p_j$  is the program receiving the event, and  $t_i$  is the time the event delegation occurred (step 2 in Figure 2).

Third, when the program  $p_j$  generates a request  $r$  for an operation  $o$  targeting a sensor  $d$ , ENTRUST models the request as a tuple  $r = (p_j, o, d, t_j)$ , where  $p_j$  is the program requesting the sensor operation,  $o$  is the type of sensor operation requested,  $d$  is the destination sensor, and  $t_j$  is the time the sensor operation request occurred (step 3 in Figure 2).

Lastly, ENTRUST connects sensor operation requests to input events via handoff events by constructing a delegation graph to regulate such operations, as shown in Figure 3. A *delegation graph* is a graph,  $G = (V, E)$ , where the edges  $(u, v) \in E$  represent the flow of input events to programs and sensors, and the vertices,  $v \in V$ , represent the affected programs and sensors. Figure 3 shows a simple flow, whereby a source sensor  $s$  receives an input event  $e$  that is delivered to a program  $p_i$ , which performs a handoff event  $h$  to a program  $p_j$  that performs an operation request  $r$  for a destination sensor  $d$ . Thus, there are three types of edges: input event to program (user input delivery), program to program (handoff), and program to sensor operation request (request delivery).

Upon mediation of a sensor request  $r$ , ENTRUST computes the associated *delegation path* by tracing backwards from the sensor request  $r$  to the original input event  $e$ . Hence, the operation request  $r = (p_j, o, d, t_j)$  above causes a delegation path:  $(c, s, p_i, t_0) \rightarrow (p_i, p_j, t_i) \rightarrow (p_j, o, d, t_j)$  to be reported in step 4 in Figure 2. Delegation paths are then presented to the user for authorization (see Section 4.3). The identified delegation path is shown to the user using natural language, in a

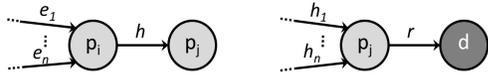

Figure 4: Two scenarios that create ambiguity. Multiple input events or handoff events delivered to the same program.

manner similar to first-use authorizations. We assess how effectively users utilize delegation paths to produce authorizations in a laboratory study in Section 6.2.

## 4.2 Computing Delegation Paths

Critical to computing delegation paths is the ability for **ENTRUST** to find an unambiguous reverse path from the sensor operation request  $r$  back to an input event  $e$ . In particular, a delegation path is said to be *unambiguous* if and only if, given an operation request  $r$  by a program  $p_j$  for a sensor  $d$ , either there was a single input event  $e$  for program  $p_j$  that preceded the request  $r$ , or there was a single path  $p_i \rightarrow p_j$  in the delegation graph, where program  $p_i$  received a single input event  $e$ .

To ensure unambiguous delegation paths without program modification, we need to define the conditions under which operations that create ambiguities cannot occur. First, ambiguity occurs if the same program  $p_i$  receives multiple input events and then performs a handoff, as depicted by the left side of Figure 4. In this case, it is unclear which one of the input events resulted in the handoff. To prevent this ambiguous case, we leverage the insight that input events are relatively infrequent, processed much more quickly than users can generate them, and have a higher priority than other processing. We observe that the time between distinct input events is much larger than the time needed to produce the operation request corresponding to the first input event. If every input event results in an operation request before the user can even produce another distinct input event, then there will be only one input event (edge)  $e$  from a source sensor (node)  $s$  to program (node)  $p_i$ , which received such input event. Therefore, there will be no ambiguous input event for program  $p_i$ . Thus, we propose to set a time limit for each input event, such that the difference between the time  $t_0$  at which an input event  $e$  is generated and the time  $t_j$  for any sensor operation request  $r$  – based on that input event – must be below that limit for the event to be processed. Note that, once an input event is authorized (Section 4.3), repeated input events (e.g., pressing down a button multiple times) are not delayed. Indeed, repeated input events are expected to generate the same delegation path. Should the programs produce a different delegation path – in the middle of a sequence of operations spawned in this manner – then **ENTRUST** would require a new authorization for the new delegation path, as described in Section 4.3.

Second, ambiguity is also possible if the same program  $p_j$  receives multiple handoff events before performing a sensor operation request, as depicted by the right side

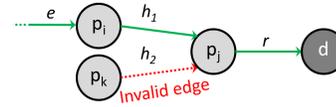

Figure 5: A program  $p_k$  attempts leveraging the input event received from program  $p_i$  to get program  $p_j$  to generate an operation request.

of Figure 4. Note that, handoff events may not be related to input events (e.g., intents not derived from input events). In this case, it is unclear which handoff is associated with a subsequent sensor operation request. Ambiguity prevention for handoff events is more subtle, but builds on the approach used to prevent ambiguity for input events. Figure 5 shows the key challenge. Suppose a malicious program  $p_k$  tries to “steal” a user authorization for a program  $p_j$  to perform a sensor operation by submitting a handoff event that will be processed concurrently to the handoff event from another program  $p_i$ , which received an input event. Should a sensor operation request occur, **ENTRUST** cannot determine whether the sensor operation request from  $p_j$  was generated in response to the event handoff  $h_1$  or to the event handoff  $h_2$ . So **ENTRUST** cannot determine the delegation path unambiguously to authorize the operation request. If **ENTRUST** knows the mapping between actions associated to handoff events and whether they are linked to sensor operations, **ENTRUST** can block a handoff from  $p_k$  that states an action that requires an input event. **ENTRUST** knows this mapping for system services, by having visibility of all inter-procedural calls for programs part of the operating system; however, **ENTRUST** may not know such mapping for third-party apps whose inter-procedural control flow is not mediated to favor backward compatibility with existing apps.

Thus, we extend the defense for input events to prevent ambiguity as follows: once the target program has begun processing a handoff associated with an input event, **ENTRUST** delays the delivery of subsequent handoff events until this processing completes or until the assigned time limit ends. Conceptually, this approach is analogous to placing a readers-writers lock [44] over programs that may receive handoffs that result from input events. Note that, the use of time limits ensures no deadlock since it ensures preemption. To avoid starving input events (e.g., delaying them until the time limit), we prioritize delivery of handoffs that derive from input events ahead of other handoffs using a simple, two-level scheduling approach. We assess the impact of the proposed ambiguity prevention mechanisms on existing programs’ functionality and performance in Section 7.

## 4.3 Authorizing Delegation Paths

For controlling when a sensor operation may be performed as the result of an input event, users are in the best position to judge the intent of their actions. This is

inline with prior work advocating that it is highly desirable to put the user in context when making permission granting decisions at runtime [16, 33, 17]. Therefore, users must be the parties to make the final authorization decisions. To achieve this objective, **ENTRUST** elicits an explicit user authorization every time that a new delegation path is constructed (step 5 in Figure 2). Hence, to express a delegation path comprehensively, **ENTRUST** builds an authorization request that specifies that delegation path to the user. Prior work presented users with information about the Graphical User Interface (GUI) used to elicit the input event, including GUI components [9, 10, 11], user interface workflows [13], and Application Programming Interface (API) calls made by applications [11, 16]. **ENTRUST**, instead, presents the delegation path that led to the sensor operation, which includes the GUI context ( $c$  in the input event) and the handoffs and sensor operations. As a result, **ENTRUST** ensures that all the programs receiving sensor data are clearly identified and reported in the authorization request presented to the user, along with the input event, handoff events, and the resulting sensor operation.

To reduce users' authorization effort, **ENTRUST** caches authorized delegation paths for reuse. After storing an authorized delegation path, **ENTRUST** proceeds in allowing the authorized sensor operation. For subsequent instances of the same input event that results in exactly the same delegation path, **ENTRUST** omits step 5 and automatically authorizes the sensor operation by leveraging the cached authorization. Note that, **ENTRUST** requires an explicit user's authorization *only* the first time a delegation path is constructed for a specific input event, similarly to the first-use permission approach. As long as the program receiving an input event does not change the way it processes that event (i.e., same handoffs and operation request), no further user authorization will be necessary. In Section 6.2, we show that such an approach does not prohibitively increase the number of access control decisions that users have to make, thus avoiding decision fatigue [45].

Further, **ENTRUST** evicts cached authorizations in two scenarios. First, if a new delegation path is identified for an input event that already has a cached delegation path, then **ENTRUST** evicts the cached authorization and requires a new user authorization for the newly constructed delegation path, before associating it to such an input event and caching it. Second, users can leverage an audit mechanism, similar to proposals in related work [11, 15], to review previous authorizations and correct them if needed. Denied authorizations are also logged for two reasons. First, they allow users to have a complete view of their past decisions; but more importantly, they allow **ENTRUST** to prevent malicious programs from annoying users by generating authorization requests over a give threshold, for operations already denied by the user in the past. Also, users may set the lifetime of cached authorizations, after which they

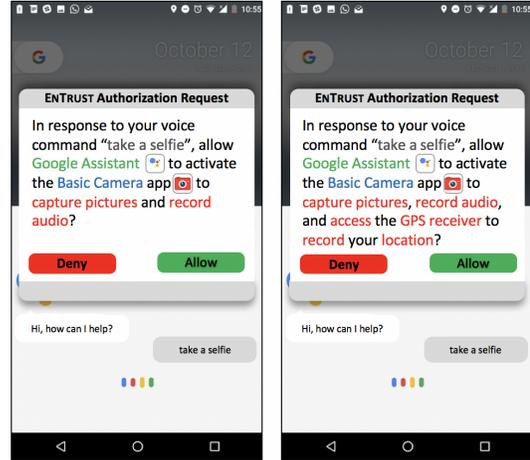

Figure 6: Authorization requests prompted to users by **ENTRUST** upon *delegation paths* creation. Screenshots showing benign (left) and attack (right) scenarios by the Basic Camera app.

are evicted. We discuss utilizing such logs for revoking mistaken authorizations and denials in Section 8.

## 5 Implementation

We implemented a prototype of the **ENTRUST** authorization system by modifying a recent release of the Android OS (Android-7.1.1\_r3) available via the Android Open Source Project (AOSP).<sup>4</sup> The choice of implementing the **ENTRUST** prototype for the Android OS was guided by its open-source nature and its wide adoption. **ENTRUST**'s footprint is 170 SLOC in C for the Linux kernel (bullhead 3.10), plus 380 SLOC in C, 830 SLOC in C++, and 770 SLOC in Java for components in the Android OS.

In this section, we provide the implementation details for event scheduling and authorization management. In Appendices C-F, we provide further implementation details regarding event authentication and mediation.

In Android, the Event Hub (part of the Input Manager server) reads raw input events from the input device driver files (`/dev/input/*`) and delivers them to the Input Reader. The Input Reader then formats the raw data and creates input event data that is delivered to the Input Dispatcher. The Input Dispatcher then consults the Window Manager to identify the target program based on the activity window currently displayed on the screen. Hence, we enhanced the Input Dispatcher to hold - for the duration of a time window - incoming input events for a target program should there be already a delivered input event for such a program that has not been processed, yet. For handoff events, instead, the Binder is the single point of mediation for inter-process communication (IPC) between isolated programs. It has the knowledge of all the pending messages exchanged as well as knowledge of the identity

of the two communicating parties. Hence, we also enhanced the Binder to hold - for the duration of a time window - incoming handoff events for a target program should the program be already involved in another communication with a third program.

ENTRUST prompts users with *authorization messages* for explicit authorizations of delegation paths, as shown in Figure 6. Users are made *aware of all the programs cooperating in serving their requests* as well as of the *entire delegation path*. Also, users are prompted with programs' names and identity marks to ease their identification. ENTRUST crosschecks developers' signatures and apps' identity (i.e., names and logos) by pulling information from the official Google Play Store to prevent identity spoofing. Also, ENTRUST prevents programs from creating windows that overlap the *authorization messages* by leveraging the Android screen overlay protection mechanism. Finally, ENTRUST prevents unauthorized modification of *authorization messages* by other programs by using isolated per-window processes forked from the Window Manager to implement a *Compartmented Mode Workstation* model [48].

## 6 ENTRUST Evaluation

We investigated the following research questions:

- ▶ *To what degree is the ENTRUST authorization assisting users in avoiding confused deputy, Trojan horse, and man-in-the-middle attacks?* We performed a *laboratory study* and found that ENTRUST significantly increased (from 47-67% improvement) the ability of participants in avoiding attacks.

- ▶ *What is the decision overhead imposed by ENTRUST on users due to explicit authorization of constructed delegation graphs?* We performed a *field study* and found that the number of decisions imposed on users by ENTRUST remained confined - in worst case scenarios - to no more than 4 explicit authorizations per program.

- ▶ *Is ENTRUST backward compatible with existing programs? How many operations from legitimate programs are incorrectly blocked by ENTRUST?* We used a well-known compatibility test suite to evaluate the compatibility of ENTRUST with 1,000 apps (selected among the most popular apps on Google Play Store) and found that ENTRUST does not cause the failure of any program.

- ▶ *What is the performance overhead imposed by ENTRUST for delegation graph construction and enforcement?* We used a well-known software exerciser to measure the performance overhead imposed by ENTRUST. We found that ENTRUST introduced a negligible overhead (order of milliseconds) unlikely noticeable to users.

### 6.1 Study Preliminaries

We designed our user studies following suggested practices for human subject studies in security to avoid common pitfalls in conducting and writing about security and privacy human subject research [49]. An Institu-

tional Review Board (IRB) approval was obtained from our institution. The data collected did not contain Personally Identifiable Information (PII) and was securely stored and accessible only to authorized researchers. We recruited study participants via local mailing lists, Craigslist, Twitter, and local groups on Facebook. We compensated them with a \$5 gift card. We excluded acquaintances from participating in the studies to avoid acquiescence bias. Before starting the study, participants had to sign our consent form and complete an entry survey containing demographic questions. We made sure to get a wide diversity of subjects, both in terms of age and experience with technology (details available in Appendix A). For all the experiments, we configured the test environment on LG Google Nexus 5X phones running the Android 7.1 Nougat OS. We used a background service, automatically relaunched at boot time, to log participants' responses to system messages and alerts, input events generated by participants while interacting with the testing programs, as well as system events and inter-process communications between programs. Furthermore, during the experiments, the researchers took note of comments made by participants to ease the analysis of user decision making.

### 6.2 Laboratory Study

We performed a *laboratory study* to evaluate the effectiveness of ENTRUST in supporting users in avoiding all the three attack vectors previously identified in Section 2. We compared ENTRUST with the *first-use* authorization used in commercial systems. We could not compare mechanisms proposed in related work [9, 10], because they are unable to handle handoff events. We divided participants into four groups, participants in **Group-FR-U** and **Group-FR-P** interacted with a *stock* Android OS implementing the *first-use* authorization mechanism. Participants in **Group-EN-U** and **Group-EN-P** interacted with a *modified* version of the Android OS integrating the ENTRUST authorization system. To account for the priming effect, we avoided influencing subjects in **Group-FR-U** and **Group-EN-U** and advertised the test as a generic "voice assistants testing" study without mentioning security implications. On the other hand, to assess the impact of priming, subjects in **Group-FR-P** and **Group-EN-P** were informed that attacks targeting sensors (e.g., camera, microphone, and GPS receiver) were possible during the interaction with programs involved in the experimental tasks, but without specifying what program performed the attacks or what attacks were performed.

*Experimental Procedures:* For our experiment, we used a test assistant developed in our research lab called Smart Assistant, which provides basic virtual assistant functionality, such as voice search, message composition, and note keeping. However, Smart Assistant is also designed to perform confused deputy attacks on

Directive	Attack Scenario	First-Use (FR)		EnTrust (EN)	
<b>TASK A</b> Ask Smart Assistant to "create a note." <b>K</b> Dictate a voice note to Notes. For example, "remind me to buy milk on the way home."	<b>Confused Deputy: Smart Assistant</b> Smart Assistant opens the Notes app and adds the specified note; however, it also requests the <b>Screen Capture</b> service to capture the content on the screen. Credit card information and passwords, visible in the notes summary, are captured and sent to a remote server controlled by the adversary.			<b>EnTrust Delegation Graph</b> 	<b>EnTrust Authorization Request</b> In response to your voice command "create a note", allow Smart Assistant to activate the Screen Capture service to capture the content on the screen? <input type="button" value="Deny"/> <input type="button" value="Allow"/>
		<b>Group-FR-U</b> 87% Attack Success 40% Prompted 27% Explicit Allows	<b>Group-FR-P</b> 53% Attack Success 47% Prompted 0% Explicit Allows	<b>Group-EN-U</b> 20% Attack Success 100% Prompted 20% Explicit Allows	<b>Group-EN-P</b> 0% Attack Success 100% Prompted 0% Explicit Allows
<b>TASK A</b> Ask Google Assistant to "take a selfie."	<b>Trojan Horse: Google Assistant</b> Google Assistant activates the Basic Camera app, which is a Trojan app that takes a selfie but also records a short audio and the user's location. The collected data is then sent to a remote server controlled by the adversary.			<b>EnTrust Delegation Graph</b> 	<b>EnTrust Authorization Request</b> In response to your voice command "take a selfie", allow Google Assistant to activate the Basic Camera app to capture pictures, record audio, and access the GPS receiver to record your location? <input type="button" value="Deny"/> <input type="button" value="Allow"/>
		<b>Group-FR-U</b> 80% Attack Success 40% Prompted 20% Explicit Allows	<b>Group-FR-P</b> 47% Attack Success 53% Prompted 0% Explicit Allows	<b>Group-EN-U</b> 13% Attack Success 100% Prompted 13% Explicit Allows	<b>Group-EN-P</b> 0% Attack Success 100% Prompted 0% Explicit Allows
<b>TASK A</b> Ask Google Assistant to "deposit bank check." <b>C</b> After logging into Mobile Banking with the provided credentials, deposit the provided check.	<b>Man-In-The-Middle: Google Assistant</b> Google Assistant launches Basic Camera registered for the voice intent "deposit bank check". The Basic Camera runs in the background, captures a picture of the check and - via a spoofed intent - launches the Mobile Banking app registered for the voice intent "deposit check". The collected data is sent to a remote server controlled by the adversary.			<b>EnTrust Delegation Graph</b> 	<b>EnTrust Authorization Request</b> In response to your voice command "deposit bank check", allow Google Assistant to activate the Basic Camera app to capture pictures? Also, allow the Basic Camera app to activate the Mobile Banking app to capture pictures? <input type="button" value="Deny"/> <input type="button" value="Allow"/>
		<b>Group-FR-U</b> 67% Attack Success 47% Prompted 13% Explicit Allows	<b>Group-FR-P</b> 53% Attack Success 47% Prompted 0% Explicit Allows	<b>Group-EN-U</b> 7% Attack Success 100% Prompted 7% Explicit Allows	<b>Group-EN-P</b> 0% Attack Success 100% Prompted 0% Explicit Allows

Table 1: Experimental tasks for the laboratory study, derived from the attack vectors described in Section 2. We report the authorization messages shown to subjects in the four groups as well as the delegation graphs used by ENTrust to construct such authorization messages. In the group names, the suffix U indicates *unprimed* subjects, whereas P indicates *primed* subjects. Notice that, authorization requests prompted by ENTrust include programs' identity marks (i.e., apps' icon and unique id).

system services, such as the Screen Capture service. We also used a test app, Basic Camera, developed in our research lab. It provides basic camera functionality, such as capturing pictures or videos and applying photographic filters. However, Basic Camera is also designed to perform man-in-the-middle and Trojan horse attacks for requests to capture photographic frames. Lastly, we used a legitimate Mobile Banking app, from a major international bank, available on Google Play Store. Apart from the testing apps and voice assistant, the smartphone provided to participants had pre-installed both the Google Assistant and the Android Camera app.

Our laboratory study was divided into two phases. A *preliminary phase* during which no attacks were performed. This phase enabled participants to familiarize themselves with the provided smartphone, the pre-installed apps and the voice assistants. This phase avoided a "cold start" and approximated a more realistic scenario in which users have some experience using relevant apps and voice assistants. Furthermore, this preliminary phase enabled capturing how malicious

programs may leverage pre-authorized operations in the first-use approach to then perform operations not expected by the users; a malicious behavior that is instead prevented by ENTrust via the construction of per-delegation authorizations. The preliminary phase was then followed by an *attack phase*, during which participants interacted with programs performing attacks. Participants were not made aware of the existence of the two experimental phases nor of the difference between the two phases.

All instructions regarding experimental tasks to be performed were provided to participants in writing via a handout at the beginning of each experimental task. During the *preliminary phase* the participants performed the following three tasks: (1) asked a voice assistant to "take a screenshot;" (2) asked a voice assistant to "record a memo;" and (3) used a camera app to "record a video." During the *attack phase*, instead, the participants performed the three tasks described in Table 1. In each phase, each participant was presented with a different randomized order of the above tasks.

*Experimental Results:* In total, 60 subjects participated in and completed our laboratory study. We randomly assigned 15 participants to each group. In this study, we did not observe denials of legitimate operations for sensitive sensors for non-attack tasks performed during the preliminary phase, but we discuss the need for more study on preventing and resolving mistaken denials in Section 8. Table 1 summarizes the results of the three experimental tasks for the *attack phase*. Our focus was to study the effectiveness of ENTRUST in reducing the success rate of attacks when compared to the first-use approach. During the *preliminary phase* and the *experimental tasks*, all the participants were prompted with the corresponding authorization messages depending on the group to which they were assigned,<sup>5</sup> as reported in Table 1. Prompted authorizations included legitimate operations, see left side of Figure 6 for an example of what a prompt for a legitimate operation looked like. Our analysis reports that each participant of each group was prompted at least 4 times for non-attack operations. Note that, as per definition of first-use authorization, participants in Group-FR-U and Group-FR-P were not prompted with authorization messages once again should they have already authorized the program in a previous task or during the preliminary phase. Instead, participants in Group-EN-U and participants in Group-EN-P were presented with a new authorization message any time a new delegation path was identified by ENTRUST. This explains the lower percentage of subjects prompted, with an authorization request, in the first-use groups.

**TASK A:** The analysis of subjects' responses revealed that 9 subjects from Group-FR-U and 8 subjects from Group-FR-P interacted with Smart Assistant during the preliminary phase, or during another task, to "take a screenshot" and granted the app permission to capture their screen; thus, they were not prompted once again with an authorization message during this task, as per default in first-use permissions. In addition, 4 subjects from Group-FR-U explicitly allowed Smart Assistant to capture their screen, therefore, resulting in a 87% and 53% attack success, respectively, as reported in Table 1. On the contrary, only 3 subjects from Group-EN-U and no subject from Group-EN-P allowed the attack (20% and 0% attack success, respectively). Also, similarly to what happened in Group-FR-U and Group-FR-P, 8 subjects from Group-EN-U and 8 subjects from Group-EN-P interacted with Smart Assistant during the preliminary phase and asked to "take a screenshot." However, since the voice command "create a note" was a different command, ENTRUST prompted all subjects with a new authorization message, as shown in Table 1.

**TASK B:** The analysis of subjects' responses revealed that 9 subjects from Group-FR-U and 7 subjects from Group-FR-P interacted with Basic Camera to take a picture or record a video, either during the preliminary phase or during another task, and authorized it to cap-

ture pictures, audio, and access the device's location. Thus, they were not prompted once again during this task as per default in first-use permissions. Also, we found that 3 subjects from Group-FR-U explicitly authorized Basic Camera to access the camera, as well as the microphone, and the GPS receiver; therefore, resulting in 80% and 47% attack success, respectively. In contrast, 2 subjects from Group-EN-U and no subject from Group-EN-P authorized access to the camera, microphone, and GPS receiver (13% and 0% attack success, respectively). Also, we found that 8 subjects from Group-EN-U and 6 subjects from Group-EN-P interacted with Basic Camera during the preliminary phase or during another task. However, none of them asked to "take a selfie" before, so all subjects were prompted by ENTRUST with a new authorization message. At the end of the experiment, among all the subjects, when asked why they authorized access to the GPS receiver, the majority said that they expected a camera app to access location to create geo-tag metadata when taking a picture. In contrast, the subjects who denied access stated not feeling comfortable sharing their location *when taking a selfie*.

**TASK C:** The analysis of subjects' responses revealed that 8 subjects from Group-FR-U and 8 subjects from Group-FR-P interacted with Basic Camera, either during the preliminary phase or during another task, and authorized the app to capture pictures. Thus, during this task, they were not prompted with an authorization message once again as per default in first-use permissions. They were only prompted to grant permission to Mobile Banking, explaining why even the primed subjects were not able to detect the attack. In addition, 2 subjects from Group-FR-U explicitly authorized Basic Camera to capture a frame with the bank check; therefore, resulting in 67% and 53% attack success, respectively. On the other hand, only 1 subject from Group-EN-U and no subject from Group-EN-P authorized Basic Camera to capture a frame with the bank check, resulting in a 7% and 0% attack success, respectively. Notice that all subjects from Group-EN-U and Group-EN-P were prompted with a new authorization message by ENTRUST for the new command "deposit bank check." Interestingly, the one subject from Group-EN-U, who allowed Basic Camera to capture a frame with the bank check, verbally expressed his concern about the permission notification presented on the screen. The subject stated observing that two apps asked permission to access the camera to take pictures. This is reasonable for an unprimed subject not expecting a malicious behavior.

*Discussion:* Comparing the results from Group-FR-U versus those from Group-FR-P, and those from Group-EN-U versus those from Group-EN-P, we observe - as expected - that primed subjects allowed fewer attacks. We find that users primed for security problems still fall victim to attacks due to first-use authorization,

even when rejecting all the malicious operations they see. On the other hand, unprimed users fail to detect attacks between 7-20% with ENTRUST. So while this is a marked improvement, over the 67-87% failure for users with first-use authorization, there is room for further improvement. However, it is apparent that the delegation graphs constructed by ENTRUST aided the subjects in avoiding attacks even when unprimed. ENTRUST performed slightly better than first-use authorization in terms of explicit authorizations (explicit allows in Table 1); which suggests that the additional information provided by ENTRUST in authorization messages (i.e., programs' name and identity mark as well as delegation information, as shown in Figure 6) may be helpful to users in avoiding unexpected program behaviors. We verified the hypothesis that the information in ENTRUST authorizations helps *unprimed* users identify attacks by calculating the difference in *explicit allows*, across the three experimental tasks, for subjects in Group-FR-U versus subjects in Group-EN-U. Our analysis indeed revealed a statistically significant difference ( $\chi^2 = 19.3966$ ;  $p = 0.000011$ ).

Also, ENTRUST was significantly more effective than first-use in keeping users "on guard" independently of whether subjects were primed (47-67% lower attack success with ENTRUST). Indeed, different from the first-use approach, ENTRUST was able to highlight whether pre-authorized programs attempted accessing sensors via unauthorized delegation paths. If so, ENTRUST prompted users for an explicit authorization for the newly identified delegation path. We verified the hypothesis that ENTRUST better helps *primed* and *unprimed* users in preventing attacks than first-use, by calculating the difference in *successful attacks*, across the three experimental tasks, for subjects in Group-FR-U and Group-FR-P, versus subjects in Group-EN-U and Group-EN-P. Our analysis indeed revealed a statistically significant difference ( $\chi^2 = 65.5603$ ;  $p = 0.00001$ ). Normally, the standard Bonferroni correction would be applied for multiple testing, but due to the small p-values such a correction was not necessary.

### 6.3 Field Study

We performed a *field study* to evaluate whether ENTRUST increases the decision-overhead imposed on users. We measured the number of explicit authorizations users had to make when interacting with ENTRUST under realistic and practical conditions, and compared it with the first-use approach adopted in commercial systems (i.e., Android OS and Apple iOS). We also measured the number of authorizations handled by ENTRUST via the cache mechanism that, transparently to users, granted authorized operations.

*Experimental Procedures:* Participants met with one of our researchers to set up the loaner device, an LG Nexus 5X smartphone running a *modified* version of the Android OS integrating the ENTRUST authorization

framework. The loaner device had pre-installed 5 voice assistants and 10 apps selected among the most popular<sup>6</sup> with up to millions of downloads from the official Google Play store. For such programs, to ensure the confidentiality of participants' personal information, mock accounts were set up instead of real accounts for all apps requiring a log-in. To facilitate daily use of the loaner device, the researcher transferred participants' SIM cards and data, as well as participants' apps in the loaner device, however no data was collected from such apps. The above protocol was a requirement for the IRB approval by our Institution and it is compliant with the protocol followed in related work [33, 15, 11]. Before loaning the device, the researcher asked each participant to use the loaner device for their everyday tasks for a period of 7 days. In addition to their everyday tasks, participants were asked to explore each of the pre-installed voice assistants and apps, at least once a day, by interacting as they would normally do. Particularly, we asked the participants to interact with each voice assistant by asking the following three questions: (1) "capture a screenshot," (2) "record a voice note," (3) "how long does it take to drive back home." Additionally, we asked participants to be creative and ask three additional questions of their choice. Table 2 summarizes all the assistants and apps pre-installed on the smartphones for the field study. Because the mere purpose of our field study was to measure the decision-overhead imposed to users by ENTRUST and to avoid participants' bias, the researcher advertised the study as a generic "voice assistants and apps testing" study without mentioning security implications or training the users about the features provided by ENTRUST. The smartphones provided to participants were running a background service with runtime logging enabled, automatically restarted at boot time, to monitor the number of times each program was launched, the users' input events, the constructed delegation graphs, the authorization decisions made by the participants, and the number of authorizations automatically granted by ENTRUST. The background service also measured the gaps between consecutive input events and handoff events, as well as the time required by each program to service each event. This data was used to perform the time constraints analysis reported in Appendix B.

*Experimental Results:* Nine subjects participated and completed the field study. The data collected during our experiment indicates that all user authorizations were obtained within the first 72 hours of interaction with the experimental device, after which we observed only operations automatically granted by ENTRUST via the caching mechanism.

The first subject allowed us to discover two implementation issues that affected the number of explicit authorizations required by ENTRUST. First, changing the orientation of the screen (portrait versus landscape) was causing ENTRUST to request a new explicit user autho-

	Expl. Authorizations		Impl. Authorizations in s 7 Days Period
	First-Use	ENTRUST

Samsung Bixby	1	4	63
Lyra Virtual Assistant	1	3	56

Table 2: Apps and voice assistants tested in the field study. The last column shows the number of operations automatically authorized by ENTRUST after user’s authorization.

rization for an already authorized widget whenever the screen orientation changed. This inconvenience was due to the change in some of the features used to model the context within which the widget was presented. To address this shortcoming, we modified our original prototype to force the Window Manager to generate in memory two graphical user interfaces for both screen orientations to allow ENTRUST to bind them with a specific widget presented on the screen. Second, for the voice commands, we noticed that differently phrased voice commands with the same meaning would be identified as different input events. For instance, “take a selfie” and “take a picture of me”. This shortcoming was causing ENTRUST to generate a new delegation graph for each differently phrased voice command. To address this issue, we leveraged the *Dialogflow* engine by Google, part of the AI API.<sup>7</sup> *Dialogflow* is a development suite for building conversational interfaces and provides a database of synonyms to group together voice commands with the same meaning. We fixed the issues and continued our experiment with other subjects.

Table 2 reports the average number of explicit authorizations performed by the subjects. We compared them with the number of explicit authorizations that would be necessary if the *first-use* permission mechanism was used instead. The results show that ENTRUST required the same number of explicit authorizations by users for all the tested apps. For all voice assistants, instead, ENTRUST may require up to 3 additional explicit authorizations, when compared with the *first-use* approach; which is far below the 8 additional explicit authorizations used in prior work, which are considered likely not to introduce significant risk of habituation or annoyance [33]. These additional authorizations are due to the fact that with the *first-use* approach the programs (activated by the voice assistant to serve the user request) may have already received the required permissions to access the sensitive sensors. ENTRUST instead captures the entire sequence of events, from the input event to any subsequent action or operation request, and then ties them together. Therefore, ENTRUST constructs a new graph for each novel interaction. Nonetheless,

the number of decisions imposed on the users remains very modest. Indeed, on average, three additional explicit user authorizations are required per voice assistant. Also, the number of explicit authorizations made by the users remained a constant factor compared to the number of operations implicitly authorized by ENTRUST, which instead grew linearly over time. We measured an average of 16 operations implicitly authorized by ENTRUST during a 24-hour period (last column of Table 2). Therefore, if we consider such a daily average number of implicitly authorized operations for a period of one year, we will have on the order of thousands of operations automatically authorized by ENTRUST, which would not require additional explicit effort for the users.

## 6.4 Backward Compatibility Analysis

To verify that ENTRUST is backward compatible with existing programs, we used the Compatibility Test Suite (CTS),<sup>8</sup> an automated testing tool released by Google via the AOSP.<sup>9</sup> In particular, this analysis verified that possible delays in the delivery of events introduced by ENTRUST or the change in scheduling of events did not impact applications’ functionality. We tested the compatibility of ENTRUST with 1,000 existing apps, among the top 2,000 most downloaded apps on Google Play Store, selected based on those declaring permissions to access sensitive sensors in their manifest. The experiment took 19 hours and 45 minutes to complete, and ENTRUST passed 132,681 tests without crashing the operating system and without incorrectly blocking any legitimate operation. Among the 1,000 tested apps, we also included 5 popular augmented reality multiplayer gaming app (Ingress, Pokémon Go, Parallel Kingdom, Run An Empire, and Father.io), which typically have a high rate of input events and are very sensitive to delays. The set of tests targeting these 5 gaming apps ran for 16 minutes, during which we continuously observed the device screen to identify possible issues in terms of responsiveness to input events or glitches in the rendering of virtual objects on the screen. However, we did not identify any discernible slowdown, glitch, or responsiveness issue.

## 7 Performance Measurements

We performed four micro-benchmarks on a standard Android developer smartphone, the LG Nexus 5X, powered by 1.8GHz hexa-core 64-bit Qualcomm Snapdragon 808 Processor and Adreno 418 GPU, 2GB of RAM, and 16GB of internal storage. All of our benchmarks are measured using Android 7.1 Nougat pulled from the Android Open Source Project (AOSP) repository.

**Delegation Graph Construction** – Our first micro-benchmark of ENTRUST measured the overhead incurred for constructing delegation graphs of varying sizes. To do this, we had several programs interacting

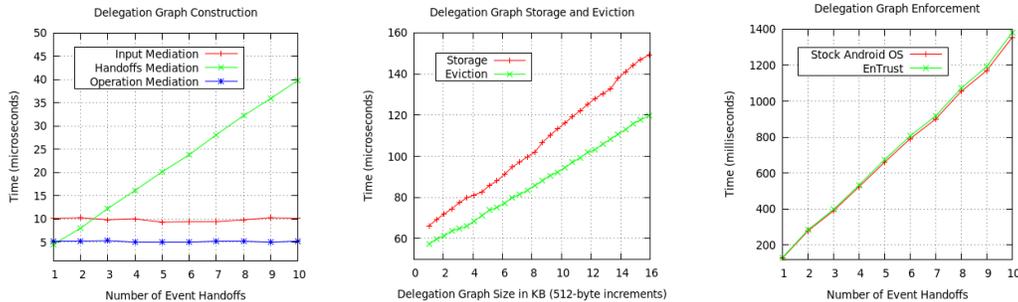

Figure 7: Overheads for Delegation Graphs Construction, Storage, Eviction, and Enforcement.

and generating a handoff-events chain varying from 1 to 10 handoffs in length and measured the time to mediate the input event, the handoff event, and the operation request. We repeated the measurements 100 times. Each set of measurements was preceded by a priming run to remove any first-run effects. We then took an average of the middle 8 out of 10 such runs for each number of handoff events. The results in Figure 7 show that the input mediation requires an overhead of 10  $\mu$ s, the handoff event mediation requires an additional overhead of 4  $\mu$ s per event handoff, whereas the operation mediation requires a fixed overhead of 5  $\mu$ s. The overheads are within our expectations and do not cause noticeable performance degradation.

**Delegation Graph Caching** – Our second micro-benchmark of **ENTrust** measures the overhead incurred for caching delegation graphs constructed at runtime. We measured the overhead introduced by **ENTrust** in the authorization process for both storing a new delegation graph, as well as evicting from cache a stale one. To do this, we simulated the creation and eviction of delegation graphs of different sizes varying from 1 to 16 Kilobytes in 512-byte increments.<sup>10</sup> We repeated the measurement 5 times for each random size and took an average of the middle 3 out of 5 such runs. The results in Figure 7 show that the storing of delegation graphs in the cache required a base overhead of 66  $\mu$ s with an additional 3  $\mu$ s per 512-byte increment. The eviction instead required a base overhead of 57  $\mu$ s with an additional 2.5  $\mu$ s for each 512-byte increment.

**Delegation Graph Enforcement** – Our third micro-benchmark was designed to compare the unmodified version of the Android Nougat build for control measurement with a modified build integrating our **ENTrust** features for the delegation graph enforcement during authorization. To guarantee fairness in the comparison between the two systems, we used the Android UI/Application Exerciser Monkey<sup>11</sup> to generate the same sequence of events for the same set of programs. For both systems, we measured the total time needed to authorize a sensor operation as the time from the input event to the authorization of the resulting operation request, corresponding to the last node of the delegation graph for **ENTrust**. We repeated the measurement 100 times for each system by varying the num-

ber of handoff events from 1 to 10. Each set of measurements was preceded by a priming run to remove any first-run effects. We then took an average of the middle 8 out of 10 such runs for each number of handoff events. Figure 7 shows that the overhead introduced by **ENTrust** for the delegation graph enforcement is negligible, with the highest overhead observed being below 0.02%. Thus, the slowdown is likely not to be noticeable by users. Indeed, none of our study participants raised any concerns about discernible performance degradation or system slowdown.

**Ambiguity Prevention** – Our fourth micro-benchmark was designed to measure the performance implications, in terms of delayed events, due to the ambiguity prevention mechanism. For this micro-benchmark, we selected the system UI (User Interface) process, which is one of the processes receiving the highest number of input events, and the media server process that receives the highest number of handoff events and performs sensor operations with higher frequency than any other process. The time window for the construction of each delegation path was set to 150 ms. We generated 15,000 input events with gaps randomly selected in the range [140-1,500]<sup>12</sup> ms. The time window and the gaps were selected based on data reported in Appendix B. The generated input events caused 2,037 handoff events and 5,252 operation requests targeting sensors (22,289 total scheduled events). The results indicated a total of 256 delayed events (1.15% of the total events), with a maximum recorded delay of 9 ms. Thus, the performance overhead introduced is negligible.

**Memory Requirement** – We also recorded the average cache size required by **ENTrust** to store both event mappings and authorized delegation graphs to be about 5.5 megabytes, for up to 1,000 programs.<sup>13</sup> Therefore, **ENTrust** required about 5.5 kilobytes of memory per program, which is a small amount of memory when compared to several gigabytes of storage available in modern systems. We ran the measurement 10 times and then took an average of the middle 8 out of 10 of such runs.

## 8 Discussion of Limitations

Evaluating mechanisms that prevent abuse of sensitive sensors while trading off privacy and usability is chal-

lenging. In this section, we discuss the limitations of our study and provide guidance on future work.

**Authorization Comprehension** – In designing our authorization messages, we have used the language adopted in current permission systems (e.g., Android OS and Apple iOS) and prior research work [47, 11, 15, 16] as references. However, such language may not be as effective in eliciting access control decisions from users as desired. Further improvements may be possible by studying NLP techniques and how access control questions may be phrased using such techniques. Also, a combination of text, sound, and visuals may be useful in conveying access questions to users. **ENTRUST** is largely orthogonal to any specific way how access control questions are presented, enabling it to be used as a platform for further study.

**Decision Revocation** – Users may make mistakes when allowing or denying authorizations. **ENTRUST** caches user decisions to reduce users’ authorization effort, allowing such mistakes to persist. Mistakes in authorizing access to sensor operations may permit malicious applications to abuse access, albeit limited to that delegation path only. Mistakes in denying access to sensor operations prevents legitimate use of sensor operations silently as a result of caching. One possible solution to these problems is to invalidate the cache periodically to prevent stale authorization decisions. However, frequent authorization prompts negatively affect user experience. Currently, **ENTRUST** enables users to review authorization decisions via an audit mechanism, as suggested elsewhere [53, 15]. However, to improve the effectiveness of such mechanisms, further laboratory studies will be necessary to examine how to present audit results (or other new approaches) to help users to investigate and resolve mistaken authorizations.

**Study Scenarios** – In this project, we focused on whether users would be able to deny attack scenarios effectively. Another problem is that users may not evaluate non-attack scenarios correctly once they become aware of possible attacks. In our study, we did not observe that users denied any legitimate sensor operations during the lab study, but it would be beneficial to extend the laboratory study to include more subtle non-attack scenarios, where we push the boundaries of what is perceived as benign, to evaluate whether these scenarios may cause false denials due to users being unable to identify that the request was indeed benign. Also, we recognize that all attacks were generated by programs unfamiliar to participants, even though they were given the opportunity to familiarize themselves with such programs during the preliminary phase of our lab study.

**Study Size** – The number of subjects recruited for this project, 60 for the laboratory study and 9 for the field study, is comparable with the number of subjects in similar studies [33, 14, 15, 11]. Other related work [47] had a higher number of subjects, but subjects were not required to be physically present in the laboratory

during the experimental tasks having been recruited via online tools (e.g., Mechanical Turk). However, research has shown, in the context of password study, that a laboratory study may produce more realistic results than an online study [58].

**Study Comprehensiveness** – Our study does not focus explicitly on long-term habituation, user annoyance, and users’ attitudes toward privacy. Researchers have already extensively studied users’ general level of privacy concerns [51, 52, 53, 15]. Other researchers have studied users’ habituation for first-use authorization systems extensively [33, 45, 50]. Our field study (Section 6.3) shows that our approach is comparable to first-use in terms of the number of times users are prompted, and the number of explicit authorizations from users is far below the 8 additional explicit authorizations used in prior work, which are considered likely not to introduce significant risk of habituation or annoyance [33].

## 9 Related Work

Researchers have extensively demonstrated that IPC mechanisms allow dangerous interactions between programs, such as unauthorized use of intents, where adversaries can hijack activities and services by stealing intents [18, 21, 22, 26]. Prior work has also shown that such interactions can be exploited by adversaries to cause permission re-delegations [7] in the attempt to leverage capabilities available to trusted programs (e.g., system services). Also, related work has demonstrated how trusted programs inadvertently or purposely (for functionality reasons) expose their interfaces to other programs [8], thus exposing attack vectors to adversaries. In this paper, we have demonstrated that dangerous interactions among programs can lead to critical attack vectors related to input event delegations.

Researchers have tried to regulate such interactions with automated tools for IPC-related vulnerability analysis. For instance, *ComDroid* is a tool that parses the disassembled applications’ code to analyze intent creation and transition for the identification of unauthorized intent reception and intent spoofing [26]. *Efficient and Precise ICC discovery* (EPICC) is a more comprehensive static analysis technique for Inter-Component Communication (ICC)<sup>14</sup> calls [19]. It can identify ICC vulnerabilities due to intents that may be intercepted by malicious programs, or scenarios where programs expose components that can be launched via malicious intents. *Secure Application INteraction (Saint)* [54] extends the existing Android security architecture with policies that would allow programs to have more control to whom permissions for accessing their interfaces are granted and used at runtime. *Quire* provides context in the form of provenance to programs communicating via Inter-Procedure Calls (IPC) [55]. It annotates IPCs occurring within a system, so that the recipient of an

IPC request can observe the full call sequence associated with it, before committing to any security-relevant decision. Although effort has been made to analyze and prevent IPC-related vulnerabilities, none of the proposed approaches above tackled the problem from our perspective, i.e., instead of giving control to application developers, we must give control to users who are the real target for privacy violations by malicious programs.

In line with our perspective of giving control to users, *User-Driven Access Control* [9, 10] proposes the use of access control gadgets, predefined by the operating systems and embedded into applications' code, to limit what operation can be associated with a specific input event. Also, *AWare* [11] proposes to bind each operation request targeting sensitive sensors to an input event and to obtain explicit authorization from the user for each event-operation combination. Similarly, *ContextIoT* [16] is a context-based permission system for IoT platforms which leverages runtime prompts with rich context information including the program execution flow that allows users to identify how a sensitive operation is triggered. Unfortunately, all of these mechanisms only control how the input event is consumed by the program receiving the input event. The proposed mechanisms to enable mediation do not mediate inter-process communication (e.g., *event delegations between programs*), which is necessary to prevent the attack vectors discussed in this paper. Also, differently from prior work on permission re-delegation [7], we do not rely on an over-restrictive defense mechanism that totally forbids programs from using their additional privileges. Such an over-restrictive defense would block necessary interactions between programs even when the interactions are benign and expected by users.

Prior work has also investigated the use of machine learning classifiers to analyze the contextuality behind user decisions to automatically grant access to sensors [14, 15]. Unfortunately, such classifiers only model the context relative to the single program that the user is currently interacting with, and the API calls that are made by such a program during the interaction. However, the context modeled by these classifiers does not account for inter-process communications, which allow programs to enlist other programs to perform sensor operations via input event delegation. Furthermore, the effectiveness of the learning depends on the accuracy of the user decisions used in training the learner. In other words, if the user's decisions suffer from inadequate information during the training phase, the learner will as well. Therefore, we firmly believe that an additional effort is necessary to support user decision making before the user decisions can be used to train a classifier.

Lastly, mechanisms based on taint analysis [29, 30, 31] or Decentralized Information Flow Control (DIFC) [13, 20] have been proposed by researchers to, respectively, track and control how sensitive data is used by or shared

between programs. However, such mechanisms solve the orthogonal problem of controlling sensitive data leakage or accidental disclosure, rather than enabling users to control *how*, *when*, and *which* programs can access sensors for the collection of sensitive data.

## 10 Conclusion

While a collaborative model allows the creation of useful, rich, and creative applications, it also introduces new attack vectors that can be exploited by adversaries. We have shown that three well-studied attack vectors become critical, in operating systems supporting a cooperating program abstraction, and proposed the **ENTRUST** authorization system to help mitigate them. **ENTRUST** demonstrates that it is possible to prevent programs from abusing the collaborative model – in the attempt to perform delegated confused deputy, delegated Trojan horse, or delegated man-in-the-middle attacks – by binding together, input event, handoff events, and sensor operation requests made by programs, and by requiring an explicit user authorization for the constructed delegation path. Our results show that existing systems have room for improvement and permission-based systems, as well as machine learning classifiers, may significantly benefit from applying our methodology.

## Appendices

**Appendix A - Study Demographics:** In total, from the 69 recruited subjects that completed our study, 34 (49%) were female; 36 (52%) were in the 18-25 years old range, 27 (39%) in the 26-50 range, and 6 (9%) were in above the 51 range; 33 (48%) were students from our Institution, 9 of them (13%) were undergraduate and 24 (35%) were graduate students, 2 (3%) were Computer Science Majors; 11 (16%) worked in Public Administration, 9 (13%) worked in Hospitality, 6 (9%) in Human Services, 6 (9%) in Manufacturing, and 4 (6%) worked in Science or Engineering. All participants reported being active smartphone users (1-5 hours/day). Also, 42 (61%) of the subjects were long-term Android users (3-5 years), others were long-term iOS users. For our laboratory and field studies, we redistributed the available participants as evenly as possible. Each lab group had 9 long-term Android users, the remaining 6 long-term Android users participated in our field study.

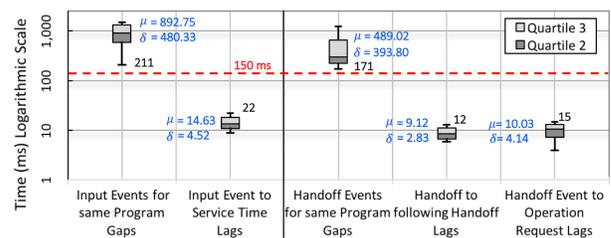

Figure 8: Time analysis used to study the possibility of ambiguous events delegation paths, as discussed in Section 4.2.

**Appendix B - Time Constraints Analysis:** We leveraged data collected via the field study to perform an analysis of time constraints for input events and action/operation requests to calibrate the time window

for the event ambiguity prevention mechanism (Section 4.2). Figure 8 reports the measurements of the gaps<sup>15</sup> between consecutive input events and consecutive handoff events, as well as the lags between each event and the corresponding response from the serving program. From the measurements, we observed: (1) the minimum gap between subsequent input events targeting the same program (211 ms) is an order of magnitude larger than the maximum lag required by the program to serve each incoming event (22 ms); and (2) the minimum gap (171 ms) between subsequent handoff events targeting the same program is an order of magnitude larger than the maximum lag required by the program to serve incoming requests (15 ms). Hence, to avoid ambiguity, we may set the time window to 150 ms to guarantee that the entire delegation path can be identified before the next event for the same program arrives. Lastly, we observed that 87% of the delegation paths had a total length of three edges (one input event, one handoff event, and one sensor operation request). The remaining 13% of the delegation paths had a maximum length of four edges (one additional handoff event), which further supports our claim that we can hold events without penalizing concurrency of such events.

**Appendix C - Program Identification:** To prove the programs' identity to users, ENTRUST specifies both the programs' name and visual identity mark (e.g., icon) in every *delegation request* as shown in Figure 6. ENTRUST retrieves programs' identity by accessing the `AndroidManifest.xml`, which must contain a unique name and a unique identity mark (e.g., icon) for the program package. ENTRUST verifies programs' identity via the crypto-checksum<sup>16</sup> of the program's binary signed with the developer's private key and verifiable with the developer's public key [46], similarly to what proposed in prior work [47, 11].

**Appendix D - Input Event Authentication:** ENTRUST leverages SEAndroid [38] to ensure that programs cannot inject input events by directly writing into input device files (i.e., `/dev/input/*`) corresponding to hardware and software input interfaces attached to the mobile platform. Hence, only device drivers can write into input device files and only the Android Input Manager, a trusted system service, can read such device files and dispatch input events to programs. Also, ENTRUST leverages the Android screen overlay mechanism to block overlay of graphical user interface components and prevent hijacking of input events. Lastly, ENTRUST accepts only voice commands that are processed by the Android System Voice Actions module.<sup>17</sup> ENTRUST authenticates input events by leveraging sixteen mediation hooks placed inside the stock Android Input Manager and six mediation hooks placed inside the System Voice Actions module.

**Appendix E - Handoff Event Mediation:** Programs communicate with each other via Inter-Component Communication (ICC) that, in Android, is

implemented as part of the Binder IPC mechanisms. The ICC includes both *intent* and *broadcast* messages that can be exchanged among programs. The Binder and the Activity Manager regulate messages exchanged among programs via the intent API.<sup>18</sup> Programs can also send intents to other programs or services by using the broadcast mechanism that allows sending intents as arguments in broadcast messages. The Activity Manager routes intents to broadcast receivers based on the information contained in the intents and the broadcast receivers that have registered their interest in the first place. To mediate intents and broadcast messages exchanged between programs completely, ENTRUST leverages mediation hooks placed inside the Activity Manager and the Binder.

Notice that, other operating systems support mechanisms similar to Android's Intents. For instance, MacOS and iOS adopt the Segue mechanism, while Chrome OS supports Web Intents, thus ENTRUST can be also implemented for other modern systems supporting the co-operating program abstraction.

#### Appendix F - Sensor Operation Mediation:

Android uses the Hardware Abstraction Layer (HAL) interface to allow only system services and privileged processes to access system sensors indirectly via a well-defined API exposed by the kernel. Moreover, SEAndroid [38] is used to ensure that only system services can communicate with the HAL at runtime. Any other programs (e.g., apps) must interact with such system services to request execution of operations targeting sensors. ENTRUST leverages such a mediation layer to identify operation requests generated by programs, by placing 12 hooks inside the stock Android Audio System, Media Server, Location Services, and Media Projection.

#### Notes

<sup>1</sup>In this paper, we use the term "delegate" to refer to the use of IPCs to request help in task processing, not the granting of permissions to other processes.

<sup>2</sup>One of the surveillance mobile apps available online (e.g., flexispy).

<sup>3</sup>Several banks are now offering these services to their clients.

## Abstract

Privacy policies are the primary mechanism by which companies inform users about data collection and sharing practices. To help users better understand these long and complex legal documents, recent research has proposed tools that summarize collection and sharing. However, these tools have a significant oversight: they do not account for contradictions that may occur within an individual policy. In this paper, we present PolicyLint, a privacy policy analysis tool that identifies such contradictions by simultaneously considering negation and varying semantic levels of data objects and entities. To do so, PolicyLint automatically generates ontologies from a large corpus of privacy policies and uses sentence-level natural language processing to capture both positive and negative statements of data collection and sharing. We use PolicyLint to analyze the policies of 11,430 apps and find that 14.2% of these policies contain contradictions that may be indicative of misleading statements. We manually verify 510 contradictions, identifying concerning trends that include the use of misleading presentation, attempted redefinition of common understandings of terms, conflicts in regulatory definitions (e.g., US and EU), and “laundering” of tracking information facilitated by sharing or collecting data that can be used to derive sensitive information. In doing so, PolicyLint significantly advances automated analysis of privacy policies.

## 1 Introduction

Mobile apps collect, manage, and transmit some of the most sensitive information that exists about users—including private communications, fine-grained location, and even health measurements. These apps regularly transmit this information to first or third parties [1, 7, 14]. Such data collection/sharing by an app is often considered (legally) acceptable if it is described in the privacy policy for the app. Privacy policies are sophisticated legal documents that are typically long, vague, and difficult for novices, experts, and algorithms to interpret. Accordingly, it is difficult to determine whether app developers adhere to privacy policies, which can help app markets and

other analysts identify privacy violations, or help end users choose more-privacy-friendly apps.

Recent work has begun studying whether or not mobile app behavior matches statements in privacy policies [26,28,29,32]. However, the prior work fails to account for contradictions within privacy policies; these contradictions may lead to incorrect interpretation of sharing and collection practices. Identifying contradictions requires overcoming two main challenges. First, privacy policies refer to information at different semantic granularities. For example, a policy may discuss its practices using broad terms (e.g., “personal information”) in one place in the policy, but later discuss its practices using more specific terms (e.g., “email address”). Prior approaches have tackled this issue by crowdsourcing data object ontologies [26, 28],<sup>1</sup> but such crowdsourced information is not complete, accurate, or easily collected. Second, prior approaches have struggled to accurately detect negative statements, relying on bi-grams (e.g., “not share”) [32] or detecting only verb modifiers [29] while neglecting the more-complicated statements (e.g., “will share X except Y”) that are common in privacy policies. Modeling negative statements is required to determine the correct meaning of a policy statement (i.e., “not sharing” versus “sharing” information). Fully characterizing contradictions requires addressing both preceding challenges.

In this paper, we present PolicyLint for automatically identifying potential contradictions of sharing and collection practices in software privacy policies. Contradictions make policies unclear, confusing both humans and any automated system that rely on interpreting the policies. Considering these uses cases, PolicyLint defines two contradiction groupings. *Logical contradictions* are contradictory policy statements that are more likely to cause harm if users and analysts are not aware of the contradictory statements. One example is a policy that initially claims not to collect personal information, but later in fine print discloses collecting a user’s name and email address for advertisers. *Narrowing definitions* may cause automated techniques that reason over policy statements

<sup>1</sup>Ontologies are graph data structures that capture relationships among entities. For example, “personal information” subsumes “your email address.”

to make incorrect or inconsistent decisions and may result in vague policies. PolicyLint is the first tool to have the sophistication necessary to reason about both negative sentiments and statements covering varying levels of specificity, being necessary for uncovering contradictions.

PolicyLint is inspired by other security lint tools [6, 8–11, 19], which analyze code for indicators of potential bugs. Like any static approach, not every lint finding is necessarily a real bug. For example, potential bug conditions could be mitigated by an external control or other context that the tool cannot verify. In many cases, only a human can verify the outputs of a lint finding. In the case of PolicyLint, we note that privacy policies are complex legal documents that may be intentionally vague, ambiguous, or misleading even for human interpretation. Despite these challenges, PolicyLint condenses long, complicated policies into a small set of candidate issues of interest to human or algorithmic analysis.

This paper makes the following main contributions:

- Automated generation of ontologies from privacy policies.** PolicyLint uses an expanded set of Hearst patterns [16] to extract ontologies for both data objects and entities from a large corpus of privacy policies (e.g., “W such as X, Y, and Z”). PolicyLint is more comprehensive and scalable than crowdsourced efforts [26, 28].
- Automated sentence-level extraction of privacy practices.** PolicyLint uses sentence-level NLP and leverages parts-of-speech and type-dependency information to capture data collection and sharing as a four-tuple: (actor, action, data object, entity). For example, “We [actor] share [action] personal information [data object] with advertisers [entity].” Sentence-level NLP is critically important for the correct identification of negative statements. We also show that prior attempts at analyzing negation would fail on 28.2% of policies.
- Automated analysis of contradictions in privacy policies.** We formally model nine types of contradictions that result from semantic relationships between terms, providing an algorithmic technique to detect contradictory policy statements. Our groupings of *narrowing definitions* and *logical contradictions* lay the foundation for ensuring the soundness of automated policy tools and identifying potentially misleading policy statements. In a study of 11,430 privacy policies from mobile apps, we are the first to find that logical contradictions and narrowing definitions are *rampant*, affecting 17.7% of policies, with logical contradictions affecting 14.2%.
- Manual analysis of contradictions to identify trends.** The high ratio of policy contradictions is surprising. We manually review 510 contradictions across 260 policies, finding that many contradictions are indeed indicators of misleading or problematic policies. These contradictions

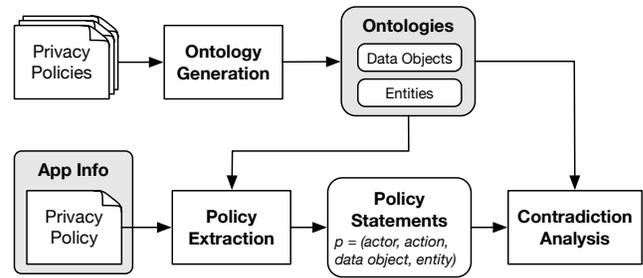

Figure 1: Overview of PolicyLint

include making broad claims to protect personal information early in a policy, yet later carving out exceptions for data that the authors attempt to redefine as not personal, that could be used to derive sensitive information (e.g., IP addresses and location), or that are considered sensitive by some regulators but not others.

PolicyLint has four main potential use cases. First, policy writers can leverage PolicyLint to reduce the risk of releasing misleading policies. In fact, when we contacted parties responsible for the contradictory policies, several fixed their policies (Section 3.4). Second, regulators can use PolicyLint’s definition of logical contradictions to identify deceptive policies. While the FTC has identified contradictory statements as problem areas within privacy policies [3], to our knowledge, there is no legal precedent regarding whether regulatory agencies would take action as a result of contradictory policies. However, we believe that some of our findings in Section 3 potentially fall under the FTC’s definition of deceptive practices [13]. We envision that regulators could deploy PolicyLint to audit companies’ privacy policies for misleading statements at large scale. Third, app markets, such as Google Play, can deploy PolicyLint similarly to ensure that apps posted in the store do not have misleading statements in their privacy policies. Furthermore, they can also use PolicyLint’s extraction of policy statements to automatically generate privacy labels to display on the markets to nudge users to less-privacy-invasive apps. Finally, automated techniques for analyzing privacy policies can use PolicyLint’s fine-grained extraction of policy statements and formalization of logical contradictions and narrowing definitions to help ensure tool soundness.

The rest of this paper is organized as follows. Section 2 describes PolicyLint’s design. Section 3 reports on our study using PolicyLint. Section 4 discusses limitations and future work. Section 5 describes related work. Section 6 concludes.

## 2 PolicyLint

PolicyLint seeks to identify contradictions within individual privacy policies for software. It provides privacy *warnings* based on contradictory sharing and collection statements within policies, but similar to lint tools for software, these warnings require manual verification. PolicyLint identifies

“candidate contradictions” within policies. A candidate contradiction is a pair of contradictory policy statements when considered in the most conservative interpretation (i.e., context-insensitive). Candidate contradictions that are validated by analysts are termed as “validated contradictions.” Manual verification is required due to the fundamental problems of ambiguity when interpreting the meaning of natural language sentences (i.e., multiple interpretations of the same sentence).

For example, consider the privacy policy for a popular recipe app (com.omniluxtrade.allrecipes). One part of the policy states “We do not collect personally identifiable information from our users.” It is clear from this sentence that the app does not collect any personal information. However, later the policy states, “We may collect your email address in order to send information, respond to inquiries, and other requests or questions.” Such sentence is a clear contradiction to the earlier sentence, as email address is considered personal information. As discussed in detail in Section 3, the cause for this underlying contradiction is that the developer does not consider email address as personal information.

To our knowledge, we are the first to characterize and automatically analyze contradictions within privacy policies. While PolicyLint is not the first NLP tool to analyze privacy policies, identifying contradictions requires addressing two broad challenges.

- *References to information are expressed at different semantic levels.* Prior work [26, 28] uses ontologies to capture subsumptive (i.e., “is-a”) relationships between terms; however, such ontologies are crowdsourced and subsumptive relationships are manually defined by the authors, leaving concerns of comprehensiveness and scalability. For example, prior work [26, 28] builds their ontology using only 50 and 30 policies, respectively. While crowdsourced ontologies could be comprehensive given unlimited time and manpower, crowdsourcing at large scale is infeasible due to limited resources. Furthermore, existing general-purpose ontologies do not capture all of the specific relationships required to reason over data types and entities mentioned within privacy policies.
- *Privacy policies include negative sharing and collection statements.* Most prior work [26, 28] operates at paragraph level and cannot capture negative sharing statements. Prior work [29, 32] that does capture negative statements misses complex statements (e.g., “will share personal information except your email address”). Such prior work extracts coarse-grained summaries of policy statements (paragraph-level [26, 28], document-level [32]) and can never precisely model negative statements or the entities involved. Their imprecision may result in incorrectly reasoning about 28.2% of policies due to their negation modeling (Finding 1 in Section 3).

We tackle these challenges using two key insights.

**Sentence structure informs semantics:** Sharing and collection statements generally follow a learnable set of templates. PolicyLint uses these templates to extract a four tuple from such statements: (actor, action, data object, entity). For example, “We [actor] share [action] personal information [data object] with advertisers [entity].” The sentence structure also provides greater insight into more complex negative sharing. For example, “We share personal information except your email address with advertisers.” PolicyLint extracts such semantics from policy statements by building on top of existing parts-of-speech and dependency parsers.

**Privacy policies encode ontologies:** Due to the legal nature of privacy policies, general terms are often defined in terms of examples or their constituent parts. While each policy might not define semantic relationships for all of the terms used in the policy, those relationships should exist in some other policies in our dataset. By processing a large number of privacy policies, PolicyLint automatically generates an ontology specific to policies (one for data objects and one for entities). PolicyLint extracts term definitions using Hearst patterns [16], which we have extended for our domain.

Figure 1 depicts the data flow within PolicyLint. There are three main components of PolicyLint: ontology generation, policy extraction, and contradiction analysis. The following sections describe these components. Readers interested in policy-preprocessing considerations can refer to Appendix A.

## 2.1 Ontology Generation

The goal of ontology generation is to define subsumptive (“is-a”) relationships between terms in privacy policies to allow reasoning over different granularities of language. PolicyLint operates on the intuition that subsumptive relationships are often embedded within the text of a privacy policy, e.g., an example of the types of data considered to be a specific class of information. The following example identifies that demographic information subsumes age and gender.

**Example 1.** *We may share demographic information, such as your age and gender, with advertisers.*

PolicyLint uses such sentences to automatically discover subsumptive relationships across a large set of privacy policies. It focuses on data objects and the entities receiving data.

PolicyLint uses a semi-automated and data-driven technique for ontology generation. It breaks ontology generation into three main parts. First, PolicyLint performs domain adaptation of an existing model of statistical-based named entity recognition (NER). NER is used to label data objects and entities within sentences, capturing not only terms, but also surrounding context in the sentence. Second, PolicyLint learns subsumptive relationships for labeled data objects and entities by using a set of 11 lexicosyntactic patterns with enforced named-entity label constraints. Third, PolicyLint takes a set

Table 1: NER Performance: Comparison of spaCy’s stock en\_core\_web\_lg model versus our adapted domain model

	Overall		Data Objects		Entities	
	Default	Adapted	Default	Adapted	Default	Adapted
Precision	43.48%	84.12%	-	82.20%	61.22%	86.75%
Recall	8.33%	81.67%	-	79.84%	17.75%	85.21%
F1-Score	13.99%	82.88%	-	81.00%	27.52%	85.97%

of seed words as input and generates data-object/entity ontologies using the subsumptive relationships discovered in the prior step. It iteratively adds relationships to the ontology until a fixed point is reached. We next describe this process.

### 2.1.1 NER Domain Adaptation

To identify subsumptive relationships for data objects and entities, PolicyLint must identify which sentence tokens represent a data object or entity. For Example 1, we seek to identify “demographic information,” “age,” and “gender” as data objects, and “we” and “advertisers” as entities. PolicyLint uses a statistical-based technique of named-entity recognition (NER) to label data objects and entities within sentences. Prior research [26, 28, 29, 32] proposed keyphrase-based techniques for identifying data objects. However, keyphrase-based techniques are less versatile in practice: they cannot handle term ambiguity and variability, and they can identify only terms in their pre-defined list. For example, “internet service provider” can be both a data object and entity, which keyphrase-based techniques cannot differentiate. In contrast, statistical-based NER both resolves ambiguity and discovers “unseen” terms.

Unfortunately, existing NER models are not trained for our problem domain (data objects and collective terms describing entities, e.g., “advertisers”). Training an NER model from scratch is time-consuming due to the large amount of training data required to achieve reasonable performance. Therefore, PolicyLint takes an existing NER model and updates it using annotated training data from our problem domain. Specifically, PolicyLint adopts spaCy’s NER engine [17], which uses deep convolutional neural networks. We adapt the *en\_core\_web\_lg* model to the privacy policy domain.

To perform domain adaptation, we gather 500 sentences as training data. Our training data is selected as follows. First, we randomly select 50 unique sentences from our policy dataset. Second, for each of the 9 lexicosyntactic patterns described in Section 2.1.2, we randomly select 50 sentences that contain the pattern (450 in total). We run the existing NER model on the training sentences to prevent the model from “forgetting” old annotations. We then manually annotate the sentences with data objects and entities.

When updating the existing NER model, we perform multiple passes over the annotated training data, shuffling at each epoch, and using minibatch training with a batch size of 4. To perform the domain adaptation, the current model predicts the NER labels for each word in the sentence and adjusts the synaptic weights in the neural network accordingly if the pre-

Table 2: Lexicosyntactic patterns for subsumptive relationships

#	Pattern
H1	$X, \text{ such as } Y_1, Y_2, \dots, Y_n$
H2	$\text{such } X \text{ as } Y_1, Y_2, \dots, Y_n$
H3	$X \text{ [or\&and] other } Y_1, Y_2, \dots, Y_n$
H4	$X, \text{ including } Y_1, Y_2, \dots, Y_n$
H5	$X, \text{ especially } Y_1, Y_2, \dots, Y_n$
H’1	$X, \text{ [e.g.  i.e.], } Y_1, Y_2, \dots, Y_n$
H’2	$X \text{ ( [e.g.  i.e.], } Y_1, Y_2, \dots, Y_n)$
H’3	$X, \text{ for example, } Y_1, Y_2, \dots, Y_n$
H’4	$X, \text{ which may include } Y_1, Y_2, \dots, Y_n$

\* H\* = Hearst Pattern; H’\* = Custom Pattern

diction does not match the annotation. We stop making passes over the training data when the loss rate begins to converge. We annotate an additional 100 randomly selected sentences as holdout data for testing the model. Table 1 shows the NER model performance before and after domain adaptation for our holdout dataset. PolicyLint achieves 82.2% and 86.8% precision for identifying data objects and entities, respectively.

### 2.1.2 Subsumptive Relationship Extraction

PolicyLint uses a set of 9 lexicosyntactic patterns to discover subsumptive relationships within sentences, as shown in Table 2. The first 5 are Hearst Patterns [16], and the last 4 are custom deviations based on observations of text in privacy policies. For each pattern, PolicyLint ensures that named-entity labels are consistent across the pattern (i.e., PolicyLint uses Hearst patterns enforcing constraints on named-entity labels). For example, Example 1 is recognized by the pattern “ $X, \text{ such as } Y_1, Y_2, \dots, Y_n$ ” where  $X$  is a noun,  $Y_1, Y_2, \dots, Y_n$  are all nouns, and the NER labels for  $X$  and each  $Y_i$  are all data objects. Note that PolicyLint merges noun phrases before applying the lexicosyntactic patterns to ease extraction.

Given the set of extracted relationships, PolicyLint normalizes the relationships by lemmatizing the text and substituting terms with their synonym. For example, consider that “blood sugar levels” is a synonym for “blood glucose level.” Lemmatization turns “blood sugar levels” into “blood sugar level,” and synonym substitution turns it into “blood glucose level.” To identify synonyms, we output non-terminal (i.e.,  $X$  value of the Hearst patterns) data objects and entities in the subsumptive relationships. We manually scan through the list and mark synonyms. We repeat the process with the terminal nodes that are included after constructing the ontology. We then output the data objects and entities labeled from all policies and sort the terms by frequency. We mark synonyms for the most frequent terms by keyword searching for related terms based on sub-strings and domain knowledge. For example, if “location” appears as a frequent term, we output all data objects that contain the word “location,” read through the list, and mark synonyms (e.g., “geographic location”). Next, we use domain knowledge to identify that “latitude and longitude” is a synonym of “location,” output the terms that contain those words, and manually identify synonyms.

Table 3: Seed terms used for ontology construction

Ontology	Seeds
Data Ontology	information, personal information, non-personal information, information about you, biometric information, financial information, device sensor information, government-issue identification information, vehicle usage information
Entity Ontology	third party

### 2.1.3 Ontology Construction

PolicyLint generates ontologies by combining the subsumptive relationships extracted from policies with a set of seed terms (Table 3). For each ontology, PolicyLint iterates through each of the seeds, selecting relationships that contain it. PolicyLint then expands the term list from the relationships in that iteration. PolicyLint continues iterating over the relationships until no new relationships are added to the ontology. If there exists any inconsistent relationship where X is subsumed under Y and Y is subsumed under X, PolicyLint uses the relationship that has a higher frequency (i.e., appearing in more privacy policies). Once a fixed point is reached, PolicyLint ensures that there is only one root node by creating connections between any nodes that do not contain inward-edges with the root of the ontology (i.e., “information” for the data ontology, and “public” for the entity ontology). Finally, PolicyLint ensures that no cycles exist in the ontology by identifying simple cycles in the graph and removing an edge between nodes to break the cycle. PolicyLint chooses which edge to remove by finding the edge that appears least frequently in the subsumptive relationships and ensures that the destination node has more than one in-edge to ensure that a new root node is not created.

## 2.2 Policy Statement Extraction

The goal of policy statement extraction is to extract a concise representation of a policy statement to allow for automated reasoning over this statement. We represent data sharing and collection statements as a tuple (*actor*, *action*, *data object*, *entity*) where the *actor* performs some *action* (i.e., share, collect, not share, not collect) on the *data object*, and the *entity* represents the entity receiving the data object. For example, the statement, “We will share your personal information with advertisers,” can be represented by the tuple of (we, share, personal information, advertisers). PolicyLint extracts complete policy statements from privacy policy text by using patterns of the grammatical structures between data objects, entities, and verbs that represent sharing or collection (for brevity we call these verbs SoC verbs). This section describes the steps in policy statement extraction.

### 2.2.1 DED Tree Construction

The goal of constructing the data and entity dependency (DED) trees is to extract a concise representation of the gram-

Table 4: SoC verbs used by PolicyLint

Type	Word
Sharing	disclose, distribute, exchange, give, provide, rent, report, sell, send, share, trade, transfer, transmit
Collection	access, check, collect, gather, know, obtain, receive, save, store, use

matical relationships between the data objects, entities, and SoC verbs (i.e., the verbs that represent sharing or collection). The main intuition behind constructing these trees is to allow PolicyLint to infer semantics of the sentence based on the grammatical relationships between the tokens (i.e., *who* collects/shares *what* with *whom*). The DED tree for a sentence is derived from the sentence’s dependency-based parse tree. However, the DED tree removes nodes and paths that are not relevant to the data objects, entities, or SoC verbs, and performs a set of simplifications to generalize the representation. The transformation for Example 2 is shown in Figure 2.

**Example 2.** *If you register for our cloud-based services, we will collect your email address.*

To construct DED trees, PolicyLint parses a sentence and uses its custom-trained NER model to label data objects and entities within the sentence (Section 2.1). PolicyLint merges noun phrases and iterates over sentence tokens to label SoC verbs by ensuring that the PoS (part-of-speech) tag of the token is a verb and the lemma of the verb is in PolicyLint’s manually curated list of terms (Table 4). PolicyLint also labels the pronouns, “we,” “I,” “you,” “me,” and “us,” as entities during this step. PolicyLint then extracts the sentence’s dependency-based parse tree whose nodes are labeled with the data object, entity, and SoC verb labels as discussed earlier.

**Negated Verbs:** PolicyLint identifies negated verbs by checking for negation modifiers in the dependency-based parse tree. If the verb is negated, PolicyLint labels the node as negative sentiment. PolicyLint propagates the negative sentiment to descendant verb nodes in three cases. First, if a descendant verb is part of a conjunctive verb phrase with the negated verb, negative sentiment is propagated. For example, “*We do not sell, rent, or trade your personal information,*” means “not sell,” “not rent,” and “not trade.” Second, if the descendant verb has an open clausal complement to the negated verb, negative sentiment is propagated. For example, “*We do not require you to disclose any personal information,*” initially has “require” marked with negative sentiment. Since “disclose” is an open clausal complement to “require,” it is marked with negative sentiment. Third, if the descendant verb is an adverbial clause modifier to the negated verb, negative sentiment is propagated. For example, “*We do not collect your information to share with advertisers,*” initially has “collect” marked with negative sentiment. Since “share” is an adverbial clause modifier to “collect,” “share” is marked with negative sentiment.

**Exception Clauses:** PolicyLint identifies exception clauses by traversing the parse tree and finding terms that represent exceptions to a prior statement, such as “except,” “unless,”

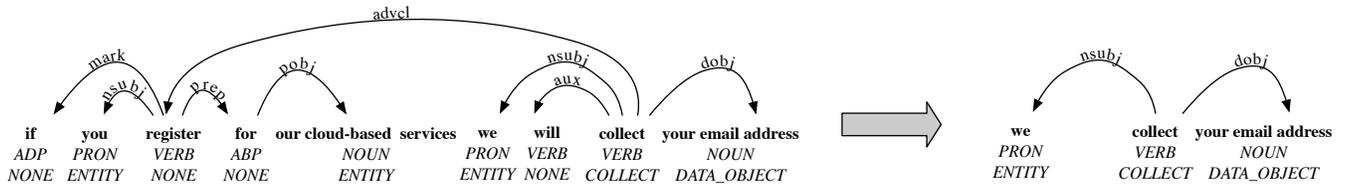

Figure 2: Transformation of Example 2 from its dependency-based parse tree to its DED tree.

“aside/apart from,” “with the exception of,” “besides,” “without,” and “not including.” For each identified exception clause, PolicyLint traverses down the parse tree from the exception clause to identify verb phrases (subject-verb-object) and noun phrases related to that exception. PolicyLint then traverses upward from the exception term to identify the nearest verb node and appends as a node attribute the list of noun phrases and verb phrases identified in the downward traversal.

In certain cases, the term may not have a subtree. For example, the exception term may be a *marker* that introduces a subordinate clause. In the sentence, “*We will not share your personal information unless consent is given,*” the term “unless” is a marker that introduces the subordinate clause “your consent is given.” For empty sub-trees, PolicyLint attempts the downward traversal from its parent node.

**DED Tree construction:** Finally, PolicyLint constructs the DED tree by computing the paths between labeled nodes on the dependency-based parse tree, copying labels and attributes described above. Note that PolicyLint also copies over all unlabeled subjects and direct objects from the parse tree, as they are needed to extract the information. PolicyLint further simplifies the tree by merging conjuncts of SoC verbs into one node if the coordinating conjunction is “and” or “or.” For example, “*We will not sell, rent, or trade your personal information,*” can be simplified by collapsing “sell,” “rent,” and “trade” into one node. The resulting node’s label is a union of all of the tags of the merged verbs (i.e., {share} + {collect} = {share, collect}). Similarly, PolicyLint repeats the same process for conjuncts of data objects and entities.

PolicyLint then prunes the DED tree by iterating through the nodes labeled as verbs in the graph and performing the following process. First, for a verb node labeled as an SoC verb, PolicyLint ensures that its sub-tree contains at least one other node labeled as an SoC verb, data object, or entity. If the node’s sub-tree does not meet this condition, PolicyLint removes the subtree rooted at the node labeled as an SoC verb. Second, for verb nodes not labeled as SoC verbs, PolicyLint ensures that at least one SoC verb is contained in its sub-tree and that it meets the preceding conditions for an SoC verb. Similarly, if these conditions are not met, PolicyLint also removes the sub-tree rooted at that non-labeled verb node. For example, this pruning step causes the sub-tree rooted at the verb “register” to be removed in Figure 2.

### 2.2.2 SoC Sentence Identification

To identify sentences that describe sharing and collection practices, PolicyLint takes a set of positive examples of sentences as input and then extracts their DED trees to use as known patterns for sharing and collection phrases. In particular, we start by feeding PolicyLint a set of 560 example sentences that describe sharing and collect practices. PolicyLint generates the DED trees from these sentences and learns 82 unique patterns. The example sentences are auto-generated from a set of 16 sentence templates (Appendix B). We choose to auto-generate the sentences, because it is challenging to manually select a set of sentences with diverse grammatical structures. Our auto-generation does not adversely impact PolicyLint’s extensibility, as adding a new pattern is as simple as feeding PolicyLint a new sentence for reflecting this new pattern.

PolicyLint iterates through each sentence of a given privacy policy. If the sentence contains at least one SoC verb and data object (labeled by NER), PolicyLint constructs the DED tree. PolicyLint then compares the sentence’s DED tree to the DED tree of each known pattern. A pattern is matched if (1) the label types of the sentence’s DED tree are equivalent to the ones of the known pattern’s DED tree (e.g., {entity, SoC\_verb, data}), and (2) the known pattern’s DED tree is a subtree of the sentence’s DED tree.

For a tree  $t_1$  to be a subtree of tree  $t_2$ , (1) the tree structure must be equivalent, (2) the dependency labels on edges between nodes must match, and (3) the following three node conditions must hold. First, for SoC verb nodes to match, they must have a common lemma. For example, a node with the lemmas {sell, rent} matches a node with lemma {rent}. Second, if the node’s part-of-speech is an apposition, the tags, dependency label, and lemmas must be equal. Third, for all other nodes, the tags and dependencies must be equal.

On sub-tree match, PolicyLint records the nodes in the sub-tree match and continues the process until either (1) each pattern is checked, or (2) the entire DED tree has been covered by prior sub-tree matches. If at least one sub-tree match is found, PolicyLint identifies the sentence as a potential SoC sentence and begins extracting the policy statement tuple.

### 2.2.3 Policy Extraction

The goal of policy extraction is to transform the DED tree into a (*actor, action, data object, entity*) tuple for a policy state-

ment. PolicyLint performs extraction starting with the SoC nodes present in the sub-tree matches. If multiple SoC nodes exist in the sub-tree matches, multiple tuples are generated. However, multiple sub-tree matches over the same SoC node result in the generation of only one tuple. The SoC determines the action (e.g., collect, not\_collect). The action's sentiment is determined based on whether the node is labeled with positive or negative sentiment, as discussed in Section 2.2.1.

**Actor Extraction:** To extract the actor, PolicyLint starts from the matching SoC verb node. The actor is a labeled entity chosen from the (1) subject, (2) prepositional object, or (3) direct object (in that order). However, if the dependency is an open clausal complement or adverbial clause modifier, PolicyLint prioritizes the direct object and prepositional object over the subject. For example, “*We do not require you to disclose any personal information,*” has “disclose” as an open clausal complement to “require.” In this case, the correct actor of this policy statement is the user (i.e., “you”) rather than the vendor (i.e., “we”), which is correctly captured due to PolicyLint's dependency-based prioritization rules. If no match is found, PolicyLint traverses up one level in the DED tree and repeats. Finally, if no match is found, PolicyLint assumes that the actor is the implicit first party.

**Data Object Extraction:** To extract the data objects, PolicyLint starts from the matching SoC verb node. It traverses down the DED tree to extract all nodes labeled as data objects. The traversal continues until another SoC verb is reached. If no data objects are found, and the verb's subject and direct object are not labeled as a data object, PolicyLint extracts the data objects from the nearest ancestor SoC verb.

**Entity Extraction:** To extract the entities, PolicyLint starts from the matching SoC verb node. It traverses down the DED tree extracting all nodes labeled as entities that are not actors. The traversal continues until another SoC verb is reached.

**Exception Clauses:** PolicyLint considers exception clauses if the verb is marked with negative sentiment (e.g., not collect, not share), creating a cloned policy statement with the sentiment to change. We do not handle exception clauses for positive sentiment. For example, “*We might also share personal information without your consent to carry out your own requests,*” still shares personal information.

For negative sentiment verbs, there are three cases. First, if the exception clause's node attribute contains only data objects, PolicyLint replaces the data objects of the new policy with the data objects under the exception clause. For example, “*We will not collect your personal information except for your name and phone number,*” produces policies: (we, not\_collect, personal information, NULL), (we, collect, [name, phone number], NULL). Second, if all noun phrases have an entity label, PolicyLint replaces the entities of the new policies with the entities under the exception attribute. For example, “*We do not share your demographics with advertisers except for AdMob,*” produces policies: (we, not\_share, demographics, advertisers) and (we, share, demographics, AdMob). Third, if

the labels are not data objects or entities, PolicyLint removes the initial policy statement. For example, “*We will not collect your personal information without your consent,*” produces the policy: (we, collect, personal information, NULL).

**Policy Expansion:** PolicyLint may extract multiple actors, actions, data objects, and entities when creating policy statements. These complex tuples are expanded. For example, ([we], [share, sell], [location, age], [Google, Facebook]) is expanded to (we, share, location, Google), (we, share, location, Facebook), (we, share, age, Google), etc.

## 2.3 Policy Contradictions

PolicyLint's components of ontology generation and policy extraction identify the sharing and collection statements in privacy policies. This section formally defines a logic for characterizing different contradictions. It then describes how PolicyLint uses this logic to identify candidate contradictions within privacy policies. We note that contradictions may occur between an app's privacy policy and the privacy policies of third-party libraries (e.g., advertisement libraries). While our study focuses specifically on contradictions within an individual privacy policy, the formal logic and subsequent analysis tools may also be used to include the privacy policies for third-party libraries with minimal modification.

### 2.3.1 Policy Simplification

PolicyLint simplifies policy statements for contradiction analysis. We refer to the (*actor, action, data object, entity*) tuple defined in Section 2.2 as a Complete Policy Statement (CPS). We simplify CPS statements about the sharing of data (i.e., *action* is share or not share) by capturing sharing as collection.

**Definition 1** (Simplified Policy Statement: SPS). *An SPS is a tuple,  $p = (e, c, d)$ , where  $d$  is the data object discussed by the statement,  $c \in \{\text{collect, not\_collect}\}$  represents whether the object is collected or not collected, and  $e$  is the entity receiving the data object.*

To transform a CPS into an SPS, we leverage three main insights. First, policies do not typically disclose whether the sharing of the data occurs at the client side or server side. Therefore, an actor sharing a data object with an entity may imply that the actor is collecting the data and performing the data sharing at the server side. In this case, a new policy statement would need to be generated for allowing the actor to collect the data object (Rule T1, Table 5). Second, a data object being shared with an entity may imply that the entity is collecting the information from the mobile device (Rule T2, Table 5). Similarly, a policy for stating that the actor does not share a data object with an entity implies that the entity is not collecting the data from the mobile device (Rule T3, Table 5). Finally, a policy for stating that the actor does not share a data object implies that the actor collects the data object, because

Table 5: Rules that transform a CPS into an SPS

Rule	Transformation Rules	Rationale
T1	(actor, share, data object, entity) $\implies$ (actor, collect, data object)	Unknown whether sharing occurs at the client side or server side
T2	(actor, share, data object, entity) $\implies$ (entity, collect, data object)	Can observe only client-side behaviors
T3	(actor, not_share, data object, entity) $\implies$ (entity, not_collect, data object)	Can observe only client-side behaviors
T4	(actor, not_share, data object, entity) $\implies$ (actor, collect, data object)	If mention not share, assume implicit collection

the policy would likely have not mentioned not sharing data that was never collected (Rule T4, Table 5).

However, there are two special cases. First, PolicyLint treats only verb lemmas “save” and “store” with positive sentiment (“not saving/storing” does not mean “not collecting”). Second, PolicyLint ignores negative statements with verb lemma “use.” This case leads to false positives, as PolicyLint does not extract the collection purpose. For example, “We do not use your location for advertising,” means that it is not collected for the specific purpose of advertising.

### 2.3.2 Contradiction Types

We model an app’s privacy policy as a set of simplified policy statements  $P$ . Let  $D$  represent the total set of data objects and  $E$  represent the total set of entities, as represented by ontologies for data objects and entities, respectively. A policy statement  $p \in P$  is a tuple,  $p = (e, c, d)$  where  $d \in D$ ,  $e \in E$ , and  $c \in \{\text{collect}, \text{not\_collect}\}$  (Definition 1).

Language describing policy statements may use different semantic granularities. One policy statement may speak in generalizations over data objects and entities while another statement may discuss specific types. For example, consider the policies  $p_1 = (\text{advertiser}, \text{not\_collect}, \text{demographics})$  and  $p_2 = (\text{Google Admob}, \text{collect}, \text{age})$ . If we want to identify contradictions, we need to know that Google AdMob is an advertiser and age is demographic information. These relationships are commonly referred to as *subsumptive relationships* where a more specific term is subsumed under a more general term (e.g., AdMob is subsumed under advertisers and age is subsumed under demographics).

We use the following notation to describe binary relationships between terms representing data objects and entities.

**Definition 2** (Semantic Equivalence). *Let  $x$  and  $y$  be terms partially ordered by an ontology  $o$ .  $x \equiv_o y$  is true if  $x$  and  $y$  are synonyms, defined with respect to an ontology  $o$ .*

**Definition 3** (Subsumptive Relationship). *Let  $x$  and  $y$  be terms partially ordered by “is-a” relationships in an ontology  $o$ .  $x \sqsubset_o y$  is true if term  $x$  is subsumed under the term  $y$  such that  $x \not\equiv_o y$ . Similarly,  $x \sqsubseteq_o y \implies x \sqsubset_o y \vee x \equiv_o y$ .*

Note that Definitions 2-3 parameterize the operators with an ontology  $o$ . PolicyLint operates on two ontologies: data objects and entities. Therefore, the following discussion parameterizes the operators with  $\delta$  for the data object ontology and  $\epsilon$  for the entity ontology. For example,  $x \equiv_\delta y$  and  $x \equiv_\epsilon y$ .

A contradiction occurs if two policy statements suggest that entities both may and may not collect or share a data object.

Table 6: Contradictions (C) and Narrowing Definitions (N)  $P = \{(e_i, \text{collect}, d_k), (e_j, \text{not\_collect}, d_l)\}$ 

Rule	Logic	Example
$C_1$	$e_i \equiv_\epsilon e_j \wedge d_k \equiv_\delta d_l$	(companyX, collect, email address) (companyX, not_collect, email address)
$C_2$	$e_i \equiv_\epsilon e_j \wedge d_k \sqsubset_\delta d_l$	(companyX, collect, email address) (companyX, not_collect, personal info)
$C_3$	$e_i \sqsubset_\epsilon e_j \wedge d_k \equiv_\delta d_l$	(companyX, collect, email address) (advertiser, not_collect, email address)
$C_4$	$e_i \sqsubset_\epsilon e_j \wedge d_k \sqsubset_\delta d_l$	(companyX, collect, email address) (advertiser, not_collect, personal info)
$C_5$	$e_i \sqsubset_\epsilon e_j \wedge d_k \sqsubseteq_\delta d_l$	(advertiser, collect, email address) (companyX, not_collect, personal info)
$N_1$	$e_i \equiv_\epsilon e_j \wedge d_k \sqsubset_\delta d_l$	(companyX, collect, personal info) (companyX, not_collect, email address)
$N_2$	$e_i \sqsubset_\epsilon e_j \wedge d_k \sqsubset_\delta d_l$	(companyX, collect, personal info) (advertiser, not_collect, email address)
$N_3$	$e_i \sqsubset_\epsilon e_j \wedge d_k \equiv_\delta d_l$	(advertiser, collect, email address) (companyX, not_collect, email address)
$N_4$	$e_i \sqsubset_\epsilon e_j \wedge d_k \sqsubseteq_\delta d_l$	(advertiser, collect, personal info) (companyX, not_collect, email address)

Contradictions can occur at the same or different semantic levels. For example, the simplest form of contradiction is an exact contradiction where a policy states that an entity will both collect and not collect the same data object, e.g., (advertiser, collect, age) and (advertiser, not\_collect, age). Due to subsumptive relationships (Definitions 3), there are 3 relationships between terms ( $x \equiv_o y$ ,  $x \sqsubset_o y$ , and  $x \sqsubseteq_o y$ ). Each binary relationship applies to both entities and data objects. Thus, there are  $3^2 = 9$  types of contradictions, as shown in Table 6.

Contradictions have two primary impacts when privacy policies are analyzed. First, all contradictions impact analysis techniques that seek to automatically reason over policies and may result in these techniques making incorrect or inconsistent decisions. For example, unlike firewall rules that have a specific evaluation sequence, privacy policy statements do not have a specific pre-defined sequence of evaluation. Therefore, analysis techniques may make incorrect or inconsistent decisions based on the order in which they evaluate policy statements. Second, contradictions may impact a human analyst’s understanding of a privacy policy, such as by containing misleading statements. We define two groupings of contradictions based on whether they may impact a human’s comprehension of privacy policies or solely impact automated analysis.

**Logical Contradictions ( $C_{1-5}$ ):** Logical contradictions are contradictory policy statements that are more likely to cause harm if users and analysts are not aware of the contradictory statements. Logical contradictions may cause difficulties when humans attempt to comprehend or interpret the sharing

Table 7: First Party Synonyms

First Party Synonyms
we, I, us, me, our app, our mobile application, our mobile app, our application, our service, our website, our web site, our site
app, mobile application, mobile app, application, service, company, business, web site, website, site

and collection practices discussed in the policy. They can be characterized as either exact contradictions ( $C_1$ ) or those that discuss *not* collecting broad types of data and later discuss collecting exact or more specific types ( $C_{2-5}$ ). One example is a policy that initially claims not to collect personal information, but later in fine print discloses collecting a user’s name and email address for advertisers. Similar to the goal of software lint tools, PolicyLint flags logical contradictions as problems within policies to allow a human analyst to manually inspect the statements and analyze intent. As shown in Section 3, these contradictions may lead to the identification of intentionally deceptive policy statements or those that may result in ambiguous interpretations.

**Narrowing Definitions ( $N_{1-4}$ ):** Narrowing definitions are contradictory policy statements where broad information is stated to be collected, and specific data types are stated not to be collected. These statements narrow the scope of the types of data that are collected, such as stating that personal information is collected while your name is *not* collected. Note that narrowing definitions are not necessarily an undesirable property of policies, because saying that a broad data type is collected does not necessarily imply that every specific subtype is collected, but narrowing definitions may result in vague policies. There may be clearer ways for policy writers to convey this information, such as explicitly stating the exact data types collected and shared. For example, if the app collects your email address, the policy could directly state, “We collect your email address,” instead of including a narrowing definition, such as “We collect personal information. We do not collect your name.” However, policies that narrow the scope of their data sharing and collection practices can be seen as more desirable in contrast to policies that just disclose practices over broad categories of data. Nonetheless, narrowing definitions impact the logic behind analysis techniques, as they must consider prioritization of data objects and entities.

### 2.3.3 Contradiction Identification

PolicyLint uses the contradiction types from Table 6 to determine a set of candidate contradictions. It then uses a set of heuristics to reduce the set of candidate contradictions that are potentially low-quality indicators of underlying problems. Next, PolicyLint prepares the contradictions for presentation by collapsing duplicate contradictions, linking other metadata (e.g., download counts of apps), and by using a set of filtering heuristics to allow the regulator or privacy analysts to focus on specific subclasses of candidate contradictions. The remainder of this section describes this process.

**Initial Candidate Set Selection:** Given policy statements  $p_1$  and  $p_2$ , PolicyLint ensures that  $p_1.c$  does not equal  $p_2.c$ , as contradictions require opposing sentiments. PolicyLint then compares entities  $p_1.e$  and  $p_2.e$ , determining whether they are equal or have a subsumptive relationship. A subsumptive relationship occurs if there is a path between the entities in the entity ontology. When comparing entities, PolicyLint treats the terms in Table 7 as synonyms for the first party (i.e., “we”). If an entity match is found, PolicyLint then performs the same steps for data objects  $p_1.d$  and  $p_2.d$  using the data object ontology. If a data object match is found, PolicyLint adds the candidate contradiction to the candidate set. Note that in policy statements PolicyLint ignores entities and data objects that are not contained in the ontologies, as it cannot reason about those relationships. However, if PolicyLint cannot find a direct match for a term in the ontologies, it will try to find sub-matches by splitting the term on the coordinating conjunction terms (e.g., “and,” “or”) and checking for their existence in the ontologies. Furthermore, PolicyLint does not identify policy statements as contradictions if they are generated from the same sentence due to the semantics of exception clauses. For example, “*We do not collect your personal information except for your name,*” produces simplified policy statements (we, not\_collect, personal information) and (we, collect, name). While the semantics of this statement is clear, our definition of contradictions would incorrectly identify these statements as a  $C_2$  contradiction. Therefore, PolicyLint ignores same-sentence contradictions to reduce false positives.

**Candidate Set Reduction:** PolicyLint uses heuristics to prune candidate contradictions that are likely low-quality indicators of underlying problems. PolicyLint removes contradictions that occur based on potentially poor relationships discovered in the ontologies. For example, PolicyLint filters out contradictions that occur between certain data object pairs, such as “usage information” and “personal information.” Contradictions whose entities refer to the user (e.g., “user,” “customer,” “child”) or involve terms for general data objects (e.g., “information,” “content”) or entities (e.g., “individual,” “public”) are also removed. Finally, PolicyLint removes candidate contradictions where a negative-sentiment policy statement may be conditioned with age restrictions or based on user choice by searching for common phrases in the sentences that are used to generate the policy statements (e.g., “under the age of,” “from children,” “you do not need to provide”). Note that some of these reductions may occur during candidate set construction to reduce complexity of the analysis.

**Candidate Set Filtering:** PolicyLint further filters the set of candidate contradictions into subsets based on the data objects involved in the contradictions to allow for targeted exploration during verification. For example, all of the contradictions with statements involving collecting email address but not collecting personal information are placed into one subset (e.g., (\*, collect, email address) and (\*, not\_collect, PII)).

**Contradiction Validation:** Given the filtered subsets of can-

didate contradictions, the next step is to explore certain subsets and validate candidate contradictions. To validate a candidate contradiction, the analyst reads through the policy statements and sentences that are used to generate them in context of the entire policy, and makes a decision.

### 3 Privacy Study

Our primary motivation for creating PolicyLint is to analyze contradictory policy statements within privacy policies. In this section, we use PolicyLint to perform a large-scale study on 11,430 privacy policies from top Android apps.

**Dataset Collection:** To select our dataset, we scrape Google Play for the privacy policy links of the top 500 free apps for each of Google Play’s 35 app categories in September 2017. Note that the “top free apps” are based on the ranking provided by Google Play (“topselling\_free” collection per app category). We download the HTML privacy policies using the Selenium WebDriver in a headless Google Chrome browser to allow for the execution of dynamic content (e.g., JavaScript). We exclude apps that do not have a privacy policy link on Google Play, those whose pages are unreachable at the time of collection, and privacy policies where the majority of the document is not English, as discussed in Appendix A. We convert the HTML policies to plaintext documents. Our final dataset consists of 11,430 privacy policies.

#### 3.1 General Policy Characteristics

PolicyLint extract sharing and collection policy statements from 91% of the policies in our dataset (10,397/11,430). From those policies, PolicyLint extract 438,667 policy statements from 177,169 sentences that PolicyLint identifies as a sharing or collection sentence. Of those policy statements, 32,876 have negative sentiment and 405,789 have positive sentiment. In particular, 60.5% (6,912/11,430) of the policies have at least one negative-sentiment policy statement and 89.6% (10,239/11,430) of the policies have at least one positive sentiment policy statement. We explore why PolicyLint does not extract policy statements for 9% of the policies by analyzing a random subset of 100 policies and find that it is mainly due to dataset collection or preprocessing errors (Appendix C).

**Finding 1:** *Policies frequently contain negative sentiment policy statements that discuss broad categories of data.* For 60.5% of the policies with at least one negative sentiment policy statement, the data object “personal information” appears in 67.7% of those policies (4,681/6,912). This result demonstrates the importance of handling negative policy statements, as around 41.0% of the policies contain a negative sentiment policy statement for claiming that a broad type of data (i.e., “personal information”) is not collected. Further, we measure the distance from the negation (i.e., “not”) to the verb that the negation modifies, and find that 28.2% (3,234/11,430) of the policies have a distance greater than one word away. This

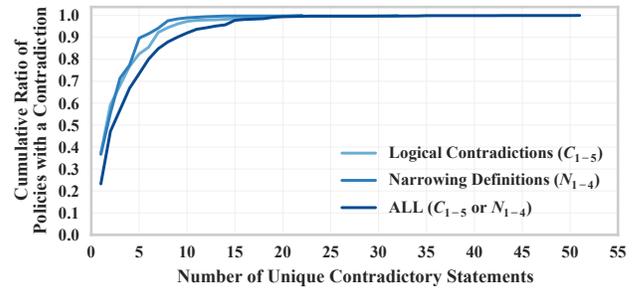

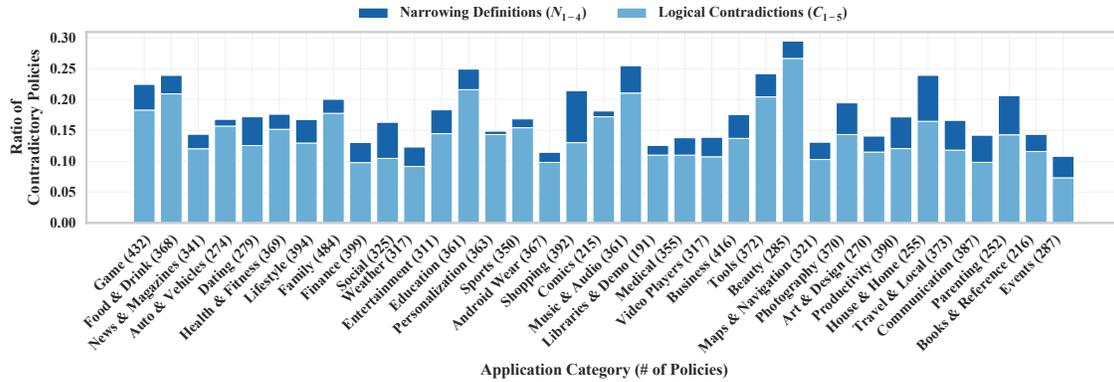

Figure 3: CDF of Contradictory Policy Statements: 50% of contradictory policies have 2 or fewer logical contradictions.

result calls into question prior approaches [26,28] that assume only positive sentiment when considering sharing and collection statements, as the prior approaches could be incorrect up to 60.5% of the time when reasoning over sharing and collection statements. Further, approaches [32] that handle negations using bigrams would have failed to reason about 28.2% of the policies.

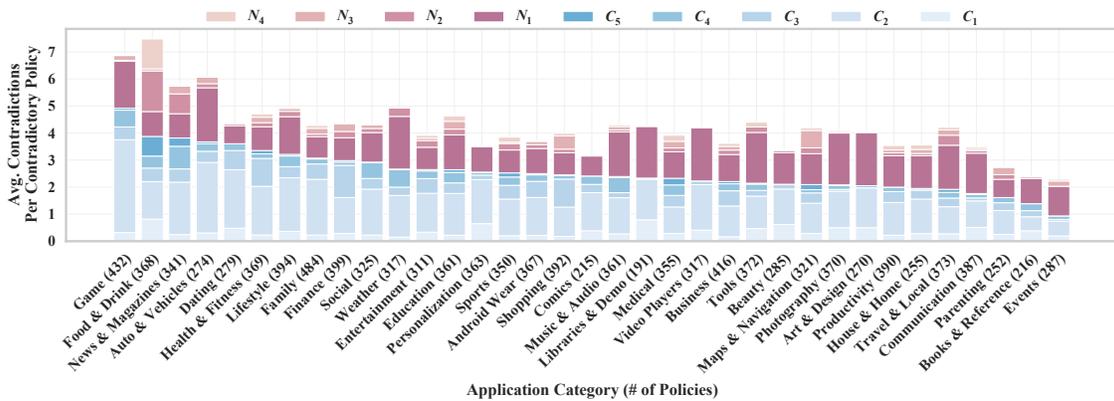

#### 3.2 Candidate Contradictions

Based on PolicyLint’s fine-grained policy statement extraction, we find that 59.1% (6,754/11,430) of the policies are candidates for contradiction analysis, as they contain at least one positive and one negative sentiment policy statements. Among these policies, there are 13,871 and 129,575 policy statements with negative and positive sentiment, respectively. **Finding 2:** *For candidate contradictions, 14.2% of the privacy policies contain logical contradictions (C<sub>1-5</sub>).* PolicyLint identifies 9,906 logical contradictions across around 14.2% (1,618/11,430) of the policies. Therefore, 14.2% of the policies may contain potentially misleading statements. Figure 3 shows that around three-fifths (59.2%) of the policies with at least one logical contradiction have 2 or fewer unique contradictions. The relatively low number of candidate contradictions per policy indicates that manual validation is feasible. As roughly 6 in 7 policies are not contradictory, writing policies without logical contradictions is possible.

**Finding 3:** *Contradiction prevalence and frequency do not substantially vary across Google Play app categories.* Figure 4a shows the ratio of policies containing candidate contradictions per each Google Play category. The categories with policies most and least prone to contradiction are *Beauty* and *Events*, respectively. However, when analyzing the policies within those categories, we find that their means are skewed by contradictory policies for apps by the same developer. When we recompute the means without the outliers, these categories follow the general trend. Policies with logical contradictions accompany 7.3% to 20.9% of apps across all categories. We find that policies with logical contradictions are not substantially more prevalent in particular categories of apps, but instead occur consistently in apps from every category. We also find that prevalence of logical contradiction

(a) Ratio of Contradictory Policies per Category: 79.7% of contradictory policies have at least one or more logical contradictions ( $C_{1-5}$ ) that may indicate potentially deceptive statements.

(b) Average number of unique candidate contradictions per category: Logical contradictions ( $C_{1-5}$ ) and narrowing definitions ( $N_{1-4}$ ) are both widely prevalent across Google Play categories.

Figure 4: Distribution of Candidate Contradictions across Google Play Categories.

does not substantially vary by download count as well.

Figure 4b displays the average number of candidate contradictions for policies containing one or more contradictions. We find that frequency of logical contradiction for contradictory policies does not substantially vary across Google Play categories. Initial analysis indicates that contradictory policies for apps in the *Games* category contain around 4.9 logical contradictions on average. Further analysis reveals that this result is due to policies with 19 unique logical contradictions in 9 apps produced by the same developer, and one app that has 31 unique logical contradictions. Excluding these outliers brings the category’s average to 3.16 logical contradictions per app, fitting the trend of the rest of the categories. This result may indicate that poor policies are linked to problematic developers. Similar analysis on categories *Food & Drink*, *Auto & Vehicles*, and *News & Magazines* produces similar results. We find that the number of logical contradictions per policy is roughly equivalent across app categories, indicating that one app category is not necessarily more contradictory on average than another.

**Finding 4:** Negative sentiment policy statements that discuss broad categories of data are problematic. Figure 5 shows the

frequency of the most common data-type pairs referred to in contradictory policy statements. The contradictory policy statements in the topmost row are most problematic. This row represents logical contradictions, which are either (1) exact contradictions or (2) discussion of not collecting broad types of data and collecting more specific data types ( $C_{1-5}$ ). As we demonstrate in Section 3.3, logical contradictions can lead to a myriad of problems when one interprets the policy including making interpretation ambiguous in certain cases. The leftmost column corresponds to narrowing definitions ( $N_{1-4}$ ), which solely impact automated analysis techniques, as discussed in Section 2.3.

**Finding 5:** For candidate contradictions, 17.7% of the privacy policies contain at least one or more logical contradictions ( $C_{1-5}$ ) or narrowing definitions ( $N_{1-4}$ ). PolicyLint identifies 17,986 logical contradictions and narrowing definitions across around 17.7% (2,028/11,430) of the policies. Figure 3 shows that slightly more than half (57.0%) of the contradictory policies have 3 or fewer unique logical contradictions and narrowing definitions. As discussed in Section 2.3, logical contradictions and narrowing definitions impact approaches that seek to automatically reason over privacy policies. To

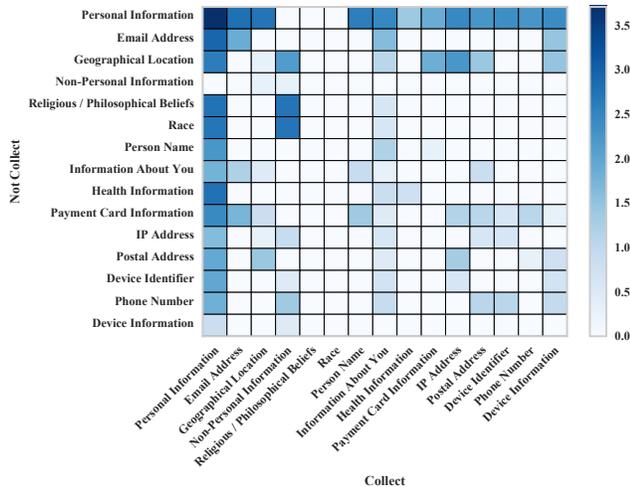

Figure 5: Log 10 Frequency of Data-Type Pairs in Contradictions: Negative statements that discuss broad categories of data are problematic (i.e.,  $C_{1-5}$ ).

correctly reason over contradictions, analysis techniques must include logic to prioritize specificity of data types and entities, and be able to identify potentially undecidable cases, such as exact contradictions ( $C_1$ ). No prior approaches [26, 28, 29, 32] that attempt to reason over policies operate at the required granularity to identify contradictions or contain the logic to correctly reason over them. Therefore, these prior approaches could make incorrect or inconsistent decisions around 17.7% of the time around 1–3 times per policy on average. We perform similar analysis across categories as Finding 3 and find that logical contradictions and narrowing definitions do not substantially vary across Google Play categories.

### 3.3 Deeper Findings

In this section, we describe the findings from validating candidate contradictions. We limit our scope to logical contradictions ( $C_{1-5}$ ), as they may be indicative of misleading policy statements. Due to resource constraints, we do not validate all 9,906 candidate logical contradictions from the 1,618 policies. Instead, we narrow the scope of our study by choosing categories of candidate contradictions to focus on. Our selection and validation methodology is described below.

**Selection Methodology:** To select the categories of candidate contradictions to focus on, we analyze Figure 5 for the data objects involved in the contradictory statements. We limit our scope to logical contradictions ( $C_{1-5}$ ) that discuss not collecting “personal information” and collecting “email address,” “device identifier,” or “personal information.” We also explore two other categories of candidate contradictions in which one type of data can be derived from the other type; these categories caught our attention when analyzing the heat map. Within each category of candidate contradictions, we choose which candidate contradictions to validate by sorting the contradictions based on the belonging app’s popularity and

working down the list. We spend around one week validating contradictions where our cutoffs are due to time constraints and attempting to achieve coverage across categories.

**Validation Methodology:** To validate candidate contradiction, one of three student authors reads through the sentences that are used to generate each policy statement for the candidate contradiction to ensure correctness of policy statement extraction. If there is an error with policy statement extraction, we record the candidate contradiction as a false positive and stop analysis. Next, we locate the sentences within the policy and view the context in which they appear (i.e., section, surrounding sentences) to determine whether the policy statements are contradictory. We try to determine why the contradiction occurs if possible and record any observations. If the author is uncertain about his/her decision, a second author analyzes it. The two authors discuss and resolve conflicts, with no conflicts left unresolved after discussion.

#### 3.3.1 Personal Information and Email Addresses

For candidate contradictions with negative statements about “personal information” and with positive statements about “email address,” we find 618 candidate contradictions across 333 policies ( $C_2, C_4, C_5$ ). We validate 204 candidate contradictions from 120 policies. We find that 5 candidate contradictions are false positives due to inaccuracies of labeling data objects by the NER model. From the 199 remaining candidate contradictions across 118 policies, we have the following main findings. Note that for the findings discussed below, the terms “personally identifiable information” and “personal information” are commonly used synonymously in USA regulations, and “personal data” is considered the EU equivalent albeit covering a broader range of information.

**Finding 6:** Policies are stating certain types of common personally identifiable information, such as email addresses, as non-personally identifiable. When validating 14 candidate contradictions, we find 14 policies for explicitly stating that they do NOT consider email address as personally identifiable information. 11 of those policies are released by the same developer (OmniDroid) where the most popular app in the set (com.omniluxtrade.allrecipes) has over 1M+ downloads. OmniDroid’s policy explicitly lists email address when defining non-personally identifiable information. The remaining 3 policies belong to another app developer, PlayToddlers. The apps are explicitly targeted toward children from 2-8 years old and have between 500K-1M+ downloads for each app. Their policy states the following sentence verbatim, “When the user provides us with an email address to subscribe to the “PlayNews” mailing list, the user confirms that this address is not a personal data, nor does it contain any personal data.”

The fact that *any* privacy policies are declaring email addresses as non-personal information is surprising, as it goes against the norms of *what* data is considered personal information as defined by regulations (e.g., CalOPPA, GDPR),

standards bureaus (NIST), and common sense.

**Finding 7:** *Services that auto-generate template-based policies for app developers are producing contradictory policies.* During our validation process, we notice that many policies have similar structural compositions and contain a lot of the same text in paragraphs. When validating 78 candidate contradictions, we find 59 contradictory policies that are automatically generated or used templates. Identical policy statements from various developers suggest that some policies may be generated automatically or acquired from a template. We investigate these cases and identify 59 policies that use 3 unique templates. We check that these policies are not ones for apps created by the developers or organization. Findings 8 and 11 discuss the problems caused by the templates. This result demonstrates that poor policy generators can be a contributing factor for numerous contradictory policies.

**Finding 8:** *Policies use blanket statements affirming that personal information is not collected and contradict themselves by stating that subtypes of personal information are collected, such as email addresses.* When validating 182 candidate contradictions, we find 104 policies for broadly making blanket statements that personal information is not collected in one part of the policy and then directly contradicting their prior statements by disclosing that they collect email addresses. We find 69 of those policies (127 validated contradictions) for stating that they do not collect personal information, but later stating that they collect email addresses for some purpose. Of those 69 policies, 32 policies define email address as personal information in one part of their policy. Due to the lack of definition of what they consider personal information in the other 37 policies, it is unclear whether they do not consider email address as personal information or are just contradictory.

The same organization (emoji-keyboard.com) produces 20 of those policies that explicitly define email addresses as personal information, but contradict themselves. The most popular app in that group has 50M+ downloads (emoji.keyboard.emoticonkeyboard). The following two sentences are in the policy verbatim: (1) “*Since we do not collect Personal Information, we may not use your personal information in any way.*”; (2) “*For users that opt in to Emoji Keyboard Cloud, we will collect your email address, basic demographic information and information concerning the words and phrases that you use (“Language Modeling Data”) to enable services such as personalization, prediction synchronization and backup.*” This case is clearly a contradictory statement and arguably a misleading practice.

A policy for a particular app with 1M+ downloads (com.picediting.haircolorchanger) appears to have been potentially trying to mislead users by using bold text to highlight desirable properties and then contradicting themselves. For example, the following excerpt is in the policy verbatim including the bold typography: “***We do not collect any Personal information*** but it may be collected in a number of ways. We may collect certain information that you voluntarily

*provide to us which may contain personal information. For example, we may collect your name, email address you provide us when you contact us by e-mail or use our services...*” The use of bold typography and general presentation of these policy statements could potentially be considered as attempting to deceive the reader, who may not perform a close read of the text in fine-print. This finding validates PolicyLint’s value in flagging problematic areas in policies to aid in the identification of deceptive statements.

**Finding 9:** *Policies consider hashed email addresses as pseudonymized non-personal information and share it with advertisers.* When validating three candidate contradictions, we find that two policies discuss sharing hashed email addresses with third parties, such as advertisers. One candidate contradiction is a false positive due to misclassifying a sentence discussing opt-out choices as a sharing or collection sentence. The other policy belongs to an app named Tango (com.sgiggle.production). Tango is a messaging and video call app, which has over 100M+ downloads on Google Play and according to their website has 390M+ users globally. Their policy states the following sentences verbatim, “*For example, we may tell our advertisers the number of users our app receives or share anonymous identifiers (such as device advertising identifiers or hashed email addresses) with advertisers and business partners.*” Tango explicitly states that they consider hashed email addresses as anonymous identifiers. It is arguable whether hashing is sufficient for pseudonymization as defined by GDPR, as it is likely that advertisers are using hashed email addresses to identify individuals.

### 3.3.2 Personal Information and Device Identifiers

For the candidate contradictions with negative statements about “personal information” and with positive statements about “device identifiers,” we find 234 candidate contradictions across 155 policies. We investigate this group of candidate contradictions as there are differing regulations across countries on whether device identifiers are considered personal information. For example, various court cases within the US (Robinson v. Disney Online, Ellis v. Cartoon Network, Eichenberger v. ESPN) rule that device identifiers are not personal information. However, the GDPR defines device identifiers as personal information. Therefore, our goal is to check whether policies are complying to the stricter GDPR definition of personal information or to the US definition, as the outcome could hint toward problems with complying to regulations across country boundaries. In total, we validate 10 candidate contradictions across 9 policies.

**Finding 10:** *Policies are considering device identifiers as non-personal information, raising concerns regarding globalization of their policies.* When validating 10 candidate contradictions, we find 9 policies for stating that they do not collect personal information, but later state that they collect device identifiers. We find that classification of device identifiers

varies across policies. We find 4 policies that explicitly describe device identifiers as non-personal information. The most popular app is Tango (com.sgiggle.production), which boasts of 390M+ global users on their website. It is likely a safe assumption that some of those users are in the EU, which is subject to GDPR. As their current policy still contains this statement, it may hint that they may not be GDPR compliant.

To reduce the threats to the validity of our claims, we re-request the 9 policies using a proxy to route the traffic through an EU country (Germany) to ensure that an EU-specific policy is not served based on the origin of the request. We request the English version of the policy where applicable and find similarly problematic statements in regard to not treating device identifiers as personal information.

### 3.3.3 Personal Information

We find 5100 candidate contradictions across 1061 policies where the data type of both the negative statement and positive statement is “personal information.” We validate 254 candidate contradictions across 153 policies.

**Finding 11:** *Policies directly contradict themselves.* When validating the 254 candidate contradictions, we find that the 153 policies directly contradict themselves on their data practices on “personal information.” For example, the policy for an app with 1M+ downloads states “We may collect personal information from our users in order to provide you with a personalized, useful and efficient experience.” However, later in the policy they state, “We do not collect Personal Information, and we employ administrative, physical and electronic measures designed to protect your Non-Personal Information from unauthorized access and use.” These scenarios are clearly problematic, as the policies state both cases and it makes it difficult, if not, impossible to determine their actual data sharing and collection practices.

### 3.3.4 Derived Data

In this section, we explore cases of candidate contradictions where the negative statements discuss data that can be derived from the data discussed in the positive statement. In particular, we explore two cases: (1) coarse location from IP address; and (2) postal address from precise location.

For “coarse location from IP,” we find 170 candidate contradictions from 167 policies that represent collecting IP address and not collecting location. We remove candidate contradictions whose statements discuss precise location, as IP address does not provide a precise location. This filtering results in 18 candidate contradictions from 18 different policies. We validate 15 candidate contradictions across 15 different policies for this case. We note that 3 candidate contradictions from 3 policies are false positives due to incorrect negation handling.

For “postal address from precise location,” we find 27 candidate contradictions across 20 policies. Note that we remove

candidate contradictions that discuss coarse location, as they are not precise enough to derive postal addresses. We validate 22 candidate contradictions across 17 apps, as 5 candidate contradictions are false positives due to sentence misclassification (4 cases) or errors of handling negations (1 case).

**Finding 12:** *Policies state that they do not collect certain data types, but state that they collect other data types in which the original can be derived.* When validating the 15 candidate contradictions for “coarse location from IP,” we find that all 15 policies are stating that they do not collect location information, but state that they automatically collect IP addresses. As coarse location information can generally be derived from the user’s IP address, it can be argued that the organization is technically collecting the user’s location information. Interestingly, two of the policies discuss that if users disable location services, then location will not be collected. It is highly unlikely that companies cease IP address collection based on device privacy settings. However, as IP address collection typically occurs passively at the server side, we cannot claim with 100% certainty that the companies still collect IP addresses when location services are disabled.

When validating 20 candidate contradictions for “postal address from precise location,” we find that 15 policies discuss not collecting postal addresses, but then state that they collect locations. Similar to the preceding case, postal addresses can be derived from location data (i.e., latitude and longitude). Again, the argument can be made that they are collecting data precise enough to be considered a postal address, causing a contradiction. For the other two candidate contradictions from two policies, it is not clear whether it is actually a contradiction, as they state that they do not collect addresses from the user’s address book, which is more specific than a general statement about not collecting addresses.

## 3.4 Notification to Vendors

For the 510 contradictions that are validated across 260 policies, we contact each vendor via the email address listed for the privacy policy’s corresponding app on Google Play. We disclose the exact statements that we find to be contradictory and explain our rationale. We ask whether they consider the statements to be contradictory and request clarifications on their policy. Figure 6 (Appendix) shows a template of the email. Overall, 244 emails are successfully delivered, as 16 email addresses are either invalid or unreachable. In total, we receive a 4.5% response rate (11/244), which is relatively substantial when considering that responding to our emails could raise liability concerns. All of the responses are received within a week or less after we send the initial emails. We have not received additional responses in the 4 months that have passed before publication. The remainder of this section discusses the responses.

**Fixed Policy:** Three vendors agree with our findings and update their policy to remove the contradiction. One ven-

dor states that there is an “error” in their privacy policy and updates it accordingly. We confirm that the policy has been updated. The remaining two vendors state that the self-contradictory portion of the policy is a leftover remnant from a prior update and should have been removed. They clarify that they do not collect email addresses.

**Disagreed with our Findings:** One vendor explicitly disagrees with our findings. Their policy states that they do not collect personal information, but also states that they collect email addresses. The vendor responds by claiming that email addresses are only personal information if it contains identifiable information, such as your name (e.g., john.doe@gmail.com), but are not personal information if it does not contain identifiable information (e.g., wxyz@gmail.com). They state that they explicitly tell users not to submit email addresses that contain personal information and thus their policy is not contradictory. This interpretation is surprising, because it goes against the definition of email addresses as personal information, as defined by regulations (e.g., CalOPPA, GDPR) and standards bureaus (NIST).

**Claimed Outdated Policy:** Four vendors respond that they do not find the reported statements in their current policy and that we analyzed an older version of their policy. One of the vendors sent us their updated policy for their mobile app. However, the policy has a link to refer to their full privacy policy, which links to the policy analyzed by us. We request clarifications on their “full policy,” but receive no response. We analyze the remaining three policies and find that they have the contradictory statements removed from their policy.

**No Comment:** Two vendors respond without providing a comment or clarification of their policy. One developer simply replies back “Thanks for the observation.” The other responds that their app is removed from Google Play.

## 4 Limitations

PolicyLint provides a set of techniques to extract a concise structured representation of both collection and sharing statements from the unstructured natural language text in privacy policies. In so doing, it provides unprecedented analysis depth, and our findings in Section 3 demonstrate the utility and value of such analysis. However, extracting structured information from unstructured natural language text continues to be an open and active area of NLP research, and there are currently no perfect techniques for this challenging problem. PolicyLint is thus limited by the current state of NLP techniques, such as the limitations of NLP parsers and named-entity recognition. Its performance also depends on its verb lists and policy statement patterns, which may be incomplete despite our best efforts, reducing overall recall. We note that as a lint tool, our goal is to provide high precision at a potential cost to high recall. We note that PolicyLint achieves 97.3% precision (496/510) based on the 14 false positives identified during our validation of contradictions.

Another limitation is that PolicyLint cannot extract the conditions or purposes behind collection and sharing statements. Extracting such information would allow for a more holistic analysis, but doing so would require advances in decades-old NLP problems, including semantic role labeling, coreference resolution, and natural language understanding.

Finally, our analysis focuses on policies of Android apps. While we cannot claim that our findings would certainly generalize to policies from other domains (e.g., iOS, web), we hypothesize that self-contradictions likely occur across the board, as policies are written for all platforms in largely the same way to describe data types collected by all platforms.

## 5 Related Work

Recent research has increasingly focused on automated analysis of privacy policies. Various approaches have used NLP for deriving answers to a limited number of binary questions [31] from privacy policies, applied topic modeling to reduce ambiguity in privacy policies [27], and used data mining [30] or deep learning [15] models to extract summaries from policies of what and how information is used. Some other approaches [26, 28] have used *crowdsourced* ontologies for policy analysis. These approaches are often limited by lack of accuracy, completeness, and collection complexity. Other approaches [12, 18] identify patterns to extract subsumptive relationships. However, they do not provide methodology to generate usable ontologies from such extracted information and rely on a fixed lexicon. Prior research has also attempted to infer negative statements in privacy policies with limited success. Zimmeck et al. [32] and Yu et al. [29] rely on keyword-based approaches of using bi-grams and verb modifiers, respectively, to detect the negative statements. In contrast to these previous approaches, our work provides a more comprehensive analysis with an automatically constructed ontology and accounting for negations and exceptions in text.

Prior approaches [2, 5, 29] identify the possibility of conflicting policy statements. However, we are the first to characterize and automatically analyze self-contradictions resulting from interactions of varying semantic levels and sentiments.

Analyzing the usability and effectiveness of privacy policies is another well-researched focus area. Research has shown that privacy policies are hard to comprehend by users [23] and proposals have been made to simplify their understanding [24]. Cranor et al. [5] perform a large-scale study of privacy notices of US financial institutions to highlight a number of concerning practices. Their policy analysis relies on standardized models used for such notices; in contrast, privacy policies in mobile apps follow no such standards making the analysis more challenging. Other approaches [20, 21, 25] have attempted to bridge the gap between users’ privacy expectations and app policies. While standardizing privacy policy specification has been attempted [4] with limited success [22], mobile apps’ privacy policies have generally failed

to adhere to any standards. The findings in our study highlight the need to renew standardization discussion.

## 6 Conclusion

In this paper, we have presented PolicyLint, a privacy policy analysis tool that conducts natural language processing to identify contradictory sharing and collection practices within privacy policies. PolicyLint reasons about contradictory policy statements that occur at different semantic levels of granularity by auto-generating domain ontologies. We apply PolicyLint on 11,430 privacy policies from popular apps on Google Play and find that around 17.7% of the policies contain logical contradictions and narrowing definitions, with 14.2% containing logical contradictions. Upon deeper inspection, we find a myriad of concerning issues with privacy policies, including misleading presentations and re-defining common terms. PolicyLint's fine-grained extraction techniques and formalization of narrowing definitions and logical contradictions lay the foundation to help ensure the soundness of automated policy analysis and identify potentially deceptive policies.

## A Preprocessing Privacy Policies

Privacy policies are commonly made available via a link on Google Play to the developer’s website and hosted in HTML. Most NLP parsers expect plaintext input; therefore, PolicyLint begins by converting the HTML privacy policy into plaintext. We next describe how PolicyLint achieves this conversion.

**Removing Non-relevant and Non-displayed Text:** Privacy policies are frequently embedded as main content on a webpage containing navigational elements and other non-relevant text. Additionally, non-displayed text should also be stripped from the HTML, as we want to analyze what is actually displayed to users. PolicyLint extracts the privacy policy portion of the webpage by iterating over the elements in the HTML document. To remove non-relevant text, PolicyLint strips comment, `style`, `script`, `nav`, and `video` HTML tags. PolicyLint also strips HTML links containing phrases commonly used for page navigation (e.g., “learn more,” “back to top,” “return to top”). Finally, PolicyLint removes HTML `span` and `div` tags using the “`display:none`” style attribute.

**Converting HTML to Flat Plaintext Documents:** Certain HTML elements, such as pop-up items, result in a non-flat structure. When flattening the HTML documents, PolicyLint must ensure that the plaintext document has a formatting style similar to the text displayed on the webpage (e.g., same paragraph and sentence breaks). PolicyLint handles pop-up elements by relocating the text within the pop-up element

to the end of the document. Pop-up elements often provide additional context, explanation, clarification, or a definition of a term. Therefore, relocating these elements should not have a significant effect on processing the referencing paragraph. To ensure that the formatting style is maintained, PolicyLint converts the HTML document to markdown using `html2text`.

**Merging Formatted Lists:** Formatted lists within text can cause NLP parsers to incorrectly detect sentence breaks or incorrectly tag parts-of-speech and typed dependencies. These parsing errors can negatively impact the semantic reasoning of sentences. Therefore, PolicyLint merges the text within list items with the preceding clauses before the list begins. PolicyLint also uses a set of heuristics for nesting list structures to ensure that list items propagate to the correct clause.

PolicyLint merges formatted lists in two phases. The first phase occurs before the aforementioned conversion to markdown. In this phase, PolicyLint iterates over HTML elements using list-related HTML tags (i.e., `ol`, `ul`, `li`) to annotate list structures and nesting depth. The second phase occurs after the conversion to markdown. In this phase, PolicyLint searches for paragraphs ending in a colon where the next sentence is a list item (e.g., starts with bullets, roman numerals, formatted numbers, or contains annotations from the first phase). It then forms complete sentences by merging the list item text with the preceding text.

PolicyLint iterates over the paragraphs in the markdown document to find those that end in a colon. For each paragraph that ends in a colon, PolicyLint checks whether the preceding paragraph is a list item. If the line of text is a list item, PolicyLint creates a new paragraph by appending the list item text to the preceding text that ends with the colon. If the list item ends in another colon, PolicyLint repeats the same preceding process but by prepending the nested list items to the new paragraph created in the last step. PolicyLint then leverages the symbols that denote list items to predict the next list item’s expected symbol, which is useful for detecting boundaries of nested lists. For example, if the current list item starts with “(1),” then we would expect the next list item to start with “(2).” If the item symbol matches the expected symbol, PolicyLint merges the list item text as discussed above and continues this process. If the item symbol does not match the expected symbol, PolicyLint stops this process and returns.

**Final Processing:** The final step converts markdown to plaintext. PolicyLint normalizes Unicode characters and strips markdown formatting, such as header tags, bullet points, list item numbering, and other format characters. PolicyLint then uses `langid` to determine whether the majority of the document is written in English. If not, PolicyLint discards the document. If so, PolicyLint outputs the plaintext document.

## B Training Sentence Generation

PolicyLint requires a training set of sharing and collection sentences to learn underlying patterns from in order to iden-

Table 8: Sentence Generation Templates

15	We require <i>VERB_PRESENT_PARTIC DATA PREP ENT</i>	We require sharing personal information with advertisers.
16	We may <i>VERB_PRESENT ENT</i> with <i>DATA</i>	We may provide advertisers with your personal information.

tify “unseen” sharing and collection sentences. As it is tedious to manually select a set of sharing and collection sentences with diverse grammatical structures, we opt to auto-generate the training sentences instead. Note that auto-generating sentences does not adversely impact the extensibility of PolicyLint, as adding a new pattern is as simple as feeding PolicyLint a new sentence for reflecting this new pattern. To identify the templates, we use our domain expertise to identify different sentence compositions that could describe sharing and collection sentences. We identify 16 sentence templates, as shown in Table 8.

To fill the templates, we substitute an entity (*ENT*), data object (*DATA*), the correct tense of an SoC verb (*VERB\_PRESENT*, *VERB\_PAST*, *VERB\_PRESENT\_PARTICIPLE*), and a preposition that describes with *whom* the sharing occurs for sharing verbs (*PREP*). We begin by identifying the present tense, past tense, and present participle forms of all of the SoC verbs (e.g., “share,” “shared,” “sharing,” respectively). We then identify common prepositions for each of the sharing verbs that describe with *whom* the sharing occurs. For example, for the terms *share*, *trade*, and *exchange*, the preposition is “with” and for the terms *sell*, *transfer*, *distribute*, *disclose*, *rent*, *report*, *transmit*, *send*, *give*, *provide*, the preposition is “to.”

For each template, we fill the placeholders accordingly. If the template has a placeholder for prepositions (*PREP*) and the verb is a collect verb, we skip the template. We also skip the templates for “send,” “give,” and “provide” if they do not contain a placeholder for a preposition (T1, T6, T8, T10, T12, T14), as those template sentences do not make sense without specifying to *whom* the data is being sent/given/provided. We set *DATA* to the phrases “your personal information” and “your personal information, demographic information, and financial information.” Similarly, we set *ENT* to the phrases “advertiser” and “advertisers, analytics providers, and our business partners.” Note that we include conjuncts of the *DATA* and *ENT* placeholders to account for deviations in the parse tree due to syntactic ambiguity (i.e., a sentence can have mul-

iple interpretations). Therefore, we generate two sentences for each template: one with a singular *DATA* and *ENT*, and second with the plural *DATA* and plural *ENT*. In total, we generate 560 sentences, which are used by PolicyLint to learn patterns to identify sharing and collection sentences.

## C Policy Statement Extraction

For the 9% of the policies from which PolicyLint does not extract policy statements, we randomly select 100 policies to explore why this situation occurs. We find that 88% (88/100) are due to an insufficient crawling strategy (i.e., privacy policy links being pointed at home pages, navigation pages, or 404 error pages). Among the remaining 12 policies, the links in 3 policies point at a PDF privacy policy while PolicyLint handles only HTML, and 2 policies are not written in English but are not caught by our language classifier. Finally, 7 policies are due to errors in extracting policy statements, such as incomplete verb lists (3 cases), tabular format policies (1 case), and policies for describing permission uses (3 cases).

## D Email Template

```
Subject: Contradictory Privacy Policy Statements in <APP_NAME>
To Whom It May Concern:
We are a team of security researchers from the WSPR Lab in the Department of Computer Science at North Carolina State University. We created a tool to analyze privacy policies and found that the privacy policy for your "<APP_NAME>" application (<PACKAGE>) that we downloaded in September 2017 may contain the following potential contradictory statements:
(1) The following statements claim that personal information is both collected and not collected.
(A) <CONTRADICTIONARY_SENTENCE_1>
(B) <CONTRADICTIONARY_SENTENCE_2>
...
Do you believe that these are contradictory statements? Any additional information that you may have to clarify this policy would be extremely helpful. If you have any questions or concerns, please feel free to contact us, preferably by February 11th.
Thank you for your time!
Best Regards,
<EMAIL_SIGNATURE>

## Abstract

Modern smartphone platforms implement permission-based models to protect access to sensitive data and system resources. However, apps can circumvent the permission model and gain access to protected data without user consent by using both covert and side channels. Side channels present in the implementation of the permission system allow apps to access protected data and system resources without permission; whereas covert channels enable communication between two colluding apps so that one app can share its permission-protected data with another app lacking those permissions. Both pose threats to user privacy.

In this work, we make use of our infrastructure that runs hundreds of thousands of apps in an instrumented environment. This testing environment includes mechanisms to monitor apps' runtime behaviour and network traffic. We look for evidence of side and covert channels being used in practice by searching for sensitive data being sent over the network for which the sending app did not have permissions to access it. We then reverse engineer the apps and third-party libraries responsible for this behaviour to determine how the unauthorized access occurred. We also use software fingerprinting methods to measure the static prevalence of the technique that we discover among other apps in our corpus.

Using this testing environment and method, we uncovered a number of side and covert channels in active use by hundreds of popular apps and third-party SDKs to obtain unauthorized access to both unique identifiers as well as geolocation data. We have responsibly disclosed our findings to Google and have received a bug bounty for our work.

## 1 Introduction

Smartphones are used as general-purpose computers and therefore have access to a great deal of sensitive system resources (*e.g.*, sensors such as the camera, microphone, or GPS), private data from the end user (*e.g.*, user email or contacts list), and various persistent identifiers (*e.g.*, IMEI). It

is crucial to protect this information from unauthorized access. Android, the most-popular mobile phone operating system [75], implements a permission-based system to regulate access to these sensitive resources by third-party applications. In this model, app developers must explicitly request *permission* to access sensitive resources in their Android Manifest file [5]. This model is supposed to give users control in deciding which apps can access which resources and information; in practice it does not address the issue completely [30, 86].

The Android operating system sandboxes user-space apps to prevent them from interacting arbitrarily with other running apps. Android implements isolation by assigning each app a separate *user ID* and further mandatory access controls are implemented using SELinux. Each running process of an app can be either code from the app itself or from SDK libraries embedded within the app; these SDKs can come from Android (*e.g.*, official Android support libraries) or from third-party providers. App developers integrate third-party libraries in their software for things like crash reporting, development support, analytics services, social-network integration, and advertising [16, 62]. By design, any third-party service bundled in an Android app inherits access to all permission-protected resources that the user grants to the app. In other words, if an app can access the user's location, then all third-party services embedded in that app can as well.

In practice, security mechanisms can often be circumvented; *side channels* and *covert channels* are two common techniques to circumvent a security mechanism. These channels occur when there is an alternate means to access the protected resource that is not audited by the security mechanism, thus leaving the resource unprotected. A *side channel* exposes a path to a resource that is outside the security mechanism; this can be because of a flaw in the design of the security mechanism or a flaw in the implementation of the design. A classic example of a side channel is that power usage of hardware when performing cryptographic operations can leak the particulars of a secret key [42]. As an example in the physical world, the frequency of pizza deliveries to government buildings may leak information about political crises [69].

A *covert channel* is a more deliberate and intentional effort between two cooperating entities so that one with access to some data provides it to the other entity without access to the data in violation of the security mechanism [43]. As an example, someone could execute an algorithm that alternates between high and low CPU load to pass a binary message to another party observing the CPU load.

The research community has previously explored the potential for covert channels in Android using local sockets and shared storage [49], as well as other unorthodox means, such as vibrations and accelerometer data to send and receive data between two coordinated apps [3]. Examples of side channels include using device sensors to infer the gender of the user [51] or uniquely identify the user [72]. More recently, researchers demonstrated a new permission-less device fingerprinting technique that allows tracking Android and iOS devices across the Internet by using factory-set sensor calibration details [90]. However, there has been little research in detecting and measuring at scale the prevalence of covert and side channels in apps that are available in the Google Play Store. Only isolated instances of malicious apps or libraries inferring users' locations from WiFi access points were reported, a side channel that was abused in practice and resulted in about a million dollar fine by regulators [82].

In fact, most of the existing literature is focused on understanding personal data collection using the system-supported access control mechanisms (*i.e.*, Android permissions). With increased regulatory attention to data privacy and issues surrounding user consent, we believe it is imperative to understand the effectiveness (and limitations) of the permission system and whether it is being circumvented as a preliminary step towards implementing effective defenses.

To this end, we extend the state of the art by developing methods to detect actual circumvention of the Android permission system, at scale in real apps by using a combination of dynamic and static analysis. We automatically executed over 88,000 Android apps in a heavily instrumented environment with capabilities to monitor apps' behaviours at the system and network level, including a TLS man-in-the-middle proxy. In short, we ran apps to see when permission-protected data was transmitted by the device, and scanned the apps to see which ones *should not* have been able to access the transmitted data due to a lack of granted permissions. We grouped our findings by *where* on the Internet *what* data type was sent, as this allows us to attribute the observations to the actual app developer or embedded third-party libraries. We then reverse engineered the responsible component to determine exactly how the data was accessed. Finally, we statically analyzed our entire dataset to measure the prevalence of the channel. We focus on a subset of the *dangerous* permissions that prevent apps from accessing location data and identifiers. Instead of imagining new channels, our work focuses on tracing evidence that suggests that side- and covert-channel abuse is occurring in practice.

We studied more than 88,000 apps across each category from the U.S. Google Play Store. We found a number of side and covert channels in active use, responsibly disclosed our findings to Google and the U.S. Federal Trade Commission (FTC), and received a bug bounty for our efforts.

In summary, the contributions of this work include:

- We designed a pipeline for automatically discovering vulnerabilities in the Android permissions system through a combination of dynamic and static analysis, in effect creating a scalable honeypot environment.
- We tested our pipeline on more than 88,000 apps and discovered a number of vulnerabilities, which we responsibly disclosed. These apps were downloaded from the U.S. Google Play Store and include popular apps from all categories. We further describe the vulnerabilities in detail, and measure the degree to which they are in active use, and thus pose a threat to users. We discovered covert and side channels used in the wild that compromise both users' location data and persistent identifiers.
- We discovered companies getting the MAC addresses of the connected WiFi base stations from the ARP cache. This can be used as a surrogate for location data. We found 5 apps exploiting this vulnerability and 5 with the pertinent code to do so.
- We discovered Unity obtaining the device MAC address using `ioctl` system calls. The MAC address can be used to uniquely identify the device. We found 42 apps exploiting this vulnerability and 12,408 apps with the pertinent code to do so.
- We also discovered that third-party libraries provided by two Chinese companies—Baidu and Salmonads— independently make use of the SD card as a covert channel, so that when an app can read the phone's IMEI, it stores it for other apps that cannot. We found 159 apps with the potential to exploit this covert channel and empirically found 13 apps doing so.
- We found one app that used picture metadata as a side channel to access precise location information despite not holding location permissions.

These deceptive practices allow developers to access users' private data without consent, undermining user privacy and giving rise to both legal and ethical concerns. Data protection legislation around the world—including the General Data Protection Regulation (GDPR) in Europe, the California Consumer Privacy Act (CCPA) and consumer protection laws, such as the Federal Trade Commission Act—enforce transparency on the data collection, processing, and sharing practices of mobile applications.

This paper is organized as follows: Section 2 gives more background information on the concepts discussed in the introduction. Section 3 describes our system to discover vulnerabilities in detail. Section 4 provides the results from our

study, including the side and covert channels we discovered and their prevalence in practice. Section 5 describes related work. Section 6 discusses their potential legal implications. Section 7 discusses limitations to our approach and concludes with future work.

## 2 Background

The Android permissions system has evolved over the years from an ask-on-install approach to an ask-on-first-use approach. While this change impacts when permissions are granted and how users can use contextual information to reason about the appropriateness of a permission request, the backend enforcement mechanisms have remained largely unchanged. We look at how the design and implementation of the permission model has been exploited by apps to bypass these protections.

### 2.1 Android Permissions

Android's permissions system is based on the security principle of *least privilege*. That is, an entity should only have the minimum capabilities it needs to perform its task. This standard design principle for security implies that if an app acts maliciously, the damage will be limited. Developers must declare the permissions that their apps need beforehand, and the user is given an opportunity to review them and decide whether to install the app. The Android platform, however, does not judge whether the set of requested permissions are all strictly necessary for the app to function. Developers are free to request more permissions than they actually need and users are expected to judge if they are reasonable.

The Android permission model has two important aspects: obtaining user consent before an app is able to access any of its requested permission-protected resources, and then ensuring that the app cannot access resources for which the user has not granted consent. There is a long line of work uncovering issues on how the permission model interacts with the user: users are inadequately informed about why apps need permissions at installation time, users misunderstand exactly what the purpose of different permissions are, and users lack context and transparency into how apps will ultimately use their granted permissions [24, 30, 78, 86]. While all of these are critical issues that need attention, the focus of our work is to understand how apps are circumventing system checks to verify that apps have been granted various permissions.

When an app requests a permission-protected resource, the resource manager (e.g., `LocationManager`, `WiFiManager`, etc.) contacts the `ActivityServiceManager`, which is the *reference monitor* in Android. The resource request originates from the sandboxed app, and the final verification happens inside the Android platform code. The platform is a Java operating system that runs in system space and acts as an interface for a customized Linux kernel, though apps can interact with

the kernel directly as well. For some permission-protected resources, such as network sockets, the reference monitor is the kernel, and the request for such resources bypasses the platform framework and directly contacts the kernel. Our work discusses how real-world apps circumvent these system checks placed in the kernel and the platform layers.

The Android permissions system serves an important purpose: to protect users' privacy and sensitive system resources from deceptive, malicious, and abusive actors. At the very least, if a user denies an app a permission, then that app should not be able to access data protected by that permission [24, 81]. In practice, this is not always the case.

### 2.2 Circumvention

Apps can circumvent the Android permission model in different ways [3, 17, 49, 51, 52, 54, 70, 72, 74]. The use of covert and side channels, however, is particularly troublesome as their usage indicates deceptive practices that might mislead even diligent users, while underscoring a security vulnerability in the operating system. In fact, the United State's Federal Trade Commission (FTC) has fined mobile developers and third-party libraries for exploiting side channels: using the MAC address of the WiFi access point to infer the user's location [82]. Figure 1 illustrates the difference between covert and side channels and shows how an app that is denied permission by a security mechanism is able to still access that information.

**Covert Channel** A covert channel is a communication path between two parties (e.g., two mobile apps) that allows them to transfer information that the relevant security enforcement mechanism deems the recipient unauthorized to receive [18]. For example, imagine that `AliceApp` has been granted permission through the Android API to access the phone's IMEI (a persistent identifier), but `BobApp` has been denied access to that same data. A covert channel is created when `AliceApp` legitimately reads the IMEI and then gives it to `BobApp`, even though `BobApp` has already been denied access to this same data when requesting it through the proper permission-protected Android APIs.

In the case of Android, different covert channels have been proposed to enable communication between apps. This includes exotic mediums such as ultrasonic audio beacons and vibrations [17, 26]. Apps can also communicate using an external network server to exchange information when no other opportunity exists. Our work, however, exposes that rudimentary covert channels, such as shared storage, are being used in practice at scale.

**Side Channel** A side channel is a communication path that allows a party to obtain privileged information without relevant permission checks occurring. This can be due to non-conventional unprivileged functions or features, as well as ersatz versions of the same information being available without

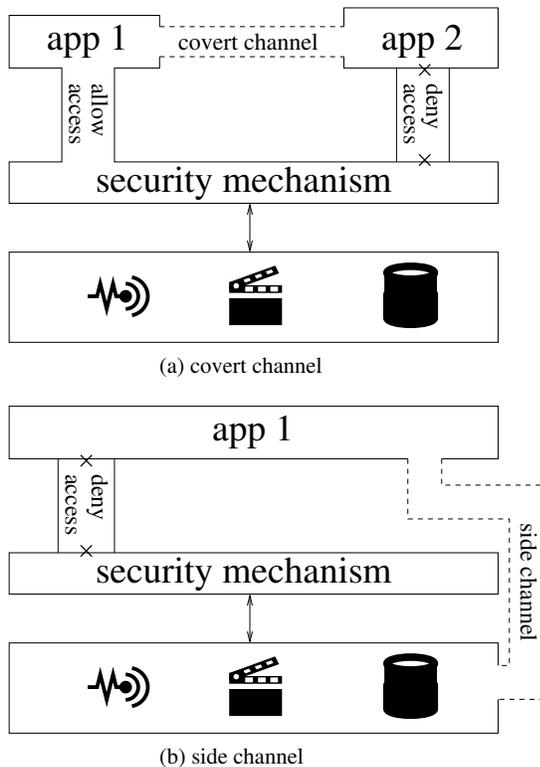

Figure 1: Covert and side channels. (a) A security mechanism allows app1 access to resources but denies app2 access; this is circumvented by app2 using app1 as a facade to obtain access over a communication channel not monitored by the security mechanism. (b) A security mechanism denies app1 access to resources; this is circumvented by accessing the resources through a side channel that bypasses the security mechanism.

being protected by the same permission. A classical example of a side channel attack is the timing attack to exfiltrate an encryption key from secure storage [42]. The system under attack is an algorithm that performs computation with the key and unintentionally leaks timing information—*i.e.*, how long it runs—that reveals critical information about the key.

Side channels are typically an unintentional consequence of a complicated system. (“Backdoors” are intentionally-created side channels that are meant to be obscure.) In Android, a large and complicated API results in the same data appearing in different locations, each governed by different access control mechanisms. When one API is protected with permissions, another unprotected method may be used to obtain the same data or an ersatz version of it.

### 2.3 App Analysis Methods

Researchers use two primary techniques to analyze app behaviour: static and dynamic analysis. In short, static analysis studies *software as data* by reading it; dynamic analysis studies *software as code* by running it. Both approaches have the

goal of understanding the software’s ultimate behaviour, but they offer insights with different certainty and granularity: static analysis reports instances of hypothetical behaviour; dynamic analysis gives reports of observed behaviour.

**Static Analysis** Static analysis involves scanning the code for all possible combinations of execution flows to understand potential execution behaviours—the behaviours of interest may include various privacy violations (*e.g.*, access to sensitive user data). Several studies have used static analysis to analyze different types of software in search of malicious behaviours and privacy leaks [4, 9–11, 19–22, 32, 37, 39, 41, 45, 92]. However, static analysis does not produce actual observations of privacy violations; it can only suggest that a violation may happen if a given part of the code gets executed at runtime. This means that static analysis provides an upper bound on hypothetical behaviours (*i.e.*, yielding false positives).

The biggest advantage of static analysis is that it is easy to perform automatically and at scale. Developers, however, have options to evade detection by static analysis because a program’s runtime behaviour can differ enormously from its superficial appearance. For example, they can use code obfuscation [23, 29, 48] or alter the flow of the program to hide the way that the software operates in reality [23, 29, 48]. Native code in unmanaged languages allow pointer arithmetic that can skip over parts of functions that guarantee pre-conditions. Java’s reflection feature allows the execution of dynamically created instructions and dynamically loaded code that similarly evades static analysis. Recent studies have shown that around 30% of apps render code dynamically [46], so static analysis may be insufficient in those cases.

From an app analysis perspective, static analysis lacks the contextual aspect, *i.e.*, it fails to observe the circumstances surrounding each observation of sensitive resource access and sharing, which is important in understanding when a given privacy violation is likely to happen. For these reasons, static analysis is useful, but is well complemented by dynamic analysis to augment or confirm findings.

**Dynamic analysis** Dynamic analysis studies an executable by running it and auditing its runtime behaviour. Typically, dynamic analysis benefits from running the executable in a controlled environment, such as an instrumented mobile OS [27, 85], to gain observations of an app’s behaviour [16, 32, 46, 47, 50, 65, 66, 73, 85, 87–89].

There are several methods that can be used in dynamic analysis, one example is taint analysis [27, 32] which can be inefficient and prone to control flow attacks [68, 71]. A challenge to performing dynamic analysis is the logistical burden of performing it at scale. Analyzing a single Android app in isolation is straightforward, but scaling it to run automatically for tens of thousands of apps is not. Scaling dynamic analysis is facilitated with automated execution and creation of behavioural reports. This means that effective dynamic analysis

requires building an instrumentation framework for possible behaviours of interest *a priori* and then engineering a system to manage the endeavor.

Nevertheless, some apps are resistant to being audited when run in virtual or privileged environments [12, 68]. This has led to new auditing techniques that involve app execution on real phones, such as by forwarding traffic through a VPN in order to inspect network communications [44, 60, 63]. The limitations of this approach are the use of techniques robust to man-in-the-middle attacks [28, 31, 61] and scalability due to the need to actually run apps with user input.

A tool to automatically execute apps on the Android platform is the UI/Application Exerciser Monkey [6]. The Monkey is a UI fuzzer that generates synthetic user input, ensuring that some interaction occurs with the app being automatically tested. The Monkey has no context for its actions with the UI, however, so some important code paths may not be executed due to the random nature of its interactions with the app. As a result, this gives a lower bound for possible app behaviours, but unlike static analysis, it does not yield false positives.

**Hybrid Analysis** Static and dynamic analysis methods complement each other. In fact, some types of analysis benefit from a hybrid approach, in which combining both methods can increase the coverage, scalability, or visibility of the analyses. This is the case for malicious or deceptive apps that actively try to defeat one individual method (*e.g.*, by using obfuscation or techniques to detect virtualized environments or TLS interception). One approach would be to first carry out dynamic analysis to triage potential suspicious cases, based on collected observations, to be later examined thoroughly using static analysis. Another approach is to first carry out static analysis to identify interesting code branches that can then be instrumented for dynamic analysis to confirm the findings.

### 3 Testing Environment and Analysis Pipeline

Our instrumentation and processing pipeline, depicted and described in Figure 2, combines the advantages of both static and dynamic analysis techniques to triage suspicious apps and analyze their behaviours in depth. We used this testing environment to find evidence of covert- and side-channel usage in 252,864 versions of 88,113 different Android apps, all of them downloaded from the U.S. Google Play Store using a purpose-built Google Play scraper. We executed each app version individually on a physical mobile phone equipped with a customized operating system and network monitor. This testbed allows us to observe apps’ runtime behaviours both at the OS and network levels. We can observe how apps request and access sensitive resources and their data sharing practices. We also have a comprehensive data analysis tool to de-obfuscate collected network data to uncover potential deceptive practices.

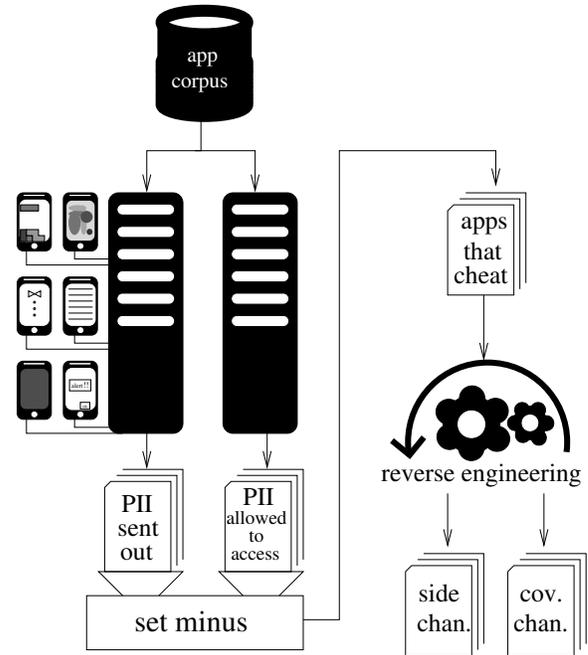

Figure 2: Overview of our analysis pipeline. Apps are automatically run and the transmissions of sensitive data are compared to what would be allowed. Those suspected of using a side or covert channel are manually reverse engineered.

Before running each app, we gather the permission-protected identifiers and data. We then execute each app while collecting all of its network traffic. We apply a suite of decodings to the traffic flows and search for the permission-protected data in the decoded traffic. We record all transmissions and later filter for those containing permission-protected data sent by apps not holding the requisite permissions. We hypothesize that these are due to the use of side and covert channels; that is, we are not looking for these channels, but rather looking for evidence of their use (*i.e.*, transmissions of protected data). Then, we group the suspect transmissions by the data type sent and the destination where it was sent, because we found that the same data-destination pair reflects the same underlying side or covert channel. We take one example per group and manually reverse engineer it to determine how the app gained permission-protected information without the corresponding permission.

Finally, we fingerprint the apps and libraries found using covert- and side-channels to identify the static presence of the same code in other apps in our corpus. A fingerprint is any string constant, such as specific filename or error message, that can be used to statically analyze our corpus to determine if the same technique exists in other apps that did not get triggered during our dynamic analysis phase.

### 3.1 App Collection

We wrote a Google Play Store scraper to download the most-popular apps under each category. Because the popularity distribution of apps is long tailed, our analysis of the 88,113 most-popular apps is likely to cover most of the apps that people currently use. This includes 1,505 non-free apps we purchased for another study [38]. We instrumented the scraper to inspect the Google Play Store to obtain application executables (APK files) and their associated metadata (e.g., number of installs, category, developer information, etc.).

As developers tend to update their Android software to add new functionality or to patch bugs [64], these updates can also be used to introduce new side and covert channels. Therefore, it is important to examine different versions of the same app, because they may exhibit different behaviours. In order to do so, our scraper periodically checks if a new version of an already downloaded app is available and downloads it. This process allowed us to create a dataset consisting of 252,864 different versions of 88,113 Android apps.

### 3.2 Dynamic Analysis Environment

We implemented the dynamic testing environment described in Figure 2, which consists of about a dozen Nexus 5X Android phones running an instrumented version of the Android Marshmallow platform.<sup>1</sup> This purpose-built environment allows us to comprehensively monitor the behaviour of each of 88,113 Android apps at the kernel, Android-framework, and network traffic levels. We execute each app automatically using the Android Automator Monkey [6] to achieve scale by eliminating any human intervention. We store the resulting OS-execution logs and network traffic in a database for offline analysis, which we discuss in Section 3.3. The dynamic analysis is done by extending a platform that we have used in previous work [66].

**Platform-Level Instrumentation** We built an instrumented version of the Android 6.0.1 platform (Marshmallow). The instrumentation monitored resource accesses and logged when apps were installed and executed. We ran apps one at a time and uninstalled them afterwards. Regardless of the obfuscation techniques apps use to disrupt static analysis, no app can avoid our instrumentation, since it executes in the system space of the Android framework. In a sense, our environment is a honeypot allowing apps to execute as their true selves. For the purposes of preparing our bug reports to Google for responsible disclosure of our findings, we retested our findings on a stock Pixel 2 running Android Pie—the most-recent version at the time—to demonstrate that they were still valid.

<sup>1</sup>While as of this writing Android Pie is the current release [35], Marshmallow and older versions were used by a majority of users at the time that we began data collection.

**Kernel-Level Instrumentation** We built and integrated a custom Linux kernel into our testing environment to record apps’ access to the file system. This module allowed us to record every time an app opened a file for reading or writing or unlinked a file. Because we instrumented the system calls to open files, our instrumentation logged both regular files and special files, such as device and interface files, and the `proc/` filesystem, as a result of the “*everything is a file*” UNIX philosophy. We also logged whenever an `ioctl` was issued to the file system. Some of the side channels for bypassing permission checking in the Android platform may involve directly accessing the kernel, and so kernel-level instrumentation provides clear evidence of these being used in practice.

We ignored the special device file `/dev/ashmem` (Android-specific implementation of asynchronous shared memory for inter-process communication) because it overwhelmed the logs due to its frequent use. As Android assigns a separate *user* (i.e., `uid`) to each app, we could accurately attribute the access to such files to the responsible app.

**Network-Level Monitoring** We monitored all network traffic, including TLS-secured flows, using a network monitoring tool developed for our previous research activities [63]. This network monitoring module leverages Android’s VPN API to redirect all the device’s network traffic through a localhost service that inspects all network traffic, regardless of the protocol used, through deep-packet inspection and in user-space. It reconstructs the network streams and ascribes them to the originating app by mapping the app owning the socket to the UID as reported by the `proc` filesystem. Furthermore, it also performs TLS interception by installing a root certificate in the system trusted certificate store. This technique allows it to decrypt TLS traffic unless the app performs advanced techniques, such as certificate pinning, which can be identified by monitoring TLS records and proxy exceptions [61].

**Automatic App Execution** Since our analysis framework is based on dynamic analysis, apps must be executed so that our instrumentation can monitor their behaviours. In order to scale to hundreds of thousands of apps tested, we cannot rely on real user interaction with each app being tested. As such, we use Android’s UI/Application Exerciser Monkey, a tool provided by Android’s development SDK to automate and parallelize the execution of apps by simulating user inputs (i.e., taps, swipes, etc.).

The Monkey injects a pseudo-random stream of simulated user input events into the app, i.e., it is a UI fuzzer. We use the Monkey to interact with each version of each app for a period of ten minutes, during which the aforementioned tools log the app’s execution as a result of the random UI events generated by the Monkey. Apps are rerun if the operation fails during execution. Each version of each app is run once in this manner; our system also reruns apps if there is unused capacity.

After running the app, the kernel, platform, and network logs are collected. The app is then uninstalled along with any other app that may have been installed through the process of automatic exploration. We do this with a white list of allowed apps; all other apps are uninstalled. The logs are then cleared and the device is ready to be used for the next test.

### 3.3 Personal Information in Network Flows

Detecting whether an app has legitimately accessed a given resource is straightforward: we compare its runtime behaviour with the permissions it had requested. Both users and researchers assess apps' privacy risks by examining their requested permissions. This presents an incomplete picture, however, because it only indicates what data an app *might* access, and says nothing about with whom it may share it and under what circumstances. The only way of answering these questions is by inspecting the apps' network traffic. However, identifying personal information inside network transmissions requires significant effort because apps and embedded third-party SDKs often use different encodings and obfuscation techniques to transmit data. Thus, it is a significant technical challenge to be able to de-obfuscate all network traffic and search it for personal information. This subsection discusses how we tackle these challenges in detail.

**Personal Information** We define "personal information" as any piece of data that could potentially identify a specific individual and distinguish them from another. Online companies, such as mobile app developers and third-party advertising networks, want this type of information in order to track users across devices, websites, and apps, as this allows them to gather more insights about individual consumers and thus generate more revenue via targeted advertisements. For this reason, we are primarily interested in examining apps' access to the persistent identifiers that enable long-term tracking, as well as their geolocation information.

We focus our study on detecting apps using covert and side channels to access specific types of highly sensitive data, including persistent identifiers and geolocation information. Notably, the unauthorized collection of geolocation information in Android has been the subject of prior regulatory action [82]. Table 1 shows the different types of personal information that we look for in network transmissions, what each can be used for, the Android permission that protects it, and the subsection in this paper where we discuss findings that concern side and covert channels for accessing that type of data.

**Decoding Obfuscations** In our previous work [66], we found instances of apps and third-party libraries (SDKs) using obfuscation techniques to transmit personal information over the network with varying degrees of sophistication. To identify and report such cases, we automated the decoding of a standard suite of standard HTTP encodings to identify

personal information encoded in network flows, such as gzip, base64, and ASCII-encoded hexadecimal. Additionally, we search for personal information directly, as well as the MD5, SHA1, and SHA256 hashes of it.

After analyzing thousands of network traces, we still find new techniques SDKs and apps use to obfuscate and encrypt network transmissions. While we acknowledge their effort to protect users' data, the same techniques could be used to hide deceptive practices. In such cases, we use a combination of reverse engineering and static analysis to understand the precise technique. We frequently found a further use of AES encryption applied to the payload before sending it over the network, often with hard-coded AES keys.

A few libraries followed best practices by generating random AES session keys to encrypt the data and then encrypt the session key with a hard-coded RSA public key, sending both the encrypted data and encrypted session key together. To de-cipher their network transmissions, we instrumented the relevant Java libraries. We found two examples of third-party SDKs "encrypting" their data by XOR-ing a keyword over the data in a Vigenère-style cipher. In one case, this was *in addition* to both using standard encryption for the data *and* using TLS in transmission. Other interesting approaches included reversing the string after encoding it in base64 (which we refer to as "46esab"), using base64 multiple times (base646464), and using a permuted-alphabet version of base64 (sa4b6e). Each new discovery is added to our suite of decodings and our entire dataset is then re-analyzed.

### 3.4 Finding Side and Covert Channels

Once we have examples of transmissions that suggest the permission system was violated (*i.e.*, data transmitted by an app that had not been granted the requisite permissions to do so), we then reverse engineer the app to determine how it circumvented the permissions system. Finally, we use static analysis to measure how prevalent this practice is among the rest of our corpus.

**Reverse Engineering** After finding a set of apps exhibiting behaviour consistent with the existence of side and covert channels, we manually reverse engineered them. While the reverse engineering process is time consuming and not easily automated, it is necessary to determine how the app actually obtained information outside of the permission system. Because many of the transmissions are caused by the same SDK code, we only needed to reverse engineer each unique *circumvention technique*: not every app, but instead for a much smaller number of unique SDKs. The destination endpoint for the network traffic typically identifies the SDK responsible.

During the reverse engineering process, our first step was to use apktool [7] to decompile and extract the smali bytecode for each suspicious app. This allowed us to analyse and identify where any strings containing PII were created and from

Table 1: The types of personal information that we search for, the permissions protecting access to them, and the purpose for which they are generally collected. We also report the subsection in this paper where we report side and covert channels for accessing each type of data, if found, and the number of apps exploiting each. The dynamic column depicts the number of apps that we directly observed inappropriately accessing personal information, whereas the static column depicts the number of apps containing code that exploits the vulnerability (though we did not observe being executed during test runs).

Data Type	Permission	Purpose/Use	Subsection	N° of Apps		N° of SDKs		Channel Type	
				Dynamic	Static	Dynamic	Static	Covert	Side
IMEI	READ_PHONE_STATE	Persistent ID	4.1	13	159	2	2	2	0
Device MAC	ACCESS_NETWORK_STATE	Persistent ID	4.2	42	12,408	1	1	0	1
Email	GET_ACCOUNTS	Persistent ID	Not Found						
Phone Number	READ_PHONE_STATE	Persistent ID	Not Found						
SIM ID	READ_PHONE_STATE	Persistent ID	Not Found						
Router MAC	ACCESS_WIFI_STATE	Location Data	4.3	5	355	2	10	0	2
Router SSID	ACCESS_WIFI_STATE	Location Data	Not Found						
GPS	ACCESS_FINE_LOCATION	Location Data	4.4	1	1	0	0	0	1

which data sources. For some particular apps and libraries, our work also necessitated reverse engineering C++ code; we used `IdaPro` [1] for that purpose.

The typical process was to search the code for strings corresponding to destinations for the network transmissions and other aspects of the packets. This revealed where the data was already in memory, and then static analysis of the code revealed where that value first gets populated. As intentionally-obfuscated code is more complicated to reverse engineer, we also added logging statements for data and stack traces as new bytecode throughout the decompiled app, recompiled it, and ran it dynamically to get a sense of how it worked.

**Measuring Prevalence** The final step of our process was to determine the prevalence of the particular side or covert channel in practice. We used our reverse engineering analysis to craft a unique fingerprint that identifies the presence of an exploit in an embedded SDK, which is also robust against false positives. For example, a fingerprint is a string constant corresponding to a fixed encryption key used by one SDK, or the specific error message produced by another SDK if the operation fails.

We then decompiled all of the apps in our corpus and searched for the string in the resulting files. Within small bytecode, we searched for the string in its entirety as a `const-string` instruction. For shared objects libraries like `Unity`, we use the `strings` command to output its printable strings. We include the path and name of the file as matching criteria to protect against false positives. The result is a set of all apps that may also exploit the side or covert channel in practice but for which our instrumentation did not flag for manual investigation, *e.g.*, because the app had been granted the required permission, the Monkey did not explore that particular code branch, etc.

## 4 Results

In this section, we present our results grouped by the type of permission that should be held to access the data; first we discuss covert and side channels enabling the access to persistent user or device IDs (particularly the IMEI and the device MAC address) and we conclude with channels used for accessing users’ geolocation (*e.g.*, through network infrastructure or metadata present in multimedia content).

Our testing environment allowed us to identify five different types of side and covert channels in use among the 88,113 different Android apps in our dataset. Table 1 summarizes our findings and reports the number of apps and third-party SDKs that we find exploiting these vulnerabilities in our dynamic analysis and those in which our static analysis reveals code that *can* exploit these channels. Note that this latter category—those that *can* exploit these channels—were not seen as doing so by our instrumentation; this may be due to the Automator Monkey not triggering the code to exploit it or because the app had the required permission and therefore the transmission was not deemed suspicious.

### 4.1 IMEI

The International Mobile Equipment Identity (IMEI) is a numerical value that identifies mobile phones uniquely. The IMEI has many valid and legitimate operational uses to identify devices in a 3GPP network, including the detection and blockage of stolen phones.

The IMEI is also useful to online services as a persistent device identifier for tracking individual phones. The IMEI is a powerful identifier as it takes extraordinary efforts to change its value or even spoof it. In some jurisdictions, it is illegal to change the IMEI [56]. Collection of the IMEI by third parties facilitates tracking in cases where the owner tries to protect their privacy by resetting other identifiers, such as the advertising ID.

Android protects access to the phone's IMEI with the `READ_PHONE_STATE` permission. We identified two third-party online services that use different covert channels to access the IMEI when the app does not have the permission required to access the IMEI.

**Salmonads and External Storage** Salmonads is a “third party developers’ assistant platform in Greater China” that offers analytics and monetization services to app developers [67]. We identified network flows to `salmonads.com` coming from five mobile apps that contained the device's IMEI, despite the fact that the apps did not have permission to access it.

We studied one of these apps and confirmed that it contained the Salmonads SDK, and then studied the workings of the SDK closer. Our analysis revealed that the SDK exploits covert channels to read this information from the following hidden file on the SD card: `/sdcard/.googlex9/.xamdecoq0962`. If not present, this file is created by the Salmonads SDK. Then, whenever the user installs another app with the Salmonads SDK embedded and with legitimate access to the IMEI, the SDK—through the host app—reads and stores the IMEI in this file.

The covert channel is the apps’ shared access to the SD card. Once the file is written, all other apps with the same SDK can simply read the file instead of obtaining access through the Android API, which is regulated by the permission system. Beyond the IMEI, Salmonads also stores the advertising ID—a resettable ID for advertising and analytics purposes that allows opting out of interest-based advertising and personalization—and the phone's MAC address, which is protected with the `ACCESS_NETWORK_STATE` permission. We modified the file to store new random values and observed that the SDK faithfully sent them onwards to Salmonads’ domains. The collection of the advertising ID alongside other non-resettable persistent identifiers and data, such as the IMEI, undermines the privacy-preserving feature of the advertising ID, which is that it can be *reset*. It also may be a violation of Google's Terms of Service [36],

Our instrumentation allowed us to observe five different apps sending the IMEI without permission to Salmonads using this technique. Static analysis of our entire app corpus revealed that six apps contained the `.xamdecoq0962` filename hardcoded in the SDK as a string. The sixth app had been granted the required permission to access the IMEI, which is why we did not initially identify it, and so it may be the app responsible for having initially written the IMEI to the file. Three of the apps were developed by the same company, according to Google Play metadata, while one of them has since been removed from Google Play. The lower bound on the number of times these apps were installed is 17.6 million, according to Google Play metadata.

**Baidu and External Storage** Baidu is a large Chinese corporation whose services include, among many others, an online search engine, advertising, mapping services [14], and geocoding APIs [13]. We observed network flows containing the device IMEI from Disney's Hong Kong Disneyland park app (`com.disney.hongkongdisneyland_goo`) to Baidu domains. This app helps tourists to navigate through the Disney-themed park, and the app makes use of Baidu's Maps SDK. While Baidu Maps initially only offered maps of mainland China, Hong Kong, Macau and Taiwan, as of 2019, it now provides global services.

Baidu's SDK uses the same technique as Salmonads to circumvent Android's permission system and access the IMEI without permission. That is, it uses a shared file on the SD card so one Baidu-containing app with the right permission can store it for other Baidu-containing apps that do not have that permission. Specifically, Baidu uses the following file to store and share this data: `/sdcard/backups/.SystemConfig/.cuid2`. The file is a base64-encoded string that, when decoded, is an AES-encrypted JSON object that contains the IMEI as well as the MD5 hash of the concatenation of “`com.baidu`” and the phone's Android ID.

Baidu uses AES in CBC mode with a static key and the same static value for the initialization vector (IV). These values are, in hexadecimal, `33303231323130326469637564696162`. The reason why this value is not superficially representative of a random hexadecimal string is because Baidu's key is computed from the binary representation of the ASCII string `30212102dicudiab`—observe that when reversed, it reads as `baidu cid 2012 12 03`. As with Salmonads, we confirmed that we can change the (encrypted) contents of this file and the resulting identifiers were faithfully sent onwards to Baidu's servers.

We observed eight apps sending the IMEI of the device to Baidu without holding the requisite permissions, but found 153 different apps in our repository that have hardcoded the constant string corresponding to the encryption key. This includes two from Disney: one app each for their Hong Kong and Shanghai (`com.disney.shanghaidisneyland_goo`) theme parks. Out of that 153, the two most popular apps were Samsung's Health (`com.sec.android.app.shealth`) and Samsung's Browser (`com.sec.android.app.sbrowser`) apps, both with more than 500 million installations. There is a lower bound of 2.6 billion installations for the apps identified as containing Baidu's SDK. Of these 153 apps, all but 20 have the `READ_PHONE_STATE` permission. This means that they have legitimate access to the IMEI and can be the apps that actually create the file that stores this data. The 20 that do not have the permission can only get the IMEI through this covert channel. These 20 apps have a total lower bound of 700 million installations.

## 4.2 Network MAC Addresses

The Media Access Control Address (MAC address) is a 6-byte identifier that is uniquely assigned to the Network Interface Controller (NIC) for establishing link-layer communications. However, the MAC address is also useful to advertisers and analytics companies as a hardware-based persistent identifier, similar to the IMEI.

Android protects access to the device's MAC address with the `ACCESS_NETWORK_STATE` permission. Despite this, we observed apps transmitting the device's MAC address without having permission to access it. The apps and SDKs gain access to this information using C++ native code to invoke a number of unguarded UNIX system calls.

**Unity and IOCTLS** Unity is a cross-platform game engine developed by Unity Technologies and heavily used by Android mobile games [77]. Our traffic analysis identified several Unity-based games sending the MD5 hash of the MAC address to Unity's servers and referring to it as a `uuid` in the transmission (*e.g.*, as an HTTP GET parameter key name). In this case, the access was happening inside of Unity's C++ native library. We reverse engineered `libunity.so` to determine how it was obtaining the MAC address.

Reversing Unity's 18 MiB compiled C++ library is more involved than Android's bytecode. Nevertheless, we were able to isolate where the data was being processed precisely because it hashes the MAC address with MD5. Unity provided its own unlabelled MD5 implementation that we found by searching for the constant numbers associated with MD5; in this case, the initial state constants.

Unity opens a network socket and uses an `ioctl` (UNIX "input-output control") to obtain the MAC address of the WiFi network interface. In effect, `ioctl`s create a large suite of "numbered" API calls that are technically no different than well-named system calls like `bind` or `close` but used for infrequently used features. The behaviour of an `ioctl` depends on the specific "request" number. Specifically, Unity uses the `SIOCGIFCONF`<sup>2</sup> `ioctl` to get the network interfaces, and then uses the `SIOCGIFHWADDR`<sup>3</sup> `ioctl` to get the corresponding MAC address.

We observed that 42 apps were obtaining and sending to Unity servers the MAC address of the network card without holding the `ACCESS_NETWORK_STATE` permission. To quantify the prevalence of this technique in our corpus of Android apps, we fingerprinted this behaviour through an error string that references the `ioctl` code having just failed. This allowed us to find a total of 12,408 apps containing this error string, of which 748 apps do not hold the `ACCESS_NETWORK_STATE` permission.

<sup>2</sup>Socket `ioctl` get interface configuration

<sup>3</sup>Socket `ioctl` get interface hardware address

## 4.3 Router MAC Address

Access to the WiFi router MAC address (BSSID) is protected by the `ACCESS_WIFI_STATE` permission. In Section 2, we exemplified side channels with router MAC addresses being ersatz location data, and discussed the FTC enacting millions of dollars in fines for those engaged in the practice of using this data to deceptively infer users' locations. Android Nougat added a requirement that apps hold an additional location permission to scan for nearby WiFi networks [34]; Android Oreo further required a location permission to get the SSID and MAC address of the connected WiFi network. Additionally, knowing the MAC address of a router allows one to link different devices that share Internet access, which may reveal personal relations by their respective owners, or enable cross-device tracking.

Our analysis revealed two side channels to access the connected WiFi router information: reading the ARP cache and asking the router directly. We found no side channels that allowed for scanning of other WiFi networks. Note that this issue affects *all* apps running on recent Android versions, not just those without the `ACCESS_WIFI_STATE` permission. This is because it affects apps *without* a location permission, and it affects apps *with* a location permission that the user has not granted using the ask-on-first-use controls.

**Reading the ARP Table** The Address Resolution Protocol (ARP) is a network protocol that allows discovering and mapping the MAC layer address associated with a given IP address. To improve network performance, the ARP protocol uses a cache that contains a historical list of ARP entries, *i.e.*, a historical list of IP addresses resolved to MAC address, including the IP address and the MAC address of the wireless router to which the device is connected (*i.e.*, its BSSID).

Reading the ARP cache is done by opening the pseudo file `/proc/net/arp` and processing its content. This file is not protected by any security mechanism, so any app can access and parse it to gain access to router-based geolocation information without holding a location permission. We built a working proof-of-concept app and tested it for Android Pie using an app that requests *no permissions*. We also demonstrated that when running an app that requests both the `ACCESS_WIFI_STATE` and `ACCESS_COARSE_LOCATION` permissions, when those permissions are denied, the app will access the data anyway. We responsibly disclosed our findings to Google in September, 2018.

We discovered this technique during dynamic analysis, when we observed one library using this method in practice: OpenX [57], a company that according to their website "creates programmatic marketplaces where premium publishers and app developers can best monetize their content by connecting with leading advertisers that value their audiences." OpenX's SDK code was not obfuscated and so we observed that they had named the responsible function

Table 2: SDKs seen sending router MAC addresses and also containing code to access the ARP cache. For reference, we report the number of apps and a lower bound of the total number of installations of those apps. We do this for all apps containing the SDK; those apps that *do not* have ACCESS\_WIFI\_STATE, which means that the side channel circumvents the permissions system; and those apps which *do* have a location permission, which means that the side channel circumvents location revocation.

SDK Name	Contact Domain	Incorporation Country	Total Prevalance		Wi-Fi Permission		No Location Permission	
			(Apps)	(Installs)	(Apps)	(Installs)	(Apps)	(Installs)
AIHelp	cs30.net	United States	30	334 million	3	210 million	12	195 million
Huq Industries	huq.io	United Kingdom	137	329 million	0	0	131	324 million
OpenX	openx.net	United States	42	1072 million	7	141 million	23	914 million
xiaomi	xiaomi.com	China	47	986 million	0	0	44	776 million
jiguang	jpsh.cn	China	30	245 million	0	0	26	184 million
Peel	peel-prod.com	United States	5	306 million	0	0	4	206 million
Asurion	mysoluto.com	United States	14	2 million	0	0	14	2 million
Cheetah Mobile	cmem.com	China	2	1001 million	0	0	2	1001 million
Mob	mob.com	China	13	97 million	0	0	6	81 million

getDeviceMacAddressFromArp. Furthermore, a close analysis of the code indicated that it would first *try* to get the data legitimately using the permission-protected Android API; this vulnerability is only used after the app has been explicitly denied access to this data.

OpenX did not directly send the MAC address, but rather the MD5 hash of it. Nevertheless, it is still trivial to compute a MAC address from its corresponding hash: they are vulnerable to a brute-force attack on hash functions because of the small number of MAC addresses (*i.e.*, an upper bound of 48 bits of entropy).<sup>4</sup> Moreover, insofar as the router’s MAC address is used to resolve an app user’s geolocation using a MAC-address-to-location mapping, one need only to hash the MAC addresses in this mapping (or store the hashes in the table) and match it to the received value to perform the lookup.

While OpenX was the only SDK that we observed exploiting this side channel, we searched our entire app corpus for the string `/proc/net/arp`, and found multiple third-party libraries that included it. In the case of one of them, `igexin`, there are existing reports of their predatory behaviour [15]. In our case, log files indicated that after `igexin` was denied permission to scan for WiFi, it read `/system/sbin/ip`, ran `/system/bin/ifconfig`, and then ran `cat /proc/net/arp`. Table 2 shows the prevalence of third-party libraries with code to access the ARP cache.

**Router UPnP** One SDK in Table 2 includes another technique to get the MAC address of the WiFi access point: it uses UPnP/SSDP discovery protocols. Three of Peel’s smart remote control apps (`tv.peel.samsung.app`, `tv.peel.smartremote`, and `tv.peel.mobile.app`) connected to `192.168.0.1`, the IP address of the router that was their gateway to the Internet. The router in this configuration was a commodity home router that supports universal plug-and-play; the app requested the `igd.xml` (Internet gateway device configuration) file through

<sup>4</sup>Using commodity hardware, the MD5 for every possible MAC address can be calculated in a matter of minutes [40].

port 1900 on the router. The router replied with, among other manufacturing details, its MAC address as part of its UUID. These apps also sent WiFi MAC addresses to their own servers and a domain hosted by Amazon Web Services.

The fact that the router is providing this information to devices hosted in the home network is not a flaw with Android *per se*. Rather it is a consequence of considering every app on every phone connected to a WiFi network to be on the trusted side of the firewall.

## 4.4 Geolocation

So far our analysis has showed how apps circumvent the permission system to gain access to persistent identifiers and data that can be used to infer geolocation, but we also found suspicious behaviour surrounding a more sensitive data source, *i.e.*, the actual GPS coordinates of the device.

We identified 70 different apps sending location data to 45 different domains without having any of the location permissions. Most of these location transmissions were not caused by circumvention of the permissions system, however, but rather the location data was provided within incoming packets: ad mediation services provided the location data embedded within the ad link. When we retested the apps in a different location, however, the returned location was no longer as precise, and so we suspect that these ad mediators were using IP-based geolocation, though with a much higher degree of precision than is normally expected. One app explicitly used `www.googleapis.com`’s IP-based geolocation and we found that the returned location was accurate to within a few meters; again, however, this accuracy did not replicate when we retested elsewhere [59]. We did, however, discover one genuine side channel through photo EXIF data.

**Shutterfly and EXIF Metadata** We observed that the Shutterfly app (`com.shutterfly`) sends precise geolocation data to its own server (`apcmobile.thislife.com`) without holding a location permission. Instead, it sent photo metadata

from the photo library, which included the phone’s precise location in its exchangeable image file format (EXIF) data. The app actually processed the image file: it parsed the EXIF metadata—including location—into a JSON object with labelled `latitude` and `longitude` fields and transmitted it to their server.

While this app may not be intending to circumvent the permission system, this technique can be exploited by a malicious actor to gain access to the user’s location. Whenever a new picture is taken by the user with geolocation enabled, any app with read access to the photo library (*i.e.*, `READ_EXTERNAL_STORAGE`) can learn the user’s precise location when said picture was taken. Furthermore, it also allows obtaining historical geolocation fixes with timestamps from the user, which could later be used to infer sensitive information about that user.

## 5 Related Work

We build on a vast literature in the field of covert- and side-channel attacks for Android. However, while prior studies generally only reported isolated instances of such attacks or approached the problem from a theoretical angle, our work combines static and dynamic analysis to automatically detect real-world instances of misbehaviours and attacks.

**Covert Channels** Marforio *et al.* [49] proposed several scenarios to transmit data between two Android apps, including the use of UNIX sockets and external storage as a shared buffer. In our work we see that the shared storage is indeed used in the wild. Other studies have focused on using mobile noises [26, 70] and vibrations generated by the phone (which could be inaudible to users) as covert channels [3, 17]. Such attacks typically involve two physical devices communicating between themselves. This is outside of the scope of our work, as we focus on device vulnerabilities that are being exploited by apps and third parties running in user space.

**Side Channels** Spreitzer *et al.* provided a good classification of mobile-specific side-channels present in the literature [74]. Previous work has demonstrated how unprivileged Android resources could be used to infer personal information about mobile users, including unique identifiers [72] or gender [51]. Researchers also demonstrated that it may be possible to identify users’ locations by monitoring the power consumption of their phones [52] and by sensing publicly available Android resources [91]. More recently, Zhang *et al.* demonstrated a sensor calibration fingerprinting attack that uses unprotected calibration data gathered from sensors like the accelerometer, gyroscope, and magnetometer [90]. Others have shown that unprotected system-wide information is enough to infer input text in gesture-based keyboards [72]. Research papers have also reported techniques that leverage

lowly protected network information to geolocate users at the network level [2, 54, 82]. We extend previous work by reporting third-party libraries and mobile applications that gain access to unique identifiers and location information in the wild by exploiting side and covert channels.

## 6 Discussion

Our work shows a number of side and covert channels that are being used by apps to circumvent the Android permissions system. The number of potential users impacted by these findings is in the hundreds of millions. In this section, we discuss how these issues are likely to defy users’ reasonable expectations, and how these behaviours may constitute violations of various laws.

We note that these exploits may not necessarily be malicious and intentional. The Shutterfly app that extracts geolocation information from EXIF metadata may not be doing this to learn location information about the user or may not be using this data later for any purpose. On the other hand, cases where an app contains both code to access the data through the permission system and code that implements an evasion do not easily admit an innocent explanation. Even less so for those containing code to legitimately access the data and then store it for others to access. This is particularly bad because covert channels can be exploited by *any app* that knows the protocol, not just ones sharing the same SDK. The fact that Baidu writes user’s IMEI to publicly accessible storage allows any app to access it without permission—not just other Baidu-containing apps.

### 6.1 Privacy Expectations

In the U.S., privacy practices are governed by the “notice and consent” framework: companies can give *notice* to consumers about their privacy practices (often in the form of a privacy policy), and consumers can *consent* to those practices by using the company’s services. While website privacy policies are canonical examples of this framework in action, the permissions system in Android (or in any other platform) is another example of the notice and consent framework, because it fulfills two purposes: (i) providing transparency into the sensitive resources to which apps request access (notice), and (ii) requiring explicit user consent before an app can access, collect, and share sensitive resources and data (consent). That apps can and do circumvent the notice and consent framework is further evidence of the framework’s failure. In practical terms, though, these app behaviours may directly lead to privacy violations because they are likely to defy consumers’ expectations.

Nissenbaum’s “Privacy as Contextual Integrity” framework defines privacy violations as data flows that defy contextual information norms [55]. In Nissenbaum’s framework, data flows are modeled by senders, recipients, data subjects, data

types, and transmission principles in specific contexts (*e.g.*, providing app functionality, advertising, etc.). By circumventing the permissions system, apps are able to exfiltrate data to their own servers and even third parties in ways that are likely to defy users' expectations (and societal norms), particularly if it occurs after having just denied an app's explicit permission request. That is, regardless of context, were a user to explicitly be asked about granting an app access to personal information and then explicitly declining, it would be reasonable to expect that the data then would not be accessible to the app. Thus, the behaviours that we document in this paper constitute clear privacy violations. From a legal and policy perspective, these practices are likely to be considered deceptive or otherwise unlawful.

Both a recent CNIL decision (France's data protection authority), with respect to GDPR's notice and consent requirements, and various FTC cases, with respect to unfair and deceptive practices under U.S. federal law—both described in the next section—emphasize the notice function of the Android permissions system from a consumer expectations perspective. Moreover, these issues are also at the heart of a recent complaint brought by the Los Angeles County Attorney (LACA) under the California State Unfair Competition Law. The LACA complaint was brought against a popular mobile weather app on related grounds. The case further focuses on the permissions system's notice function, while noting that, “users have no reason to seek [geolocation data collection] information by combing through the app's lengthy [privacy policy], buried within which are opaque discussions of [the developer's] potential transmission of geolocation data to third parties and use for additional commercial purposes. Indeed, on information and belief, the vast majority of users do not read those sections at all” [76].

## 6.2 Legal and Policy Issues

The practices that we highlight in this paper also highlight several legal and policy issues. In the United States, for example, they may run afoul of the FTC's prohibitions against deceptive practices and/or state laws governing unfair business practices. In the European Union, they may constitute violations of the General Data Protection Regulation (GDPR).

The Federal Trade Commission (FTC), which is charged with protecting consumer interests, has brought a number of cases under Section 5 of the Federal Trade Commission (FTC) Act [79] in this context. The underlying complaints have stated that circumvention of Android permissions and collection of information absent users' consent or in a manner that is misleading is an unfair and deceptive act [84]. One case suggested that apps requesting permissions beyond what users expect or what are needed to operate the service were found to be “unreasonable” under the FTC Act. In another case, the FTC pursued a complaint under Section 5 alleging that a mobile device manufacturer, HTC, allowed developers

to collect information without obtaining users' permission via the Android permission system, and failed to protect users from potential third-party exploitation of a related security flaw [81]. Finally, the FTC has pursued cases involving consumer misrepresentations with respect to opt-out mechanisms from tailored advertising in mobile apps more generally [83].

Also in the United States, state-level Unfair and Deceptive Acts and Practices (UDAP) statutes may also apply. These typically reflect and complement the corresponding federal law. Finally, with growing regulatory and public attention to issues pertaining to data privacy and security, data collection that undermines users' expectations and their informed consent may also be in violation of various general privacy regulations, such as the Children's Online Privacy Protection Act (COPPA) [80], the recent California Privacy Protection Act (CCPA), and potentially data breach notification laws that focus on unauthorized collection, depending on the type of personal information collected.

In Europe, these practices may be in violation of GDPR. In a recent landmark ruling, the French data regulator, CNIL, levied a 50 million Euro fine for a breach of GDPR's transparency requirements, underscoring informed consent requirements concerning data collection for personalized ads [25]. This ruling also suggests that—in the context of GDPR's consent and transparency provisions—permission requests serve a key function of both informing users of data collection practices and as a mechanism for providing informed consent [81].

Our analysis brings to light novel permission circumvention methods in actual use by otherwise legitimate Android apps. These circumventions enable the collection of information either without asking for consent or after the user has explicitly refused to provide consent, likely undermining users' expectations and potentially violating key privacy and data protection requirements on a state, federal, and even global level. By uncovering these practices and making our data public,<sup>5</sup> we hope to provide sufficient data and tools for regulators to bring enforcement actions, industry to identify and fix problems before releasing apps, and allow consumers to make informed decisions about the apps that they use.

## 7 Limitations and Future Work

During the course of performing this research, we made certain design decisions that may impact the comprehensiveness and generalizability of this work. That is, all of the findings in this paper represent lower bounds on the number of covert and side channels that may exist in the wild.

Our study considers a subset of the permissions labeled by Google as *dangerous*: those that control access to user identifiers and geolocation information. According to Android's documentation, this is indeed the most concerning and privacy intrusive set of permissions. However, there may be

<sup>5</sup><https://search.appcensus.io/>

other permissions that, while not labeled as *dangerous*, can still give access to sensitive user data. One example is the BLUETOOTH permission; it allows apps to discover nearby Bluetooth-enabled devices, which may be useful for consumer profiling, as well as physical and cross-device tracking. Additionally, we did not examine all of the dangerous permissions, specifically data guarded by content providers, such as address book contacts and SMS messages.

Our methods rely on observations of network transmissions that suggest the existence of such channels, rather than searching for them directly through static analysis. Because many apps and third-party libraries use obfuscation techniques to disguise their transmissions, there may be transmissions that our instrumentation does not flag as containing permission-protected information. Additionally, there may be channels that are exploited, but during our testing the apps did not transmit the accessed personal data. Furthermore, apps could be exposing channels, but never abuse them during our tests. Even though we would not report such behavior, this is still an unexpected breach of Android's security model.

Many popular apps also use certificate pinning [28, 61], which results in them rejecting the custom certificate used by our man-in-the-middle proxy; our system then allows apps to continue without interference. Certificate pinning is reasonable behaviour from a security standpoint; it is possible, however, that it is being used to thwart attempts to analyse and study the network traffic of a user's mobile phone.

Our dynamic analysis uses the Android Exerciser Monkey as a UI fuzzer to generate random UI events to interact with the apps. While in our prior work we found that the Monkey explored similar code branches as a human for 60% of the apps tested [66], it is likely that it still fails to explore some code branches that may exploit covert and side channels. For example, the Monkey fails to interact with apps that require users to interact with login screens or, more generally, require specific inputs to proceed. Such apps are consequently not as comprehensively tested as apps amenable to automated exploration. Future work should compare our approaches to more sophisticated tools for automated exploration, such as Moran et al.'s Crashescope [53], which generates inputs to an app designed to trigger crash events.

Ultimately, these limitations only result in the possibility that there are side and covert channels that we have not yet discovered (*i.e.*, false negatives). It has no impact on the validity of the channels that we did uncover (*i.e.*, there are no false positives) and improvements on our methodology can only result in the discovery of more of these channels.

Moving forward, there has to be a collective effort coming from all stakeholders to prevent apps from circumventing the permissions system. Google, to their credit, have announced that they are addressing many of the issues that we reported to them [33]. However, these fixes will only be available to users able to upgrade to Android Q—those with the means to own a newer smartphone. This, of course, positions privacy as a lux-

ury good, which is in conflict with Google's public pronouncements [58]. Instead, they should treat privacy vulnerabilities with the same seriousness that they treat security vulnerabilities and issue hotfixes to all supported Android versions.

Regulators and platform providers need better tools to monitor app behaviour and hold app developers accountable by ensuring apps comply with applicable laws, namely by protecting users' privacy and respecting their data collection choices. Society should support more mechanisms, technical and other, that empower users' informed decision-making with greater transparency into what apps are doing on their devices. To this end, we have made the list of all apps that exploit or contain code to exploit the side and covert channels we discovered available online [8].

## Acknowledgments

## Abstract

Modern microarchitectures incorporate optimization techniques such as *speculative loads* and *store forwarding* to improve the memory bottleneck. The processor executes the load speculatively before the stores, and forwards the data of a preceding store to the load if there is a potential dependency. This enhances performance since the load does not have to wait for preceding stores to complete. However, the dependency prediction relies on partial address information, which may lead to false dependencies and stall hazards.

In this work, we are the first to show that the dependency resolution logic that serves the speculative load can be exploited to gain information about the physical page mappings. Microarchitectural side-channel attacks such as Rowhammer and cache attacks like Prime+Probe rely on the reverse engineering of the virtual-to-physical address mapping. We propose the SPOILER attack which exploits this leakage to speed up this reverse engineering by a factor of 256. Then, we show how this can improve the Prime+Probe attack by a 4096 factor speed up of the eviction set search, even from sandboxed environments like JavaScript. Finally, we improve the Rowhammer attack by showing how SPOILER helps to conduct DRAM row conflicts deterministically with up to 100% chance, and by demonstrating a double-sided Rowhammer attack with normal user's privilege. The later is due to the possibility of detecting contiguous memory pages using the SPOILER leakage.

## 1 Introduction

Microarchitectural attacks have evolved over the past decade from attacks on weak cryptographic implementations [5] to devastating attacks breaking through layers of defenses provided by the hardware and the Operating System (OS) [52]. These attacks can steal secrets such as cryptographic keys [4, 44] or keystrokes [33]. More advanced attacks can entirely subvert the OS memory isolation to read the memory content from more privileged security domains [35], and to bypass

defense mechanisms such as Kernel Address Space Layout Randomization (KASLR) [11, 17]. Rowhammer attacks can further break the data and code integrity by tampering with memory contents [29, 47]. While most of these attacks require local access and native code execution, various efforts have been successful in conducting them remotely [50] or from within a remotely accessible sandbox such as JavaScript [42].

Memory components such as DRAM [29] and cache [43] are not the only microarchitectural attack surfaces. *Spectre* attacks on the branch prediction unit [30, 38] imply that side channels such as caches can be used as a primitive for more advanced attacks on speculative engines. Speculative engines predict the outcome of an operation before its completion, and they enable execution of the following dependent instructions ahead of time based on the prediction. As a result, the pipeline can maximize the instruction level parallelism and resource usage. In rare cases where the prediction is wrong, the pipeline needs to be flushed resulting in performance penalties. However, this approach suffers from a security weakness, in which an adversary can fool the predictor and introduce arbitrary mispredictions that leave microarchitectural footprints in the cache. These footprints can be collected through the cache side channel to steal secrets.

Modern processors feature further speculative behavior such as *memory disambiguation* and speculative loads [10]. A load operation can be executed speculatively before preceding store operations. During the speculative execution of the load, false dependencies may occur due to the unavailability of physical address information. These false dependencies need to be resolved to avoid computation on invalid data. The occurrence of false dependencies and their resolution depend on the actual implementation of the memory subsystem. Intel uses a proprietary memory disambiguation and *dependency resolution logic* in the processors to predict and resolve false dependencies that are related to the speculative load. In this work, we discover that the dependency resolution logic suffers from an unknown false dependency independent of the 4K aliasing [40, 49]. The discovered false dependency happens during the 1 MB aliasing of speculative memory accesses

which is exploited to leak information about physical page mappings.

The state-of-the-art microarchitectural attacks [25, 45] either rely on knowledge of physical addresses or are significantly eased by that knowledge. Yet, knowledge of the physical address space is only granted with root privileges. Cache attacks such as *Prime+Probe* on the Last-Level Cache (LLC) are challenging due to the unknown mapping of virtual addresses to cache sets and slices. Knowledge about the physical page mappings enables more attack opportunities using the *Prime+Probe* technique. Rowhammer [29] attacks require efficient access to rows within the same bank to induce fast row conflicts. To achieve this, an adversary needs to reverse engineer layers of abstraction from the virtual address space to DRAM cells. Availability of physical address information facilitates this reverse engineering process. In sandboxed environments, attacks are more limited, since in addition to the limited access to the address space, low-level instructions are also inaccessible [18]. Previous attacks assume special access privileges only granted through weak software configurations [25, 34, 55] to overcome some of these challenges. In contrast, SPOILER only relies on simple operations, `load` and `store`, to recover crucial physical address information, which in turn enables Rowhammer and cache attacks, by leaking information about physical pages without assuming any weak configuration or special privileges.

## 1.1 Our Contribution

We have discovered a novel microarchitectural leakage which reveals critical information about physical page mappings to user space processes. The leakage can be exploited by a limited set of instructions, which is visible in all Intel generations starting from the 1<sup>st</sup> generation of Intel Core processors, independent of the OS and also works from within virtual machines and sandboxed environments. In summary, this work:

1. exposes a previously unknown microarchitectural leakage stemming from the false dependency hazards during speculative load operations.
2. proposes an attack, SPOILER, to efficiently exploit this leakage to speed up the reverse engineering of virtual-to-physical mappings by a factor of 256 from both native and JavaScript environments.
3. demonstrates a novel eviction set search technique from JavaScript and compares its reliability and efficiency to existing approaches.
4. achieves efficient DRAM row conflicts and the first *double-sided Rowhammer* attack with normal user-level privilege using the contiguous memory detection capability of SPOILER.

5. explores how SPOILER can track nearby load operations from a more privileged security domain right after a context switch.

## 1.2 Related Work

Kosher et al. [30] and Maisuradze et al. [38] have exploited vulnerabilities in the speculative branch prediction unit. Transient execution of instructions after a fault, as exploited by Lipp et al. [35] and Bulck et al. [52], can leak memory content of protected environments. Similarly, transient behavior due to the lazy store/restore of the FPU and SIMD registers can leak register contents from other contexts [48]. New variants of both Meltdown and Spectre have been systematically analyzed [7]. The Speculative Store Bypass (SSB) vulnerability [21] is a variant of the Spectre attack and relies on the stale sensitive data in registers to be used as an address for speculative loads which may then allow the attacker to read this sensitive data. In contrast to previous attacks on speculative and transient behaviors, we discover a new leakage on the undocumented memory disambiguation and dependency resolution logic. SPOILER is **not** a Spectre attack. The root cause for SPOILER is a weakness in the address speculation of Intel's proprietary implementation of the memory subsystem which directly leaks timing behavior due to physical address conflicts. Existing spectre mitigations would therefore not interfere with SPOILER.

The timing behavior of the 4K aliasing false dependency on Intel processors have been studied [12, 61]. *MemJam* [40] uses this behavior to perform a side-channel attack, and Sullivan et al. [49] demonstrate a covert channel. These works only mention the 4K aliasing as documented by Intel [24], and the authors conclude that the address aliasing check is a two stage approach: Firstly, it uses page offset for the initial guess. Secondly, it performs the final resolution based on the exact physical address. On the contrary, we discover that the undocumented *address resolution* logic performs additional partial address checks that lead to an unknown, but observable aliasing behavior based on the physical address.

Several microarchitectural attacks have been discovered to recover virtual address information and break KASLR by exploiting the Translation Lookaside Buffer (TLB) [22], Branch Target Buffer (BTB) [11] and Transactional Synchronization Extensions (TSX) [27]. Additionally, Gruss et al. [17] exploit the timing information obtained from the `prefetch` instruction to leak the physical address information. The main obstacle to this approach is that the `prefetch` instruction is not accessible in JavaScript, and it can be disabled in native sandboxed environments [62], whereas SPOILER is applicable to sandboxed environments including JavaScript.

Knowledge of the physical address enables adversaries to bypass OS protections [28] and ease other microarchitectural attacks [34]. For instance, the `procfs` filesystem exposes physical addresses [34], and *Huge pages* allocate contiguous

physical memory [25, 36]. *Drammer* [55] exploits the Android *ION memory allocator* to access contiguous memory. However, access to the aforementioned primitives is restricted on most environments by default. We do not have any assumption about the OS and software configuration, and we exploit a hardware leakage with minimum access rights to find virtual pages that have the same least significant 20 physical address bits. *GLitch* [13] detects contiguous physical pages by exploiting row conflicts through the GPU interface. In contrast, our attack does not rely on a specific integrated GPU configuration, and it is widely applicable to any system running on an Intel CPU. We use *SPOILER* to find contiguous physical pages with a high probability and verify it by producing row conflicts. *SPOILER* is particularly helpful for attacks in sandboxed low-privilege environments such as JavaScript, where previous methods require a time-consuming brute forcing of the memory addresses [18, 42, 47].

## 2 Background

### 2.1 Memory Management

The virtual memory manager shares the DRAM across all running tasks by assigning isolated virtual address spaces to each task. The assigned memory is allocated in pages, which are typically 4 kB each, and each virtual page will be stored as a physical page in DRAM through a virtual-to-physical page mapping. Memory instructions operate on virtual addresses, which are translated within the processor to the corresponding physical addresses. The page offset comprising the least significant 12 bits of the virtual address is not translated. The processor only translates the bits in the rest of the virtual address, the virtual page number. The OS is the reference for this translation, and the processor stores the translation results inside the TLB. As a result, repeated translations of the same address are performed more efficiently.

### 2.2 Cache Hierarchy

Modern processors incorporate multiple levels of caches to avoid the DRAM access latency. The cache memory on Intel processors is organized into sets and slices. Each set can store a certain number of lines, where the line size is 64 bytes. The 6 Least Significant Bits (LSBs) of the physical address are used to determine the offset within a line and the remaining bits are used to determine which set to store the cache line in. The number of physical address bits that are used for mapping is higher for the LLC, since it has a large number of sets, e.g., 8192 sets. Hence, the untranslated part of the virtual address bits which is the page offset, cannot be used to index the LLC sets. Instead, higher physical address bits are used. Further, each set of LLC is divided into multiple slices, one slice for each logical processor. The mapping of the physical addresses to the slices uses an undocumented function [26]. When the

processor accesses a memory address, a cache hit or miss occurs. If a miss occurs in all cache levels, the memory line has to be fetched from DRAM. Accesses to the same memory address would be served from the cache unless other memory accesses evict that cache line. In addition, we can use the `clflush` instruction, which follows the same memory access check as other memory operations, to evict our own cache lines from the entire cache hierarchy.

### 2.3 Prime+Probe Attack

In the Prime+Probe attack, the attacker first fills an entire cache set by accessing memory addresses that are mapped to the same set, an *eviction set*. Later, the attacker checks whether the victim program has displaced any entry in the cache set by accessing the eviction set again and measuring the execution time. If this is the case, the attacker can detect congruent addresses, since the displaced entries cause an increased access time. However, finding the eviction sets is difficult due to the unknown translation of virtual addresses to physical addresses. Since an unprivileged attacker has no access to `hugepages` [23] or the virtual-to-physical page mapping such as the `pagemap` file [34], knowledge about the physical address bits greatly speeds up the eviction set search.

### 2.4 Rowhammer Attack

DRAM consists of multiple memory banks, and each bank is subdivided into rows. When the processor accesses a memory location, the corresponding row needs to be activated and loaded into the row buffer. If the processor accesses the same row again, it is called a row hit, and the request will be served from the row buffer. Otherwise, it is called a row conflict, and the previous row will be deactivated and copied back to the original row location, after which the new row is activated. DRAM cells leak charge over time and need to be refreshed periodically to maintain the data. A Rowhammer [29] attack causes cells of a victim row to leak faster by activating the neighboring rows repeatedly. If the refresh cycle fails to refresh the victim row fast enough, that leads to bit flips. Once bit flips are found, they can be exploited by placing any security-critical data structure or code page at that particular location and triggering the bit flip again [16, 47, 60]. The Rowhammer attack requires fast access to the same DRAM cells by bypassing the CPU cache, e.g., using `clflush` [29]. Additionally, cache eviction based on an eviction set can also result in access to DRAM cells when `clflush` is not available [3, 18]. Efficiently building eviction sets may thus also enhance Rowhammer attacks. For a successful Rowhammer attack, it is essential to collocate multiple memory pages within the same bank and adjacent to each other. A number of physical address bits, depending on the hardware configuration, are used to map memory pages to banks [45]. Since the rows are generally placed sequentially within the banks,

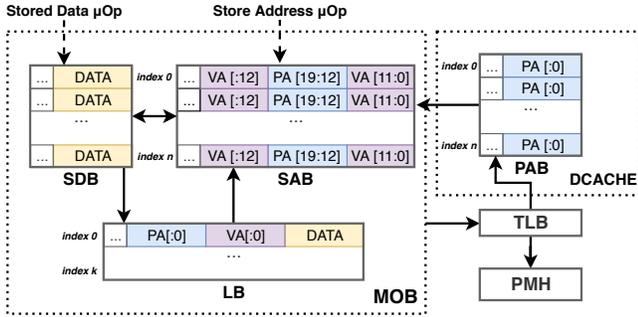

Figure 1: The Memory Order Buffer includes circular buffers SDB, SAB and LB. SDB, SAB and PAB of the DCACHE have the same number of entries. SAB may initially hold the virtual address and the partial physical address. MOB requests the TLB to translate the virtual address and update the PAB with the translated physical address.

access to adjacent rows within the same bank can be achieved if we have access to contiguous physical pages.

## 2.5 Memory Order Buffer

The processor manages memory operations using the Memory Order Buffer (MOB). MOB is tightly coupled with the data cache. The MOB assures that memory operations are executed efficiently by following the Intel memory ordering rule [39] in which memory stores are executed in-order and memory loads can be executed out-of-order. These rules have been enforced to improve the efficiency of memory accesses, while guaranteeing their correct commitment. Figure 1 shows the MOB schematic according to Intel [1, 2]. The MOB includes circular buffers, *store buffer*<sup>1</sup> and *load buffer* (LB). A store will be decoded into two micro ops to store the address and data, respectively, to the store buffer. The store buffer enables the processor to continue executing other instructions before commitment of the stores. As a result, the pipeline does not have to stall for the stores to complete. This further enables the MOB to support out-of-order execution of the load.

Store forwarding is an optimization mechanism that sends the store data to a load if the load address matches any of the store buffer entries. This is a speculative process, since the MOB cannot determine the true dependency of the load on stores based on the store buffer. Intel’s implementation of the store buffer is undocumented, but a potential design suggests that it will only hold the virtual address, and it may include part of the physical address [1, 2, 31]. As a result, the processor may falsely forward the data, although the physical addresses do not match. The complete resolution will be delayed until the load commitment, since the MOB needs to ask

<sup>1</sup>Store buffer consists of *Store Address Buffer* (SAB) and *Store Data Buffer* (SDB). For simplicity, we use *Store Buffer* to mention the logically combined SAB and SDB units.

the TLB for the complete physical address information, which is time consuming. Additionally, the data cache (DCACHE) may hold the translated store addresses in a Physical Address Buffer (PAB) with equal number of entries as the store buffer.

## 3 Speculative Load Hazards

As we mentioned earlier, memory loads can be executed out-of-order and before the preceding memory stores. If one of the preceding stores modifies the content of a location in memory, the memory load address is referring to, out-of-order execution of the load will operate on stale data, which results in invalid execution of a program. This out-of-order execution of the memory load is a speculative behavior, since there is no guarantee during the execution time of the load that the virtual addresses corresponding to the memory stores do not conflict with the load address after translation to physical addresses. Figure 2 demonstrates this effect on a hypothetical processor with 7 pipeline stages. As multiple stores may be blocked due to limited resources, the execution of the load and dependent instructions in the pipeline, the *load block*, will bypass the stores since the MOB assumes the load block to be independent of the stores. This speculative behavior improves the memory bottleneck by letting other instructions continue their execution. However, if the dependency of the load and preceding stores is not verified, the load block may be computed on incorrect data which is either falsely forwarded by store forwarding (false dependency), or loaded from a stale cache line (unresolved true dependency). If the processor detects a false dependency before committing the load, it has to flush the pipeline and re-execute the load block. This will cause observable performance penalties and timing behavior.

### 3.1 Dependency Resolution

Dependency checks and resolution occur in multiple stages depending on the availability of the address information in the store buffer. A load instruction needs to be checked against all preceding stores in the store buffer to avoid false dependencies and to ensure the correctness of the data. A potential design [20, 31],<sup>2</sup> suggests the following stages for the dependency check and resolution, as shown in Figure 3:

1. **Loosenet:** The first stage is the *loosenet* check where the page offsets of the load and stores are compared<sup>3</sup>. In case of a loosenet hit, the compared load and store may be dependent and the processor will proceed to the next check stage.

<sup>2</sup>The implementation of the MOB used in Intel processors is unpublished and therefore we cannot be certain about the precise architecture. Our results agree with some of the possible designs that are described in the Intel patents.

<sup>3</sup>According to `Ld_Blocks_Partial:Address_Alias` Hardware Performance Counter (HPC) event [24], *loosenet* is defined by Intel as the mechanism that only compare the page offsets.

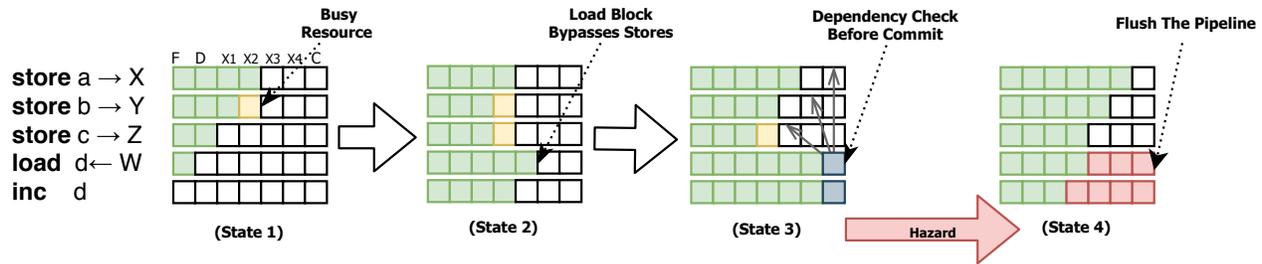

Figure 2: The speculative load is demonstrated on a hypothetical processor with 7 pipeline stages:  $F$  = Fetch,  $D$  = Decode,  $X_{1-4}$  = Executions, and  $C$  = Commit. When the memory stores are blocked competing for resources (State 1), the load will bypass the stores (State 2). The load block including the dependent instructions will not be committed until the dependency of the address  $W$  versus  $X, Y, Z$  are resolved (State 3). In case of a dependency hazard (State 4), the pipeline is flushed and the load is restarted.

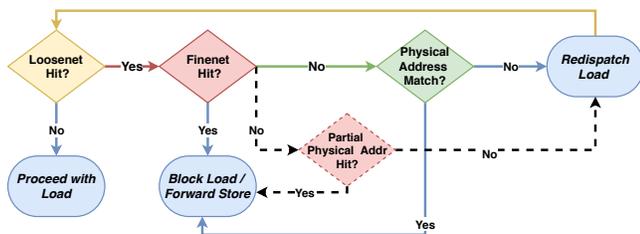

Figure 3: The dependency check logic: *loosenet* initially checks the least 12 significant bits (page offset) and the *finenet* checks the upper address bits, related to the page number. The final dependency using the physical address matching might still fail due to partial physical address checks.

2. **Finenet:** The next stage, called *finenet*, uses upper address bits. The *finenet* can be implemented to check the upper virtual address bits [20], or the physical address tag [31]. Either way, it is an intermediate stage, and it is not the final dependency resolution. In case of a *finenet* hit, the processor blocks the load and/or forwards the store data, otherwise, the dependency resolution will go into the final stage.
3. **Physical Address Matching:** At the final stage, the physical addresses will be checked. Since this stage is the final chance to resolve potential false dependencies, we expect the full physical address to be checked. However, one possible design suggests that if the physical addresses are not available, the physical address matching returns true and continues with the store forwarding [20].

Since the page offset is identical between the virtual and physical address, *loosenet* can be performed as soon as the store is decoded. [2] suggests that the store buffer only holds bit 19 to 12 of the physical address. Although the PAB holds the full translated physical address, it is not clear in which stage this information can be available to the MOB. As a result,

the *finenet* check may be implemented based on checking the partial physical address bits. As we verify later, the dependency resolution logic may fail to resolve the dependency at multiple intermediate stages due to unavailability of the full physical address.

## 4 The SPOILER Attack

The attack model for SPOILER is the same as Rowhammer and cache attacks where the attacker's code is needed to be executed on the same underlying hardware as of the victim. As described in Section 3, speculative loads may face other aliasing conditions in addition to the 4K aliasing, due to the partial checks on the higher address bits. To confirm this, we design an experiment to observe timing behavior of a speculative load based on higher address bits. For this purpose, we propose Algorithm 1 that executes a speculative load after multiple stores and further make sure to fill the store buffer with addresses that cause 4K aliasing during the execution of the load. Having  $w$  as the window size, the algorithm iterates over a number of different memory pages, and for each page, it performs stores to that page and all previous  $w$  pages within a window. Since the size of the store buffer varies between different processor generations, we choose a big enough window ( $w = 64$ ) to ensure that the load has 4K aliasing with the maximum number of entries in the store buffer and hence maximum potential conflicts. Following the stores, we measure the timing of a load operation from a different memory page, as defined by  $x$ . Since we want the load to be executed speculatively, we can not use a store fence such as `m fence` before the load. As a result, our measurements are an estimate of execution time for the speculatively load and nearby microarchitectural events. This may include a negligible portion of overhead for the execution of stores, and/or any delay due to the dependency resolution. If we iterate over a diverse set of addresses with different virtual and physical page numbers, but the same page offset, we should be able to monitor any discrepancy.

Figure 4: SPOILER’s timing measurements and hardware performance counters recorded simultaneously.

## 4.1 Speculative Dependency Analysis

In this section, we use [Algorithm 1](#) and Hardware Performance Counters (HPC) to perform an empirical analysis of the dependency resolution logic. HPCs can keep track of low-level hardware-related events in the CPU. The counters are accessible via special purpose registers and can be used to analyze the performance of a program. They provide a powerful tool to detect microarchitectural components that cause bottlenecks. Software libraries such as Performance Application Programming Interface (PAPI) [51] simplifies programming and reading low-level HPC on Intel processors. Initially, we execute [Algorithm 1](#) for 1000 different virtual pages. [Figure 4\(a\)](#) shows the cycle count for each iteration with a set of 4 kB aliased store addresses. Interestingly, we observe multiple step-wise peaks with a very high latency. Then, we use PAPI to monitor 30 different performance counters listed in [Table 5](#) in the appendix while running the same

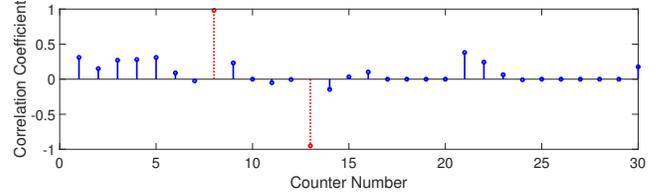

Figure 5: Correlation with HPCs listed in [Table 5](#) in the appendix. `Ld_Blocks_Partial:Address_Alias` and `Cycle_Activity:Stalls_Ldm_Pending` (both dotted red) have strong positive and negative correlations, respectively.

experiment. At each iteration, only one performance counter is monitored alongside the aforementioned timing measurement. After each speculative load, the performance counter value and the load time are both recorded. Finally, we obtain the timings and performance counter value pairs as depicted in [Figure 4](#).

To find any relation between the observed high latency and a particular event, we compute correlation coefficients between counters and the timing measurements. Since the latency only occurs in the small region of the trace where the timing increases, we only need to compute the correlation on these regions. When an increase of at least 200 clock cycles is detected, the next  $s$  values from timing and the HPC traces are used to calculate the correlations, where  $s$  is the number of steps from [Table 1](#) and 200 is the average execution time for a load.

As shown in [Figure 5](#), two events have a high correlation with the leakage: `Cycle_Activity:Stalls_Ldm_Pending` has the highest correlation of 0.985. This event shows the number of cycles for which the execution is stalled and no instructions are executed due to a pending load. `Ld_Blocks_Partial:Address_Alias` has an inverse correlation with the leakage. This event counts the number of false dependencies in the MOB when `loosenet` resolves the 4K aliasing condition. Separately, `Exe_Activity:Bound_on_Stores` increases with more number of stores within the inner window loop in [Algorithm 1](#), but it does not have a correlation with the leakage. The reason behind this behavior is that the store buffer is full, and additional store operations are pending. However, since there is no correlation with the leakage, this shows that the timing behavior is not due to the stores delay. We also attempt to profile any existing counters related to the memory disambiguation. However, the events `Memory_Disambiguation.Success` and `Memory_Disambiguation.Reset` are not available on the modern architectures that are tested.

CPU Model	Architecture	Steps	SB Size

Table 1: 1 MB aliasing on various architectures: The tested AMD and ARM architectures, and Intel Core generation do not show similar effects. The Store Buffer (SB) sizes are gathered from Intel Manual [24] and *wikichip.org* [57–59].

## 4.2 Leakage of the Physical Address Mapping

In this experiment, we evaluate whether the observed step-wise latency has any relationship with the physical page numbers by observing the `pagemap` file. As shown in Figure 6, we observe step-wise peaks with a very high latency which appear once in every 256 pages on average. The 20 least significant bits of physical address for the `load` matches with the physical addresses of the `stores` where high peaks for virtual pages are observed. In our experiments, we always detect peaks with different virtual addresses, which have the matching least 20 bits of physical address. This observation clearly discovers the existence of 1 MB aliasing effect based on the physical addresses. This 1 MB aliasing leaks information about 8 bits of mapping that were unknown to the user space processes.

Matching this observation with the previously observed `Cycle_Activity:Stalls_Ldm_Pending` with a high correlation, the speculative load has been stalled to resolve the dependency with conflicting store buffer entries after the occurrence of a 1 MB aliased address. This observation verifies that the latency is due to the pending load. When the latency is at the highest point, `Ld_Blocks_Partial:Address_Alias` drops to zero, and it increments at each down step of the peak. This implies that the `loosenet` check does not resolve the rest of the store dependencies whenever there is a 1 MB aliased address in the store buffer.

## 4.3 Evaluation

In the previous experiment, the execution time of the `load` operation that is delayed by 1 MB aliasing decreases gradually in each iteration (Figure 6). The number of steps to reach the normal execution time is consistent on the same processor. When the first store in the window loop accesses a memory

address with the matching 1 MB aliased address, the latency is at its highest point, marked as “1” in Figure 6. As the window loop accesses this address later in the loop, it appears closer to the `load` with a lower latency like the steps marked as 5, 15 and 22. This observation matches the *carry chain algorithm* described by Intel [20] where the aliasing check starts from the most recent `store`. As shown in Table 1, experimenting with various processor generations shows that the number of steps has a linear correlation with the size of the store buffer which is architecture dependent. While the leakage exists on all Intel Core processors starting from the first generation, the timing effect is higher for the more recent generations with a bigger store buffer size. The analyzed ARM and AMD processors do not show similar behavior<sup>4</sup>.

As our time measurement for speculative load suggests, it is not possible to reason whether the high timing is due to a very slow `load` or commitment of store operations. If the step-wise delay matches the store buffer entries, this delay may be either due to the dependency resolution logic performing a pipeline flush and restart of the `load` for each 4 kB aliased entry starting from the 1 MB aliased entry, or due to the `load` waiting for all the remaining `stores` to commit because of an unresolved hazard. To explore this further, we perform an additional experiment with all store addresses replaced with non-aliased addresses except for one. This experiment shows that the peak disappears if there is only a single 4 kB and 1 MB aliased address in the store buffer.

Lastly, we run the same experiments on a shuffled set of virtual addresses to assure that the contiguous virtual addresses may not affect the observed leakage. Our experiment with the shuffled virtual addresses exactly match the same step-wise behavior suggesting that the upper bits in virtual addresses do not affect the leakage behavior, and the leakage is solely due to the aliasing on physical address bits.

### 4.3.1 Comparison of Address Aliasing Scenarios

We further test other address combinations to compare additional address aliasing scenarios using Algorithm 1. As shown by Figure 7, when `stores` and the `load` access different cache sets without aliasing, the `load` is executed in 30 cycles, which is the typical timing for an L1 data cache load including the `rdtscp` overhead. When the `stores` have different memory addresses with the same page offset, but the `load` has a different offset, the `load` takes 100 cycles to execute. This shows that even memory addresses in the store buffer having 4K Aliasing conditions with each other that are totally unrelated to the speculative load create a memory bottleneck for the `load`. In the next scenario, 4K aliasing between the `load` and all `stores`, the average load time is about 200 cycles. While the aforementioned 4K aliasing scenarios may leak cross domain information about memory accesses

<sup>4</sup>We use `rdtscp` for Intel and AMD processors and the `clock_gettime` for ARM processors to perform the time measurements.

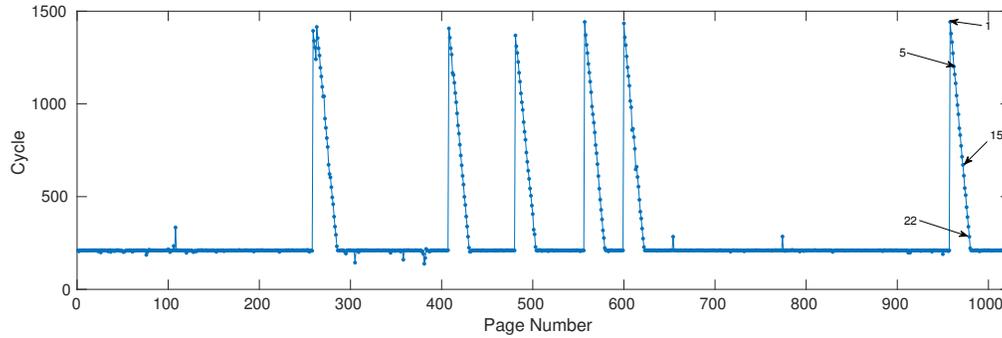

Figure 6: Step-wise peaks with 22 steps and a high latency can be observed on some of the pages (*Core i7-8650U* processor).

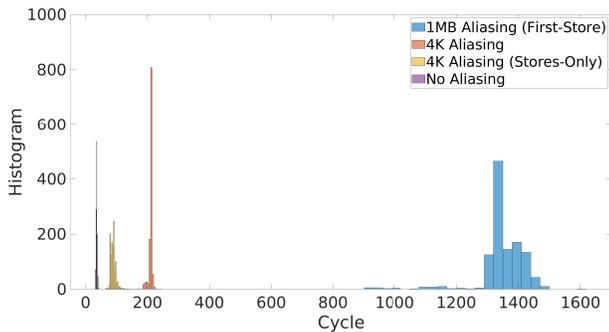

Figure 7: Histogram of the measurement for the speculative load with various store addresses. Load will be fast, 30 cycles, without any dependency. If there exists 4K aliasing only between the stores, the average is 100. The average is 200 when there is 4K aliasing of load and stores. The 1 MB aliasing has a distinctive high latency.

(Section 7), the most interesting scenario is the 1 MB aliasing which takes more than 1200 cycles for the highest point in the peak. For simplicity, we refer to the 1 MB aliased address as *aliased address*, in the rest of the paper.

## 4.4 Discussion

### 4.4.1 The Curious Case of Memory Disambiguation

The processor uses an additional speculative engine, called the *memory disambiguator* [10, 32], to predict memory false dependencies and reduce the chance of their occurrences. The main idea is to predict if a load is independent of preceding stores and proceed with the execution of the load by ignoring the store buffer. The predictor uses a hash table that is indexed with the address of the load, and each entry of the hash table has a saturating counter. If the pre-commitment dependency resolution does not detect false dependencies, the counter is incremented, otherwise it will be reset to zero. After multiple successful executions of the same load instruction, the predictor assumes that the load is safe to execute.

Every time the counter resets to zero, the next iteration of the load will be blocked to be checked against the store buffer entries. Mispredictions result in performance overhead due to pipeline flushes. To avoid repeated mispredictions, a watchdog mechanism monitors the success rate of the prediction, and it can temporarily disable the memory disambiguator.

The predictor of the memory disambiguator should go into a stable state after the first few iterations, since the memory load is always truly independent of any aliased store. Hence the saturating counter for the target speculative load address passes the threshold, and it never resets due to a false prediction. As a result, the memory disambiguator should always fetch the data into the cache without any access to the store buffer. However, since the memory disambiguation performs speculation, the dependency resolution at some point verifies the prediction. The misprediction watchdog is also supposed to only disable the memory disambiguator when the misprediction rate is high, but in this case we should have a high prediction rate. Accordingly, the observed leakage occurs after the disambiguation and during the last stages of dependency resolution, i.e., the memory disambiguator only performs prediction on the 4K aliasing at the initial loosenet check, and it cannot protect the pipeline from 1 MB aliasing that appears at a later stage.

### 4.4.2 Hyperthreading Effect

Similar to the 4K Aliasing [40, 49], we empirically test whether the 1 MB aliasing can be used as a covert/side channel through logical processors. Our observation shows that when we run our experiments on two logical processors on the same physical core, the number of steps in the peaks is exactly halved. This matches the description by Intel [24] where it is stated that the store buffer is split between the logical processors. As a result, the 1 MB aliasing effect is not visible and exploitable across logical cores. [31] suggests that loosenet checks mask out the stores on the opposite thread.

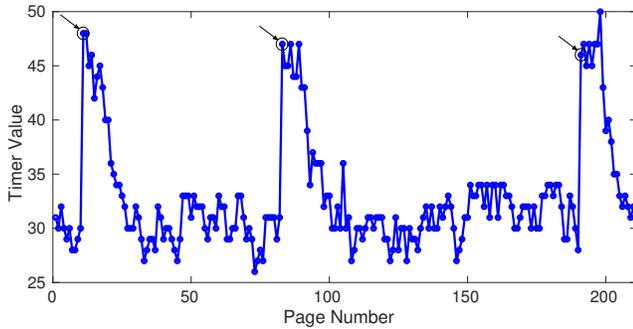

Figure 8: Reverse engineering physical page mappings in JavaScript. The markers point to addresses having same 20 bits of physical addresses being part of the same eviction set.

## 5 SPOILER from JavaScript

Microarchitectural attacks from JavaScript have a high impact as drive-by attacks in the browser can be accomplished without any privilege or physical proximity. In such attacks, collocation is automatically granted by the fact that the browser loads a website with malicious embedded JavaScript code. The browsers provide a sandbox where some instructions like `clflush` and `prefetch` and file systems such as `procfs` are inaccessible, limiting the opportunity for attack. Genkin et al. [14] showed that side-channel attacks inside a browser can be performed more efficiently and with greater portability through the use of *WebAssembly*. Yet, *WebAssembly* introduces an additional abstraction layer, i.e. it emulates a 32-bit environment that translates the internal addresses to virtual addresses of the host process (the browser). *WebAssembly* only uses addresses of the emulated environment and similar to JavaScript, it does not have direct access to the virtual addresses. Using *SPOILER* from JavaScript opens the opportunity to puncture these abstraction layers and to obtain physical address information directly. Figure 8 shows the address search in JavaScript using *SPOILER*. Compared to native implementations, we replace the `rdtscp` measurement with a timer based on a shared array buffer [19]. We cannot use any fence instruction such as `lfence`, and as a result, there remains some negligible noise in the JavaScript implementation. However, the aliased addresses can still be clearly seen, and we can use this information to improve the state-of-the-art eviction set creation for both Rowhammer and cache attacks.

### 5.1 Efficient Eviction Set Finding

We use the algorithm proposed in [14]. It is a slight improvement to the former state-of-the-art brute force method [42] and consists of three phases:

- *expand*: A large pool of addresses  $P$  is allocated with the last twelve bits of all addresses being zero. A random

address is picked as a witness  $t$  and tested against a candidate set  $C$ . If  $t$  is not evicted by  $C$ , it is added to  $C$  and a new witness will be picked. As soon as  $t$  gets evicted by  $C$ ,  $C$  forms an eviction set for  $t$ .

- *contract*: Addresses are subsequently removed from the eviction set. If the set still evicts  $t$ , the next address is removed. If it does not evict  $t$  anymore, the removed address is added back to the eviction set. At the end of this phase, we have a minimal eviction set of the size of the set associativity.
- *collect*: All addresses mapping to the already found eviction set are removed from  $P$  by testing if they are evicted by the found set. After finding 128 initial cache sets, this approach utilizes the linearity property of the cache: For each found eviction set, the bits 6-11 are enumerated instead. This provides 63 more eviction sets for each found set, leading to full cache coverage.

We test this approach on an Intel Core i7-4770 with four physical cores and a shared 8MB 16-way L3 cache with Chromium 68.0.3440.106, Firefox 62 and Firefox Developer Edition 63. The approach yields an 80% accuracy rate to find all 8192 eviction sets when starting with a pool of 4096 pages. The entire eviction set creation process takes an average of 46s. We improve the algorithm by 1) using the addresses removed from the eviction set in the contract phase as a new candidate set and 2) removing more than one address at a time from the eviction set during the contract phase. The improved eviction set creation process takes 35s on average.

#### 5.1.1 Evaluation

The probability of finding a congruent address is  $P(C) = 2^{\gamma-c-s}$ , where  $c$  is the number of bits determining the cache set,  $\gamma$  is the number of bits attackers know, and  $s$  is the number of slices [56]. Since *SPOILER* allows us to control  $\gamma \geq c$  bits, we are only left with uncertainty about a few address bits that influence the slice selection algorithm [26]. In theory, the eviction set search is sped up by a factor of 4096 by using aliased addresses in the pool, since on average one of  $2^8$  instead of one of  $2^{20}$  addresses is an aliased address. Additionally, the address pool is much smaller, where 115 addresses are enough to find all the eviction sets. In native code, the overhead involved in finding the aliased addresses is negligible, less than a second in our experiments. However, in JavaScript, due to the noise, it takes 9s for finding aliased addresses and then 3s for eviction set as compared to the baseline of 46s for classic method in Table 2. Success rate however is 100% with *SPOILER* as compared to 80% for the classic method. Besides, success rate of the classical method can be affected by the availability and consumption of memory on the system.

From each aliased address pool, 4 eviction sets can be found (corresponding to the 4 slices which are the only unknown

Algorithm	$R$	$t_{total}$	$t_{AAS}$	$t_{ESS}$	Success
Classic [42]	3	46s	-	100%	80%
Improved [14]	3	35s	-	100%	80%
AA (ours)	10	10s	54%	46%	67%
AA (ours)	20	12s	75%	25%	100%

Table 2: Comparison of different eviction set finding algorithms on an Intel Core i7-4770. Classic is the method from [42], improved is the same method with slight improvement, *Aliased Address (AA)* uses SPOILER.  $t_{AAS}$  is the time percentage used for finding aliased addresses.  $t_{ESS}$  is the time percentage for finding eviction sets.  $R$  is the number of Rounds.

part in the mapping). These can be enumerated again to form 63 more eviction sets since we still kept the bits 6-11 fixed. To accomplish full cache coverage, the aliased address pool has to be constructed 32 times. The SPOILER variant for finding eviction sets is more susceptible to system noise, which is why it needs more repetitions i.e.  $R$  rounds to get reliable values. On the other hand, it is less prone to values deviating largely from the mean, which is a problem in the classic eviction set creation algorithm. The classic method does not succeed about one out of five times in our experiments, as shown in Table 2. The unsuccessful attempts occur due to aborts if the algorithm takes much longer than statistically expected. As a result, SPOILER can be incorporated in an end-to-end attack such as drive-by key-extraction cache attacks by Genkin et al. [14]. SPOILER increases both speed and reliability of the eviction set finding and therefore the entire attack.

## 6 Rowhammer Attack using SPOILER

To perform a Rowhammer attack, the adversary needs to efficiently access DRAM rows adjacent to a victim row. In a single-sided Rowhammer attack, only one row is activated repeatedly to induce bit flips on one of the nearby rows. For this purpose, the attacker needs to make sure that multiple virtual pages co-locate on the same bank. The probability of co-locating on the same bank is low without the knowledge of physical addresses and their mapping to memory banks. In a double-sided Rowhammer attack, the attacker tries to access two different rows  $n + 1$  and  $n - 1$  to induce bit flips in the row  $n$  placed between them. While double-sided Rowhammer attacks induce bit flips faster due to the extra charge on the nearby cells of the victim row  $n$ , they further require access to contiguous memory pages. In this section, we show that SPOILER can help boosting both single and double-sided Rowhammer attacks by its additional 8-bit physical address information and resulting detection of contiguous memory.

System Model	DRAM Configuration	# of Bits
Dell XPS-L702x (Sandy Bridge)	1 x (4GB 2Rx8)	21
	2 x (4GB 2Rx8)	22
Dell Inspiron-580 (Nehalem)	1 x (2GB 2Rx8) (b)	21
	2 x (2GB 2Rx8) (c)	22
	4 x (2GB 2Rx8) (d)	23
Dell Optiplex-7010 (Ivy Bridge)	1 x (2GB 1Rx8) (a)	19
	2 x (2GB 1Rx8)	20
	1 x (4GB 2Rx8) (e)	21
	2 x (4GB 2Rx8)	22

Table 3: Reverse engineering the DRAM memory mappings using DRAMA tool, # of Bits represents the number of physical address bits used for the bank, rank and channel [45].

### 6.1 DRAM Bank Co-location

DRAMA [45] reverse engineered the memory controller mapping. This requires elevated privileges to access physical addresses from the `pagemap` file. The authors have suggested that prefetch side-channel attacks [17] may be used to gain physical address information instead. SPOILER is an alternative way to obtain partial address information and is still feasible when the `prefetch` instruction is not available, e.g. in JavaScript. In our approach, we use SPOILER to detect aliased virtual memory addresses where the 20 LSBs of the physical addresses match. The memory controller uses these bits for mapping the physical addresses to the DRAM banks [45]. Even though the memory controller may use additional bits, the majority of the bits are known using SPOILER. An attacker can directly hammer such aliased addresses to perform a more efficient single-sided Rowhammer attack with a significantly increased probability of hitting the same bank. As shown in Table 3, we reverse engineer the DRAM mappings for different hardware configurations using the DRAMA tool, and only a few bits of physical address entropy beyond the 20 bits will remain unknown.

To verify if our aliased virtual addresses co-locate on the same bank, we use the row conflict side channel as proposed in [13] (timings in the appendix, Section 10.2). We observe that whenever the number of physical address bits used by the memory controller to map data to physical memory is equal to or less than 20, we always hit the same bank. For each additional bit the memory controller uses, the probability of hitting the same bank is divided by 2 as there is one more bit of entropy. In general, we can formulate that our probability  $p$  to hit the same bank is  $p = 1/2^n$ , where  $n$  is the number of unknown physical address bits in the mapping. We experimentally verify the success rate for the setups listed in Table 3, as depicted in Figure 9. In summary, SPOILER drastically improves the efficiency of finding addresses mapping to the same bank without administrative privilege or reverse engineering the memory controller mapping.

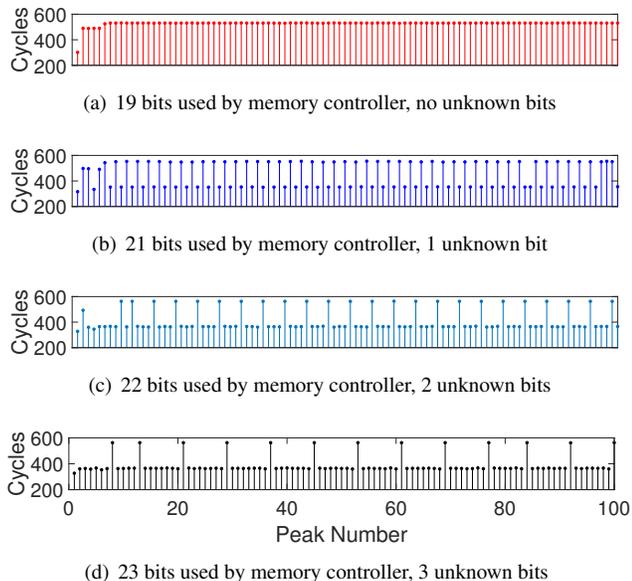

Figure 9: Bank co-location for various DRAM configurations (a), (b), (c) & (d) from Table 3. The regularity of the peaks shows that the allocated memory was contiguous, which is coincidental.

## 6.2 Contiguous Memory

For a double-sided Rowhammer attack, we need to hammer rows adjacent to the victim row in the same bank. This requires detecting contiguous memory pages in the allocated memory, since the rows are written to the banks sequentially. Without contiguous memory, the banks will be filled randomly and we will not be able to locate neighboring rows. We show that an attacker can use SPOILER to detect contiguous memory using 1 MB aliasing peaks. For this purpose, we compare the physical frame numbers to the SPOILER leakage for 10000 different virtual pages allocated using `malloc`. Figure 10 shows the relation between 1 MB aliasing peaks and physical page frame numbers. When the distance between the peaks is random, the trend of frame numbers also change randomly. After around 5000 pages, we observe that the frame numbers increase sequentially. The number of pages between the peaks remains constant at 256 where this distance comes from the 8 bits of physical address leakage due to 1 MB aliasing.

We also compare the accuracy of obtaining contiguous memory detected by SPOILER by analyzing the actual physical addresses from the `pagemap` file. By checking the difference between physical page numbers for each detected virtual page, we can determine the accuracy of our detection method: the success rate for finding contiguous memory is above 99% disregarding the availability of the contiguous pages. For detailed experiment on the availability of the contiguous pages, see Section 10.3 in the appendix.

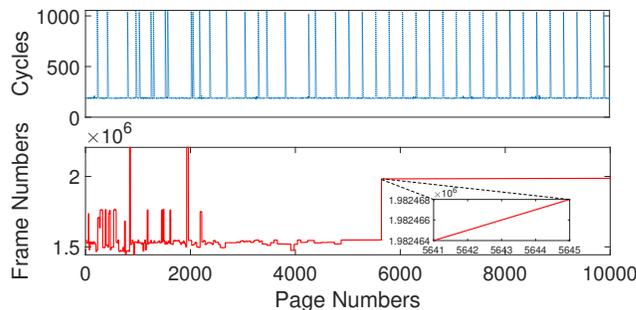

Figure 10: Relation between leakage peaks and the physical page numbers. The dotted plot shows the leakage peaks from SPOILER. The solid plot shows the decimal values of the physical frame numbers from the `pagemap` file. Once the peaks in the dotted plot become regular, the solid plot is linearly increasing, which shows contiguous memory allocation.

## 6.3 Double-Sided Rowhammer with SPOILER

As double-sided Rowhammer attacks are based on the assumption that rows within a bank are contiguous, we mount a practical double-sided Rowhammer attack on several DRAM modules using SPOILER without any root privileges. First, we use SPOILER to detect a suitable amount of contiguous memory. If enough contiguous memory is available in the system, SPOILER finds it, otherwise a double-sided Rowhammer attack is not feasible. In our experiments, we empirically configure SPOILER to detect 10 MB of contiguous memory. Second, we apply the row conflict side channel only to the located contiguous memory, and get a list of virtual addresses which are contiguously mapped within a bank. Finally, we start performing a double-sided Rowhammer attack by selecting 3 consecutive addresses from our list. While we have demonstrated the bit flips in our own process, we can free that memory which can then be assigned to a victim process by using previously known techniques like spraying and memory waylaying [16]. As the bit flips are highly reproducible, we can again flip the same bits in the victim process to demonstrate a full attack. Table 4 shows some of the DRAM modules susceptible to Rowhammer attack.

The native version of Rowhammer in this work is also applicable in JavaScript. The JavaScript-only variant implementation of Rowhammer by Gruss et al. [18], named `rowhammer.js`<sup>5</sup>, can be combined with SPOILER to implement an end-to-end attack. In the original `rowhammer.js`, 2MB huge pages were assumed to get a contiguous chunk of physical memory. With SPOILER, this assumption is no longer required as explained in Section 6.3.

Figure 11 shows the number of hammers compared to the amount of bit flips for configuration (e) in Table 3. We

Table 4: DRAM modules susceptible to double-sided Rowhammer attack using SPOILER.

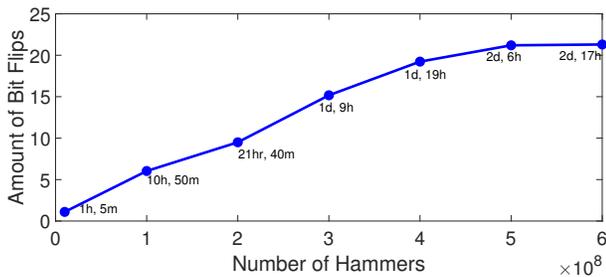

Figure 11: Amount of bit flips increases with the increase in number of hammerings. The timings do not include the time taken for reboots and 1 minute sleep time.

repeat this experiment 30 times for every measurement and the results are then averaged out. On every experiment, the system is rebooted using a script because once the memory becomes fragmented, no more contiguous memory is available. The number of bit flips increases with more number of hammerings. Hammering for 500 million times is found to be an optimal number for this DRAM configuration, as the continuation of hammering is not increasing bit flips.

## 7 Tracking Speculative Loads With SPOILER

Single-threaded attacks can be used to steal information from other security contexts running before/after the attacker code on the same thread [8, 41]. Example scenarios are I) context switches between processes of different users, or II) between a user process and a kernel thread, and III) Intel Software Guard eXtensions (SGX) secure enclaves [41, 54]. In such attacks, the adversary puts the microarchitecture to a particular state, waits for the context switch and execution of the victim thread, and then tries to observe the microarchitectural state after the victim’s execution. We propose an attack where the adversary 1) fills the store buffer with arbitrary addresses, 2) issues the victim context switch and lets the victim perform a secret-dependent memory access, and 3) measures the execution time of the victim. Any correlation between the victim’s

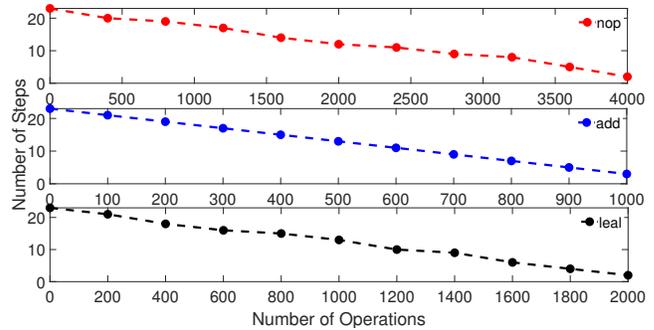

Figure 12: The depth of SPOILER leakage with respect to different instructions and execution units.

timing and the load address can leak secrets [61]. Due to the nature of SPOILER, the victim should access the memory while there are aliased addresses in the store buffer, i.e. if the stores are committed before the victim’s speculative load, there will be no dependency resolution hazard.

We first perform an analysis of the depth of the operations that can be executed between the stores and the load to investigate the viability of SPOILER. In this experiment, we repeat a number of instructions between stores and the load that are free from memory operations. Figure 12 shows the number of stall steps due to the dependency hazard with the added instructions. Although `nop` is not supposed to take any cycle, adding 4000 `nop` will diffuse the timing latency. Then, we test `add` and `leal`, which use the Arithmetic Logic Unit (ALU) and the Address Generation Unit (AGU), respectively. Figure 12 shows that only 1000 `adds` can be executed between the stores and load before the SPOILER effect is lost. Since each `add` typically takes about 1 cycle to execute, this roughly gives a 1000 cycle depth for SPOILER. Considering the observed depth, we discuss potential attacks that can track the speculative load in the following two scenarios.

### 7.1 SPOILER Context Switch

In this attack, we are interested in tracking a memory access in the privileged kernel environment after a context switch. First, we fill the store buffer with addresses that have the same page offset, and then execute a system call. During the execution of the system call, we expect to observe a delayed execution if a secret load address has aliasing with the stores. We utilize SPOILER to iterate over various virtual pages, thus some of the pages have more noticeable latency due to the 1 MB aliasing. We analyze multiple `syscalls` with various execution times. For instance, Figure 13 shows the execution time for `mincore`. In the first experiment (red/1 MB Conflict), we fill the store buffer with addresses that have aliasing with a memory load operation in the kernel code space. The 1 MB aliasing delay with 7 steps suggests that we can track the

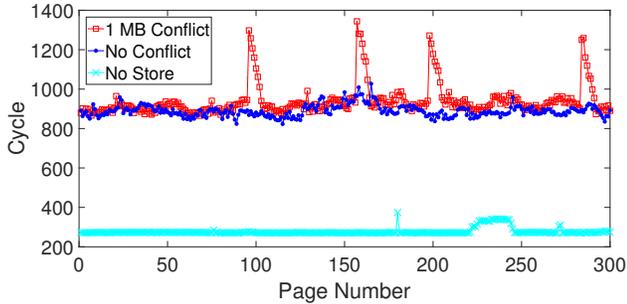

Figure 13: Execution time of `mincore` system call. When a kernel load address has aliasing with the attacker’s stores (red/1MB Conflict), the step-wise delay will appear. These timings are measured with Kernel Page Table Isolation disabled.

address of a kernel memory `load` by the knowledge of our arbitrary filled store addresses. The blue (No Conflict) line shows the timing when there is no aliasing between the target memory `load` and the attackers `store`. Surprisingly, only by filling the store buffer, the system call executes much slower: the normal execution time for `mincore` should be around 250 cycles (cyan/No Store). This proof of concept shows that SPOILER can be used to leak information from more privileged contexts, however this is limited only to `loads` that appear at the beginning of the next context.

## 7.2 Negative Result: SPOILER SGX

In this experiment, we try to combine SPOILER with the *CacheZoom* [41] approach to create a novel single-threaded side-channel attack against SGX enclaves with high temporal and spatial resolution (4-byte) [40]. We use *SGX-STEP* [53] to precisely interrupt every single instruction. *Nemesis* [54] shows that the interrupt handler context switch time is dependent on the execution time of the currently running instruction. On our test platform, *Core i7-8650U*, each context switch on an enclave takes about 12000 cycles to execute. If we fill the store buffer with memory addresses that match the page offset of a `load` inside the enclave in the interrupt handler, the context switch timing is increased to about 13500 cycles. While we cannot observe any correlation between the matched 4 kB or 1 MB aliased addresses, we do see unexpected periodic downward peaks with a similar step-wise behavior as SPOILER (Figure 14). We later reproduce a similar behavior by running SPOILER before an `ioctl` routine that flushes the TLB on each call. Intel SGX also performs an implicit TLB flush during each context switch. We can thus infer that the downward peaks occur due to the TLB flush, especially since the addresses for the downward peaks do not have any address correlation with the `load` address. This suggests that the TLB flush operation itself is affected by SPOILER. This effect eliminates the opportunity to observe any potential cor-

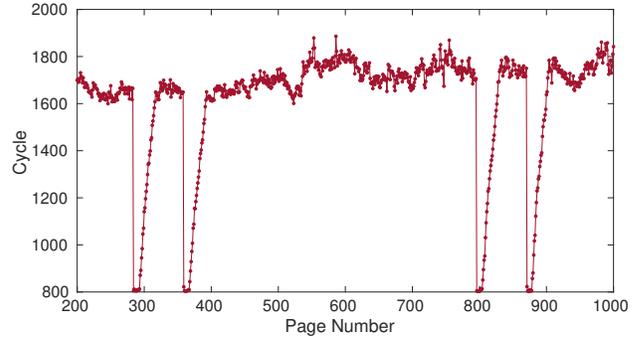

Figure 14: The effect of SPOILER on TLB flush. The execution cycle always increases for 4 kB aliased addresses, except for some of the virtual pages inside in the store buffer where we observe step-wise hills.

relation due to the speculative load. As a result, we can not use SPOILER to track memory accesses inside an enclave. Further exploration of the root cause of the TLB flush effect can be carried out as a future work.

## 8 Mitigations

**Software Mitigations** The attack exploits the fact that when there is a `load` instruction after a number of `store` instructions, the physical address conflict causes a high timing behavior. This happens because of the speculatively executed `load` before all the `stores` are finished executing. There is no software mitigation that can completely erase this problem. While the timing behavior can be removed by inserting store fences between the `loads` and `stores`, this cannot be enforced to the user’s code space, i.e., the user can always leak the physical address information. Another yet less robust approach is to execute other instructions between the `loads` and `stores` to decrease the depth of the attack. However, both of the approaches are only applicable to defend against attacks such as the one described in Section 7.

As for most attacks on JavaScript, removing accurate timers from the browser would be effective against SPOILER. Indeed, some timers have been removed or distorted by jitters as a response to attacks [35]. There is however a wide range of timers with varying precision available, and removing all of them seems impractical [13, 46].

When it is not possible to mitigate the microarchitectural attacks, developers can use dynamic tools to at least detect the presence of such leakage [6, 9, 63]. One of the dynamic approaches is gained by monitoring hardware performance counters in real-time. As explained in Section 4.1, two of the counters `Ld_Blocks_Partial:Address_Alias` and `Cycle_Activity:Stalls_Ldm_Pending` have high correlations with the leakage.

**Hardware Mitigations** The hardware design for the memory disambiguator may be revised to prevent such physical address leakage, but modifying the speculative behavior may cause performance impacts. For instance, partial address comparison was a design choice for performance. Full address comparison may address this vulnerability, but will also impact performance. Moreover, hardware patches are difficult to be applied to legacy systems and take years to be deployed.

## 9 Conclusion

We introduced SPOILER, a novel approach for gaining physical address information by exploiting a new information leakage due to speculative execution. To exploit the leakage, we used the speculative load behavior after jamming the store buffer. SPOILER can be executed from user space and requires no special privileges. We exploited the leakage to reveal information on the 8 least significant bits of the physical page number, which are critical for many microarchitectural attacks such as Rowhammer and cache attacks. We analyzed the causes of the discovered leakage in detail and showed how to exploit it to extract physical address information.

Further, we showed the impact of SPOILER by performing a highly targeted Rowhammer attack in a native user-level environment. We further demonstrated the applicability of SPOILER in sandboxed environments by constructing efficient eviction sets from JavaScript, an extremely restrictive environment that usually does not grant any access to physical addresses. Gaining even partial knowledge of the physical address will make new attack targets feasible in browsers even though JavaScript-enabled attacks are known to be difficult to realize in practice due to the limited nature of the JavaScript environment. Broadly put, the leakage described in this paper will enable attackers to perform existing attacks more efficiently, or to devise new attacks using the novel knowledge. The source code for SPOILER is available on GitHub<sup>6</sup>.

**Responsible Disclosure** We informed the *Intel Product Security Incident Response Team* (iPSIRT) of our findings. iPSIRT thanked for reporting the issue and for the coordinated disclosure. iPSIRT then released the public advisory and CVE. Here is the time line for the responsible disclosure:

- **12/01/2018:** We informed our findings to iPSIRT.
- **12/03/2018:** iPSIRT acknowledged the receipt.
- **04/09/2019:** iPSIRT released public advisory (INTEL-SA-00238) and assigned CVE (CVE-2019-0162).

## Acknowledgments

We thank Yuval Yarom, our shepherd Eric Wustrow and the anonymous reviewers for their valuable comments for improving the quality of this paper.

### 10.2 Row conflict Side Channel

The row conflict side channel retrieves the timing information of the CPU while doing direct accesses (using `clflush`) from the DRAM. A higher timing indicates that the two addresses are mapped to the same bank in the DRAM because reading an address from the same bank forces the row buffer to copy the previous contents back to the original row and then load the newly accessed data into the row buffer. Whereas, a low timings indicates that two addresses are not in the same bank (not sharing the same row buffer) and are loaded into separate row buffers. **Figure 15** shows a wide gap (around 100 cycles) between row hits and row conflicts.

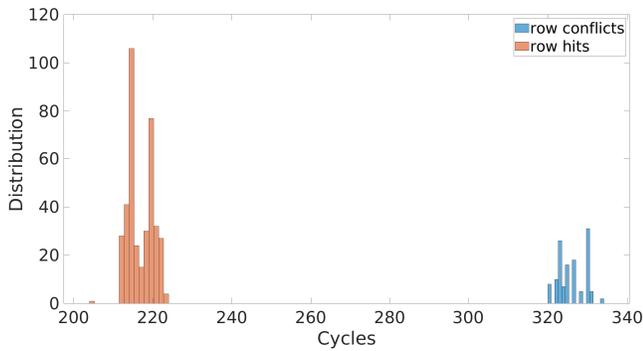

Figure 15: Timings for accessing the aliased virtual addresses (random addresses where 20 LSB of the physical address match). Row hits (orange/low timings) are clearly distinguishable from row conflicts (blue/high timings).

### 10.3 Memory Utilization and Contiguity

The probability of obtaining contiguous memory depends on memory utilization of the system. We conduct an experiment to examine the effect of memory utilization on availability of contiguous memory. In this experiment, 1 GB memory is allocated. During the experiment, the memory utilization of the system is increased gradually from 20% to 90%. We measure the probability of getting the contiguous memory with two methods. The first one is checking the physical frame numbers from `pagemap` file to look for 520 kB of contiguous memory. The second method is using SPOILER to find the 520 kB of contiguous memory. This 520 kB is required to get three consecutive rows within a bank for a DRAM configuration having 256 kB row offset and 8 kB row size.

Figure 16 and Figure 17 show that when the memory has been fragmented after intense memory usage, it gets more difficult to allocate a contiguous chunk of memory. Even decreasing the memory usage does not help to get a contiguous block of memory. Figure 17 depicts that after the memory utilization has been decreased from 70% to 60% and so on, there is not enough contiguous memory to mount a successful double-sided Rowhammer attack. Until the machine is restarted, the memory remains fragmented which makes a double-sided Rowhammer attack difficult, especially on tar-

gets like high-end servers where restarting is impractical.

The observed behavior can be explained by the *binary buddy allocator* which is responsible for the physical address allocation in the Linux OS [15]. This type of allocator is known to fragment memory significantly under certain circumstances [37]. The Linux OS uses a *SLAB/SLOB allocator* in order to circumvent the fragmentation problems. However, the allocator only serves the kernel directly. User space memory therefore still suffers from the fragmentation that the buddy allocator introduces. This also means that getting the contiguous memory required for a double-sided Rowhammer attack becomes more difficult if the system under attack has been active for a while.

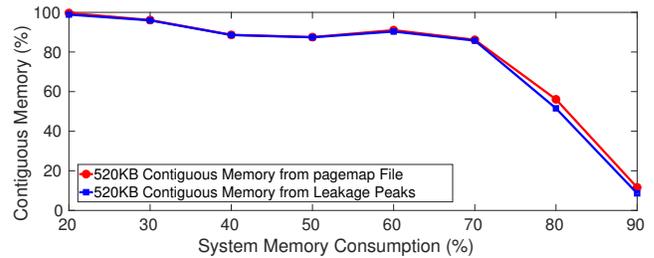

Figure 16: Finding contiguous memory of 520 kB with increasing memory utilization. The overlap between the red and blue plot indicates the high accuracy of the contiguous memory detection capability of SPOILER as verified by the `pagemap` file.

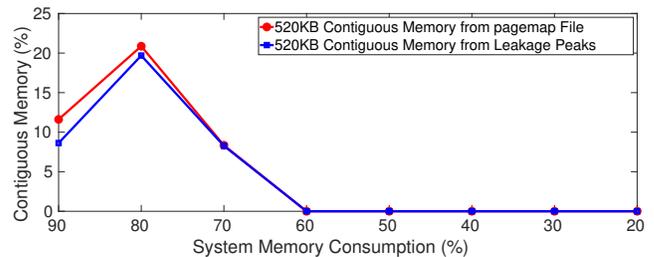

Figure 17: Finding contiguous memory of 520 kB with decreasing memory utilization.

# Robust Website Fingerprinting Through the Cache Occupancy Channel

## Abstract

Website fingerprinting attacks, which use statistical analysis on network traffic to compromise user privacy, have been shown to be effective even if the traffic is sent over anonymity-preserving networks such as Tor. The classical attack model used to evaluate website fingerprinting attacks assumes an *on-path adversary*, who can observe all traffic traveling between the user's computer and the secure network.

In this work we investigate these attacks under a different attack model, in which the adversary is capable of sending a small amount of malicious JavaScript code to the target user's computer. The malicious code mounts a cache side-channel attack, which exploits the effects of contention on the CPU's cache, to identify *other* websites being browsed. The effectiveness of this attack scenario has never been systematically analyzed, especially in the open-world model which assumes that the user is visiting a mix of both sensitive and non-sensitive sites.

We show that cache website fingerprinting attacks in JavaScript are highly feasible. Specifically, we use machine learning techniques to classify traces of cache activity. Unlike prior works, which try to identify cache conflicts, our work measures the overall occupancy of the last-level cache. We show that our approach achieves high classification accuracy in both the open-world and the closed-world models. We further show that our attack is more resistant than network-based fingerprinting to the effects of response caching, and that our techniques are resilient both to network-based defenses and to side-channel countermeasures introduced to modern browsers as a response to the Spectre attack. To protect against cache-based website fingerprinting, new defense mechanisms must be introduced to privacy-sensitive browsers and websites. We investigate one such mechanism, and show that generating artificial cache

activity reduces the effectiveness of the attack and completely eliminates it when used in the Tor Browser.

## 1 Introduction

Over the last decades the World Wide Web has grown from an academic exercise to a communication tool that encompasses all aspects of modern life. Users use the web to acquire information, manage their finances, conduct their social life, and more. This shift to the so called virtual life has resulted in new challenges to users' privacy. Monitoring the online behavior of users may reveal personal or sensitive information about the users, including information such as sexual orientation or political beliefs and affiliations.

Several tools have been developed to protect the online privacy of users and hide information about the websites they visit [18, 20, 71]. Prime amongst these is the Tor network [20], an overlay network of collaborating servers, called *relays*, that anonymously forward Internet traffic between users and web servers. Tor encrypts the network traffic of all of the users, and transmits it between relays in a way that prevents external observers from identifying the traffic of specific users. In addition to the network itself, the Tor Project also provides the *Tor Browser* [82], a modified version of the Mozilla Firefox web browser, that further protects users by disabling features that may allow web sites to track the users.

Past research has demonstrated that encrypting traffic is not sufficient for protecting the privacy of the users [10, 29, 35, 36, 37, 45, 46, 53, 60, 66, 67, 73, 88, 89, 93]. Observable patterns in the metadata of encrypted traffic, specifically, the size of the transmitted data, its direction, and its timing, may reveal the web page that the user is visiting. Applying such *website fingerprinting* techniques to Tor traffic results in a

success rate of over 90% in identifying the websites that a user visits over Tor [73].<sup>1</sup>

In this paper, we focus on an alternative attack model of exploiting micro-architectural side-channels, a less explored option for website fingerprinting. The attack model assumes a victim that visits a web site under the attacker's control. The web site monitors the state of the victim computer's cache, and uses that information to infer the victim's web activity in other tabs of the same browser, or even in other browsers.

Because the attack observes the internal state of the target PC, rather than the network traffic. It offers the potential of overcoming traffic shaping, often proposed as a defense for website fingerprinting [11, 12, 15, 63, 90]. Similarly, the attack may be applicable in scenarios where network-based fingerprinting is known to be less effective, such as when the browser caches the contents of the website [36].

We note that the malicious web site does not need to be fully under the control of the attacker. The attacker only needs to be able to inject JavaScript code via the web site to the victim's browser. This can be done, for example, through a malicious advertisement or pop-up window. Alternatively, documents released by former NSA contractor Edward Snowden indicate that some nation-state agencies have the operational capability to exploit this vector on a wide scale. In March 2013 the German magazine Der Spiegel reported on the existence of a tool called QUANTUMINSERT, which the GCHQ and the NSA could use to inject malicious code to any website [78]. The Der Spiegel claims that the GCHQ successfully used this tool to attack the computers of employees at the partly-government-held Belgian telecommunications company Belgacom, and that the NSA used the same technology to target high-ranking members of the Organization of the Petroleum Exporting Countries (OPEC) at the organization's Vienna headquarters. Finally, malicious advertisements are a viable option for injecting cache side-channel attacks to browsers [28].

For a small number of websites, under the closed-world model, Oren et al. [64] show the possibility of fingerprinting via malicious JavaScript code. However, beyond showing the ability to distinguish between a handful of websites, their work does not provide an analysis of the effectiveness of the technique. Furthermore, following the disclosure of the Spectre and the Meltdown attacks, which can also be potentially delivered via malicious JavaScript injection [48, 57], major vendors deployed defenses against browser-borne side-channel attacks. In particular, all modern browsers have reduced the resolution of the JavaScript time function, `performance.now()`, by several orders of magnitude [69, 87], making it difficult to tell apart cache hits

---

<sup>1</sup> *Website fingerprinting* is a misnomer. Fingerprinting identifies individual web pages rather than sites. Following this misnomer, in this work we use the term *website* to refer to specific pages, typically the homepage of the site.

and cache misses. Traditionally, cache attacks require high-resolution timers, and while mechanisms to generate such timers in web browsers have been published [31, 49, 76], it is not clear that these can be used for website fingerprinting.

Thus, in this paper we ask: *Are cache-based attacks a viable option for website fingerprinting?*

## Our Contribution

We answer this question in the affirmative. We design and implement a cache-based website fingerprinting attack, and evaluate it in both the closed-world and the open-world models. We show that in both models our JavaScript-based attacker achieves high fingerprinting accuracy even when executed on modern mainstream browsers that include all recently introduced countermeasures for side-channel (Spectre) attacks. Even when taking these countermeasures to the extreme, as is done in the Tor Browser, our attack remains effective, although with a drop in accuracy.

Our attack consists of collecting traces of cache *occupancy* while the browser downloads and renders web sites. Adapting the techniques of Rimmer et al. [73], we use deep neural networks to analyze and to classify the collected traces. By focusing on cache occupancy rather than on activity within specific cache sets, our attack avoids the need for high resolution timers required by prior cache-based attacks. Furthermore, because our technique does not depend on the layout of the cache, it can overcome proposed countermeasures that randomize the cache layout [58, 70, 91].

We investigate the source of the information in the cache occupancy traces and show that they contain information from both the networking activity and the rendering activity of the browser. Using information from the rendering activity allows our attack to remain effective even in scenarios that thwart network-based fingerprinting, such as when the browser retrieves data from its response cache and not from the network, or when the network traffic is shaped.

Finally, we investigate a potential countermeasure that introduces a high level of activity into the last level cache. We show that the countermeasure reduces the success rate of the attack. In particular, the noise completely masks the activity of the Tor Browser, reducing the attack accuracy to that of a random guess. This countermeasure results in a mean slowdown of 5% for CPU benchmarks, which we consider reasonable when visiting privacy-sensitive web sites.

More specifically, we make the following contributions:

- We design and implement the cache occupancy side-channel attack, a cache-based side channel attack technique which can operate with the low timer resolution supported in modern JavaScript engines. Our attacks only require a sampling rate six orders of magnitude *lower* than required for the prior attacks of Oren et al. [64] (Section 4).

- We evaluate the use of two machine learning techniques, CNN and LSTM, for fingerprinting websites based on the cache activity traces collected while loaded by the browsers (Section 5).
- We show that cache-based fingerprinting has high accuracy in both the closed- and the open-world models, under a variety of operating systems and browsers (Section 6).
- We evaluate both fingerprinting methods without deleting the browser response cache, and show that while the accuracy of network-based fingerprinting drops significantly, the accuracy of cache-based fingerprinting is not affected (Section 7.3).
- We show that cache-based fingerprints contain information both from the network activity and from the rendering activity of the target device. Therefore, cache-based fingerprinting maintains a high accuracy even in the presence of traffic molding countermeasures which force a constant bit rate on network traffic (Section 7.4).
- We design and evaluate a countermeasure that introduces noise in the cache. The countermeasure is applicable from both native code and from JavaScript, completely blocks the attack on the Tor Browser, and only causes a small performance degradation on CPU-bound workloads (Section 9).

## 2 Background

### 2.1 Tor

Tor [20], is a collection of collaborating servers called *relays*, designed to provide privacy for network communication. Tor aims to protect users from *on-path* adversaries that can observe the network traffic. In this scenario, a user uses a PC to browse the web, and an adversary positioned between the user's PC and the destination web server captures the information that the user exchanges with the web server.

A common protection for such an attack model is to use encryption, e.g., using protocols such as TLS [19] which underlies the security of the HTTPS scheme [72]. However, this solution only protects the contents of the communication, leaving the identity of the communicating parties exposed to the adversary. Knowing that users merely connected to a certain sensitive website may be enough to incriminate them, even if the actual data exchanged over the secure connection is not known. This risk became a reality in 2016, as tens of thousands of individuals were persecuted by the Turkish government for accessing the domain `bylock.net` [50].

The main aim of Tor is thus to protect the identity of the communicating parties. Tor achieves this protection by forwarding the users' communication through a *circuit* consist-

ing of a few (typically three) Tor relays. The user encrypts the network traffic with multiple layers of encryption, and each relay in the circuit decrypts a successive layer to find out where to forward the traffic. See Dingledine et al. [20] for further information.

### 2.2 Website Fingerprinting Attacks and Defences

In the conventional attack model of a network-level attacker, much previous work has demonstrated the ability of an adversary to make probabilistic inferences about users' communications via statistical analysis, even if these communications are in their encrypted form. These works have investigated both the selection of features (such as packet sizes, packet timings, direction of communication), as well as the design of classifiers (such as support vector machines, random forests, Naive Bayes) to make accurate predictions [10, 29, 35, 36, 37, 45, 46, 53, 60, 66, 67, 73, 88, 89, 93]. In response, several defense mechanisms have been proposed in the literature [11, 12, 15, 63, 90]. The common idea behind these defenses is to inject random delays and spurious cover traffic to perturb the traffic features and therefore obfuscate users' communications. A common point of all of these defenses is a typical trade-off between latency/bandwidth and privacy, and thus they face deployment hurdles. Rimmer et al. [73] have recently proposed a family of classifiers based on deep learning algorithms such as SDAE, CNN and LSTM, which operate on the raw network traces and are therefore less sensitive to ad-hoc defenses against particular traffic features.

### 2.3 Cache Side-Channel Attacks

When programs execute on a processor, they share the use of micro-architectural components such as the cache. This sharing may result in unintended communication channels, often called *side channels*, between programs [27, 39], which may be used to leak secret information. In particular, cache-based attacks, which exploit contention on one of the processor's caches, can leak secrets such as cryptographic keys [4, 26, 65, 68, 83], keystrokes [32], address layout [23, 31, 33], etc.

**Cache Operation.** Caches bridge the speed gap between the faster processor and the slower memory. The cache is a small bank of memory, which stores the contents of recently accessed memory locations. Most caches in modern processors are *set associative*. The cache is divided into partitions called *sets*. Each memory location maps to a single set and can only be cached in the set it maps to. When the processor needs to access a specific memory location, it successively searches in a hierarchy of caches. In a *cache hit*, when the contents of the required address is found in the cache, access is performed on the cached contents. Otherwise, in a *cache*

miss, the process repeats on the next cache level. A miss on the last-level cache (LLC) results in a time-consuming access to the RAM.

**The Prime+Probe Technique.** Past cache-based attacks from web browsers [28, 64] employ the *Prime+Probe* technique [65, 68], which exploits the set-associative structure. Each round of attack consists of three steps. In the first step, the cache is *primed*, i.e., the attacker completely fills some of the cache sets with its own data. The attacker then waits some time to allow the victim to execute. Finally, the attacker *probes* the cache by measuring the time it takes to access the previously-cached data in each of the sets. If the victim accesses memory locations that map to a monitored cache set, the victim’s memory contents will replace the attacker contents in the cache. Hence, the attacker will need to retrieve the data from lower levels in the hierarchy, increasing the access time to its data. Prime+Probe has been used for attacks on data [65, 68] and instruction [3, 4] caches, as well as for attacks on the LLC [43, 59]. It has been shown practical in multiple settings, including across different virtual machines in cloud environments [40] and from mobile code [28, 64].

**Countermeasures in JavaScript.** The time difference between the latencies of a memory access and cache access is on the order of  $0.1 \mu\text{s}$ . To distinguish between cache hits and misses, cache attacks typically require a high resolution timer. Following the publication of the first demonstration of a cache attack in JavaScript [64], some browsers started reducing the resolution of the timers they provide as a countermeasure for cache side channel attacks. This approach had become wide-spread after the disclosure of the Spectre attack [48], and now all mainstream browsers incorporate this countermeasure. Furthermore, while non-traditional timers in browsers have been identified [25, 49, 76], browsers and extensions have since disabled many of the features that allow sub-microsecond resolution [61, 69, 77]. An extreme case of this behavior can be found in the Tor Browser, which restricts the timer resolution to 100 ms, or 10 Hz.

Several of the previously discovered timers rely on browser features that are accessible from JavaScript. These are not accessible in environments such as Cloudflare Workers [7], which rely on the absence of high-resolution timers to protect against timing attacks [85].

## 2.4 Related Work

Several past works have looked at the possibility of performing website fingerprinting based on local side-channel information. In all of these works, which we survey in Table 1, the adversary observes some property of the system while the victim browser is rendering a webpage. The adversary then applies a machine learning classifier to the observed side-channel trace to identify the rendered website.<sup>2</sup> Some

<sup>2</sup> A different but closely related class of attacks are “history sniffing” attacks, such as [54, 92], in which the attacker wishes to learn which websites

of these works assume that the adversary has malicious control over a hardware component or peripheral [16, 56, 94]. Others assume that the adversary can execute arbitrary native code on the target hardware [34, 44, 51, 80]. Yet others make the much more modest assumption that the adversary can induce the victim to render a webpage containing malicious JavaScript code [8, 47, 64, 86]. We mainly investigate the last model.

Kim et al. [47] abuse a data leak in the Chrome implementation of the Quota Management API, which has been since fixed. Our attack, in contrast, is based on a fundamental property of the CPU running the browser application, which is far less trivial to fix. (See Section 9.) Moreover, the mitigations put in place as part of the response to the Spectre and Meltdown disclosures make the high sampling rates exploited thus far [64, 86] unattainable in modern secure browsers. Our attack, in contrast, achieves high accuracy at drastically lower sampling rates and is capable of classifying a significant number of websites at sampling rates as low as 10 Hz. To the best of our knowledge, no cache attack that uses such low clock resolutions has been demonstrated.

In addition, Oren et al. [64] only recorded a small number of traces from a few popular websites, and did not investigate the effectiveness of cache-based fingerprinting in open-world contexts, or in scenarios where various anti-fingerprinting measures are in place. We address all of these shortcomings in this work. Furthermore, while Oren et al. [64] do target the Tor Browser, the attack code executes in a different mainstream browser. Unlike our work, they do not demonstrate an attack from JavaScript code running within the Tor Browser.

Booth [8] is able to classify a moderate amount of websites using a non-cache-based method with a millisecond clock. Their attack, however, saturates all of the victim’s CPU cores with math-intensive worker threads, making it highly noticeable and easy to detect by the victim.

Cock et al. [17] implement a covert channel using an L1 cache occupancy channel. Ristenpart et al. [74] show that a cache occupancy channel can detect keystroke timing and network load in co-located virtual machines on cloud servers. Both use the technique with high resolution (sub nanosecond) timers. We are not aware of any prior use of the cache occupancy channel to overcome low resolution timers.

## 3 The Website Fingerprinting Attack Model

The classical attack model used to evaluate website fingerprinting attacks is presented in Figure 1. In this model, a targeted user uses a web browser to display a sensitive website. To protect their privacy, the user does not connect to the website directly, but instead uses a secure network, such as the Tor network, for the connection. The attacker is typ-

the victim has visited in the **past**.

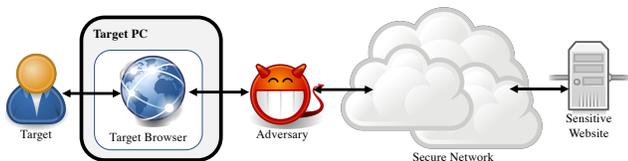

Figure 1: The classical website fingerprinting attack model. The (passive) adversary monitors the traffic between the target user and the secure network.

ically modeled as an *on-path adversary*, who is capable of observing all traffic entering and leaving the Tor network in the direction of the target user. The adversary cannot understand the contents of the network traffic since it is encrypted when it enters the Tor network. The adversary is furthermore unable to directly determine the ultimate destination of the communications after it exits the Tor network, thanks to Tor’s routing protocol. Finally, due to the encryption and the validation of the Tor network, the attacker is unable to modify the traffic without terminating the connection. An important thread of research on the security of Tor has investigated the ability of such an adversary to perform statistical traffic analysis of encrypted traffic, and then to make probabilistic inferences about users’ communications [10, 35, 36, 37, 45, 46, 53, 60, 66, 67, 73, 88, 89, 93].

Gong et al. [29] suggest a variation on this scheme, in which the attacker remotely probes routers to estimate the load of the network traffic they process and performs the statistical analysis based on this estimated traffic. Jansen et al. [45] suggest another variation in which the attacker monitors the traffic inside the Tor network, rather than monitoring traffic at the network’s edge.

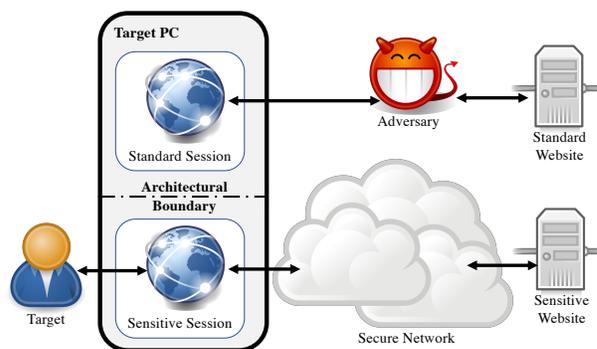

Figure 2: Remote cache-based website fingerprinting attack model. The remote attacker injects malicious JavaScript code into a browser running on the target machine.

In this work we discuss a different attack model, presented in Figure 2. In this model, the target user has two concurrent browsing sessions. In one session, the user browses to

an adversary-controlled site, which contains some malicious JavaScript code. In the other session, the user browses to some sensitive web site. Due to architectural boundaries, such as sandboxing or process isolation, the malicious code cannot directly observe the internal state of the sensitive session. Hence, the adversary cannot directly determine the ultimate destination of *any* communication issued from the sensitive session, even when the sensitive session is using a direct unencrypted connection to the remote server. The malicious code can, however, observe the micro-architectural state of the processor, and use this information to spy on the sensitive session.

Our attack can therefore be considered in the following scenarios:

- A *cross-tab scenario*, where a user is made to visit an attacker-controlled website containing malicious JavaScript, and this website tries to learn what other sensitive sites the user is visiting at the same time. These attacker-controlled and sensitive browsing sessions can be carried out on the same browser, on two different browsers belonging to the same user, or even on two browsers residing in two completely isolated virtual machines which share the same underlying hardware [75].  
One possible way of causing the user to browse to such an attacker-controlled site is through a phishing attack, where the attacker sends fraudulent messages, purporting to be from a benign source, that induces the victim to click on a link to a malicious web site. Alternatively, the attacker may pay an advertisement service to display a (malicious) advertisement when the user visits a third-party website [28].
- A *cross-network scenario*, where the attacker is an active on-path adversary capable of injecting JavaScript into any non-encrypted page. The attacker would like to leverage that access to try to learn about the user's sensitive activity, even though the attacker cannot manipulate or access this traffic directly. For example, the user may simultaneously run one browsing session over an unsecured connection for mundane tasks, and another browsing session over a second, secured connection for sensitive tasks. An attacker capable of modifying traffic on the standard link can learn about activity carried out over the secured link, whether this secure connection made through a VPN, through the Tor network, or even through a separate network adapter which the attacker cannot see.

The main challenge of the our attack model is the extremely restricted JavaScript runtime, which requires the attacker code to be written in a particular way, as we describe further in [Section 4](#).

Regardless of the delivery vector, cache-based fingerprinting has a strong potential advantage over network-based fin-

gerprinting, since it can indirectly observe both the computer's network activity and the browser's rendering process. As we demonstrate in [Section 7.4](#), both of these elements contribute to the accuracy of our classifier.

## 4 Data Collection

### 4.1 Creating memorygrams

The raw data trace for network-based attacks takes the form of a *network trace*, commonly in the `pcap` file format, which contains a timestamped sequence of all traffic observed on a certain network link. The corresponding data trace in the case of cache attacks is the *memorygram* [64]—a trace of the cache access latency measured at a constant sampling rate over a given time period. The memorygrams of Oren et al. [64] describe the latency of multiple individual sets or groups of sets at each point in time, resulting in a two-dimensional array. In contrast, in this work we use a simplified, one-dimensional memorygram form. The contents of each entry in our memorygrams is a proxy for the occupancy of the cache at the specific time period. We collect memorygrams while the browser loads and displays websites, and use the data as fingerprints for website classification.

**The Cache Occupancy Channel.** Unlike prior works [28, 64], which use the Prime+Probe side-channel attack from JavaScript, we use a cache occupancy channel. The main difference is that the Prime+Probe attack measures contentions in specific cache sets, whereas our attack measures contention over the whole cache. Specifically, our JavaScript attack allocates an LLC-sized buffer and measures the time to access the entire buffer. The victim's access to memory evicts the contents of our buffer from the cache, introducing delays for our access. Thus, the time to access our buffer is roughly proportional to the number of cache lines that the victim uses. Cache occupancy has previously been implemented in native code and used for covert channels and for measuring co-resident activity [17, 74]. Both of these implementations rely on high resolution timers. To our knowledge, we are the first to use the cache occupancy channel with a low resolution timer.

**Overcoming Hardware Prefetchers.** Ideally, we would like to collect information across the whole cache. Intel processors, however, try to optimize memory accesses by prefetching memory locations that the processor predicts will be accessed in the future. Because prefetching changes the cache state, we need to fool the prefetchers. To fool the spatial prefetcher [42], we use the technique of Yarom and Benger [96] and do not probe adjacent cache sets. To fool the streaming prefetcher, which tries to identify sequences of cache accesses, we use a common approach of masking access patterns by randomizing the order of the memory accesses we perform [59, 65].

**Spatial Information.** Compared with the Prime+Probe attack, the cache occupancy channel does not provide any spatial information. That is, the adversary does not learn any information on the addresses that the victim accesses. While this is a clear disadvantage of the cache occupancy channel, our attack does not require spatial information. The main reason is that modern browsers have complex memory allocation patterns. Consequently, the location that data is allocated changes each time a page is downloaded, and the location carries little information on the downloaded page. In practice, not having spatial information is also an advantage. Without it, there is no need to build eviction sets for cache sets, a process that can take significant time [28].

**Website Memorygrams.** We capture memorygrams when the browser navigates to websites and displays them. We use a JavaScript-based memorygrammer to probe the cache at a fixed rate of one sample every 2 ms. We continue the probe for 30 seconds, resulting in a vector of length 15,000. When a probe takes longer than 2 ms, we miss the slot of the next probe. We use a special value to indicate this case. We use this collection method for all mainstream browsers other than the Tor Browser,

When the attack code is launched from within the Tor Browser, where the timer resolution is limited to 100 ms, we do not measure how long a sweep over the cache takes, but instead count how many sweeps over the entire cache fit into a single 100 ms timeslot. In addition, we do not probe for 30 seconds in this setting, but rather for 50 seconds, to account for the slower response time over the Tor network. Hence, Tor memorygrams contain 500 measurements over the entire 50 second measurement time period.

The native code memorygrammer used for the evaluations in Section 7 does not suffer from a reduced timing resolution when measuring the Tor Browser. Therefore, on mainstream browsers it runs for 30 seconds and produces 15,000 entries, and on the Tor Browser it runs for 50 seconds and produces 25,000 entries.

**Sanity Check.** Before proceeding, we want to verify that memorygrams can be used for fingerprinting. Indeed, Figure 3 shows graphical representations of memorygrams of three sites: Wikipedia (<https://www.wikipedia.com>), Github (<https://www.github.com>), and Oracle (<https://www.oracle.com>), collected through the native code memorygrammer. Each memorygram is displayed as a colored strip, where time goes from left to right and the shade corresponds to cache activity at each time. (Lighter shades correspond to fewer evictions.) We see that the three memorygrams of each site, while not identical, are similar to each other. The memorygrams of different websites are, however, very different from each other. This indicates that memorygrams may be used for identifying websites.

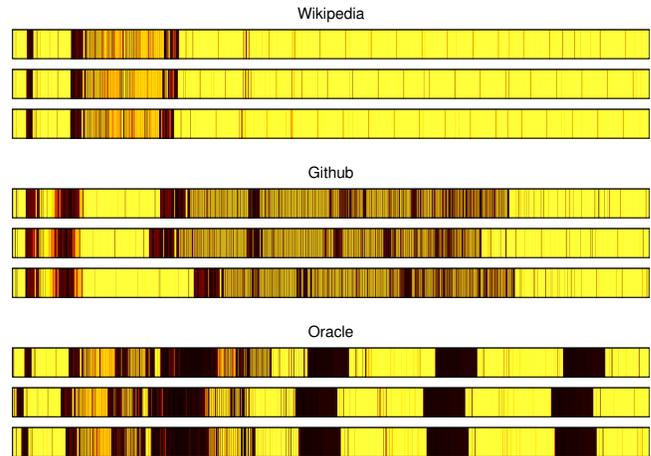

Figure 3: Examples of memorygrams. Time progresses from left to right, shade indicates the number of evictions. (Darker shades correspond to more eviction.)

## 4.2 Datasets

**Closed World Datasets.** We evaluate our cache-based fingerprinting on six different combinations of browsers and operating systems, summarized in Table 2. Many early works on website fingerprinting operated under a *closed world assumption*, where the attacker’s aim is to distinguish among accesses to a relatively small list of websites. Our closed world datasets follow this line of work. These datasets consist of 100 traces each for a set of 100 websites, to a total of 10,000 memorygrams. We use the same list of 100 websites that Rimmer et al. [73] selected from the top Alexa sites. (See Appendix B for a complete list of websites included.) Similar to previous works, no traffic molding is applied and only one tab is opened at a time. The browser’s response cache, however, is not cleared before accessing each website, an aspect of the experiment we analyze in more detail in Section 7.

**Open World Datasets.** One common criticism of the closed world assumption is that it requires the attacker to know the complete set of websites the victim is planning to visit, allowing the attacker to prepare and train classifiers for each of these websites. This assumption was challenged by many authors, for example Juárez et al. [46]. To address this criticism, website fingerprinting methods are often evaluated in an open-world setting. In this setting, the attacker wishes to monitor access to a set of sensitive websites, and is expected to classify them with high accuracy. Additionally, there is a large set of non-sensitive web pages, all of which the attacker is expected to generally label as “non-sensitive”.

To evaluate our fingerprinting method in the open-world settings, we augment the closed-world datasets with additional 5,000 traces, each collected for a single unique web-

site, again using the list of websites provided by Rimmer et al. [73]. The base rate for this setting is 33.3%, since a trivial classifier can simply decide that all pages are non-sensitive.

## 5 Machine Learning

### 5.1 Problem Formulation

Website fingerprinting is generally formulated as a supervised learning problem, consisting of a template building step and an attack step. In the template building step, the adversary visits each target website multiple times and collects a set of labeled traces (either network traces or memorygrams), each corresponding to a visit to a certain website. Next, the adversary trains a classifier algorithm on these labeled traces, using either classical machine learning methods or deep learning methods.

In the attack step, the adversary is presented with a set of unlabeled traces, each one corresponding to a visit to an unknown website. The adversary then applies the previously trained classifier to each of these traces and outputs a guess for each trace. The accuracy of the classifier is finally calculated as the percentage of the correctly assigned labels.

### 5.2 Deep Learning Models

Early works on website fingerprinting, starting from Cheng and Avnur [14], used classical machine learning methods such as Naive Bayes, Support Vector Machine (SVM) and k-Nearest Neighbors (k-NN). As a prerequisite step to running these classical machine learning methods, the adversary needs to apply an additional feature extraction step which transforms the raw trace into a more succinct representation. Since these features were chosen through human insight into the nature of network traffic, there was no immediate way of directly applying them to memorygram analysis.

Abe and Goto [2] and later Rimmer et al. [73] suggest using deep learning for website fingerprinting. Deep learning performs automatic feature learning from the raw data, reducing the reliance on human insight at the cost of a larger required training set. Rimmer et al. [73] show that, given a large enough training set, deep-learning website-fingerprinting approaches are as effective as earlier methods which require manual feature selection. An advantage of this approach is that it allows us to compare network-based and cache-based fingerprinting based on the merit of the raw data, rather than on the specific choice of features.

**Deep Neural Network Configuration.** A deep neural network (DNN) is typically configured as a sequence of non-linear layers which transform the raw data, first extracting salient features and then selecting the appropriate ones [30]. Every layer in a DNN consists of a set of artificial neurons, each connected to a set of outputs from the previous layers. At the forward propagation stage, the activation func-

tion is applied to the product of the each neuron's input and its weight value, and then forwarded to the next layer.

For the last layer in the DNNs we evaluate we use a softmax layer, which outputs a vector containing a-posteriori probabilities for each one of the classes.

The process of training the neural network uses back-propagation to update the weights of each neuron to achieve a minimum loss at the output. First, the model calculates the cost between the true classification of the measurement and the predicted value using a loss function. Next, the model updates the weights of the each neuron based on the calculated loss. Every round of forward propagation and back-propagation is called an epoch. A neural network model runs multiple epochs to learn the weights for accurate classification.

We evaluate deep learning using two classifier models, Convolutional Neural Networks (CNN) and Long Short-Term Memory (LSTM) networks [38]. A CNN uses a sequence of feature mapping layers alternating between convolutions and max-pooling. Each of the layers sub-samples the previous layer, iteratively reducing the size of the input to a more succinct representation, while preserving the information they encode. Each convolutional layer is a neural network specialised for detecting complex patterns in its input. The convolution layer applies several filters to the input vector, each of which is designed to identify an abstract pattern in a sequence of input elements it is provided with. The max-pooling layers reduce the dimensionality of the data by subsampling the filters, choosing the maximum value from adjacent groups of neurons applied by the filters. This alternating sequence of layers extracts complicated features from the input and produces vectors short enough for the classifiers. The feature mapping layers are followed by a *dense* layer, in which every neuron is connected to every output of the feature extraction phase. The LSTM-based network has an initial feature selection step similar to the CNN, but then adds an additional layer in which each neuron has a memory cell, with the output of this neuron determined both by its inputs and by the value of this memory cell. This allows the classifier to identify patterns in time-based data.

**Hyperparameter Selection.** *Hyperparameters* describe the overall structure of the DNN and of each layer. The choice of hyperparameters depends on the specific classification problem. For network-based fingerprinting, we replicated the parameters specified in the dataset provided by Rimmer et al. [73]. For cache-based fingerprinting, we manually evaluated several choices for each hyperparameter.

To prevent overfitting, we use 10-fold cross validation. We split each dataset consisting of traces into 10 folds of equal size, and select one fold, consisting of 10% of the traces, as a *test set*. The remaining 90% of the traces are used for training the classifier, with 81% serving as the *training set* and 9% as the *validation set*. The model trains on the training set and the evaluation is done on the test set. The number of

epochs is regulated with an Early-Stop function which stops the epochs when the accuracy of the validation set no longer increases over successive iterations. The selected hyperparameters are summarized in [Appendix A](#).

For the CNN classifier we use three pairs of convolution and max pooling layers. For the LSTM classifier we use two. As discussed above, the traces captured by the code running within the Tor Browser contain only 500 measurements, due to the reduced timer resolution. For these shorter traces, we modified the architecture of our LSTM-based classifier. The feature selection of this classifier contains only one convolution layer. We therefore used a pool-size of three for the max-pooling layer to limit the feature reduction before the LSTM layer. In addition, because of the small amount of features, we could increase the number of LSTM units to 128 and learn more complex patterns from the features.

## 6 Results

All of the results in this section were obtained by using keras version 2.1.4, with TensorFlow version 1.7 as the back end, running on two Ubuntu Linux 16.04 servers, one with two Xeon E5-2660 v4 processors and 128 GB of RAM, and one with two Xeon E5-2620 v3 processors and 128 GB of RAM. Our machine learning instances took approximately 40 minutes to run in this configuration.

[Table 2](#) presents the fingerprinting accuracy we obtain. Recall that in this scenario the JavaScript interpreter of the targeted browser executes the memorygrammer. Considering that all modern browsers reduced their timer resolution and some added jitter as a countermeasure for the Spectre attack [69, 87], the first question we need to address is whether it is even possible to implement cache-based fingerprinting attacks in such an environment.

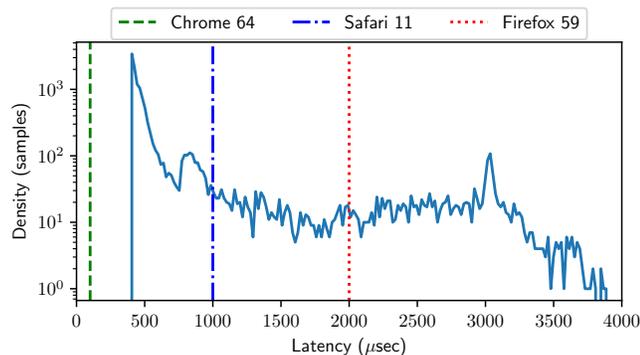

Figure 4: Cache probe latencies compared to modern browser timing resolutions.

To answer this question, we measured the latencies of the cache occupancy channel using a high-resolution timer while the browser was downloading a web page. [Figure 4](#) shows the distribution of these latencies. The figure also uses ver-

tical lines to indicate the timer resolutions of the various browsers. (See [Table 2](#).) As we can see, even at the 2 ms resolution of the Firefox 59 timer, it is possible to distinguish between 80% of the probes which take less than 2 ms and the remaining 20%. This is a welcome side-effect of the use of a large buffer which is accessed at every probing step. None of the cache probes we measured, however, took longer than the 100 ms clock period of the Tor Browser. Hence, when running within the Tor Browser, we count the number of probes we can perform within each clock tick. (See [Section 4](#).)

The next question is whether the information we collect with this low resolution is sufficient for fingerprinting. Indeed, [Table 2](#) shows that in all of the environments we test our classifier is significantly better than a random guess. Remarkably, as our results show, even the highly restricted Tor Browser can be used for mounting cache attacks, albeit with a significantly lower accuracy than that of general-purpose browsers.

### 6.1 Closed World Results

We first look at the typical closed-world scenario investigated by past works. In mainstream browsers, our JavaScript attack code is consistently able to provide classification accuracies of 70–90%, well over the base rate of 1%. The Tor Browser attack, however, achieves a lower accuracy of 47%. If we, however, look not only at the top result output by the classifier, but also check whether the correct website is one of the top 5 detected websites, the accuracy of the Tor Browser attack climbs to 72%, with a base rate of 5%. This method of looking at the few most probable outputs of a classifier was previously used in similar classification problems [13, 62]. With some a-priori information an attacker can deduce which of the top 5 pages the victim has accessed.

We can compare the accuracy of our cache-based fingerprinting to the one obtained by state-of-the-art network-based methods, as reported by Rimmer et al. [73]. We see that while there are differences between the classification accuracy achieved in each case, the overall accuracy is comparable, assuming both attacks capture the same amount of traces per website. As in the network-based setting, we believe that capturing more than 100 traces per website is likely to increase the accuracy and the stability of our classifier.

### 6.2 Open World Results

We next turn to the more challenging open-world scenario, in which the 100 sensitive webpages must be distinguished from an additional set of 5,000 non-sensitive pages. As seen in [Table 2](#) the JavaScript-based website fingerprinting code performs well under this scenario as well, again achieving classification accuracy of 70–90%. We note that in most cases the results are slightly better than the closed-world results. The reason is the larger size of the “non-sensitive”

Table 2: Accuracy obtained by in-browser memorygrammer— Mean (percents) and standard deviation.

Operating System	CPU	LLC Size	Browser	Timer Resolution	Closed World		Open World	
					CNN	LSTM	CNN	LSTM
Linux	i5-2500	6 MB	Firefox 59	2.0 ms	78.5±1.7	80.0±0.6	86.8±0.9	87.4±1.2
Linux	i5-2500	6 MB	Chrome 64	0.1 ms	84.9±0.7	91.4±1.2	84.3±0.7	86.4±0.3
Windows	i5-3470	6 MB	Firefox 59	2.0 ms	86.8±0.7	87.7±0.8	84.3±0.6	87.7±0.3
Windows	i5-3470	6 MB	Chrome 64	0.1 ms	78.2±1.0	80.0±1.6	86.1±0.8	80.6±0.2
Mac OS	i7-6700	8 MB	Safari 11.1	1.0 ms	72.5±0.7	72.6±1.3	80.5±1.0	72.9±0.9
Linux	i5-2500	6 MB	Tor Browser 7.5	100.0 ms	45.4±2.7	46.7±4.1	60.5±2.2	62.9±3.3
Linux	i5-2500	6 MB	Tor Browser 7.5 (top 5)	100.0 ms	71.9±2.1	70.0±1.7	80.4±1.7	82.7±1.8

class. As discussed earlier, this also significantly increases the base rate for open-world scenarios to 33.3%.

As in the case of the closed-world setting, we can evaluate the accuracy of the Tor Browser under a top-5 assumption, i.e. when checking for the correct website in the top five outputs of the classifier. Under this relaxation the Tor Browser attack achieves a high accuracy rate of 83%, with a base rate of 37.3%.

The classification to sensitive vs. non-sensitive site is a binary classification problem. We can, therefore, apply standard analysis techniques to this aspect of the results. We achieved a near perfect classification in all of the open world settings we evaluated, achieving an area under curve (AUC) of more than 99% in all cases.

## 7 Robustness Tests

Having demonstrated the effectiveness of our website fingerprinting technique, we now turn our attention to its robustness and test its resilience to issues known to affect network-based fingerprinting.

### 7.1 Evaluation Setup

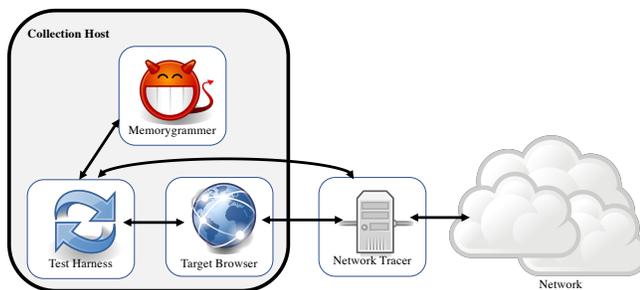

Figure 5: Data Collection Setup for the Robustness Tests.

To compare the results of network fingerprinting with cache-based fingerprinting, we need to modify our data collection setup. The setup, illustrated in Figure 5, consists

of two data collection hosts. The *memorygram collection host*, which simulates the victim’s machine, runs both the target browser and the memorygrammer software. The *network tracer* sits on-path between the memorygram collection hosts and the Internet, and collects a record of the network traffic. A test harness written in Perl and Python invokes the memorygrammer, the network tracer and the target browser at the same time, then saves a correlated data record consisting of the memorygram, the network trace in pcap format, and a screenshot of the target web page for monitoring purposes. For data collection, we use HP Elite 8300 desktop computers featuring Intel Core i5-2500 CPUs at 3.30 GHz, with a 6 MB last-level cache, running CentOS 7.2.1511 and either Firefox 59 or Tor Browser 7.5.

For the robustness tests we use a native-code memorygrammer, which is based on the Prime+Probe implementation of Mastik, a side-channel toolkit released under the GNU Public License [95]. We apply two modifications to the Mastik code. First, we change the Prime+Probe code to measure cache occupancy rather than activity in specific cache sets. Secondly, we use the processor’s performance counters [41] to count the number of cache evictions rather than use the high resolution timer to identify evictions. The use of performance counters for attack purposes has already been proposed and investigated in the past [6, 9, 52, 84].

### 7.2 Baseline Scenario

Our baseline scenario replicates the results of our closed world JavaScript memorygrammer, as well as some of the results of Rimmer et al. [73]. As we can see in Table 3, the native-code memorygrammer gives a slightly better accuracy than the JavaScript memorygrammer on Firefox. When attacking the Tor Browser, the native code memorygrammer achieves much better results than the in-browser JavaScript code. We believe that the cause of the improvement is the higher probing accuracy afforded by the native-code memorygrammer. In both browsers, the results of the native-code memorygrammer are similar to those achievable with network-based fingerprinting.

Table 3: Accuracy obtained in robustness tests — Mean (percents) and Standard deviation.

Test	Firefox Network		Firefox Cache		Tor Network		Tor Cache	
	CNN	LSTM	CNN	LSTM	CNN	LSTM	CNN	LSTM
Baseline	86.4±1.0	93.2±0.5	<b>94.9±0.5</b>	<b>94.8±0.5</b>	77.6±1.6	90.9±0.7	<b>72.7±0.7</b>	<b>80.4±0.5</b>
Response cache enabled	56.1±1.5	70.6±1.5	<b>92.2±0.8</b>	<b>92.2±0.5</b>	55.5±1.7	65.9±1.0	<b>86.1±0.5</b>	<b>86.3±0.6</b>
Render only	—	—	—	—	1.0±0.0	1.0±0.0	<b>63.3±1.1</b>	<b>63.9±1.5</b>
Network only	—	—	—	—	77.6±1.6	90.9±0.7	<b>19.9±1.8</b>	<b>51.9±2.7</b>
Temporal drift	—	—	—	—	64.5±2.2	81.0±0.6	<b>68.3±0.5</b>	<b>75.6±0.7</b>

### 7.3 Enabling the Response Cache

Network-based fingerprinting methods, by definition, must rely on network traffic to perform classification. Typically, due to caching, many web pages are loaded with partial or no network traffic. As specified in RFC 7234 [24], the performance of web browsers is typically improved by the use of response caches. When a web browser client requests a remote resource from a web server, the server can specify that a particular response is cacheable, and the web browser can then store this response locally, either on disk or in memory. When the page is next requested, the web browser can ask the server to send the response only if it has been modified since the last time it was accessed by the client. In the case of a response cache hit, the server only returns a short header instead of the complete remote resource, resulting in a very short network traffic sequence. In some cases, the client can even reuse the cached response without querying the server for a remote copy, resulting in no network traffic at all. Herrmann et al. [36] demonstrate a significant decrease in the accuracy of web fingerprinting when the browser uses the response cache. Indeed, deleting or disabling the browser cache prior to fingerprinting attacks is a common practice [66, 88].

We enable caching of page contents by the browser, and measure the effect on fingerprinting accuracy. In the Firefox browser we simply refrain from clearing the response cache between sessions. For privacy reasons, the response cache in the Tor Browser does not persist across session restarts. Hence, when collecting data on the Tor Browser we “prime” the cache before every recording by opening the web page in another tab, allowing it to load for 15 seconds, then closing the tab.

When we keep the browser’s response cache, the advantage of cache-based website fingerprinting starts to emerge. As Table 3 shows, the accuracy of the standard network-based methods degrades when the response caching is enabled. We can see a degradation in accuracy of over 20% in the fingerprinting accuracy.

In contrast, the cache-based methods are largely unaffected by the reduction in network traffic, achieving high

accuracy rates. This result supports the conclusion that the cache-based detection methods are not simply detecting the CPU activity related to the handling of network traffic, making them essentially a special case of network-based classifiers, but are rather detecting rendering activities of the browser process.

### 7.4 Net-only and Render-only Results

Oren et al. [64] show that cache activity is correlated with network activity, raising the possibility that cache-based fingerprinting basically identifies the level of network activity. To rule out this possibility and show that website rendering also contributes to fingerprinting, we separate rendering (or more precisely, data processing) activity from handling of network data.

**Render-Only Fingerprinting.** To capture the data processing activity, we neutralize the network activity by guaranteeing constant traffic levels. More specifically, we apply molding to the network traffic, ensuring that data flow between the collection host and the network at a fixed bandwidth of 10 KB every 250 ms. To achieve that, we queue data transmitted at a higher rate, or send dummy packets when the transmitted data does not fill the desired bandwidth. These dummy packets are silently dropped by the receiver. The approach is, basically, BuFLO [22], with  $\tau = \infty$ , i.e., when the data stream continues indefinitely. This approach has a high bandwidth overhead compared to WTF-PAD and WT, however, it is designed to ensure that the network traffic is constant irrespective of the contents of the website. As expected, the raw network captures in this scenario all have the exact same size, which happens to be twice as large as the largest network capture recorded without traffic molding.

Because all the traces are identical, the network-based classifier assigns the same class to all of the traces, and its accuracy is the same as a random guess. The results of cache-based fingerprinting show a drop in accuracy compared with unmolded traffic. However, the accuracy is still significantly better than a random guess. This experiment demonstrates the resilience of cache-based website fingerprinting to mitigation techniques aimed at network-based fingerprinting,

and suggests that this privacy threat should be countered using a different class of mitigation techniques, as we explore further in [Section 9](#).

**Network-Only Fingerprinting.** In a complementing experiment, we aim to capture only the network traffic. To collect this dataset, we first capture actual traffic data from a real browsing session. We then use a mock setup, that does not involve a browser at all. Instead, we use two `tcpreplay` [1] instances, one at the collection host, and the other at a server, to emulate the network traffic, by replaying the data from the `pcap` file.

The results for this experiment show that the cache-based classifier is capable of classifying many pages even when no rendering activity is taking place. However, the accuracy is significantly lower than in the case that rendering activity does take place. In particular, our CNN classifier only detects the correct website in about 20% of the cases, significantly lower than the 73% we get for the matching closed-world scenario. (But still much better than the 1% expected for a random guess.) The accuracy of the network-based classifier is the same as for the baseline, simply because the network traffic is replicated.

Combining these two experiments we therefore conclude that cache-based fingerprinting identifies features both in the network traffic patterns and in the actual *contents* of the displayed web pages.

## 7.5 Dealing with Temporal Drift

The accuracy of network-based website fingerprinting decays over time, when the contents of the website changes [73]. Many websites use content management systems (CMS), in which the page layout is based on a fixed template design, and only the resources loaded into this template vary over time. Since, as we have shown, the cache-based fingerprints capture rendering activities as well as network activities, it would seem that the rendering-related traces recorded by the cache-based method would have a longer lifetime, and be more resistant to drift, than the network-related traces captured by the traditional method.

To test this hypothesis, we repeat the data collection of the baseline experiment after a delay of 36 days (start to start). We then measure the ability of both cache-based and network-based classifiers to accurately classify the new traces, after being trained on the old traces. In this setting, we see a drop of 5–10% in the accuracy of both classifiers. We believe that further experiments are required for accurately assessing how cache-based and network-based fingerprinting handle temporal drifts.

## 8 Detecting Unknown Hardware Configurations

In contrast to network-based fingerprinting, which is largely target agnostic, cache-based fingerprinting needs to be tailored to the precise hardware configuration of the victim machine, specifically the set count and associativity of its last-level cache. Using a too large or a too small buffer reduces the effectiveness of the technique, and eventually the accuracy of the classifier. There are, however, not that many popular configurations. For example, four cache configurations (4096 or 8192 sets, 12 or 16 ways) cover most of the Intel Core processor models.

If the target hardware configuration is known beforehand (assuming, for example, that a particular user is singled out for attack) the attacker can customize the parameters of the JavaScript attack code to match the target PC's parameters. It would be interesting, however, to see how well an attacker can remotely determine an unknown target's cache configuration using JavaScript. To investigate this, we created a JavaScript program that allocates a 20MB array in memory and iterates over it in several patterns which should fit in well into different configurations of cache set-counts and associativities. We then recorded the minimum, maximum and mean access time per element, plus the standard deviation, for each of these configurations. We collected 1,350 such measurements from multiple systems with cache sizes of 3 MB, 4 MB, 6 MB, and 8 MB. We then used MATLAB's classification learner tool to apply a variety of machine learning classifiers to the measured data. Using both KNN and SVM classifiers, we were able to correctly classify the configuration of the target's last-level cache with over 99.8% classification accuracy under 5-fold cross validation. Interestingly, even a simple tree-based classifier which compared the minimum iteration time of three different configurations to a predefined threshold was 99.6% accurate. We ported this simple tree-based classifier to JavaScript, creating an LLC cache size detector which we tested and found capable of accurately detecting the cache sizes of 15 different machines with diverse browser, hardware and operating system configurations, taking less than 300 ms to run in all cases. Thus generic attacks that adapt to the specific hardware configuration seem feasible.

## 9 Countermeasures

We now discuss potential countermeasures to our fingerprinting attack. We first describe a cache masking technique we experimented with. We then follow with a review of other cache attack countermeasures suggested in the literature.

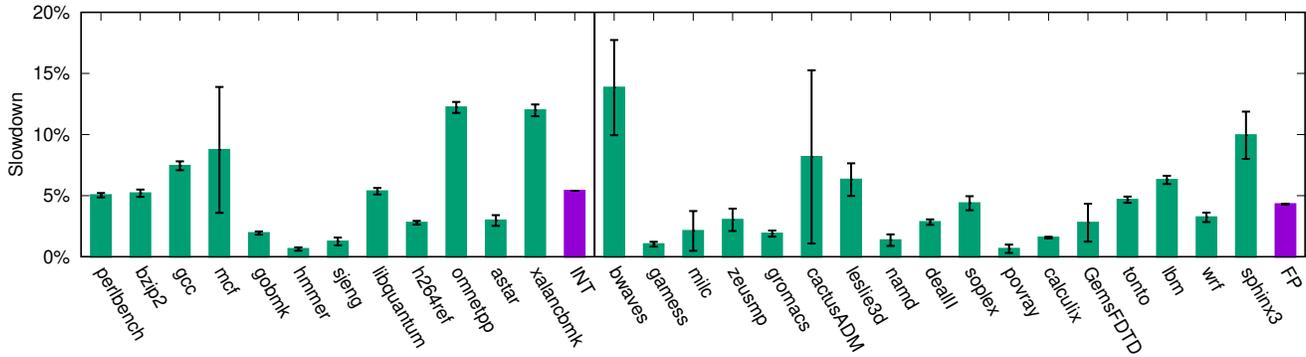

Figure 6: Performance slowdown of our countermeasure on the SPEC benchmark. Error bars indicate one standard deviation. INT and FP show the geometric mean of the SPEC integer and floating point benchmarks, respectively.

## 9.1 Cache Activity Masking

One well-studied mitigation method from the domain of network-based cache fingerprinting involves creating spurious network activity to mask the actual website traffic [22]. It is possible to adapt such a masking technique to our domain and mask the actual website rendering activity by creating spurious activity in the cache. Our initial experiments show that this is a promising mitigation, but further research is needed to assess its effectiveness and its effect on performance and on power consumption.

**Masking implementation.** Our countermeasure repeatedly evicts the entire last-level. More specifically, we allocate a cache-sized buffer and access every cache line in the buffer in a loop. Such masking could be applied in the browser, in the operating system, as a browser plugin, and even incorporated into a security-conscious website in the form of JavaScript delivered to the client. For our initial proof of concept implementation we chose to implement the countermeasure as a standalone native code application, based on a modification of the Mastik side-channel toolkit [95]. This setting allows us to investigate the effectiveness of our countermeasure while leaving deployment complexities for future work.

**Evaluation.** We evaluated this countermeasure on a desktop computer featuring an Intel Core i5-2500, running CentOS Linux version 7.6.1810. We enabled the countermeasure, then collected website traces both for Firefox (Linux) and for the Tor Browser, using the same mix of traces described in Section 4.2—10,000 traces for the closed-world scenario, consisting of 100 traces for each of the Alexa top 100 websites, and 5,000 additional traces for the open-world scenario, each collected for a single unique website. We split the data set into training, testing and validation sets and applied 10-fold cross validation, as described in more detail in Section 5.2.

Our experiments show that the countermeasure com-

pletely thwarts the attack when training is done on an unprotected system—the accuracy of our classifier was at or below the base rate of 1% for the closed-world scenario and 33% for the open-world scenario. We also evaluated a scenario in which the adversary is allowed to train on traces with the countermeasure applied. In this more challenging scenario, the countermeasure completely thwarts the attack when the attack code is running from the Tor Browser. On Firefox, however, we only noticed a moderate reduction in the effectiveness of the attack. In the closed world scenario, the attack achieves 73% success and in the open world the success rate is 77%. (Down from 79% and 86%, respectively.)

**Performance Impact.** To understand the effect that our countermeasure has system performance, we used the industry-standard SPEC CPU benchmark [79], the de-facto standard benchmark for measuring the performance of the CPU and the memory subsystems. Figure 6 shows the results of the SPEC CPU 2006 benchmarks with our countermeasure, relative to no countermeasure. The countermeasure causes a slowdown of around 5% (geometric mean across the benchmarks) with a worst case slowdown of 14% for the bwaves benchmark. These results are from the average of ten executions of the benchmarks for each case. With Tor network performance being as it is, we believe that the performance hit on CPU benchmarks is acceptable for this scenario.

## 9.2 Other Countermeasures

Most of the past research into cache attacks has been done in the context of side-channel cryptanalysis. Due to the different scenario, many of the countermeasures typically suggested for cache-based attack are no longer effective. Techniques such as constant-time programming [5] are only applicable to regular code, typically found in implementations of cryptographic primitives. It is hard to see how such techniques can be applied to web browsers. Similarly, as

this work demonstrates, timer-based defenses that reduce the timer frequency or add jitter are not effective.

Cache randomization techniques [58, 70, 91] dissociate victim and adversary cache sets, and prevent the adversary from monitoring victim access to specific addresses. However, our attack measures the overall cache activity rather than looking at specific victim accesses. As such, such techniques are unlikely to be effective against our attack.

Cache partitioning, either using dedicated hardware [21, 91] or via page coloring [55], is a promising approach for mitigating cache attacks. In a nutshell, the approach partitions the cache between security domains, preventing cross-domain contention. Web pages are often rendered within the same browser process. A page-coloring countermeasure will, therefore, need to adapt to the browser scenario. Alternatively, the current shift to strict site isolation [81] as part of the mitigations for Spectre [48], may assist in applying page coloring to protect against our attack. A further limitation of page coloring is that caches support only a handful of colors. Hence, colors need to be shared, particularly when a large number of tabs are open. To provide protection, page coloring will have to be augmented with a solution that prevents concurrent use of the same color by multiple sites.

CACHEBAR [97] limits the contention caused by each process as a protection for the Prime+Probe attack. Like cache partitioning, this approach works at a process resolution and may require adaptations to work in the web browser scenario. Furthermore, unlike past cryptographic attacks that aim to identify specific memory accesses, our technique measures the overall memory use of the victim. Consequently, unless CACHEBAR is configured to partition the cache, some cross-process contention will remain, allowing our attack to work.

## 10 Limitations and Future Work

While the work demonstrates the feasibility of cache-based website fingerprinting and provides an analysis of the attack, it does leave some areas for further study. Being the first analysis of its kind, the scope of the work does not match the scope of similar works on network-based website fingerprinting. In particular, our datasets are significantly smaller than those of Rimmer et al. [73], for example. Providing larger datasets would allow better analysis of the effectiveness of the technique and would be a beneficial service for the research community as a whole.

In this work we collected the memorygrams on the same hardware configuration used by the victim PC. While we show that we can adapt the data collection to the specific victim hardware (Section 8), at this stage it is not clear how much a classifier trained on data collected with one hardware configuration would be effective for classifying memorygrams collected on a different configuration.

In the network-based website fingerprinting scenario, little to no traffic travels through the network unless the user

is actively fetching a webpage. In the cache-based scenario, however, the cache is always active to a degree, even before the browser starts to receive and render the webpage. Recognizing the start of a trace may therefore be more difficult in the cache-based setting than in the network-based setting, especially in the case of a real attack. Our framework implicitly synchronizes the trace with the start of the download. Due to varying network conditions, we see differences of up to six seconds between trace start and render start. As such, we believe that our technique can identify web sites even without the synchronization. Further experimentation is required, however, to verify this fact. We also note that if the machine is otherwise idle, cache activity can serve as a (slightly noisy) indicator of the start of the trace.

The work further shares many of the limitations of network-based fingerprinting [46]. In particular, websites tend to change over time or based on the identity of the user or the specifications of the computer used for displaying them. Furthermore, our work, like most previous works, assumes that only one website is displayed at each time. Both Rimmer et al. [73] and our work briefly discuss temporal aspects of website fingerprinting, and we also looked a bit into the issue (Section 7.5). However, further work is required to assess the impact of this and other variables on the efficacy of cache-based fingerprinting.

## 11 Conclusions

In this work we investigate the use of cache side channels for website fingerprinting. We implement two memorygrammers, which capture the cache activity of the browser, and show how to use deep learning to identify websites based on the cache activity that displaying them induces.

We show that cache-based website fingerprinting achieves results comparable with the state-of-the-art network-based fingerprinting. We further show that cache-based fingerprinting outperforms network-based fingerprinting under a common operating scenario, where the browser maintains cached objects. Finally, we demonstrate that cache-based fingerprinting is resilient to both traffic molding and to reduced timer resolution. The former being the standard defense for network-based website fingerprinting and the latter the currently implemented countermeasure for mobile-code-based microarchitectural attacks. To the best of our knowledge, this is the first cache-based side channel attack that works with the 100 ms clock rate of the Tor Browser.

## A Selected Hyperparameters

Tables 4, 5, and 6 summarize the hyperparameters for the classifiers used in this work.

Table 4: Hyperparameters for the CNN classifier

Hyperparameter	Value	Space
Optimizer	Adam	Adamax, Adam, SGD, RMSprop
Learning rate	0.001	0.001–0.002
Batch size	100	40–100
Training epoch	20–30	Early stop by accuracy
Convolution layers	3	3–4
Input units (FF)	15000	15000–25000
Input units (Tor)	25000	15000–25000
CNN activation	relu	relu, tanh
Kernels	256	2–512
Kernel size	16,8,4	2–31
Pool size	4	2–8

Table 5: Hyperparameters for the LSTM classifier

Hyperparameter	Value	Space
Optimizer	Adam	Adamax, Adam, SGD, RMSprop
Learning rate	0.001	0.001–0.002
Batch size	100	40–100
Training epoch	20–30	Early stop by accuracy
Convolution layers	2	1–3
Input units (FF)	15000	15000–25000
Input units (Tor)	25000	15000–25000
CNN activation	relu	relu, tanh
LSTM activation	tanh	relu,tanh
Kernels	256	2–512
Kernel size	16,8	2–32
Pool size	4	2–8
Dropout	0.2	0.1–0.2
LSTM units	32	8,32

Table 6: Hyperparameters for the LSTM classifier for the Tor attack

Hyperparameter	Value	Space
Optimizer	Adam	Adamax, Adam, SGD, RMSprop
Learning rate	0.001	0.001–0.002
Batch size	100	40–100
Training epoch	20–30	Early stop by accuracy
Convolution layers	1	1–3
Input units	500	500
CNN activation	relu	relu, tanh
LSTM activation	tanh	relu, tanh
Kernels	256	2–512
Kernel size	32	2–32
Pool size	3	2–8
Dropout	0.4	0.1–0.4
LSTM units	128	8,32,128

## Abstract

Cache-based side channels enable a dedicated attacker to reveal program secrets by measuring the cache access patterns. Practical attacks have been shown against real-world crypto algorithm implementations such as RSA, AES, and ElGamal. By far, identifying information leaks due to cache-based side channels, either in a static or dynamic manner, remains a challenge: the existing approaches fail to offer high precision, full coverage, and good scalability simultaneously, thus impeding their practical use in real-world scenarios.

In this paper, we propose a novel static analysis method on binaries to detect cache-based side channels. We use abstract interpretation to reason on program states with respect to abstract values at each program point. To make such abstract interpretation scalable to real-world cryptosystems while offering high precision and full coverage, we propose a novel abstract domain called the Secret-Augmented Symbolic domain (SAS). SAS tracks program secrets and dependencies on them for precision, while it tracks only coarse-grained public information for scalability.

We have implemented the proposed technique into a practical tool named CacheS and evaluated it on the implementations of widely-used cryptographic algorithms in real-world crypto libraries, including Libgcrypt, OpenSSL, and mbedTLS. CacheS successfully confirmed a total of 154 information leaks reported by previous research and 54 leaks that were previously unknown. We have reported our findings to the developers. And they confirmed that many of those unknown information leaks do lead to potential side channels.

## 1 Introduction

Cache-based timing channels enable attackers to reveal secret program information, such as private keys, by measuring the runtime cache behavior of the victim program. Practical attacks have been executed with different attack scenarios, such as time-based [16, 44], access-based [37, 60, 62], and trace-based [5], each of which exploits a victim program through either coarse-grained or fine-grained monitoring of

cache behavior. Additionally, previous research has successfully launched attacks on commonly used cryptographic algorithm implementations, for example, AES [37, 60, 74, 16], RSA [23, 44, 7, 62, 86], and ElGamal [90].

Pinpointing cache-based side channels from production cryptosystems remains a challenge. Existing research employs either static or dynamic methods to detect underlying issues [77, 32, 33, 41, 82, 22, 81]. However, the methods are limited to low detection coverage, low precision, and poor scalability, which impede their usage in analyzing real-world cryptosystems in the wild.

Abstract interpretation is a well-established framework that can be tuned to balance precision and scalability for static analysis. It models program execution within one or several carefully-designed *abstract domains*, which abstract program concrete semantics by tracking certain program states of interest in a concise representation. Usually, the elements in an abstract domain form a complete lattice of finite height, and the operations of the program concrete semantics are mapped to the abstract transfer functions over the abstract domain. A well-designed abstract interpretation framework can correctly approximate program execution and usually yields a terminating analysis within a finite step of computations. Nevertheless, the art is to carefully design an abstraction domain that fits the problem under consideration, while over-approximating others to bound the analysis to a controllable size; this enables the analysis of non-trivial cases.

We propose a novel abstract domain named the Secret-Augmented Symbolic domain (SAS), which is specifically designed to perform abstract interpretation on *large-scale* secret-aware software, such as real-world cryptosystems. SAS is designed to perform fine-grained tracking of program secrets (e.g., private keys) and dependencies on them, while coarsely approximating non-secret information to speed up the convergence of the analysis.

We implement the proposed technique as a practical tool named CacheS, which models program execution within the SAS and pinpoints cache-based side channels with constraint solving techniques. Like many bug finding tech-

<sup>\*</sup>Most of this work is done while Shuai Wang and Pei Wang were working at PSU.

niques [55, 84, 54], CacheS is soundy [53]; the implementation is unsound for speeding up analysis and optimizing memory usage, due to its lightweight but unsound treatment of memory. However, in contrast to previous studies that analyze only small-size programs, single procedure or single execution trace [32, 33, 77, 22, 81], CacheS is scalable enough to deliver whole program static analysis of real-world cryptosystems without sacrificing much accuracy. We have evaluated CacheS on multiple popular crypto libraries. Although most libraries have been checked by many previous tools, CacheS is able to detect 54 unknown information leakage sites from the implementations of RSA/ElGamal algorithms in three real-world cryptosystems: Libgcrypt (ver. 1.6.3), OpenSSL (ver. 1.0.2k and 1.0.2f), and mbedTLS (ver. 2.5.1). We show that CacheS has good scalability as it largely outperforms previous research regarding coverage; it is able to complete context-sensitive interprocedural analysis of over 295 K lines of instructions within 0.5 CPU hour. In summary, we make the following contributions:

- We propose a novel abstract interpretation-based analysis to pinpoint information leakage sites that may lead to cache-based side channels. We propose a novel abstract domain named **SAS**, which performs fine-grained tracking of program secrets and dependencies, while over-approximating non-secret values to enable precise reasoning in a scalable way.
- Enabled by the “symbolic” representation of abstract values in **SAS**, we facilitate information leak checking in this research with constraint solving techniques. Compared with previous abstract interpretation-based methods, which only reason on the information leakage upper-bound, our technique adequately simplifies the process of debugging and fixing side channels.
- We implement the proposed technique into a practical tool named CacheS and apply it to detect cache-based side channels in real-world cryptosystems. From five popular crypto library implementations, CacheS successfully identified 208 information leakage sites (with only one false positive), among which 54 are unknown to previous research, to the best of our knowledge.

## 2 Background

**Abstract Interpretation.** Abstract interpretation is a well-established framework to perform sound approximation of program semantics [28]. Considering that program concrete semantics forms a value domain  $\mathbf{C}$ , abstract interpretation maps  $\mathbf{C}$  to an abstract (and usually more concise) representation, namely, an abstract domain  $\mathbf{A}$ . The design of the abstraction is usually based on certain program properties of interest, and (possibly infinite) sets of concrete program states are usually represented by one abstract state in  $\mathbf{A}$ . To ensure termination, abstract states could form a lattice with a finite height, and computations of program concrete semantics are mapped into operators over the abstract elements in  $\mathbf{A}$ .

The abstract function ( $\alpha$ ) and concretization function ( $\gamma$ ) need to be defined jointly with an abstract domain  $\mathbf{A}$ . Func-

tion  $\alpha$  lifts the elements in  $\mathbf{C}$  to their corresponding abstract elements in  $\mathbf{A}$ , while  $\gamma$  casts an abstract value to a set of values in  $\mathbf{C}$ . To establish the correctness of an abstract interpretation, the abstract domain and the concrete domain need to form a Galois connection, and operators defined upon elements in an abstract domain are required to form the local and global soundness notions [28].

**Cache Structure and Cache-Based Timing Channels.** A cache is a fast on-CPU data storage unit with a very limited capacity compared to the main memory. Caches are usually organized to be set-associative, meaning that the storage is partitioned into several disjoint sets while each set exclusively stores data of a particular part of the memory space. Each cache set can be further divided into smaller storage units of equal size, namely cache lines. Given the size of each cache line as  $2^L$  bytes, usually the upper  $N - L$  bits of a  $N$ -bit memory address uniquely locate a cache line where the data from that address will be temporally held.

When the requested data is not found in the cache, the CPU will have to fetch them from the main memory. This is called a cache miss and causes a significant delay in execution, compared with fetching data directly from the cache. Therefore, an attacker may utilize the timing difference to reveal the cache access pattern and further infer any information on which this pattern may depend.

**Threat Model.** As mentioned above, some bits of a memory address can be directly mapped to cache lines being visited, which potentially enables information leakage via *secret-dependent memory traffic*. In this research, attackers are assumed to share the same hardware platform with the victim program, and therefore are able to “probe” the shared cache state and infer cache lines being accessed by the victim. As illustrated in Fig. 2, our threat model assumes that the attacker can observe the address of every memory access, expect for the low bits of addresses that distinguish locations in the same cache line. Overall, by tracking the secret-dependent cache access of the victim, several bits of program secrets (w.r.t. entropy) could be leaked to the attacker.

We note that this threat model indeed captures most infamous and practical side channel attacks [39], including prime-and-probe [60], flush-and-reload [86], and prime-and-abort [31], which are designed to infer the cache line access by measuring the latency of the victim program or attacker’s program at different scales and for different attack scenarios. Additionally, while this threat model is aligned with many existing side channel detection works [77, 33, 41, 82, 22], novel techniques proposed in this work enable us to perform scalable static analysis and reveal much more information leaks of real-world cryptosystems.<sup>1</sup> In addition, while this

<sup>1</sup>Consistent with this line of research, CacheS pinpoints information leaks in cryptosystems where cache access depends on secrets. Cryptosystem developers can fix the code with information provided by CacheS. Contrarily, the exploitability of the leaks (e.g., reconstruct the entire key by recovering half bits of the RSA private key [19]) is beyond the scope of this work.

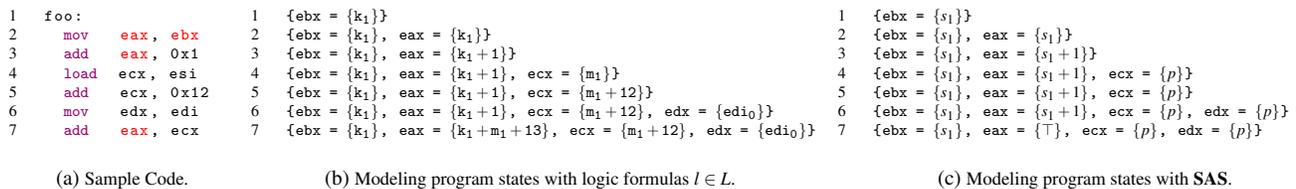

Figure 1: Execute assembly code with different program representations. Program secrets and all the affected registers are marked as red in Fig. 1a. Program states at line 1 of Fig. 1b and Fig. 1c represent the initial state. Here  $k_1$  is a symbol exhibiting one piece of program secrets (e.g., the first element in a key array), and  $m_1$  is a free symbol representing non-secret content of unknown memory cells.  $edi_0$  is a symbol representing the initial value of register  $edi$ . Symbol  $s_1$ ,  $p$ , and  $\top$  defined in SAS stand for one piece of secret, entire non-secret information and all the program information, respectively (see Sec. 4).

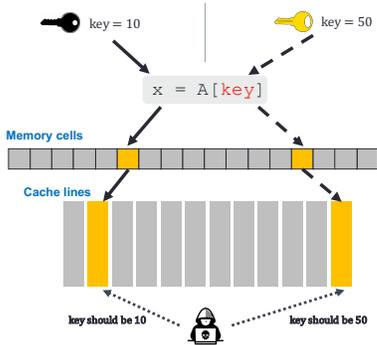

Figure 2: The threat model. Different secrets lead to the access of different cache lines at one particular program point, which may leak secret information to the attackers by indirectly observing cache line access variants. At least one bit information (w.r.t. entropy) could be leaked in this example.

model is relatively stronger than those based on cache status [32], cache status at any point can be determined by analyzing the accessed cache units in execution.

### 3 Motivation

In general, capturing cache-based side channels requires modeling program secret-dependent semantics (we will discuss the connection between program semantics and cache access in Sec. 5). In this section we begin by discussing two baseline approaches to modeling program semantics; the limitations of both approaches naturally motivate the design of our novel abstract domain.

**Modeling Program Semantics with Logic Formulas.** An intuitive way is to represent program concrete semantics with logic formulas (as in a typical symbolic execution approach [77]), and perform whole-program static reasoning until a fixed point is reached. The overall workflow exhibits a typical dataflow analysis procedure, and upon termination, each program point maintains a program state that maps variables (i.e., registers, CPU flags, and memory cells) to sets of formulas representing the possible values each variable may hold regarding any execution paths and inputs. For ease of

presentation, we name the value domain formed by logic formulas  $l$  as logic domain  $L$ .

An example is given in Fig. 1, where we model the execution of instructions with logic formulas (Fig. 1b). While the overall approach will precisely model program semantics, some tentative studies indicate its low scalability. Indeed, we implement this approach and evaluate it with two real-world cases: the AES and RSA implementations of OpenSSL. We report that both tests are unable to terminate (evaluation results are given in Sec. 8). In summary, the analysis is impeded for the following reasons:

- Typically, more and more memory cells would be modeled throughout the analysis, and for each variable, its value set (i.e., set of formulas) would also continue to increase. Therefore, the memory usage could become significant to even unrealistic for real-world cases.
- Program states could be continuously updated within loop iterations. In addition, “loops” on the call graph (e.g., recursive calls) could exist in cryptosystems as well and complicate the analysis.

We implement algorithms to detect loop induction variables [11] considering both registers and stack memories. Identified induction variables are lifted into a linear function of symbolic loop iterators; operations on induction variables are “merged” into the linear function, thereby leading to a stable stage. While the simpler AES case terminated when we re-ran the test, the RSA case still yielded a “timeout” due to the practical challenges mentioned above (see results in Sec. 8.1).

**Modeling Program Semantics with Free Symbols.** Another “baseline” approach is to model program semantics in a permissive way. That is, we introduce two free symbols: one for any public information and the other for secrets. Any secret-related computation outputs the same secret symbol, while others preserve the same public symbol. Note that this is comparable to static taint tracking, where each value is either “tainted” or “untainted”. Despite its simplicity, our tentative study reveals new hurdles as follows:

- Memory tracking becomes pointless. Every memory address becomes (syntactically) identical because it

holds the same public or secret symbol. Therefore, a memory store could overturn the entire memory space.

- Even if memory addresses are tracked in a more precise way, representing any secret value and their dependencies coarsely as one free secret symbol yields many false positives (since secret-dependent memory accesses do not necessarily lead to vulnerable cache accesses; see our cache modeling in Sec. 5). Tentative tests of the AES case report a false positive rate of 20% (8 out of 40) due to such modeling. In contrast, our novel program modeling yields no false positive when testing this case (see Sec. 8).

**Motivation of Our Approach.** This paper presents a novel abstract domain that enables abstract interpretation of large-scale cryptosystems in the wild. Our observation is that imprecise tracking of secrets impedes the accurate modeling of cache behaviors (cache access modeling is discussed in Sec. 5). Nevertheless, tracking too much information, such as modeling whole-program semantics with logic formulas, could face scalability issues when analyzing real-world cryptosystems due to various practical challenges.

Our study of real-world cryptosystems actually reveals an interesting and intuitive finding. That is, program secrets and their dependencies usually exhibit at a very *small portion* of program points, and even in such secret-carrying points, most variables maintain *only public information*. It should be noted that in common scenarios non-secret information is not critical for modeling cache-based timing channels. Hence, based on our observation, we promote a novel abstract domain that is particularly designed to *model the secret-dependent semantics of real-world crypto systems*. Our abstract domain delivers fine-grained tracking of program secrets and their dependencies with different identifiers for each piece of secret information, while performing coarse-grained tracking of other public values to effectively enhance scalability.

## 4 Secret-Augmented Symbolic Domain

This section presents the definition of our abstract domain **SAS**. We formally define each component following convention, including the concrete semantics, the abstract domain, and the abstract transfer functions. We also prove that the computations specified in **SAS** correctly over-approximate concrete semantics. Due to space limitations, we highlight only certain necessary components to make the paper self-contained. We refer readers to the extended version of this paper for more details [76].

### 4.1 Abstract Values

We start by defining abstract values  $f \in \mathbf{AV}$  (soon we will show that **SAS** is defined as the powerset of **AV**). Comparable to “symbolic formulas” in symbolic execution,  $f$  combines symbols and constants via operators. Elementary symbols in each abstract value are defined as follows:

- $p$ : a unique symbol representing all the program public information.

Literal	$n \in \mathbb{Z}$
OP <sub>1</sub>	$\oplus ::= + \mid -$
OP <sub>2</sub>	$\otimes ::= \times \mid \div \mid \% \mid \text{AND} \mid \text{OR} \mid \text{XOR} \mid \text{SHIFT}$
Atom	$t ::= \top \mid p \mid s_i \mid n$
Expression	$exp ::= t \mid t \oplus exp \mid t \otimes exp$
Formula	$f ::= e \mid exp \mid e \oplus exp$

Figure 3: Syntax of abstract value.

- $s_i$ : a symbol representing a piece of program secrets; for instance, the  $i$ -th element of a secret array.
- $e$ : a unique symbol representing the initial value of the x86 stack register `esp`.

While only one free symbol  $p$  is used to represent any and all unknown non-secret information (e.g., initial value `edi` of register `edi` in Fig. 1b), we retain finer-grained information about program secrets. Multiple  $s_i$  are generated, and are mapped to different pieces of program secrets (e.g., a symbol  $s_1$  representing `k1` in Fig. 1c). Therefore, different  $s_i$  symbols are *semantically different*, meaning each of them stands for different secrets.

**Syntax.** The syntax of a core of abstract values  $f \in \mathbf{AV}$  is defined in Fig. 3. Literal specifies that concrete data is preserved in **AV**. OP<sub>1</sub> and OP<sub>2</sub> explain typical operators in **AV**. Atom includes symbols and literals, among which  $\top$  (top) is the abstraction of any concrete value. Expression and Formula additionally define expressions and formulas. Note that stack memory expands linearly in the process address space, and stack register `esp` at any program point shall hold a value which adds or subtracts an offset from the initial value of `esp` (i.e.,  $e$ ). In the syntax definition, stack memory offsets could be a constant or an  $exp$ .

Since the symbol  $\{s_i\}$  represents the secrets, which our analysis intends to keep track of, the formulas that contain these symbols usually need to be specially treated. We denote this infinite set of special formulas by  $\mathbf{AV}_s$ , where  $\mathbf{AV}_s = \{f \in \mathbf{AV} \mid \exists s \in \{s_i\} \text{ s.t. } s \text{ occurs in } f\}$ .

**Reduction of Abstract Formulas.** We now define the operator semantics of abstract value  $f \in \mathbf{AV}$ . For any operator  $\odot \in \{\oplus\} \cup \{\otimes\}$ , we define a reduction rule  $T_\odot : \mathbf{AV} \times \mathbf{AV} \rightarrow \mathbf{AV}$  such that  $\llbracket a_1 \odot a_2 \rrbracket = T_\odot(\llbracket a_1 \rrbracket, \llbracket a_2 \rrbracket)$  for any  $a_1, a_2 \in \mathbf{AV}$ , where  $\llbracket \cdot \rrbracket$  denotes the semantics. We then define  $T_\odot(a_1, a_2)$  as follows:

$$T_\odot(a_1, a_2) = \begin{cases} \top & \text{if } a_1 = \top \text{ or } a_2 = \top \\ \top & \text{else if } a_1 = p \wedge a_2 \in \mathbf{AV}_s \text{ or} \\ & a_2 = p \wedge a_1 \in \mathbf{AV}_s \\ p & \text{else if } a_1 = p \wedge a_2 \notin \mathbf{AV}_s \text{ or} \\ & a_2 = p \wedge a_1 \notin \mathbf{AV}_s \\ a_1 \odot a_2 & \text{otherwise} \end{cases}$$

Essentially, the first three cases perform reasonable over-approximation on  $f \in \mathbf{AV}$  with different degrees of abstraction. The last case would apply if no other case can be matched; indeed similar to symbolic execution, most operations on  $f \in \mathbf{AV}$  “concatenates” abstract values via abstract

operators following this rule. For the implementation, we also implement “constant folding” rules for operands of concrete data; such rules help the reduction of stack increment and decrement operations.

Since abstract interpretation typically needs to process sets of facts, we extend  $T_{\odot}$  so that it can be applied to pairs of subsets of abstract values  $f \in \mathbf{AV}$ , where

$$\forall X, Y \in \mathcal{P}(\mathbf{AV}), \forall \odot \in \{\oplus\} \cup \{\otimes\}, \\ T_{\odot}(X, Y) = \{T_{\odot}(a, b) \mid a \in X, b \in Y\}$$

## 4.2 Abstract Domain

Naturally, each element in **SAS** represents the possible values that a program variable may hold; therefore each element in **SAS** forms a set of abstract values. That is,

**Definition 1.** Let **AV** be the set of abstract values. Then

$$\mathbf{SAS} = \mathcal{P}(\mathbf{AV})$$

forms a domain whose elements are subsets of all valid abstract values.

**Claim 1.** **SAS** forms a lattice, with the top element  $\top_{\mathbf{SAS}}$ , bottom element  $\perp_{\mathbf{SAS}}$  and a join operator  $\sqcup$  defined over **SAS**.

We specify the  $\top$ ,  $\perp$ , and join operator  $\sqcup$  in Appendix A. We bound the size of each element in **SAS** with a maximal number  $N$  (therefore the lattice has a finite height) and give corresponding evaluations in Appendix B. For further discussion, see the extended version [76].

**Example.** Fig. 1 explains typical computations within **SAS**. We present a set of abstract values for each register in Fig. 1c. While the computations over secret symbol  $s_i$  are precisely tracked (line 3 in Fig. 1c), the computations over  $p$  preserve this symbol (line 5 in Fig. 1c), and the computations between abstract value  $a \in \mathbf{AV}_s$  and  $p$  lead to  $\top$  (line 7 in Fig. 1c).

## 5 Pinpointing Information Leakage Sites

Upon the termination of static analysis, we check abstract memory addresses of each memory load and store instruction. When a secret-dependent address  $a \in \mathbf{AV}_s$  is identified, its corresponding memory access instruction is considered to be “secret-dependent.” We then translate each secret-dependent address  $a$  into an SMT formula  $f$  for constraint checking (this translation is discussed in Sec. 6.4).

In this research, we adopt a cache model proposed by the existing work to check each secret-dependent memory access [77]. Given an SMT formula  $f$  translated from  $a \in \mathbf{AV}_s$  that represents a memory address, CacheS checks potential cache line access variants by solving the satisfiability of the following predicate:

$$f \gg L \neq f[s'_i/s_i] \gg L \quad (1)$$

As discussed in Sec. 2, assuming the cache has the line size of  $2^L$  bytes, for a memory address of  $N$  bits, the upper  $N - L$  bits map a memory access to its corresponding

cache line access. In other words, the upper  $N - L$  bits decide which cache line the upcoming memory access would visit. Therefore, for an SMT formula  $f$  derived from  $a \in \mathbf{AV}_s$ , we right shift  $f$  by  $L$  bits, and the result  $f \gg L$  indicates the cache line being accessed. Furthermore, by replacing each  $s_i$  with a fresh secret symbol  $s'_i$ , we obtain  $f[s'_i/s_i] \gg L$ . As a standard setting, the cache line size is assumed to be 64 ( $2^6$ ) in this work; therefore, we set  $L$  as 6.

The constructed constraint checks whether different secrets ( $s_i$  and  $s'_i$ ) can lead to the access of different cache lines at this memory access. Recall the threat model shown in Fig. 2, the existence of at least one satisfiable solution reveals potential side channels at this point. From an attacker’s perspective, by (indirectly) observing the access of different cache lines, a certain number of secrets could be leaked to adversaries. In addition, while this constraint assumes that accesses to different offsets within cache lines are indistinguishable, Constraint 1 can be extended to detect related issues. For example, information leaks which enable cache bank attacks can be detected by changing  $L$  from 6 to 2 [87].

## 6 Design of CacheS

We now present CacheS, a tool that uses precise and scalable static analysis to detect cache-based timing channels in real-world cryptosystems. Fig. 4 presents the workflow of CacheS. Given a binary as the input, CacheS first leverages a reverse engineering tool to recover the assembly code and the control flow structures from the input. The assembly instructions are further lifted into *platform-independent* representations before analysis. Technical details on reverse engineering are discussed in Sec. 7.

Given all the recovered program information, we initialize the abstract program state at each program point. In particular, we update the initial state of certain program points with one or several “secret” symbols to represent program secrets (e.g., a sequence of memory cells) when the analysis starts. We then perform abstract interpretation on the whole program until the fixed point in **SAS** is reached.

Abstract interpretation reasons the program execution within **SAS** (Sec. 6.1), and as mentioned, the proposed abstract domain performs fine-grained tracking of program secret-related semantics while maintaining only coarse-grained public information for scalability. The entire analysis framework forms a standard worklist algorithm, where each program point maintains its own program state mapping variables to sets of abstract values (Sec. 6.1.2).

We define information flow rules to propagate secret information (Sec. 6.2) in our context-sensitive and interprocedural analysis (Sec. 6.3). Upon the termination of analyzing one function, we identify secret-dependent memory accesses and translate corresponding memory addressing formulas into SMT formulas (Sec. 6.4) and check for side channels (Sec. 5).

**Application Scope.** In this research we design our abstract domain **SAS** to analyze assembly code: program memory access can be accurately uncovered by analyzing assembly

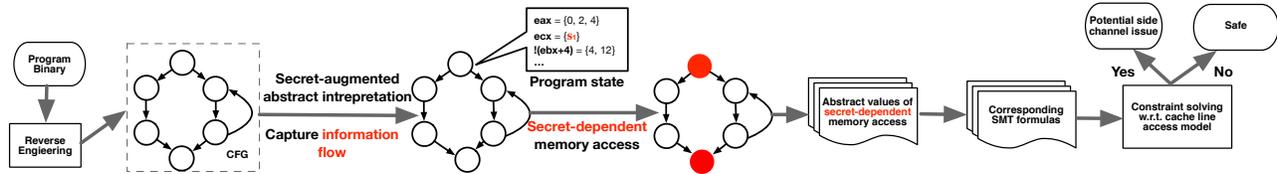

Figure 4: The overall workflow of CacheS.

code, thus supporting a “down-to-earth” modeling of cache behavior (see Sec. 5).

To assist the analysis of off-the-shelf cryptosystems and capture information leaks in the wild, we designed CacheS to directly process binary executables, including stripped executables with no debug or relocation information. We rely on reverse engineering tools to recover program control structures from the input binary, and further build our analysis framework on top of that (see Sec. 7).

## 6.1 Abstract Interpretation

In this section, we discuss how the proposed abstract domain **SAS** is adopted in our tool, and elaborate on several key points to deliver a practical and scalable analysis.

### 6.1.1 Initialization

Before the analysis, we first initialize certain program points with  $\{s_i\}$  to represent the initial secret program information; for the rest their corresponding initial states are naturally defined as  $\{\}$ , or  $\{e\}$  for the stack register  $\text{esp}$ .

Program secrets are maintained in registers or memory cells (e.g., on the stack) during execution. Since CacheS is designed to directly analyze binary code, we must first recognize the location of program secrets. We reverse-engineer the input binary and mark the location of secrets manually. Once the locations of secrets are flagged, we update the initial value set of corresponding variables (i.e., registers or memory cells) with a secret symbol  $s_i$ . Additionally, while “manual reverse engineering” is sufficient for studies in this research, it is always feasible to leverage automatic techniques [26] to search for secrets directly from executables or secret-aware compilers to track secret locations when source code is available. We leave this to future work.

In addition, since program secrets may be stored in a region of sequential memory cells (e.g., in an array), we create another identifier named  $u$  to represent the base address of the secret memory region. While  $u$  itself is treated as *public information*, we specify that memory loading from  $u$  will obtain program secrets; that is, we introduce one  $s_i$  for each memory loading via  $u$ .

### 6.1.2 Program State

At each program point, CacheS maintains a lookup table that maps variables to value sets; each value set  $S \in \mathbf{SAS}$  consists of abstract values  $f \in \mathbf{AV}$  representing possible values of a variable at the current program point. While the “lookup table” is an essential piece of any non-trivial analysis framework, our study has shown that naively-designed program state representations in CacheS could consume significant

new key	key	value	new value
ebx	ebx	$\{14 + \text{esi} \cdot 4\}$	$\{p\}$
ecx	ecx	$\{12\}$	$\{12\}$
eax	eax	$\{8 + k \cdot 4\}$	$\{8 + s_2 \cdot 4\}$
esp	esp	$\{\text{esp}_0 - 120\}$	$\{e - 120\}$
!(ebx)	!( $14 + \text{esi} \cdot 4$ )	$\{k\}$	$\{s_2\}$
!(ecx-4)	!(8)	$\{\text{eax} + 4\}$	$\{p\}$
!(eax)	!( $8 + k \cdot 4$ )	$\{14\}$	$\{14\}$
!(e-120)	!( $\text{esp} - 120$ )	$\{33\}$	$\{33\}$

Figure 5: A sample program state lookup table.  $\text{esp}_0$ ,  $\text{eax}_0$  and  $\text{esi}_0$  in the “key” and “value” entries are symbols representing the register initial values. Symbol ! means pointer dereference, for example !(eax) means memory loading from address stored in  $\text{eax}$ . Lookup tables at each program point are the major factor for memory usage, and we optimize the design by replacing “key” and “value” columns with “new key” and “new value” columns, respectively (see Sec. 6.1.2). Hence, shaded boxes are eliminated in CacheS.

amounts of computing resources and impede the analysis of non-trivial programs. Thus, at this step we seek to design a *concise* and *practical* representation of program states. For the rest of this section, we first explain a “baseline” implementation of the lookup table, and further discuss two refinements.

**The “Baseline” Approach.** A sample lookup table is shown in Fig. 5 (the “key” and “value” columns), where each table maps registers and memory addressing formulas to their corresponding sets for logic formulas  $l \in \mathbf{L}$ . When it encounters a memory access instruction, CacheS computes the memory addressing formula and searches for its existence in the lookup table. (This requires some “equivalence checking”; the details will be explained in Sec. 6.1.4). If the search identifies an entry in the table, CacheS extracts or updates the content of that entry accordingly. Consider the example in Listing 1, where we first store concrete data 14 into memory via address stored in  $\text{eax}$ , and further load it out into  $\text{ebx}$ .

Listing 1: Sample instructions.

```
store eax, 14
load ebx, eax
```

Knowing that value set of `eax` is  $8+k_2*4$  (third entry in Fig. 5), the first instruction creates an entry from address  $8+k_2*4$  to 14 (Fig. 5 shows program states after executing the first instruction). Further memory loading would acquire the value set in `eax`, and then reset the entry of `ebx` with 14 in the state lookup table of the second instruction.

Reading from unknown registers and memory locations would introduce symbols of different credentials regarding our information flow policy (see Sec. 6.2 for details).

**Optimization of Table Values.** While the precisely tracked logic formulas  $l \in \mathbf{L}$  result in notable computing resource usage (Sec. 3), the proposed abstract domain **SAS** (Sec. 4) enables succinct representation of abstract values. As shown in Fig. 5, the “value” column of the lookup table is now replaced by the “new value” column. Consequently, memory consumption is considerably reduced (details are reported in our evaluation section).

**Optimization of Table Keys.** Since only abstract values are traced in **SAS**, the “key” column can be updated into a compact representation as well. However, using symbols such as  $p$  as the key will result in an imprecise modeling of memory addresses.

CacheS optimizes the “key” column in the following way. For most memory related entries, instead of using abstract memory addressing formulas, memory access expressions (expressions of registers and constant offsets) are used as keys. For example, the first instruction in Listing 1 uses memory access expression (i.e., “`eax`”) instead of its abstract value  $8 + s_2 * 4$  for memory lookup. Hence, when analyzing the store instruction, CacheS creates (or updates) an entry in the lookup table, which uses `!(eax)` as the key (here symbol “!” means pointer dereference). Likewise, for memory load, `!(eax)` will be used to look up the program state table. To safely preserve lookup entries via expressions, whenever the value set of a register is reset in the analysis, entries in the table are deleted if their keys are memory access expressions via the newly-updated register.

Nevertheless, since stack register `esp` is frequently manipulated to access stack memory, we preserve abstract addressing formulas via  $e$  to keep track of stack memory access precisely (e.g., the last entry in the “new key” column of Fig. 5).

### 6.1.3 Order of Program State

When multiple program states are possible for a program point, it is important to define the “merge” operation in abstract interpretation. Such an operation can be defined based on the least upper bound operation  $\sqcup$  of **SAS** (recall that **SAS** forms a lattice (Sec. 4.2)).

Given lookup tables  $T_1$  and  $T_2$  representing two program states,  $T_1 \sqcup T_2$  is defined as the following table, say  $T_3$ :

- $T_3$ ’s key set is the union of the key sets of  $T_1$  and  $T_2$ ;
- For each key  $k$  in  $T_3$ ,  $T_3[k] = T_1[k] \sqcup T_2[k]$  (assuming  $T_1[k]$  or  $T_2[k]$  is an empty set if  $k$  is not in the table).

Moreover, the least upper bound of program states entails the partial order of any two program states:  $T_1 \sqcup T_2 = T_1 \leftrightarrow T_2 \subseteq T_1$ .

### 6.1.4 Memory Model

When encountering a memory load and store operation, we must decide which memory cell is accessed by tracing the memory address. However, considering CacheS models program semantics with abstract values, a memory address can usually contain one or several symbols instead of only concrete data. Therefore, policies (i.e., a “memory model”) are usually required to determine the location of an accessed memory cell given a symbolic pointer.

When defining the abstract semantics within **SAS** (see our technical report [76]), we assume the assistance of a sound points-to analysis module as pre-knowledge. Nevertheless, finding such a convenient tool for assembly code of large-scale cryptosystems is quite difficult in practice. We have tried several popular “end-to-end” binary analysis platforms that take an executable as the input and perform various reverse engineering campaigns including points-to analysis; nevertheless, so far we cannot find a practical and robust solution to our scenario.

Therefore, we aim to implement a rigorous memory model by solving the *equality constraints* of two abstract formulas. However, tentative tests show that such a memory model may lose considerable precision in terms of reasoning symbolic pointers and may also not be scalable enough. On the other hand, since keys in the memory lookup table are formulas of  $e$  (for stack pointers; recall that  $e$  represents the initial value of `esp`) or memory access expressions (for other pointers), the current implementation of CacheS rigorously reasons on the equality constraints if abstract values are composed of  $e$  and concrete offsets, which is indeed often the case in analyzing assembly code. For the rest (e.g.,  $e$  and symbolic offsets), we reason on the syntactical equivalence of memory access expressions. This design tradeoff may incorrectly deem equivalent symbolic pointers inequivalent (due to the symbolic “alias” issue) but not vice versa. Experiments show that this memory model is efficient enough to handle real-world cryptosystems while being promisingly accurate.

## 6.2 Information Flow

Considering that information leaks detected in this research are derived from secret-dependent memory accesses, CacheS keeps track of the secret program information flow throughout the analysis. In this section we elaborate on cases where the secret information can be propagated.

**Variable-Level Information Flow.** The explicit information flow is modeled in a straightforward way. Since variables (i.e., registers, memory cells, and CPU flags) are modeled as abstract formulas, high credential information (exhibited as abstract value  $f \in \mathbf{AV}_s$ ) would naturally “flow” among variables during the computations. Moreover, reading from unknown variables (those with empty value sets) generates a symbol  $p$  as a proper over-approximation.

**Information Flow via Memory Loading.** By knowing the underlying memory layout, it could be feasible to infer table lookup indexes by observing the memory load outputs,

hence leaking table indexes of secrets to attackers. It should be noted that such cases are not rare in real-world cryptosystems, where many precomputed data structures are deployed in the memory to speed up computations. Thus, we define policies to capture information flow through memory loading. To do so, for a load operation, whenever the value sets of its base address or memory offset include formula  $f \in \mathbf{AV}_s$ , CacheS assigns the memory content to a fresh  $s_i$ , indicating secret information could have potentially propagated to the value being read. In contrast, when loading from unknown memory cells (memory cells of empty value sets) via non-secret addresses, we create a  $p$  to update the memory reader.

While most memory addressing formulas refer to specific locations in the memory, symbols  $p$  and  $\top$  represent any program (public) information. To safely approximate memory read access via  $p$  and  $\top$ , CacheS assigns  $\top$  to the memory reader. In case a memory storing is via symbol  $p$  or  $\top$ , we terminate the analysis since this would rewrite the whole memory space. Additionally, we note that memory loading and storing via  $\top$  are considered to be information leaks as well since  $\top$  implies that a variable has certain residual secrets (see Sec. 6.4).

### 6.3 Interprocedural Analysis

Our interprocedural analysis is context-sensitive. We build a classic function summary-based interprocedural analysis framework, where a summary  $(\langle f', i \rangle, o)$  of a function call towards  $f$  maps the calling context  $\langle f', i \rangle$  ( $f'$  is the caller name and  $i$  is the input) to the function call output  $o$ . CacheS maintains a set of summaries for each function  $f$ , and for an upcoming call of  $f$ , its calling context is first checked regarding the existing summaries of  $f$ . In case the context is a subset of any recorded entries (the partial order of calling context is derived from the order of program states defined in Sec. 6.1.2), the analysis will be skipped and we directly return the corresponding output.

To recover the function inputs, we inquire the employed reverse engineering platform (details are given in Sec. 7) to obtain the number of parameters the approaching function has. According to the calling convention of 32-bit x86 platforms, a memory stack is used to store function parameters; thus, we construct stack memory addresses of function parameters and acquire the value set of each parameter from the program state lookup table at the call site. If some memory cells of function parameters are absent, symbol  $p$  is used as an over-approximation. To compute the output information of a function, we join program states at every return instruction when the analysis of the target function terminates, which over-approximates the function return states.

### 6.4 Translating Abstract Values into SMT Formulas

As noted earlier (Sec. 5), cache-access side channels are summarized into SMT constraints. Upon the termination of analyzing each function, we identify secret-dependent memory addresses  $a \in \mathbf{AV}_s$  and build the side channel constraints. SMT solvers are used to solve the constraint and check

whether different secrets can lead to cache line access variants. Nevertheless, while many works to date leverage symbolic execution to construct SMT formulas, here we reason on program states within SAS. Therefore, before constraint checking, we first translate abstract formulas into SMT formulas.

Each abstract formula is maintained as a symbolic “tree” in CacheS, where tree leaves are symbols and concrete data while other nodes are operators. At this step, we translate each leaf on the tree into a bit vector implemented by a widely-used SMT solver—Z3 [30]; a bit vector would be instantiated with a numeric value if it was derived from a constant. In addition, we translate abstract operators on the tree into bit vector operations in Z3. Hence, an abstract formula tree would be reduced bottom-up into an SMT formula.

**Translate Secret Symbols into Unique Bit Vectors.** As noted earlier,  $s_i$  symbols are semantically different, each of which represents different pieces of secrets. For the implementation, we assign a unique id for each newly-created  $s_i$  symbol, which further leads to the creation of unique bit vectors at this step. In contrast,  $p$  (and  $e$ ) symbols are transformed into identical bit vectors.

**Memory Access via  $\top$ .** It is easy to see that  $\top$  implies that a variable has some residual secrets along with possibly public information. Hence, in addition to checking the constructed SMT constraints with Z3, memory accesses are flagged as vulnerable whenever their corresponding addressing formulas are  $\top$ .

## 7 Implementation

CacheS is mainly written in Scala (in 6,764 LOC; counted by CLOC [29]). The tentative implementation (in 7,163 LOC), which models program semantics with logic formulas (Sec. 3), is maintained as a separate “branch” of the code base.

Starting from an input binary code, the first step is to recover the assembly program as well as control flow and call graphs. Here we employ a popular reverse engineering tool, IDA-Pro (version 6.9) for the reverse engineering task [1]. We use the default configurations of IDA-Pro to recover assembly code and program control structures from the input executables.

**Assembly Lifting.** Many existing binary analysis infrastructures have provided facilities to lift x86 assembly code into a high-level intermediate representation. Without reinventing the wheel, here we employ a well-developed binary analysis platform BINNAVI [34] to transform x86 assembly code into a *platform-independent* intermediate language, REIL [72]. Our analysis procedures are built on top of the recovered representations. In addition, for a formal definition of program concrete semantics in terms of the REIL language, please refer to our technical report [76].

The current implementation of CacheS analyzes ELF binaries on the x86 platform. Nevertheless, since REIL language is designed as *platform-independent*, there is no fundamental limitation for CacheS to analyze binaries of other

Table 1: Cryptosystems analyzed by CacheS.

Implementation	Versions	Analysis Starting Function	Implement Which Algorithm
Libgcrypt [48]	1.6.1, 1.7.3	<code>_gcry_mpi_powm</code>	RSA/ElGamal
OpenSSL [59]	1.0.2f, 1.0.2k	<code>BN_mod_exp_mont_consttime</code>	
mbedtls [57]	2.5.1	<code>mbedtls_mpi_exp_mod</code>	RSA
OpenSSL [59]	1.0.2f, 1.0.2k	<code>_x86_AES_decrypt_compact</code>	AES
mbedtls [57]	2.5.1	<code>mbedtls_internal_aes_decrypt</code>	

formats or from other platforms (e.g., PE binaries on Windows) as long as the assembly instructions can be translated into REIL statements. As aforementioned, our current prototype focuses on 32-bit ELF binaries since the state-of-the-art REIL lifter (BinNavi [34]) does not have an official support for 64-bit binaries. However, the proposed technique shall be applicable to 64-bit binaries with no additional technical hurdles.

**Recover x86 Memory Access Instructions from REIL Statements.** As noted in Sec. 6.1.2, we use memory access expressions instead of address formulas as the key to simplify the memory lookup. While the memory access expressions can be acquired by checking assembly instructions, note that our analysis is launched on REIL IR; one memory access instruction is extended into multiple IR statements. Hence, we perform def-use analysis to “collapse” IR statements belonging to the same instruction and recover the corresponding memory access expression.

**Critical Functions.** CacheS is designed to perform both inter and intra-procedural analysis on any binary code component. For the evaluations in this research, instead of starting from the program entry point, analyses were launched on critical functions of cryptosystems that have become the target for many previous attacks. Such critical functions are the starting points of our interprocedural analysis, and we recursively discover all the reachable functions on the call graph. As reported in our evaluation (see Table 2), these recursively collected functions usually form a non-trivial sub-graph on the program call graph. In addition, taking these critical functions as the starting points of CacheS makes it easier to compare our findings with existing work.

## 8 Evaluation

In contrast to many previous studies in which cache-based side channels are detected from only simple cases, CacheS is evaluated on several real-world cryptosystems. As reported in Table 1, three cryptosystems are evaluated in this research. OpenSSL and Libgcrypt are widely used cryptosystems on multi-purpose computers, while mbedtls is commonly adopted by embedded devices. Eight critical functions are selected as the starting point of our analysis, which covers major security-sensitive components in three crypto algorithm implementations: RSA, AES, and ElGamal.

To prepare CacheS inputs, we compile test programs shipped in each cryptosystem and link with the corresponding libraries. All the crypto libraries are written in C. We build each library and test program into a 32-bit ELF binary on Ubuntu 12.04 with gcc compiler (version 4.6.3).

## 8.1 Evaluation Result Overview

Table 2 presents the evaluation result overview. In summary, 208 information leak points are reported from the real world cryptosystems evaluated in this research. We interpret the results as promising; most of the evaluated cryptosystems contain information leaks due to cache-based side channels, and CacheS helps to pinpoint these leaks with program-wide static analysis.

It is commonly acknowledged that the table lookup implementation of the AES decryption routine is vulnerable to various real-world cache attacks. CacheS identifies 32 information leaks from the AES implementations of OpenSSL (versions 1.0.2f and 1.0.2k), and 64 leaks from mbedtls. Indeed, all of these issues are lookup table queries via direct usages of secrets, which is consistent with findings in existing research [25, 77].

Existing research has pinpointed multiple information leaks in the modular exponentiation implementation of OpenSSL and Libgcrypt [77, 52]; vulnerable functions are adopted by both RSA and ElGamal for decryption. CacheS confirmed these findings (see Sec. 8.4 for one false positive in OpenSSL). Furthermore, CacheS successfully revealed a much larger information leakage surface than existing trace and static analysis based techniques, because of its scalable modeling of program semantics. Table 2 shows that CacheS identifies more information leaks from Libgcrypt and OpenSSL in addition to confirming all issues reported by CacheD [77]. Moreover, CacheS identifies multiple information leakage sites from the modular exponentiation implementation of mbedtls, which, to the best of our knowledge, is unknown to the research community.

While 40 information leakage sites are reported in Libgcrypt (version 1.6.1), our study shows that they have been fixed in version 1.7.3. Without secret-dependent memory accesses, the RSA/ElGamal implementation of Libgcrypt 1.7.3 is generally accepted as safe regarding our threat model. Our evaluation reports consistent findings that no leak is detected regarding our threat model on secret-dependent cache-line accesses (but we do find secret-dependent control flows, see Sec. 8.5).

**Computing Resource.** Our evaluation is launched on a machine with 2.90 GHz Intel Xeon(R) E5-2690 CPU and 128 GB memory. For each context-sensitive analysis campaign, Table 2 presents the covered functions, contexts, and processed IR instructions. We report that CacheS takes less than 1700 CPU seconds to process all the test cases, and on average the peak memory usage to evaluate one case is less than 5 GB. Overall, CacheS finished all the analysis campaigns with reasonable amount of computing resources, and we interpret that the promising results demonstrate the high scalability of CacheS in analyzing real-world cryptosystems.

**Modeling Program Semantics with Logic Formulas.** As noted in Sec. 3, we tentatively implement the idea of modeling program concrete semantics with logic formulas. Note that in addition to the semantics modeling, all the design and evaluation settings are unchanged.

Table 2: Evaluation result overview. We compare the identified information leakage sites by CacheS with a recent research (CacheD [77]), and we report CacheS can identify all the leakage sites reported by CacheD. A summary of all leaks can be found at the extended version of this paper [76].

Algorithm	Implementation	Information Leakage Sites (known/unknown)	# of Analyzed Procedures	# of Analyzed Contexts	Processing Time (CPU Seconds)	# of Processed REIL Instructions	Peak Memory Usage (MB)	Information Leakage Units	Results Reported in CacheD [77]		
									Leakage Sites	Processing Time	Leakage Units
RSA/EIGamal	Libcrypt 1.6.1	22/18	60	81	228.8	50,436	7,749	11	22	14293.6	5
RSA/EIGamal	Libcrypt 1.7.3	0/0	59	59	182.2	33,386	5,823	0	0	11626.0	0
RSA/EIGamal	OpenSSL 1.0.2k	2/3	71	81	179.2	83,183	6,134	2	N/A	N/A	N/A
RSA/EIGamal	OpenSSL 1.0.2f	2/4	68	72	169.5	80,096	6,113	3	2	165.6	2

AES	OpenSSL 1.0.2f	32/0	1	1	35.8	3,748	578	1	32	48.5	1
AES	mbedtls 2.5.1	64/0	1	1	32.8	4,803	619	1	N/A	N/A	N/A
<b>Total</b>		154/54	290	332	1,637.4	295,363	37,290	21	56	26,133.7	8

Table 3: Model program semantics in the logic formulas  $l \in \mathbf{L}$  and  $\mathbf{SAS}$  and test OpenSSL 1.0.2k. The second and third rows report the modeling results with logic formulas, while the last row reports results in  $\mathbf{SAS}$ . The comparison of these two program modelings is given in Sec. 3.

Algorithm	Execution Time (CPU Second)	# of Processed Function	# of Processed Context	Peak Memory Usage (MB)	Detected Leaks
RSA/EIGamal	timeout (> 5 CPU hours)	15	28	7,283	N/A
AES	timeout (> 5 CPU hours)	1	1	47,798	N/A
RSA/EIGamal	timeout (> 5 CPU hours)	28	85	53,054	N/A
AES	115.8	1	1	621	32
RSA/EIGamal	179.2	71	81	6,134	5
AES	33.2	1	1	620	32

The first two rows of Table 3 give the evaluation results for the AES and RSA/EIGamal implementations in OpenSSL 1.0.2k, both of which report a “timeout” after 5 CPU hours. As explained in Sec. 3, we extend the prototype with loop induction variable detection, and the third row reports the results of the re-launched tests. Still, the RSA/EIGamal case throws a timeout (a reflection on this tentative evaluation is given in Sec. 3). In summary, we interpret that the  $\mathbf{SAS}$  proposed in this research has largely improved the analysis scalability, which serves as an indispensable component to pinpoint cache-based timing channels in real-world cryptosystems.

**Comparison with CacheAudit.**<sup>2</sup> Besides CacheD [77], we also compare our results with CacheAudit [32]. CacheAudit failed on all of our test cases for two reasons. First, two of our cases contain some x86 instructions that are not handled by CacheAudit. Second, CacheAudit refuses to analyze indirect function calls when constructing the control flow graph. In addition, we also describe the key differences between CacheS and CacheAudit in Sec. 10.

**Identifying Information Leakage Units.** Considering some occurrences of information leaks are on adjacent lines of a code component (a summary of all leaks can be found at the extended version of this paper [76]), once a leak is flagged by CacheS, presumably any competent programmer shall spot and remove all the related defects. Therefore, we group the flagged information leaks to assess the utility of CacheS and also estimate the bug fixing effort. Though it can be slightly subjective, we propose a metric according to the source code locations of defects: information leaks will be grouped to-

gether as a “leakage unit” if they are within the same or adjacent C statements (e.g., within the same loop or adjacent if branches). Also, if a macro is expanded at different program points (e.g., the macro `MPN_COPY` which contains information leaks in Libcrypt 1.6.1), we count it only once.

As reported in Table 2, CacheS identified 21 units of information leaks. We also grouped the findings of CacheD with the same metric. We have confirmed that CacheS covered all leakage units reported in CacheD, and further revealed new leakage units within statements or functions not covered by CacheD (e.g., 6 new leakage units in Libcrypt 1.6.1). Overall, we interpret the evaluation results as promising; trace-based analysis, like CacheD, is incapable of modeling the program collecting semantics, and therefore underestimates the attack surface.

**Confirmation with Library Authors.** As shown in Table 2, we found unknown information leaks from OpenSSL (versions 1.0.2f and 1.0.2k) and mbedtls (version 2.5.1). Our findings were reported and promptly confirmed by the OpenSSL developers [4]; the latest OpenSSL has been patched to eliminate these leaks (the leaks are discussed shortly in Sec. 8.4). At the time of writing, we are waiting for responses from the mbedtls developers.

## 8.2 Exploring the Leaks in mbedtls

Although mbedtls developers have not confirmed our findings, we conduct further study of the 29 flagged information leakage sites from this library to check whether they can lead to cache-based side channels.

As mentioned above, the constraint solver provides at least one pair of satisfiable solutions (a pair of secrets  $k$  and  $k'$ ) to each leakage site (Sec. 5). To verify one leak, we instrument the program source code and modify secrets with  $k$  and  $k'$ . We then compile the instrumented programs into two binaries and monitor the execution of each binary executable via a widely-used hardware simulator (gem5 [18]). The compiled code is fed with test cases shipped with the cryptosystems, and we use the full-system simulation mode of gem5 to monitor the execution of the instrumented program. The full-system simulation mode uses 64-bit Ubuntu 12.04 (this mode only supports 64-bit OS) to host the application code. We compile the instrumented source code into 64-bit binaries since executing 32-bit binaries on the 64-bit OS throws some TLB translation exceptions (this issue is also reported in [77]). The configuration of gem5 is reported in Table 4. At

<sup>2</sup><https://github.com/cacheaudit/cacheaudit>

Table 4: gem5 configurations.

ISA	x86
Processor type	single core, out-of-order
L1 Cache	4-way, 32KB, 2-cycle latency
L2 Cache	8-way, 1MB, 50-cycle latency
Cache line size	64 Bytes
Cache replacement policy	LRU

Table 5: Hardware simulation results.

# of CacheS Detected Leakage Sites	# of Executed Leakage Sites	Cache Line Access Variants	Cache Status Variants
29	14	14	6

the leakage point, we intercept the cache access from CPU to L1 Data Cache; the accessed cache line and corresponding cache status (hit vs. miss) are recorded.

As shown in Table 5, among 29 information leakage sites found in mbedTLS, 14 sites are covered during simulation. We observe that different cache lines are accessed at these leakage points, when instrumenting the program with secrets  $k$  and  $k'$ . In other words, by observing the access of different cache lines, attackers will be able to infer a certain amount of secret information. In addition, we report that cache status variants (in terms of cache hit vs. miss) are observed in several cases. In summary, we interpret the verification results as highly promising; we have confirmed that all the executed information leakages are *true positives* since cache line access variants are observed.

Although the employed program inputs cannot lead to the full coverage of every leakage site, we manually checked all the uncovered cases, and we found that these cases share the same pattern as the covered leaks. For instance, the covered and uncovered leaks are the same inline assembly sequences residing within different paths. Overall, we interpret it as convincing to conclude that all the detected information leaks in mbedTLS are true positives.

### 8.3 Case Study of Leaks in mbedTLS

This section presents a thorough case study of several information leaks identified by our tool. As presented in Table 2, we identified 29 information leakage points in mbedTLS 2.5.1. In particular, the first four leaks were found in the function `mpi_montmul` (source code is given in Fig. 6(a)), which is a major component of the modular exponentiation implementation in mbedTLS. The value of function parameter  $B$  is derived from a window size of the secret key (line 2). In `mpi_montmul`,  $B$  is used as a pointer to access elements in a C struct (line 6, line 10, line 11). We envision that different program secrets would derive into different values of  $B$ , which further lead to the access of different cache lines in secret-dependent memory accesses.

The evaluation shows consistent findings. As shown in Fig. 6(b), CacheS identifies four suspicious memory accesses in `mpi_montmul` (two pointer dereferences at line 6 of Fig. 6(a) are optimized into one memory load at line 2 of Fig. 6(b)). By checking the constraint solver, we find a

pair of program secrets that affect the value of  $B$  and further lead to the access of different cache lines at the first memory access (the solution is given in Fig. 6(c)).

We then instrument the program private key with the solver provided solutions in Fig. 6(c) and observe the runtime cache access within gem5. This secret pair is generated by analyzing the first leakage memory access, but since variants of  $B$  may affect the following memory traffic as well, we report the cache status at all the suspicious memory accesses in `mpi_montmul`. We note that while CacheS analyzes 32-bit binaries, at this step we compile the instrumented source code into 64-bit binaries since the simulated OS throws some exceptions when running 32-bit code. After compilation, the five leakage points in the source code actually produce three memory load instructions in the 64-bit assembly code. Cache behaviors, including the accessed cache line and the corresponding cache status, are recorded at these points. Fig. 6(d) presents the simulation results. Due to the limited space, we provide only the first seven records (59568 records in total). Program counters 0x40770a, 0x407744 and 0x40775d represent the three identified memory loads of information leaks. It is easy to see that different cache lines are accessed at each point. Additionally, a timing window of one cache hit vs. miss is found (this memory access represents a table lookup in the first element of  $B \rightarrow p$ ).

### 8.4 Information Leaks in the Modular Exponentiation Algorithm

Both RSA and ElGamal algorithms employ the modular exponentiation algorithm for decryption. Existing research has reported that such an algorithm is vulnerable to cache-based timing channel attacks [77, 52]. Here, we evaluate the corresponding implementations in OpenSSL, Libgcrypt, and mbedTLS. As reported in Table 2, CacheS successfully revealed a much larger leakage surface, including 80 (54 unknown and 26 known) information leaks, from our test cases.

**Information Leaks in Libgcrypt.** A large number of leakage points are reported from the sliding window-based modular exponentiation implementation in Libgcrypt 1.6.1. Existing research has pointed out the direct usages of (window-size) secret keys as *exploitable* [52], and CacheS pinpointed this issue. In addition to the 4 direct usages of secrets, we further uncovered 36 leaks due to the propagation of secret information flows, as CacheS keeps track of both variable-level and memory loading based information flows (Sec. 6.2).

While previous trace-based analysis also keeps track of information flow propagation (i.e., CacheD [77]), CacheS still outperforms CacheD because of its program-wide analysis. With the help of CacheD’s authors, we confirmed that CacheS can detect all 22 leaks reported in CacheD [77], and further reveals 18 additional points.

**Information Leaks in mbedTLS.** CacheS has also identified leaks in another commonly used cryptosystem, mbedTLS. Appendix E presents several leaks found in the mbedTLS case. In general, function `mbedtls_mpi_exp_mod` implements a sliding window-

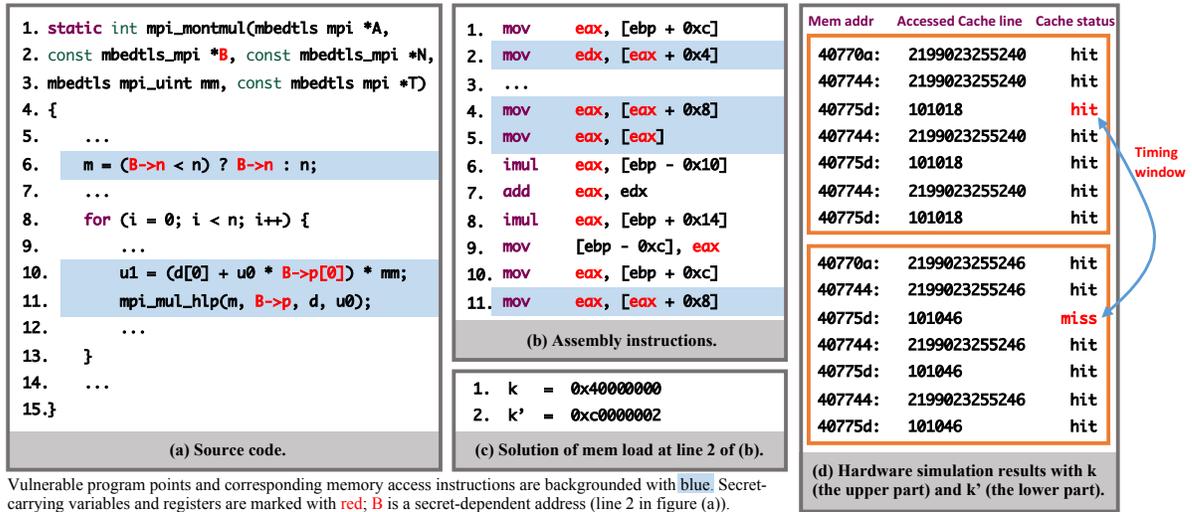

Figure 6: Case study of information leaks in mbedTLS. The constraint solver finds a pair of secrets (k and k') which leads to the access of different cache lines at line 2 of (b).

based modular exponentiation, which leads to secret-dependent memory accesses (precomputed table lookup). The table lookup statement (line 10) does not generate a leak point since it only gets a pointer referring to an array element, however, further memory dereferences on the acquired pointer reveal 4 direct usages of secrets (discussed in Sec. 8.3). We also find 25 leaks due to the propagation of secret information flows (Sec. 6.2).

We note that mbedTLS uses RSA exponent blinding as a countermeasure [43], which practically introduces noise and mitigates cache side channels (but is still exploitable with enough collisions or if the attacker can derive the exponent from a single trace). We leave it as future work to model the feasibility of exploitations, given the identified leaks and also taking program randomness (e.g., exponent blinding) into consideration.

**Information Leaks in OpenSSL.** Information leaks in OpenSSL are within or derived from functions counting the length of a secret array. Fig. 7 presents a function that contains 4 memory accesses which engender information leaks: `BIGNUM` maintains an array of 32-bit elements, and `BN_num_bits` counts the number of bits within a given big number. Since the last element of the array may be less than 32 bits, a lookup table is used to determine the exact bits in the last element of the secret array (function call at line 7 in Fig. 7). By storing secrets within a big number structure, table queries in `BN_num_bits_word` could lead to secret-dependent memory accesses.

While CacheD [77] flags only one information leak (line 26 in Fig. 7) covered by its execution trace, CacheS detects more leaks. As shown in Fig. 7, four table queries are analyzed by CacheS, and all of them are flagged as leaks. In addition to these four direct usages of secrets, CacheS also

finds one more leak in OpenSSL 1.0.2k, and two in OpenSSL 1.0.2f, both are due to the propagation of secret information flows.

**False Positive.** In addition to the issues in Appendix C that have been confirmed and fixed by the OpenSSL developers, we also find one *false positive* when analyzing OpenSSL 1.0.2f. To defeat side channel attacks against the precomputed table lookup, OpenSSL forces the cache access at the table lookup point in a constant order [33]. This constant order table lookup is demonstrated with a sample C code in Appendix D. The base address of the lookup table is aligned to zero the least-significant bits, and scatter and gather methods are employed to mimic the Fortran-style memory allocation to access the table in a constant order and remove timing channels.

Ideally, with the base address being aligned, the table access should not produce an information leak regarding the cache line access model (but scatter-gather implementation can also be exploited with cache bank attacks [87]). As discussed in Sec. 5, our cache access constraint can be further extended to capture cache bank side channels). However, since public information (e.g., base address of the table) is abstracted as a symbol  $p$  in CacheS, the alignment is not modeled. Therefore, CacheS incorrectly flags the table lookup as a leak point, which leads to a false positive.

## 8.5 Flag Secret-Dependent Control Flow

To reduce false negatives and also show the versatility of CacheS, we extend CacheS to search for secret-dependent branch conditions. Similar to the detection of secret-dependent memory accesses (Sec. 5), we check each conditional jump and flag secret-dependent jump conditions. The conditional jump in REIL IR is `jcc`, and the value of its first operand specifies whether the jump is taken or not. We trans-

late each secret-dependent condition  $c$  into an SMT formula  $f$  and solve the following constraint:

$$f \neq f[s'_i/s_i] \quad (2)$$

where a satisfiable solution indicates that different secrets lead to the execution of different branches. In addition, since REIL IR creates *additional* `jcc` statements to model certain x86 instructions (e.g., the shift arithmetic right `sar` and bit scan forward `bsf`), we rule out `jcc` statements if their corresponding x86 instructions are *not* conditional jumps. In this research we do not take `jcc` into consideration if it does not represent an x86 conditional jump, since in general the silicon implementations of x86 instructions on mainstream CPUs have *fixed latency* [2].

Table 6 presents the evaluation results, including the information leakage units produced by the same metric used in Table 2. While secret-dependent control flow is absent in all the AES cases, CacheS pinpoints multiple instances in every RSA/EIGamal implementation. We further manually studied each of them, and we report that besides 4 false positives (explained later in this section), all the other cases represent secret-dependent branch conditions. In the example given in Appendix F, the value of `bits`, which is derived from the private key, is used to construct several conditions. Similar patterns are also found in other cases.

**False Negative.** Bernstein et al. exploited the secret-dependent control flows in Libgcrypt 1.7.6 [17], where the leading and trailing zeros of a window-size secret are used to compute a branch condition. While the corresponding vulnerable branches also exist in Libgcrypt 1.7.3, they are not detected by CacheS. In general, 32-bit x86 opcode `bsr` and `bsf` are used to count the leading and trailing zeros of a given operand, and both opcodes are lifted into a while loop implemented by a `jcc` statement (for the definition of their semantics, see the `bsr` and `bsf` sections of the x86 developer manual [3]). Consider a proof-of-concept pseudo-code below:

```

1 t = 0;
2 while (getBit(t, src) == 0) //src could be a secret
3 {
4   t += 1;
5 }
6 return t; // the number of trailing zeros in src

```

where the lifted while loop entails implicit information flow, which is not supported (see Sec. 6.2 for the information flow policy). In addition, although we disable the checking of `jcc` regarding Constraint 2 if its corresponding x86 instruction is *not* a conditional jump (like the `bsr` and `bsf` cases), we report that once enabling the checking of such `jcc` statements, secret-dependent control flows (e.g., line 3 of the pseudo-code) are detected for both cases.

**False Positive.** We find 4 false positives when analyzing Libgcrypt 1.6.1. This is due to the imprecise modeling of interprocedural call sites. Consider a sample pseudo-code below:

```

1 foo(k, p) { // k is {T} and p is {12}
2   if (...) {

```

Table 6: Secret-dependent control branches. We found no issue in the AES implementations. A summary of all leakage points can be found at the extended version of this paper [76].

Implementation	Algorithm	# of Secret-dependent conditions	False Positive	Information Leakage Unit
Libgcrypt 1.6.1	RSA/EIGamal	21	4	9
Libgcrypt 1.7.3	RSA/EIGamal	6	0	4
mbedtls 2.5.1	RSA	8	0	4
OpenSSL 1.0.2f	RSA/EIGamal	12	0	5
OpenSSL 1.0.2k	RSA/EIGamal	12	0	5
Total		59	4	27

```

3   r = bar(k); // r is {T}
4   } else {
5   r = bar(p); // r is {T} since ⟨foo,{12}⟩ ⊆ ⟨foo,{T}⟩
6   if (r) // false positive
7     ...
8   }
9
10  bar(i){return i;}

```

where `foo` performs two function calls to `bar` with different parameters. The summary of the first call (line 3) is represented as  $(\langle foo, \{T\} \rangle, \{T\})$ , where  $\langle foo, \{T\} \rangle$  forms the calling context (as explained in Sec. 6.3, a calling context includes the caller name and the input), and the second  $\{T\}$  is the function call output. Then the following function call (line 5) with  $\langle foo, \{12\} \rangle$  as the calling context will directly return  $\{T\}$  and cause a false positive (line 6) according to the recorded summary, since  $\langle foo, \{12\} \rangle \subseteq \langle foo, \{T\} \rangle$ . Our study shows that such sound albeit imprecise modeling caused 4 false positives when analyzing Libgcrypt 1.6.1.

## 9 Discussion

**Soundness.** Our abstraction is sound (see our technical report for the proof [76]), but the CacheS implementation is soundy [53] as it roots the same assumption as previous techniques that aim to find bugs rather than performing rigorous verification [55, 84, 54].

CacheS adopts a lightweight but unsound memory model implementation; program state representations are optimized to reduce the memory usage and speed up the analysis. There is a line of research aiming to deliver a (nearly) sound memory model when analyzing x86 assembly [13, 64, 65, 21]. We leave it to future work to explore practical methods to improve CacheS with a sound model without undermining the strength of CacheS in terms of scalability and precision.

**Reduce False Positives.** Our abstract domain **SAS** models public program information with free public symbols. To further improve the analysis precision and eliminate false positives, such as in the case discussed in Sec. 8.4, one approach is to perform a finer-grained modeling of public program information. To this end, so-called “lazy abstraction” can be adopted to postpone abstraction until necessary [71]. In contrast to our current approach where analyses are performed directly over **SAS**, lazy abstraction provides a flexible abstraction strategy on demand, where different program points can exhibit distinct levels of precision. Well-selected program points for lazy abstraction are critical to achieve scalability. For example, abstraction can be performed at ev-

ery loop merge point or whenever abstract formulas become too large and exhaust the memory resource. We leave it to future work to explore practical strategies for lazy abstraction.

## 10 Related Work

**Timing Attacks.** Kocher’s seminal paper [44] identifies timing attacks as a potential threat to crypto system. Later work finds that timing information reveals the victim program’s usage of data/instruction cache, leading to efficient timing attacks against real world cryptography software, including AES [37, 60, 74, 16, 20, 6], DES [75], RSA [7, 62, 86], El-Gamal [90], and ECDSA [15]. Recent work shows that such cache-based timing attacks are possible on emerging platforms, such as cloud computing, VM environments, trusted computing environments, and mobile platforms [66, 85, 83, 89, 52, 49, 56, 69, 24, 36].

**Detect Cache-Based Timing Channels.** CacheAudit leverages static analysis techniques (i.e., abstract interpretation) to reason information leakage due to cache side channels [32, 33]. CacheS outperforms CacheAudit due to our novel abstract domain. CacheAudit uses relational and numerical abstract domains to only infer the information leakage bound, while our abstract domain models semantics with symbolic formulas, pinpoints information leaks with constraint solving, and enables the generation of counter examples to promote debugging. In addition, we propose a principled way to improve the scalability by tracking secrets and public information with *different granularities*. This enables a context-sensitive interprocedural analysis of real-world cryptosystems for which CacheAudit is not capable of handling. Brotzman et al. [22] propose a static symbolic reasoning technique that also covers multiple program paths. However, their analysis lacks abstraction of public values, and can analyze only small-size programs.

In contrast, dynamic analysis-based approaches, such as taint analysis or trace-based symbolic execution, are incapable of analyzing the whole program [77, 82, 41, 81, 38]. CacheD [77] performs symbolic execution towards a single trace to detect side channels. In contrast, abstract interpretation framework approximates the program *collecting semantics*, which formalizes program abstract semantics at arbitrary program points regarding any path and any input. This is fundamentally different and much more comprehensive comparing to a path-based tool, like CacheD. Wichelmann et al. [82] log execution traces and perform differential analysis of various granularities to detect side channels. Weiser et al. [81] detect address-based side-channels by executing test programs under input variants and further compare traces to detect leakages.

**Countermeasure.** Existing countermeasures against cache side-channel attacks can be categorized into hardware-based and software-based approaches. Hardware-based solutions focus on randomizing the cache accesses with new cache design [79, 80, 45, 78, 51, 50], or enforcing fine-grained isolation with respect to cache usage [70, 42]. Wang et al.

propose locking the cache lines and hiding cache access patterns [79], which further obfuscates cache accesses by diversifying the cache mappings [80]. Tiwari et al. [73] devise a novel micro architecture for information-flow tracking by design, where noninterference is deployed as the baseline confidentiality property. Another direction at the hardware level is based on contracts between software and hardware [91, 47, 88], where contracts are enforced by formal methods (e.g., type systems) on the hardware side. Furthermore, some advanced hardware extensions, like hardware transactional memory, have also been leveraged to prevent side channels even inside Intel SGX [35].

Analyses are also conducted on the software level to mitigate side channel attacks [27, 12, 63, 67, 68]. Program transformation techniques are leveraged to remove control-flow timing leaks by equalizing branches of conditionals with secret guards [8], together with a binary static checker [58], and its practicality is evaluated [27]. Constant time code defeats timing attacks by ensuring the control flow, memory accesses, and execution time of individual instruction is secret independent [10, 40, 61, 14, 9, 46].

## 11 Conclusion

In this paper, we have presented CacheS for cache-based timing channel detection. Based on a novel abstract domain SAS, CacheS does fine-grained tracking of sensitive information and its dependencies, while performing scalable analysis with over-approximated public information. We evaluated CacheS on multiple real-world cryptosystems. CacheS confirmed over 154 information leaks reported by previous research and pinpointed 54 leaks not known previously.

## 12 Acknowledgments

We thank the Usenix Security anonymous reviewers and Gary T. Leavens for their valuable feedback. ## A SAS as a Lattice

To further make **SAS** a lattice, we will need to specify a top element  $\top \in \mathbf{SAS}$ , a bottom element  $\perp \in \mathbf{SAS}$ , and a join operator  $\sqcup$  over **SAS**.

**Set Collapse and Bound.** Each element in **SAS** is a set of abstract values  $f \in \mathbf{AV}$ . Considering  $f$  with different degrees

of abstractions may exist in one set, here we define reasonable rules to “collapse” elements in a set. The “collapse” function  $\text{COL} : \mathbf{SAS} \rightarrow \mathbf{SAS}$  is given by:

$$\text{COL}(X) = \begin{cases} \{\top\} & \text{if } \top \in X \\ \{\top\} & \text{else if } p \in X \wedge \mathbf{AV}_s \cap X \neq \emptyset \\ \{p\} & \text{else if } p \in X \wedge \mathbf{AV}_s \cap X = \emptyset \\ X & \text{otherwise} \end{cases}$$

While the first three rules introduce single symbols as a safe and concise approximation, the last rule preserve a set in **SAS**.

In addition, each set in **SAS** is also bounded with a maximum size of  $N$  through function **BOU** as follows:

$$\text{BOU}(X) = \begin{cases} \{\top\} & \text{if } |X| > N \wedge \mathbf{AV}_s \cap X \neq \emptyset \\ \{p\} & \text{else if } |X| > N \wedge \mathbf{AV}_s \cap X = \emptyset \\ X & \text{otherwise} \end{cases}$$

Hence, the abstract value set of any variable is bounded by  $N$  during computations within **SAS**, which practically speed ups the analysis convergence ( $N$  is set as 50 in this research, see Appendix B for a discussion of different configurations).

With **COL** and **BOU** defined, we can finally complete **SAS** as a lattice.

**Claim 2.**  $\mathbf{SAS} = \mathcal{P}(\mathbf{AV})$  forms a lattice with the top element

$$\top_{\mathbf{SAS}} = \{\top\}$$

bottom element

$$\perp_{\mathbf{SAS}} = \{\}$$

and the join operator

$$\sqcup = \text{BOU} \circ \text{COL} \circ \cup$$

For further discussion of **SAS**, including the concrete and abstract semantics, soundness proof, etc., please refer to the extended version of this paper [76].

## B Evaluating Different Configurations of the BOU Function

The definition of the **BOU** function includes a parameter  $N$  as the maximum size of each abstract value set. Table 7 reports the evaluation results of **CacheS** with respect to different  $N$ . As expected, with the increase of the allowed size, analyses took more time before reaching the fixed point. Also, when the allowed size is small (i.e.,  $N$  is 1 or 10), the value set of certain registers is lifted into  $\{p\}$  rapidly and terminates the analysis due to memory write accesses through  $p$  (see Sec. 6.2; we terminate the analysis for memory access of  $p$  since it rewrites the whole memory). The full evaluation data in terms of different configurations is available in the extended paper [76].

Table 7: Evaluating different configurations of BOU. When  $N$  is set as 1 and 10, several analyses terminated before reaching the fixed point due to memory write accesses through the public symbol  $p$ . The full evaluation data in terms of each configuration can be found at [76].

Value of $N$	True Positive	False Positive	Processing Time (CPU Seconds)
1	N/A	N/A	N/A
10	167	1	584.5
25	207	1	1,446.8
50 (the default config)	207	1	1,637.4
100	207	1	3,563.46

## C Unknown Information Leaks in OpenSSL

```

# SCATTERCACHE: Thwarting Cache Attacks via Cache Set Randomization

Mario Werner, Thomas Unterluggauer, Lukas Giner,  
Michael Schwarz, Daniel Gruss, Stefan Mangard  
*Graz University of Technology*

## Abstract

Cache side-channel attacks can be leveraged as a building block in attacks leaking secrets even in the absence of software bugs. Currently, there are no practical and generic mitigations with an acceptable performance overhead and strong security guarantees. The underlying problem is that caches are shared in a predictable way across security domains.

In this paper, we eliminate this problem. We present SCATTERCACHE, a novel cache design to prevent cache attacks. SCATTERCACHE eliminates fixed cache-set congruences and, thus, makes eviction-based cache attacks unpractical. For this purpose, SCATTERCACHE retrofits skewed associative caches with a keyed mapping function, yielding a security-domain-dependent cache mapping. Hence, it becomes virtually impossible to find fully overlapping cache sets, rendering current eviction-based attacks infeasible. Even theoretical statistical attacks become unrealistic, as the attacker cannot confine contention to chosen cache sets. Consequently, the attacker has to resort to eviction of the entire cache, making deductions over cache sets or lines impossible and fully preventing high-frequency attacks. Our security analysis reveals that even in the strongest possible attacker model (noise-free), the construction of a reliable eviction set for PRIME+PROBE in an 8-way SCATTERCACHE with 16384 lines requires observation of at least 33.5 million victim memory accesses as compared to fewer than 103 on commodity caches. SCATTERCACHE requires hardware and software changes, yet is minimally invasive on the software level and is fully backward compatible with legacy software while still improving the security level over state-of-the-art caches. Finally, our evaluations show that the runtime performance of software is not curtailed and our design even outperforms state-of-the-art caches for certain realistic workloads.

## 1 Introduction

Caches are core components of today’s computing architectures. They bridge the performance gap between CPU cores

and a computer’s main memory. However, in the past two decades, caches have turned out to be the origin of a wide range of security threats [10, 15, 27, 38, 39, 43, 44, 51, 76]. In particular, the intrinsic timing behavior of caches that speeds up computing systems allows for cache side-channel attacks (cache attacks), which are able to recover secret information.

Historically, research on cache attacks focused on cryptographic algorithms [10, 44, 51, 76]. More recently, however, cache attacks like PRIME+PROBE [44, 48, 51, 54, 62] and FLUSH+RELOAD [27, 76] have also been used to attack address-space-layout randomization [23, 25, 36], keystroke processing and inter-keystroke timing [26, 27, 60], and general purpose computations [81]. For shared caches on modern multi-core processors, PRIME+PROBE and FLUSH+RELOAD even work across cores executing code from different security domains, e.g., processes or virtual machines.

The most simple cache attacks, however, are covert channels [46, 48, 72]. In contrast to a regular side-channel attack, in a covert channel, the “victim” is colluding and actively trying to transmit data to the attacker, e.g., running in a different security domain. For instance, Meltdown [43], Spectre [38], and Foreshadow [15] use cache covert channels to transfer secrets from the transient execution domain to an attacker. These recent examples highlight the importance of finding practical approaches to thwart cache attacks.

To cope with cache attacks, there has been much research on ways to identify information leaks in a software’s memory access pattern, such as static code [19, 20, 41, 45] and dynamic program analysis [34, 71, 74, 77]. However, mitigating these leaks both generically and efficiently is difficult. While there are techniques to design software without address-based information leaks, such as unifying control flow [17] and bitsliced implementations of cryptography [37, 40, 58], their general application to arbitrary software remains difficult. Hence, protecting against cache attacks puts a significant burden on software developers aiming to protect secrets in the view of microarchitectural details that vary a lot across different Instruction-Set Architecture (ISA) implementations.

A different direction to counteract cache attacks is to design

more resilient cache architectures. Typically, these architectures modify the cache organization in order to minimize interference between different processes, either by breaking the trivial link between memory address and cache index [22, 55, 67, 69, 70] or by providing exclusive access to cache partitions for critical code [53, 57, 69]. While cache partitioning completely prevents cache interference, its rather static allocation suffers from scalability and performance issues. On the other hand, randomized cache (re-)placement [69, 70] makes mappings of memory addresses to cache indices random and unpredictable. Yet, managing these cache mappings in lookup tables inheres extensive changes to the cache architecture and cost. Finally, the introduction of a keyed function [55, 67] to pseudorandomly map the accessed memory location to the cache-set index can counteract PRIME+PROBE attacks. However, these solutions either suffer from a low number of cache sets, weakly chosen functions, or cache interference for shared memory and thus require to change the key frequently at the cost of performance.

Hence, there is a strong need for a practical and effective solution to thwart both cache attacks and cache covert channels. In particular, this solution should (1) make cache attacks sufficiently hard, (2) require as little software support as possible, (3) embed flexibly into existing cache architectures, (4) be efficiently implementable in hardware, and (5) retain or even enhance cache performance.

**Contribution.** In this paper, we present SCATTERCACHE, which achieves all these goals. SCATTERCACHE is a novel and highly flexible cache design that prevents cache attacks such as EVICT+RELOAD and PRIME+PROBE and severely limits cache covert channel capacities by increasing the number of cache sets beyond the number of physically available addresses with competitive performance and implementation cost. Hereby, SCATTERCACHE closes the gap between previous secure cache designs and today's cache architectures by introducing a minimal set of cache modifications to provide strong security guarantees.

Most prominently, SCATTERCACHE eliminates the fixed cache-set congruences that are the cornerstone of PRIME+PROBE attacks. For this purpose, SCATTERCACHE builds upon two ideas. First, SCATTERCACHE uses a keyed mapping function to translate memory addresses and the active security domain, e.g., process, to cache set indices. Second, similar to skewed associative caches [63], the mapping function in SCATTERCACHE computes a different index for each cache way. As a result, the number of different cache sets increases exponentially with the number of ways. While SCATTERCACHE makes finding fully identical cache sets statistically impossible on state-of-the-art architectures, the complexity for exploiting inevitable partial cache-set collisions also rises heavily. The reason is in part that the mapping of memory addresses to cache sets in SCATTERCACHE is different for each security domain. Hence, and as our security analysis shows, the construction

of a reliable eviction set for PRIME+PROBE in an 8-way SCATTERCACHE with 16384 lines requires observation of at least 33.5 million victim memory accesses as compared to fewer than 103 on commodity caches, rendering these attacks impractical on real systems with noise.

Additionally, SCATTERCACHE effectively prevents FLUSH+RELOAD-based cache attacks, e.g., on shared libraries, as well. The inclusion of security domains in SCATTERCACHE and its mapping function preserves shared memory in RAM, but prevents any cache lines to be shared across security boundaries. Yet, SCATTERCACHE supports shared memory for inter-process communication via dedicated separate security domains. To achieve highest flexibility, managing the security domains of SCATTERCACHE is done by software, e.g., the operating system. However, SCATTERCACHE is fully backwards compatible and already increases the effort of cache attacks even without any software support. Nevertheless, the runtime performance of software on SCATTERCACHE is highly competitive and, on certain workloads, even outperforms cache designs implemented in commodity CPUs.

SCATTERCACHE constitutes a comparably simple extension to cache and processor architectures with minimal hardware cost: SCATTERCACHE essentially only adds additional index derivation logic, *i.e.*, a lightweight cryptographic primitive, and an index decoder for each scattered cache way. Moreover, to enable efficient lookups and writebacks, SCATTERCACHE stores the index bits from the physical address in addition to the tag bits, which adds  $< 5\%$  storage overhead per cache line. Finally, SCATTERCACHE consumes one bit per page-table entry ( $\approx 1.5\%$  storage overhead per page-table entry) for the kernel to communicate with the user space.

**Outline.** This paper is organized as follows. In [Section 2](#), we provide background information on caches and cache attacks. In [Section 3](#), we describe the design and concept of SCATTERCACHE. In [Section 4](#), we analyze the security of SCATTERCACHE against cache attacks. In [Section 5](#), we provide a performance evaluation. We conclude in [Section 6](#).

## 2 Background

In this section, we provide background on caches, cache side-channel attacks, and resilient cache architectures.

### 2.1 Caches

Modern computers have a memory hierarchy consisting of many layers, each following the principle of locality, storing data that is expected to be used in the future, e.g., based on what has been accessed in the past. Modern processors have a hierarchy of caches that keep instructions and data likely to be used in the future near the execution core to avoid the latency of accesses to the slow (DRAM) main memory. This cache hierarchy typically consists of 2 to 4 layers, where the

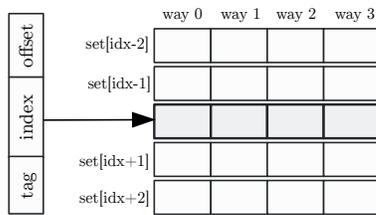

Figure 1: Indexing cache sets in a 4-way set-associative cache.

lowest layer is the smallest and fastest, typically only a few kilobytes. The last-level cache is the largest cache, typically in the range of several megabytes. On most processors, the last-level cache is shared among all cores. The last-level cache is often inclusive, *i.e.*, any cache line in a lower level cache must also be present in the last-level cache.

Caches are typically organized into *cache sets* that are composed of multiple *cache lines* or *cache ways*. The cache set is determined by computing the cache index from address bits. Figure 1 illustrates the indexing of a 4-way set-associative cache. As the cache is small and the memory large, many memory locations map to the same cache set (*i.e.*, the addresses are *congruent*). The replacement policy (e.g., pseudo-LRU, random) decides which way is replaced by a newly requested cache line. Any process can observe whether data is cached or not by observing the memory access latency which is the basis for cache side-channel attacks.

## 2.2 Cache Side-Channel Attacks

Cache side-channel attacks have been studied for over the past two decades, initially with a focus on cryptographic algorithms [10, 39, 51, 52, 54, 68]. Today, a set of powerful attack techniques enable attacks in realistic cross-core scenarios. Based on the access latency, an attacker can deduce whether or not a cache line is in the cache, leaking two opposite kinds of information. (1) By continuously removing (*i.e.*, evicting or flushing) a cache line from the cache and measuring the access latency, an attacker can determine whether this cache line has been accessed by another process. (2) By continuously filling a part of the cache with attacker-accessible data, the attacker can measure the contention of the corresponding part, by checking whether the attacker-accessible data remained in the cache. Contention-based attacks work on different layers:

**The Entire Cache or Cache Slices.** An attacker can measure contention of the entire cache or a cache slice. Maurice et al. [46] proposed a covert channel where the sender evicts the entire cache to leak information across cores and the victim observes the cache contention. A similar attack could be mounted on a cache slice if the cache slice function is known [47]. The granularity is extremely coarse, but with statistical attacks can leak meaningful information [61].

**Cache Sets.** An attacker can also measure the contention of a cache set. For this, additional knowledge may be required,

such as the mapping from virtual addresses to physical addresses, as well as the functions mapping physical addresses to cache slices and cache sets. The attacker continuously fills a cache set with a set of congruent memory locations. Filling a cache set is also called cache-set eviction, as it evicts any previously contained cache lines. Only if some other process accessed a congruent memory location, memory locations are evicted from a cache set. The attacker can measure this for instance by measuring runtime variations in a so-called EVICT+TIME attack [51]. The EVICT+TIME technique has mostly been applied in attacks on cryptographic implementations [31, 42, 51, 65]. Instead of the runtime, the attacker can also directly check how many of the memory locations are still cached. This attack is called PRIME+PROBE [51]. Many PRIME+PROBE attacks on private L1 caches have been demonstrated [3, 14, 51, 54, 80]. More recently, PRIME+PROBE attacks on last-level caches have also been demonstrated in various generic use cases [4, 44, 48, 50, 59, 79].

**Cache Lines.** At a cache line granularity, the attacker can measure whether a memory location is cached or not. As already indicated above, here the logic is inverted. Now the attacker continuously evicts (or flushes) a cache line from the cache. Later on, the attacker can measure the latency and deduce whether another process has loaded the cache line into the cache. This technique is called FLUSH+RELOAD [28, 76]. FLUSH+RELOAD has been studied in a long list of different attacks [4–6, 27, 32, 35, 42, 76, 78, 81]. Variations of FLUSH+RELOAD are FLUSH+FLUSH [26] and EVICT+RELOAD [27, 42].

### Cache Covert Channels

Cache covert channels are one of the simplest forms of cache attacks. Instead of an attacker process attacking a victim process, both processes collude to covertly communicate using the cache as transmission channel. Thus, in this scenario, the colluding processes are referred to as sender and receiver, as the communication is mostly unidirectional. A cache covert channel allows bypassing all architectural restrictions regarding data exchange between processes.

Cache covert channels have been shown using various cache attacks, such as PRIME+PROBE [44, 48, 73, 75] and FLUSH+RELOAD [26]. They achieve transmission rates of up to 496 kB/s [26]. Besides native attacks, covert channels have also been shown to work within virtualized environments, across virtual machines [44, 48, 75]. Even in these restricted environments, cache-based covert channels achieve transmission rates of up to 45 kB/s [48].

## 2.3 Resilient Cache Architectures

The threat of cache-based attacks sparked several novel cache architectures designed to be resilient against these attacks. While fixed cache partitions [53] lack flexibility, randomized

cache allocation appears to be more promising. The following briefly discusses previous designs for a randomized cache.

**RPCache [69] and NewCache [70]** completely disrupt the meaningful observability of interference by performing random (re-)placement of lines in the cache. However, managing the cache mappings efficiently either requires full associativity or content addressable memory. While optimized addressing logic can lead to efficient implementations, these designs differ significantly from conventional architectures.

**Time-Secure Caches [67]** is based on standard set-associative caches that are indexed with a keyed function that takes cache line address and Process ID (PID) as an input. While this design destroys the obvious cache congruences between processes to minimize cache interference, a comparably weak indexing function is used. Eventually, re-keying needs to be done quite frequently, which amounts to flushing the cache and thus reduces practical performance. SCATTERCACHE can be seen as a generalization of this approach with higher entropy in the indexing of cache lines.

**CEASER [55]** as well uses standard set-associative caches with keyed indexing, which, however, does not include the PID. Hence, inter-process cache interference is predictable based on in-process cache collisions. As a result, CEASER strongly relies on continuous re-keying of its index derivation to limit the time available for conducting an attack. For efficient implementation, CEASER uses its own lightweight cryptographic primitive designed for that specific application.

### 3 ScatterCache

As Section 2 showed, caches are a serious security concern in contemporary computing systems. In this section, we hence present SCATTERCACHE—a novel cache architecture that counteracts cache-based side-channel attacks by skewed pseudorandom cache indexing. After discussing the main idea behind SCATTERCACHE, we discuss its building blocks and system integration in more detail. SCATTERCACHE’s security implications are, subsequently, analyzed in Section 4.

#### 3.1 Targeted Properties

Even though contemporary transparent cache architectures are certainly flawed from the security point of view, they still feature desirable properties. In particular, for regular computations, basically no software support is required for cache maintenance. Also, even in the case of multitasking and -processing, no dedicated cache resource allocation and scheduling is needed. Finally, by selecting the cache size and the number of associative ways, chip vendors can trade hardware complexity and costs against performance as desired.

SCATTERCACHE’s design strives to preserve these features while adding the following three security properties:

1. Between software defined security domains (e.g., different processes or users on the same machine, different

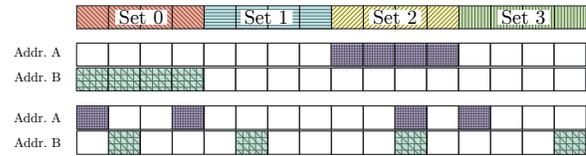

Figure 2: Flattened visualization of mapping addresses to cache sets in a 4-way set-associative cache with 16 cache lines. *Top*: Standard cache where index bits select the cache set. *Middle*: Pseudorandom mapping from addresses to cache sets. The mapping from cache lines to sets is still static. *Bottom*: Pseudorandom mapping from addresses to a set of cache lines that dynamically form the cache set in SCATTERCACHE.

VMs, ...), even for exactly the same physical addresses, cache lines should only be shared if cross-context coherency is required (i.e., writable shared memory).

2. Finding and exploiting addresses that are congruent in the cache should be as hard as possible (i.e., we want to “break” the direct link between the accessed physical address and the resulting cache set index for adversaries).
3. Controlling and measuring complete cache sets should be hard in order to prevent eviction-based attacks.

Finally, to ease the adoption and to utilize the vast knowledge on building efficient caches, the SCATTERCACHE hardware should be as similar to current cache architectures as possible.

#### 3.2 Idea

Two main ideas influenced the design of SCATTERCACHE to reach the desired security properties. First, addresses should be translated to cache sets using a keyed, security-domain aware mapping. Second, which exact  $n_{ways}$  cache lines form a cache set in a  $n_{ways}$ -way associative cache should not be fixed, but depend on the currently used key and security domain too. SCATTERCACHE combines both mappings in a single operation that associates each address, depending on the key and security domain, with a set of up to  $n_{ways}$  cache lines. In other words, in a generic SCATTERCACHE, any possible combination of up to  $n_{ways}$  cache lines can form a cache set.

Figure 2 visualizes the idea and shows how it differs from related work. Traditional caches as well as alternative designs which pseudorandomly map addresses to cache sets statically allocate cache lines to cache sets. Hence, as soon as a cache set is selected based on (possibly encrypted) index bits, always the same  $n_{ways}$  cache lines are used. This means that all addresses mapping to the same cache set are congruent and enables PRIME+PROBE-style attacks.

In SCATTERCACHE, on the other hand, the cache set for a particular access is a pseudorandom selection of arbitrary  $n_{ways}$  cache lines from all available lines. As a result, there is a much higher number of different cache sets and finding addresses with identical cache sets becomes highly unlikely.

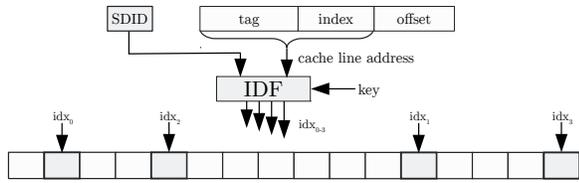

Figure 3: Idea: For an  $n_{ways}$  associative cache,  $n_{ways}$  indices into the cache memory are derived using a cryptographic IDF. This IDF effectively randomizes the mapping from addresses to cache sets as well as the composition of the cache set itself.

Instead, as shown at the bottom of Figure 2, at best, partially overlapping cache sets can be found (cf. Section 4.3), which makes exploitation tremendously hard in practice.

A straightforward concept for SCATTERCACHE is shown in Figure 3. Here, the Index Derivation Function (IDF) combines the mapping operations in a single cryptographic primitive. In a set-associative SCATTERCACHE with set size  $n_{ways}$ , for each input address, the IDF outputs  $n_{ways}$  indices to form the cache set for the respective access. How exactly the mapping is performed in SCATTERCACHE is solely determined by the used key, the Security Domain Identifier (SDID), and the IDF. Note that, as will be discussed in Section 3.3.1, hash-based as well as permutation-based IDFs can be used in this context.

Theoretically, a key alone is sufficient to implement the overall idea. However, separating concerns via the SDID leads to a more robust and harder-to-misuse concept. The key is managed entirely in hardware, is typically longer, and gets switched less often than the SDID. On the other hand, the SDID is managed solely by the software and, depending on the implemented policy, has to be updated quite frequently. Importantly, as we show in Section 4, SCATTERCACHE alone already provides significantly improved security in PRIME+PROBE-style attack settings even without software support (*i.e.*, SDID is not used).

### 3.3 SCATTERCACHE Design

In the actual design we propose for SCATTERCACHE, the indices (*i.e.*, IDF output) do not address into one huge joint cache array. Instead, as shown in Figure 4, each index addresses a separate memory, *i.e.*, an independent cache way.

On the one hand, this change is counter-intuitive as it decreases the number of possible cache sets from  $\binom{n_{ways} \cdot 2^{b_{indices}} + n_{ways} - 1}{n_{ways}}$  to  $2^{b_{indices} \cdot n_{ways}}$ . However, this reduction in possibilities is acceptable. For cache configurations with up to 4 cache ways, the gap between both approaches is only a few bits. For higher associativity, the exponential growth ensures that sufficiently many cache sets exist.

On the other hand, the advantages gained from switching to this design far outweigh the costs. Namely, for the original idea, no restrictions on the generated indices exist. Therefore, a massive  $n_{ways}$ -fold multi-port memory would be required to

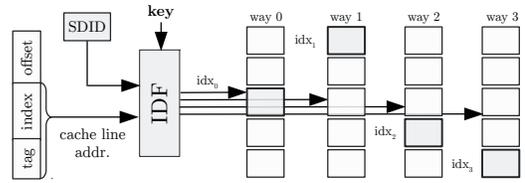

Figure 4: 4-way set-associative SCATTERCACHE where each index addresses exclusively one cache way.

be able to lookup a  $n_{ways}$ -way cache-set in parallel. The design shown in Figure 4 does not suffer from this problem and permits to instantiate SCATTERCACHE using  $n_{ways}$  instances of simpler/smaller memory. Furthermore, this design guarantees that even in case the single index outputs of the IDF collide, the generated cache always consists of exactly  $n_{ways}$  many cache lines. This effectively precludes the introduction of systematic biases for potentially “weak” address-key-SDID combinations that map to fewer than  $n_{ways}$  cache lines.

In terms of cache-replacement policy, SCATTERCACHE uses simple random replacement to ensure that no systematic bias is introduced when writing to the cache and to simplify the security analysis. Furthermore, and as we will show in Section 5, the performance of SCATTERCACHE with random replacement is competitive to regular set associative caches with the same replacement policy. Therefore, evaluation of alternative replacement policies has been postponed. Independent of the replacement policy, it has to be noted that, for some IDFs, additional tag bits have to be stored in SCATTERCACHE. In particular, in case of a non invertible IDF, the original index bits need to be stored to facilitate write back of dirty cache lines and to ensure correct cache lookups. However, compared to the amount of data that is already stored for each cache line, the overhead of adding these few bits should not be problematic ( $< 5\%$  overhead).

In summary, the overall hardware design of SCATTERCACHE closely resembles a traditional set-associative architecture. The only differences to contemporary fixed-set designs is the more complex IDF and the amount of required logic which permits to address each way individually. However, both changes are well understood. As we detail in the following section, lightweight (*i.e.*, low area and latency) cryptographic primitives are suitable building blocks for the IDF. Similarly, duplication of addressing logic is already common practice in current processors. Modern Intel architectures, for example, already partition their Last-Level Cache (LLC) into multiple smaller cache slices with individual addressing logic.

#### 3.3.1 Suitable Index Derivation Functions

Choosing a suitable IDF is essential for both security and performance. In terms of security, the IDF has to be an unpredictable (but still deterministic) mapping from physical addresses to indices. Following Kerckhoffs’s principle, even

for attackers which know every detail except the key, three properties are expected from the IDF: (1) Given perfect control over the public inputs of the function (*i.e.*, the physical address and SDID) constructing colliding outputs (*i.e.*, the indices) should be hard. (2) Given colliding outputs, determining the inputs or constructing further collisions should be hard. (3) Recovering the key should be infeasible given input and output for the function.

**Existing Building Blocks:** Cryptographic primitives like (tweakable) block ciphers, Message Authentication Codes (MACs), and hash functions are designed to provide these kind of security properties (e.g., indistinguishability of encryptions, existential unforgeability, pre-image and collision resistance). Furthermore, design and implementation of cryptographic primitives with tight performance constraints is already a well-established field of research which we want to take advantage of. For example, with PRINCE [13], a low-latency block cipher, and QARMA [8], a family of low-latency tweakable block ciphers, exist and can be used as building blocks for the IDF. Such tweakable block ciphers are a flexible extension to ordinary block ciphers, which, in addition to a secret key, also use a public, application-specific tweak to en-/decrypt messages. Similarly, sponge-based MAC, hash and cipher designs are a suitable basis for IDFs. These sponge modes of operation are built entirely upon permutations, e.g., Keccak- $p$ , which can often be implemented with low latency [7, 11]. Using such cryptographic primitives, we define the following two variants of building IDFs:

**Hashing Variant (SCv1):** The idea of SCv1 is to combine all IDF inputs using a single cryptographic primitive with pseudo random output. MACs (e.g., hash-based) are examples for such functions and permit to determine the output indices by simply selecting the appropriate number of disjunct bits from the calculated tag. However, also other cryptographic primitives can be used for instantiating this IDF variant.

It is, for example possible to slice the indices from the ciphertext of a regular block cipher encryption which uses the concatenation of cache line address and the SDID as the plaintext. Similarly, tweakable block ciphers allow to use the SDID as a tweak instead of connecting it to the plaintext. Interestingly, finding cryptographic primitives for SCv1 IDFs is comparably simple given that the block sizes do not have to match perfectly and the output can be truncated as needed.

However, there are also disadvantages when selecting the indices pseudo randomly, like in the case of SCv1. In particular, when many accesses with high spatial locality are performed, index collisions get more likely. This is due to the fact that collisions in SCv1 output have birthday-bound complexity. Subsequently, performance can degrade when executing many different accesses with high spatial locality. Fortunately, this effect weakens with increasing way numbers, *i.e.*, an increase in associativity decreases the probability that all index outputs of the IDF collide.

In summary, SCv1 translates the address without distin-

guishing between index and tag bits. Given a fixed key and SDID, the indices are simply pseudo random numbers that are derived using a single cryptographic primitive.

**Permutation Variant (SCv2):** The idea behind the permutation variant of the IDF is to distinguish the index from the tag bits in the cache line address during calculation of the indices. Specifically, instead of generating pseudo random indices from the cache line address, tag dependent permutations of the input index are calculated.

The reason for preferring a permutation over pseudo random index generation is to counteract the effect of birthday-bound index collisions, as present in SCv1. Using a tag dependent permutation of the input index mitigates this problem by design since permutations are bijections that, for a specific tag, cannot yield colliding mappings.

Like in the hashing variant, a tweakable block cipher can be used to compute the permutation. Here, the concatenation of the tag bits, the SDID and the way index constitutes the tweak while the address' index bits are used as the plaintext. The resulting ciphertext corresponds to the output index for the respective way. Note that the block size of the cipher has to be equal to the size of the index. Additionally, in order to generate all indices in parallel, one instance of the tweakable block cipher is needed per cache way. However, as the block size is comparably small, each cipher instance is also smaller than an implementation of the hashing IDF (SCv1).

Independently of the selected IDF variant, we leave the decision on the actually used primitive to the discretion of the hardware designers that implement SCATTERCACHE. They are the only ones who can make a profound decision given that they know the exact instantiation parameters (e.g., SDID/key/index/tag bit widths, number of cache ways) as well as the allocatable area, performance, and power budget in their respective product. However, we are certain that, even with the already existing and well-studied cryptographic primitives, SCATTERCACHE implementations are feasible for common computing platforms, ranging from Internet of Things (IoT) devices to desktop computers and servers.

Note further that we expect that, due to the limited observability of the IDF output, weakened (*i.e.*, round reduced) variants of general purpose primitives are sufficient to achieve the desired security level. This is because adversaries can only learn very little information about the function output by observing cache collisions (*i.e.*, no actual values). Subsequently, many more traces have to be observed for mounting an attack. Cryptographers can take advantage of this increase in data complexity to either design fully custom primitives [55] or to decrease the overhead of existing designs.

### 3.3.2 Key Management and Re-Keying

The key in our SCATTERCACHE design plays a central role in the security of the entire approach. Even when the SDIDs are known, it prevents attackers from systematically constructing

eviction sets for specific physical addresses and thwarts the calculation of addresses from collision information. Keeping the key confidential is therefore of highest importance.

We ensure this confidentiality in our design by mandating that the key of is fully managed by hardware. There must not be any way to configure or retrieve this key in software. This approach prevents various kinds of software-based attacks and is only possible due to the separation of key and SDID.

The hardware for key management is comparably simple as well. Each time the system is powered up, a new random key is generated and used by the IDF. The simplicity of changing the key during operation strongly depends on the configuration of the cache. For example, in a write-through cache, changing the key is possible at any time without causing data inconsistency. In such a scenario, a timer or performance-counter-based rekeying scheme is easily implementable. Note, however, that the interval between key changes should not be too small as each key change corresponds to a full cache flush.

On the other hand, in a cache with write-back policy, the key has to be kept constant as long as dirty cache lines reside in the cache. Therefore, before the key can be changed in this scenario without data loss, all modified cache lines have to be written back to memory first. The x86 Instruction-Set Architecture (ISA), for example, features the `WBINVD` instruction that can be used for that purpose.

If desired, also more complex rekeying schemes, like way-wise or cache-wide dynamic remapping [55], can be implemented. However, it is unclear if adding the additional hardware complexity is worthwhile. Even without changing the key, mounting cache attacks against SCATTERCACHE is much harder than on traditional caches (see Section 4). Subsequently, performing an occasional cache flush to update the key can be the better choice.

### 3.3.3 Integration into Existing Cache Architectures

SCATTERCACHE is a generic approach for building processor caches that are hard to exploit in cache-based side channel attacks. When hardening a system against cache attacks, independent of SCATTERCACHE, we recommend to restrict flush instructions to privileged software. These instruction are only rarely used in benign userspace code and restricting them prevents the applicability of the whole class of flush-based attacks from userspace. Fortunately, recent ARM architectures already support this restriction.

Next, SCATTERCACHES can be deployed into the system to protect against eviction based attacks. While not inherently limited to, SCATTERCACHES are most likely to be deployed as LLCs in modern processor architectures. Due to their large size and the fact that they are typically shared across multiple processor cores, LLCs are simply the most prominent cache attack target and require the most protection. Compared to that, lower cache levels that typically are only accessible by a single processor core, hold far less data and are much harder

to attack on current architectures. Still, usage of (unkeyed) skewed [63] lower level caches is an interesting option that has to be considered in this context.

Another promising aspect of employing a SCATTERCACHE as LLC is that this permits to hide large parts of the IDF latency. For example, using a fully unrolled and pipelined IDF implementation, calculation of the required SCATTERCACHE indices can already be started, or even performed entirely, in parallel to the lower level cache lookups. While unneeded results can easily be discarded, this ensures that the required indices for the LLC lookup are available as soon as possible.

Low latency primitives like QARMA, which is also used in recent ARM processors for pointer authentication, are promising building blocks in this regard. The minimal latency Avanzi [8] reported for one of the QARMA-64 variants is only 2.2 ns. Considering that this number is even lower than the time it takes to check the L1 and L2 caches on recent processors (e.g., 3 ns on a 4 GHz Intel Kabylake [2], 9 ns on an ARM Cortex-A57 in an AMD Opteron A1170 [1]), implementing IDFs without notable latency seems feasible.

## 3.4 Processor Interaction and Software

Even without dedicated software support, SCATTERCACHE increases the complexity of cache-based attacks. However, to make full use of SCATTERCACHE, software assistance and some processor extensions are required.

**Security Domains.** The SCATTERCACHE hardware permits to isolate different security domains from each other via the SDID input to the IDF. Unfortunately, depending on the use case, the definition on what is a security domain can largely differ. For example, a security domain can be a chunk of the address space (e.g., SGX enclaves), a whole process (e.g., TrustZone application), a group of processes in a common container (e.g., Docker, LXC), or even a full virtual machine (e.g., cloud scenario). Considering that it is next to impossible to define a generic policy in hardware that can capture all these possibilities, we delegate the distinction to software that knows about the desired isolation properties, e.g., the Operating System (OS).

**SCATTERCACHE Interface.** Depending on the targeted processor architecture, different design spaces can be explored before deciding how the current SDID gets defined and what channels are used to communicate the identifier to the SCATTERCACHE. However, at least for modern Intel and ARM processors, binding the currently used SDID to the virtual memory management via user defined bits in each Page Table Entry (PTE) is a promising approach. In more detail, one or more bits can be embedded into each PTE that select from a list, via one level of indirection, which SDID should be used when accessing the respective page.

Both ARM and Intel processors already support a similar mechanism to describe memory attributes of a memory mapping. The x86 architecture defines so-called Page Attribute Ta-

bles (PATs) to define how a memory mapping can be cached. Similarly, the ARM architecture defines Memory Attribute Indirection Registers (MAIRs) for the same purpose. Both PAT and MAIR define a list of 8 memory attributes which are applied by the Memory Management Unit (MMU). The MMU interprets a combination of 3 bits defined in the PTE as index into the appropriate list, and applies the corresponding memory attribute. Adding the SDID to these attribute lists permits to use up to 8 different security domains within a single process. The absolute number of security domains, on the other hand, is only limited by the used IDF and their number of bits that represent the SDID.

Such indirection has a huge advantage over encoding data directly in a PTE. The OS can change a single entry within the list to affect all memory mappings using the corresponding entry. Thus, such a mechanism is beneficial for SCATTERCACHE, where the OS wants to change the SDID for all mappings of a specific process.

**Backwards Compatibility.** Ensuring backwards compatibility is a key factor for gradual deployment of SCATTERCACHE. By encoding the SDID via a separate list indexed by PTE bits, all processes, as well as the OS, use the same SDID, *i.e.*, the SDID stored as first element of the list (assuming all corresponding PTE bits are ‘0’ by default). Thus, if the OS is not aware of the SCATTERCACHE, all processes—including the OS—use the same SDID. From a software perspective, functionally, SCATTERCACHE behaves the same as currently deployed caches. Only if the OS specifies SDIDs in the list, and sets the corresponding PTE bits to use a certain index, SCATTERCACHE provides its strong security properties.

**Implementation Example.** In terms of capabilities, having a single bit in each PTE, for example, is already sufficient to implement security domains with process granularity and to maintain a dedicated domain for the OS. In this case,  $SDID_0$  can always be used for the OS ID while  $SDID_1$  has to be updated as part of the context switch and is always used for the scheduled user space process. Furthermore, by reusing the SDID of the OS, also shared memory between user space processes can easily be implemented without security impact.

Interestingly, SCATTERCACHE fully preserves the capability of the OS to share read-only pages (*i.e.*, libraries) also across security domains as no cache lines will be shared. In contrast, real shared memory has to always be accessed via the same SDID in all processes to ensure data consistency. In general, with SCATTERCACHE, as long as the respective cache lines have not been flushed to RAM, data always needs to be accessed with the same SDID the data has been written with to ensure correctness. This is also true for the OS, which has to ensure that no dirty cache lines reside in the cache, *e.g.*, when a page gets assigned to a new security domain.

A case which has to be explicitly considered by the OS is copying data from user space to kernel space and vice versa. The OS can access the user space via the direct-physical map or via the page tables of the process. Thus, the OS has to

select the correct SDID for the PTE used when copying data. Similarly, if the OS sets up page tables, it has to use the same SDID as the MMU uses for resolving page tables.

## 4 Security Evaluation

SCATTERCACHE is a novel cache design to efficiently thwart cache-based side-channel attacks. In the following, we investigate the security of SCATTERCACHE in terms of state-of-the-art side-channel attacks using both theoretical analysis and simulation-based results. In particular, we elaborate on the complexity of building the eviction sets and explore the necessary changes to the standard PRIME+PROBE technique to make it viable on the SCATTERCACHE architecture.

### 4.1 Applicability of Cache Attacks

While certain types of cache attacks, such as FLUSH+FLUSH, FLUSH+RELOAD and EVICT+RELOAD, require a particular cache line to be shared, attacks such as PRIME+PROBE have less stringent constraints and only rely on the cache being a shared resource. As sharing a cache line is the result of shared memory, we analyze the applicability of cache attacks on SCATTERCACHE with regard to whether the underlying memory is shared between attacker and victim or not.

**Shared, read-only memory.** Read-only memory is frequently shared among different processes, *e.g.*, in case of shared code libraries. SCATTERCACHE prevents cache attacks involving shared read-only memory by introducing security domains. In particular, SCATTERCACHE maintains a separate copy of shared read-only memory in cache for each security domain, *i.e.*, the cache lines belonging to the same shared memory region are not being shared in cache across security domains anymore. As a result, reloading data into or flushing data out of the cache does not provide any information on another security domain’s accesses to the respective shared memory region. Note, however, that the cache itself is shared, leaving attacks such as PRIME+PROBE still feasible.

**Shared, writable memory.** Exchanging data between processes requires shared, writable memory. To ensure cache coherency, writing shared memory regions must always use the same cache line and hence the same security domain for that particular memory region—even for different processes. While attacks on these shared memory regions involving flush instructions can easily be mitigated by making these instructions privileged, EVICT+RELOAD remains feasible. Still, SCATTERCACHE significantly hampers the construction of targeted eviction sets by skewing, *i.e.*, individually addressing, the cache ways. Moreover, its susceptibility to EVICT+RELOAD attacks is constrained to the processes sharing the respective memory region. Nevertheless, SCATTERCACHE requires writable shared memory to be used only as an interface for data transfer rather than sensitive computations. In addition, PRIME+PROBE attacks are still possible.

**Unshared memory.** Unshared memory regions never share the same cache line, hence making attacks such as FLUSH+FLUSH, FLUSH+RELOAD and EVICT+RELOAD infeasible. However, as the cache component itself is shared, cache attacks such as PRIME+PROBE remain possible.

As our analysis shows, SCATTERCACHE prevents a wide range of cache attacks that exploit the sharing of cache lines across security boundaries. While PRIME+PROBE attacks cannot be entirely prevented as long as the cache itself is shared, SCATTERCACHE vastly increases their complexity in all aspects. The pseudorandom cache-set composition in SCATTERCACHE prevents attackers from learning concrete cache sets from memory addresses and vice versa. Even if attackers are able to profile information about the mapping of memory addresses to cache-sets in their own security domain, it does not allow them infer the mapping of cache-sets to memory addresses in other security domains. To gain information about memory being accessed in another security domain, an attacker needs to profile the mapping of the attacker’s address space to cache lines that are being used by the victim when accessing the memory locations of interest. The effectiveness of PRIME+PROBE attacks thus heavily relies on the complexity of such a profiling phase. We elaborate on the complexity of building eviction sets in [Section 4.3](#).

## 4.2 Other Microarchitectural Attacks

Many other microarchitectural attacks are not fully mitigated but hindered by SCATTERCACHE. For instance, Melt-down [43] and Spectre [38] attacks cannot use the cache efficiently anymore but must resort to other covert channels. Also, DRAM row buffer attacks and Rowhammer attacks are negatively affected as they require to bypass the cache and reach DRAM. While these attacks are already becoming more difficult due to closed row policies in modern processors [24], we propose to make flush instructions privileged, removing the most widely used cache bypass. Cache eviction gets much more difficult with SCATTERCACHE and additionally, spurious cache misses will open DRAM rows during eviction. These spurious DRAM row accesses make the row hit side channel impractical and introduce a significant amount of noise on the row conflict side channel. Hence, while these attacks are not directly in the scope of this paper, SCATTERCACHE arguably has a negative effect on them.

## 4.3 Complexity of Building Eviction Sets

Cache skewing significantly increases the number of different cache sets available in cache. However, many of these cache sets will overlap partially, *i.e.*, in  $1 \leq i < n_{ways}$  ways. The complexity of building eviction sets for EVICT+RELOAD and PRIME+PROBE in SCATTERCACHE thus depends on the overlap of cache sets.

### 4.3.1 Full Cache-Set Collisions

The pseudorandom assembly of cache sets in SCATTERCACHE results in  $2^{b_{indices} \cdot n_{ways}}$  different compositions. For a given target address, this results in a probability of  $2^{-b_{indices} \cdot n_{ways}}$  of finding another address that maps exactly to the same cache lines in its assigned cache set. While dealing with this complexity alone can be considered impractical in a real-world scenario, note that it will commonly even exceed the number of physical addresses available in current systems, rendering full cache-set collisions completely infeasible. A 4-way cache, for example, with  $b_{indices} = 12$  index bits yields  $2^{48}$  different cache sets, which already exceeds the address space of state-of-the-art systems.

### 4.3.2 Partial Cache-Set Collisions

While full cache-set collisions are impractical, partial collisions of cache sets frequently occur in skewed caches such as SCATTERCACHE. If the cache sets of two addresses overlap, two cache sets will most likely have a single cache line in common. For this reason, we analyze the complexity of eviction for single-way collisions in more detail.

**Randomized Single-Set Eviction.** Without knowledge of the concrete mapping from memory addresses to cache sets, the trivial approach of eviction is to access arbitrary memory locations, which will result in accesses to pseudorandom cache sets in SCATTERCACHE. To elaborate on the performance of this approach, we consider a cache with  $n_{lines} = 2^{b_{indices}}$  cache lines per way and investigate the eviction probability for a single cache way, which contains a specific cache line to be evicted. Given that SCATTERCACHE uses a random (re-)placement policy, the probabilities of each cache way are independent, meaning that each way has the same probability of being chosen. Subsequently, the attack complexity on the full SCATTERCACHE increases linearly with the number of cache ways, *i.e.*, the attack gets harder.

The probability of an arbitrary memory accesses to a certain cache way hitting a specific cache line is  $p = n_{lines}^{-1}$ . Performing  $n_{accesses}$  independent accesses to this cache way increases the odds of eviction to a certain confidence level  $\alpha$ .

$$\alpha = 1 - (1 - n_{lines}^{-1})^{n_{accesses}}$$

Equivalently, to reach a certain confidence  $\alpha$  in evicting the specific cache line, attackers have to perform

$$\mathbb{E}(n_{accesses}) = \frac{\log(1 - \alpha)}{\log(1 - n_{lines}^{-1})}$$

independent accesses to this cache way, which amounts to their attack complexity. Hence, to evict a certain cache set from an 8-way SCATTERCACHE with  $2^{11}$  lines per way with  $\alpha = 99\%$  confidence, the estimated attack complexity using this approach is  $n_{accesses} \cdot n_{ways} \approx 2^{16}$  independent accesses.

**Randomized Multi-Set Eviction.** Interestingly, eviction of multiple cache sets using arbitrary memory accesses has

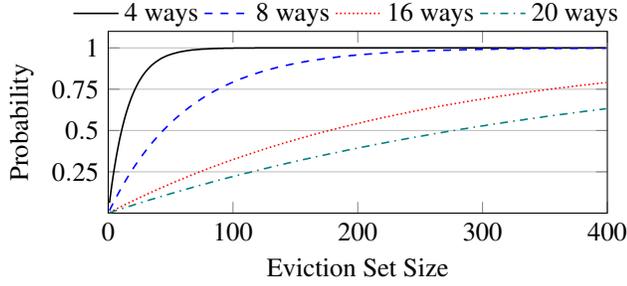

Figure 5: Eviction probability depending on the size of the eviction set and the number of ways.

similar complexity. In this regard, the *coupon collector's problem* gives us a tool to estimate the number of accesses an attacker has to perform to a specific cache way to evict a certain percentage of cache lines in the respective way. In more detail, the coupon collector's problem provides the expected number of accesses  $n_{accesses}$  required to a specific cache way such that  $n_{hit}$  out of all  $n_{lines}$  cache lines in the respective way are hit.

$$\mathbb{E}(n_{accesses}) = n_{lines} \cdot (H_{n_{lines}} - H_{n_{lines} - n_{hit}})$$

Hereby,  $H_n$  denotes the  $n$ -th Harmonic number, which can be approximated using the natural logarithm. This approximation allows to determine the number of cache lines  $n_{hit}$  that are expected to be hit in a certain cache way when  $n_{accesses}$  random accesses to the specific way are performed.

$$\mathbb{E}(n_{hit}) = n_{lines} \cdot \left(1 - e^{-\frac{n_{accesses}}{n_{lines}}}\right) \quad (1)$$

Using  $n_{hit}$ , we can estimate the number of independent accesses to be performed to a specific cache way such that a portion  $\beta$  of the respective cache way is evicted.

$$\mathbb{E}(n_{accesses}) = -n_{lines} \cdot \ln(1 - \beta)$$

For the same 8-way SCATTERCACHE with  $2^{11}$  lines per way as before, we therefore require roughly  $2^{16}$  independent accesses to evict  $\beta = 99\%$  of the cache.

**Profiled Eviction for PRIME+PROBE.** As shown, relying on random eviction to perform cache-based attacks involves significant effort and yields an overapproximation of the eviction set. Moreover, while random eviction is suitable for attacks such as EVICT+RELOAD, in PRIME+PROBE settings random eviction fails to provide information related to the concrete memory location that is being used by a victim. To overcome these issues, attackers may profile a system to construct eviction sets for specific memory addresses of the victim, *i.e.*, they try to find a set of addresses that map to cache sets that partially overlap with the cache set corresponding to the victim address. Eventually, such sets could be used to speed up eviction and to detect accesses to specific memory locations. In the following, we analyze the complexity of finding these eviction sets. In more detail, we perform analysis w.r.t. eviction addresses whose cache sets overlap with the cache set of a victim address in a single cache way only.

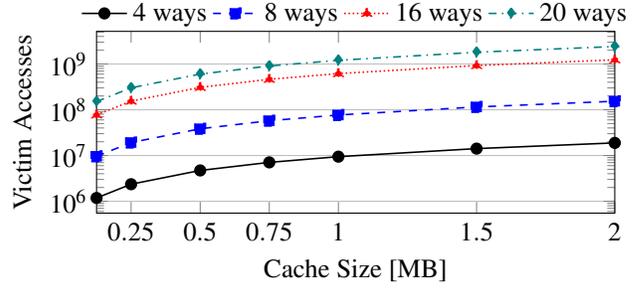

Figure 6: Number of required accesses to the target address to construct a set large enough to achieve 99% eviction rate when no shared memory is available (cache line size: 32 bytes).

To construct a suitable eviction set for PRIME+PROBE, the attacker needs to provoke the victim process to perform the access of interest. In particular, the attacker tests a candidate address for cache-set collisions by accessing it (prime), waiting for the victim to access the memory location of interest, and then measuring the time when accessing the candidate address again (probe). In such a profiling procedure, after the first attempt, we have to assume that the cache line belonging to the victim access already resides in the cache. As a result, attackers need to evict a victim's cache line in their prime step. Hereby, hitting the right cache way and index have probability  $n_{ways}^{-1}$  and  $2^{-b_{indices}}$ , respectively. To be able to detect a collision during the probe step, the victim access must then fall into the same cache way as the candidate address, which has a chance of  $n_{ways}^{-1}$ . In total, the expected number of memory accesses required to construct an eviction set of  $t$  colliding addresses hence is

$$\mathbb{E}(n_{accesses}) = n_{ways}^2 \cdot 2^{b_{indices}} \cdot t.$$

The number of memory addresses  $t$  needs to be chosen according to the desired eviction probability for the victim address with the given set. When the eviction set consists of addresses that collide in the cache with the victim in exactly one way each, the probability of evicting the victim with an eviction set of size  $t$  is

$$p(\text{Eviction}) = 1 - \left(1 - \frac{1}{n_{ways}}\right)^{\frac{t}{n_{ways}}}.$$

Figure 5 depicts this probability for the size of the eviction set and different numbers of cache ways. For an 8-way SCATTERCACHE with  $2^{11}$  cache lines per way, roughly 275 addresses with single-way cache collisions are needed to evict the respective cache set with 99% probability. Constructing this eviction set, in the best case, requires profiling of approximately  $8^2 \cdot 2^{11} \cdot 275 \approx 2^{25}$  (33.5 million) victim accesses. Figure 6 shows the respective number of PRIME+PROBE experiments needed to generate sets with 99% eviction probability for different cache configurations. We were able to empirically confirm these numbers within a noise-free standalone simulation of SCATTERCACHE.

For comparison, to generate an eviction set on a commodity cache, e.g., recent Intel processors, for a specific victim memory access, an attacker needs fewer than 103 observations of that access in a completely noise-free attacker-controlled scenario. Hence, our cache increases the complexity for the attacker by factor 325 000. In a real-world scenario the complexity is even higher.

**Profiled Eviction for EVICT+RELOAD.** For shared memory, such as in EVICT+RELOAD, the construction of eviction sets, however, becomes easier, as shared memory allows the attacker to simply access the victim address. Hence, to build a suitable eviction set, the attacker first primes the victim address, then accesses a candidate address, and finally probes the victim address. In case a specific candidate address collides with the victim address in the cache way the victim access falls into, the attacker can observe this collision with probability  $p = n_{ways}^{-1}$ . As a result, the expected number of memory accesses required to build an eviction set of  $t$  colliding addresses for EVICT+RELOAD is

$$\mathbb{E}(n_{accesses}) = n_{ways} \cdot 2^{b_{indices}} \cdot t.$$

For an 8-way SCATTERCACHE with  $2^{11}$  lines per way, constructing an EVICT+RELOAD eviction set of 275 addresses (i.e., 99% eviction probability) requires profiling with roughly  $8 \cdot 2^{11} \cdot 275 = 2^{22}$  memory addresses. Note, however, that EVICT+RELOAD only applies to writable shared memory as used for Inter Process Communication (IPC), whereas SCATTERCACHE effectively prevents EVICT+RELOAD on shared read-only memory by using different cache-set compositions in each security domain. Moreover, eviction sets for both PRIME+PROBE and EVICT+RELOAD must be freshly created whenever the key or the SDID changes.

## 4.4 Complexity of PRIME+PROBE

As demonstrated, SCATTERCACHE strongly increases the complexity of building the necessary sets of addresses for PRIME+PROBE. However, the actual attacks utilizing these sets are also made more complex by SCATTERCACHE.

In this section, we make the strong assumption that an attacker has successfully profiled the victim process such that they have found addresses which collide with the victim's target addresses in exactly 1 way each, have no collisions with each other outside of these and are sorted into subsets corresponding to the cache line they collide in.

Where in normal PRIME+PROBE an attacker can infer victim accesses (or a lack thereof) with near certainty after only 1 sequence of priming and probing, SCATTERCACHE degrades this into a probabilistic process. At best, one PRIME+PROBE operation on a target address can detect an access with a probability of  $n_{ways}^{-1}$ . This is complicated further by the fact that any one set of addresses is essentially single-use, as the addresses will be cached in a non-colliding cache line with a probability of  $1 - n_{ways}^{-1}$  after only 1 access, where they

cannot be used to detect victim accesses anymore until they themselves are evicted again.

Given the profiled address sets, we can construct general probabilistic variants of the PRIME+PROBE attack. While other methods are possible, we believe the 2 described in the following represent lower bounds for either victim accesses or memory requirement.

**Variant 1: Single collision with eviction.** We partition our set of addresses, such that one PRIME+PROBE set consists of  $n_{ways}$  addresses, where each collides with a different way of the target address. To detect an access to the target, we prime with one set, cause a target access, measure the primed set and then evict the target address. We repeat this process until the desired detection probability is reached. This probability is given by  $p(n_{accesses}) = 1 - (1 - n_{ways}^{-1})^{n_{accesses}}$ . The eviction of the target address can be achieved by either evicting the entire cache or using preconstructed eviction sets (see Section 4.3.2). After the use of an eviction set, a different priming set is necessary, as the eviction sets only target the victim address. After a full cache flush, all sets can be reused. The amount of colliding addresses we need to find during profiling depends on how often a full cache flush is performed. This method requires the least amount of accesses to the target, at the cost of either execution time (full cache flushes) or memory and profiling time (constructing many eviction sets).

**Variant 2: Single collision without eviction.** Using the same method but without the eviction step, the detection probability can be recursively calculated as

$$p(n_{acc.}) = p(n_{acc.} - 1) + (1 - p(n_{acc.} - 1)) \left( \frac{2 \cdot n_{ways} - 1}{n_{ways}^3} \right)$$

with  $p(1) = n_{ways}^{-1}$ . This variant provides decreasing benefits for additional accesses. The reason for this is that the probability that the last step evicted the target address influences the probability to detect an access in the current step. While this approach requires many more target accesses, it has the advantage of a shorter profiling phase.

These two methods require different amounts of memory, profiling time and accesses to the target, but they can also be combined to tailor the attack to the target. Which is most useful depends on the attack scenario, but it is clear that both come with considerable drawbacks when compared to PRIME+PROBE in current caches. For example, achieving a 99% detection probability in a 2 MB Cache with 8 ways requires 35 target accesses and 9870 profiled addresses in 308 MB of memory for variant 1 if we use an eviction set for every probe step. Variant 2 would require 152 target accesses and 1216 addresses in 38 MB of memory. In contrast, regular PRIME+PROBE requires 1 target access and 8 addresses while providing 100% accuracy (in this ideal scenario). Detecting non-repeating events is made essentially impossible; to measure any access with confidence requires either the knowledge that the victim process repeats the same access pattern for long periods of time or control of the victim in a way that

allows for repeated measurements. In addition to the large memory requirements, variant 1 also heavily degrades the temporal resolution of a classical PRIME+PROBE attack because of the necessary eviction steps. This makes trace-based attacks like attacks on square-and-multiply in RSA [76] much less practical. Variant 2 does not suffer from this drawback, but requires one PRIME+PROBE set for each time step, for as many high-resolution samples as one trace needs to contain. This can quickly lead to an explosion in required memory when thousands of samples are needed.

## 4.5 Challenges with Real-World Attacks

We failed at mounting a real-world attack (*i.e.*, with even the slightest amounts of noise) on SCATTERCACHE. Generally, for a PRIME+PROBE attack we need to (1) generate an eviction set (cf. Section 4.3), and (2) use the eviction set to monitor a victim memory access. If we assume step 1 to be solved, we can mount a cache attack (*i.e.*, step 2) with a complexity increases by a factor of 152 (cf. Section 4.4). For some real-world attacks this would not be a problem, in particular if a small fast algorithm is attacked, e.g., AES with T-tables. Gülmezoglu et al. [29] recovered the full AES key from an AES T-tables implementation with only 30 000 encryptions in a fully synchronized setting (that can be implemented with PRIME+PROBE as well [26]), taking 15 seconds, *i.e.*, 500  $\mu$ s per encryption. The same attack on SCATTERCACHE takes  $4.56 \cdot 10^6$  encryptions, *i.e.*, 38 minutes assuming the same execution times, which is clearly viable.

However, the real challenge is solving step 1, which we did not manage for any real-world example. In particular, even if AES would only perform a single attacker-chosen memory access (instead of 160 to the T-tables alone, plus additional code and data accesses), which would be ideal for the attacker in the profiling during step 1, we would need to observe 33.5 million encryptions. In addition to the runtime reported by Gülmezoglu et al. [29] we also need a full cache flush after each attack round (*i.e.*, each encryption). For a 2 MB cache, we need to iterate over a 6 MB array to have a high probability of covering all cache lines. The time for an L3-cache access is e.g., for Kaby Lake 9.5 ns [2]. The absolute minimum number of cache misses here is 65536 (=4 MB), but in practice it will be much higher. A cache miss takes around 50 ns, hence, the full cache eviction will take at least 3.6 ms. Consequently, with 33.5 million tests required to generate the eviction set and a runtime of 4.1 ms per test, the total runtime to generate the eviction set is 38 hours.

This number still only considers the theoretical setting of a completely noise-free and idle system. The process doing AES computations must not be restarted during these 38 hours. The operating system must not replace any physical pages and, most importantly, our hypothetical AES implementation only performs a single memory access. In any realistic setting with only the slightest amount of activity (noise) on the system, this

easily explodes to multiple weeks or months. With a second memory access, these two memory accesses can already not be distinguished anymore with the generated eviction set, because the eviction set is generated for an invocation of the entire victim computation, not for an address.

## 4.6 Noise Sampling

The previous analysis considered a completely noise-free scenario, where the attacker performs PRIME+PROBE on a single memory access executed by the victim. However, in a real system, an attacker will typically not be able to perform an attack on single memory accesses, but face different kinds of noise. Namely, on real systems cache attacks will suffer from both systematic and random noise, which reduces the effectiveness of profiling and the actual attack.

**Systematic noise** is introduced, for example, by the victim as it executes longer code sequences in between the attacker's prime and probe steps. The victim's code execution intrinsically performs additional memory accesses to fetch code and data that the attacker will observe in the cache deterministically. In SCATTERCACHE, the mappings of memory addresses to cache lines is unknown. Hence, without additional knowledge, the attacker is unable to distinguish the cache collision belonging to the target memory access from collisions due to systematic noise. Instead, the attacker can only observe and learn both simultaneously. As a result, larger eviction sets need to be constructed to yield the same confidence level for eviction. Specifically, the size of an eviction set must increase proportionally to the number of systematic noise accesses to achieve the same properties. While this significantly increases an attacker's profiling effort, they may be able to use clustering techniques to prune the eviction set prior to performing an actual attack.

**Random noise**, on the other hand, stems from arbitrary processes accessing the cache simultaneously or as they are scheduled in between. Random noise hence causes random cache collisions to be detected by an attacker during both profiling and an actual attack, *i.e.*, produces false positives. While attackers cannot distinguish between such random noise and systematic accesses in a single observation, these random noise accesses can be filtered out statistically by repeating the same experiment multiple times. Yet, it increases an attacker's effort significantly. For instance, when building eviction sets an attacker can try to observe the same cache collision multiple times for a specific candidate address to be certain about its cache collision with the victim.

Random noise distributes in SCATTERCACHE according to Equation 1 and hence quickly occupies large parts of the cache. As a result, there is a high chance of sampling random noise when checking a candidate address during the construction of eviction sets. Also when probing addresses of an eviction set in an actual attack, random noise is likely to be sampled as attacks on SCATTERCACHE demand for large

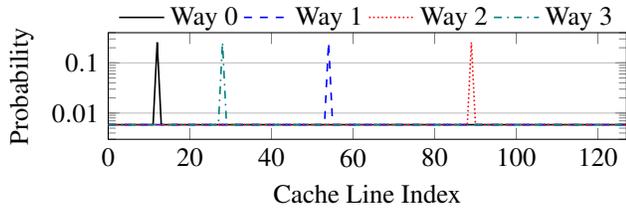

Figure 7: Example distribution of cache indices of addresses in profiled eviction sets ( $n_{ways} = 4$ ,  $b_{indices} = 7$ ).

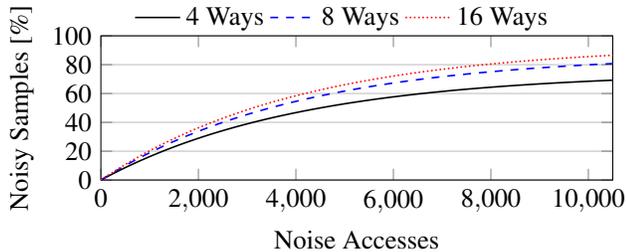

Figure 8: Expected percentage of noisy samples in an eviction set for a cache consisting of  $2^{12}$  cache lines.

eviction sets. As our analysis shows, for a single cache way the distribution of cache line indices corresponding to the memory accesses of profiled eviction sets (cf. Section 4.3) adheres to Figure 7. Clearly, due to profiling there is a high chance of roughly  $1/n_{ways}$  to access the index that collides with the victim address. However, with  $p = (n_{ways} - 1)/n_{ways}$  the index adheres to a uniformly random selection from all possible indices and hence provides a large surface for sampling random noise. Consequently, for a cache with  $n_{lines} = 2^{b_{indices}}$  lines per way and  $n_{noise}$  lines being occupied by noise in each way, the probability of sampling random noise when probing an eviction set address is

$$p(\text{Noise}) \approx \frac{n_{ways} - 1}{n_{ways}} \frac{n_{noise}}{n_{lines}}.$$

Figure 8 visualizes this effect and in particular the percentage of noisy samples encountered in an eviction set for different cache configurations and noise levels. While higher random noise clearly increases an attackers effort, the actual noise level strongly depends on the system configuration and load.

## 4.7 Further Remarks

In the previous analysis, the SDIDs of both attacker and victim were assumed to be constant throughout all experiments for statistical analysis to be applicable. Additionally, systematic and random noise introduced during both profiling and attack further increase the complexity of actual attacks, rendering attacks on most real-world systems impractical.

Also note that the security analysis in this section focuses on SCv1. In a noise-free scenario, SCv2 may allow to construct eviction sets slightly more efficiently since its IDF is

a permutation. This means that, once a collision in a certain cache way is found, there will not be any other colliding address for that cache way in the same index range, *i.e.*, for the same address tag. Considering the expected time to find the single collision in a given index range, this could give an attacker a benefit of up to a factor of two in constructing eviction sets. However, in practice multiple cache ways are profiled simultaneously, which results in a high chance of finding a collision in any of the cache ways independent of the address index bits, *i.e.*, the  $n_{ways}$  indices for a certain memory address will very likely be scattered over the whole index range. Independent of that, the presence of noise significantly hampers taking advantage of the permuting property of SCv2.

## 5 Performance Evaluation

SCATTERCACHE significantly increases the effort of attackers to perform cache-based attacks. However, a countermeasure must not degrade performance to be practical as well. This section hence analyzes the performance of SCATTERCACHE using the gem5 full system simulator and GAP [9], MiBench [30], Imbench [49], and the C version of scimark2<sup>1</sup> as micro benchmarks. Additionally, to closer investigate the impact of SCATTERCACHE on larger workloads, a custom cache simulator is used for SPEC CPU 2017 benchmarks. Our evaluations indicate that, in terms of performance, SCATTERCACHE behaves basically identical to traditional set-associative caches with the same random replacement policy.

### 5.1 gem5 Setup

We performed our cache evaluation using the gem5 full system simulator [12] in 32-bit ARM mode. In particular, we used the CPU model TimingSimpleCPU together with a cache architecture such as commonly used in ARM Cortex-A9 CPUs: the cache line size was chosen to be 32 bytes, the 4-way L1 data and instruction caches are each sized 32 kB, and the 8-way L2 cache is 512 kB large. We adapted the gem5 simulator such as to support SCATTERCACHE for the L2 cache. This allows to evaluate the impact of six different cache organizations. Besides SCATTERCACHE in both variants (1) SCv1 and (2) SCv2 and standard set-associative caches with (3) LRU, (4) BIP, and (5) random replacement, we also evaluated (6) skewed associative caches [63] with random replacement as we expect them to have similar performance characteristics as SCv1 and SCv2.

On the software side, we used the Poky Linux distribution from Yocto 2.5 (Sumo) with kernel version 4.14.67 after applying patches to run within gem5. We then evaluated the performance of our micro benchmarks running on top of Linux. In particular, we analyzed the cache statistics provided by

<sup>1</sup><https://math.nist.gov/scimark2/>

gem5 after booting Linux and running the respective benchmark. Using this approach, we reliably measure the cache performance and execution time for each single application, *i.e.*, without concurrent processes. Since only the L2-cache architecture (*i.e.*, replacement policy, skewed vs. fixed sets) changed between the individual simulation runs, execution performance is simply direct proportional to the resulting cache hit rate. To enable easier comparison between the individual benchmarks as well as with related work we therefore mainly report L2-cache hit results.

**SCATTERCACHE IDF Instantiations.** Both SCATTERCACHE variants have been instantiated using the low-latency tweakable block cipher QARMA-64 [8]. In particular, in the SCv1 variant, the index bits for the individual cache ways have been sliced from the ciphertext of encrypting the cache line address under the secret key and SDID. On the other hand, due to the lack of an off-the-shelf tweakable block cipher with the correct block size, a stream cipher construction was used in the SCv2 variant. Namely, the index is computed as the XOR between the original index bits and the ciphertext of the original tag encrypted using QARMA-64. Note, however, that, although this construction for SCv2 is a proper permutation and entirely sufficient for evaluating the performance of SCv2, we do not recommend the construction as pads are being reused for addresses having the same tag bits.

While the majority of the following results are latency agnostic LLC hit rates, all following results are reported for the zero cycle latency case. For QARMA-64 with 5 rounds, ASIC implementation results with as little as 2.2 ns latency have been reported [8]. We are therefore confident that, if desired, hiding the latency of the IDF by computing it in parallel to the lower level cache lookup is feasible.

However, we still also conducted simulations with latency overheads between 1 and 5 cycles by increasing the `tag_latency` of the cache in gem5. The acquired results show that, even for IDFs which introduce 5 cycles of latency, less than 2% performance penalty are encountered on the GAP benchmark suite. These numbers are also in line with Qureshi's results reported for CEASER [55].

## 5.2 Hardware Overhead Discussion

SCATTERCACHE is designed to be as similar to modern cache architectures as possible in terms of hardware. Still, area and power overheads have to be expected due to the introduction of the IDF and the additional addressing logic. Unfortunately, while probably easy for large processor and SoC vendors, determining reliable overhead numbers for these two metrics is a difficult task for academia that requires an actual ASIC implementation of the cache. To the best of our knowledge, even in the quite active RISC-V community, no open and properly working LLC designs are available that can be used as foundation. Furthermore, for merely simulating such a design with a reasonably large cache, commercial EDA tools,

access to state-of-the-art technology libraries, and large memory macros with power models are required. As the result, secure cache designs typically fail to deliver hardware implementation results (see Table 6 in [18]).

Because of these problems, similar to related work, we can also not provide concrete numbers for the area and power overhead. However, due to the way we designed SCATTERCACHE and the use of lightweight cryptographic primitives, we can assert that the hardware overhead is reasonable. For example, the 8-way SCv1 SCATTERCACHE with 512 kB that is simulated in the following section, uses two parallel instances of QARMA-64 with 5 rounds as IDF. One fully unrolled instance has a size of 22.6 kGE [8] resulting in an IDF size of less than 50 kGE even in case additional pipeline registers are added. The added latency of such an IDF is the same as the latency of the used primitive which has been reported as 2.2 ns. However, this latency can (partially or fully) be hidden by computing the IDF in parallel to the lower level cache lookup. Interestingly, with similar size, also a sponge-based SCv1 IDF (e.g., 12 rounds of Keccak[200] [11]) can be instantiated. Finally, there is always the option to develop custom IDF primitives [55] that demand even less resources.

For comparison, in the BROOM chip [16], the SRAM macros in the 1 MB L2 cache already consume roughly 50% of the 4.86 mm<sup>2</sup> chip area. Assuming an utilization of 75% and a raw gate density of merely 3 MGate/mm<sup>2</sup> [21] for the used 28 nm TSMC process, these 2.43 mm<sup>2</sup> already correspond to 5.5 MGE. Subsequently, even strong IDFs are orders of magnitude smaller than the size of a modern LLC.

In terms of overhead for the individual addressing of the cache ways, information is more sparse. Spjuth et al. [64] observed a 17% energy consumption overhead for a 2-way skewed cache. They also report that skewed caches can be built with lower associativity and still reach similar performance as traditional fixed set-associative caches. Furthermore, modern Intel architectures already feature multiple addressing circuits in their LLC as they partition it into multiple smaller caches (*i.e.*, cache slices).

## 5.3 gem5 Results and Discussion

Figure 9 visualizes the cache hit rate of our L2 cache when executing programs from the GAP benchmark suite. To ease visualization, the results are plotted in percentage points (pp), *i.e.*, the differences between percentage numbers, using the fixed set-associative cache with random replacement policy as baseline. All six algorithms (*i.e.*, bc, bfs, cc, pr, sssp, tc) have been evaluated. Moreover, as trace sets, both synthetically generated `kron (-g16 -k16)` and `urand (-u16 -k16)` sets have been used. As can be seen in the graph, the BIP and LRU replacement policies outperform random replacement on average by 4.6 pp and 4 pp respectively. Interestingly, however, all random replacement based schemes, including the skewed variants, perform basically identical.

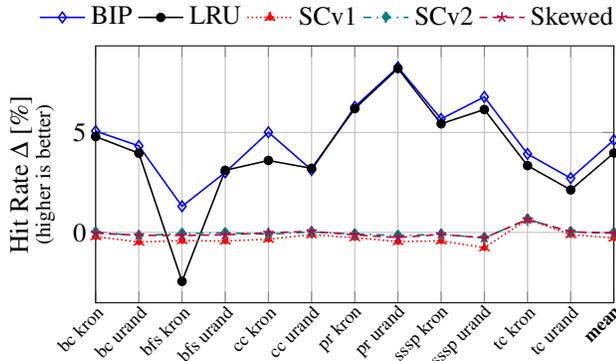

Figure 9: Cache hit rate, simulated with gem5, for the synthetic workloads in the GAP benchmark suite with random replacement policy as baseline.

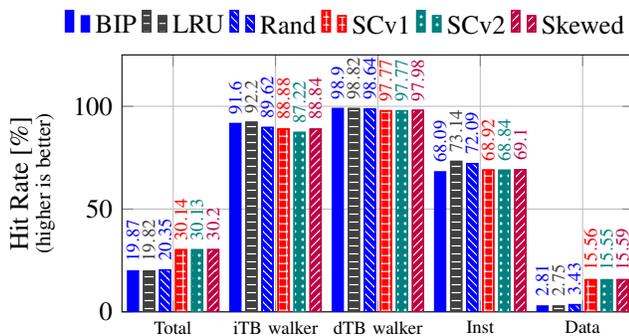

Figure 10: Cache hit rate, simulated with gem5, for scimark2.

The next benchmark, we visualized in [Figure 10](#), is scimark2 (-large 0.5). This benchmark shows an interesting advantage of the skewed cache architectures over the fixed-set architectures, independent of the replacement policy, of approximately 10 pp for the total hit rate. This difference is mainly caused by the 5x difference in hit rate for data accesses. Comparing the achieved benchmark scores in [Figure 11](#) further reveals that the `fft` test within scimark2 is the reason for the observed discrepancy in cache performance.

To investigate this effect in more detail, we measured the memory read latency using `lat_mem_rd 8M 32` from `lmbench` in all cache configurations. The respective results in [Figure 12](#) feature two general steps in the read latency at 32 kB (L1-cache size) and at 512 kB (L2-cache size). Notably, configurations with random replacement policy feature a smoother transition at the second step, *i.e.*, when accesses start to hit main memory instead of the L2 cache.

Even more interesting results, as shown in [Figure 13](#), have been acquired by increasing the stride size to four times the cache line size. Skewed caches like SCATTERCACHE break the strong alignment of addresses and cache set indices. As a consequence, a sparse, but strongly aligned memory access pattern such as in `lat_mem_rd`, which in a standard

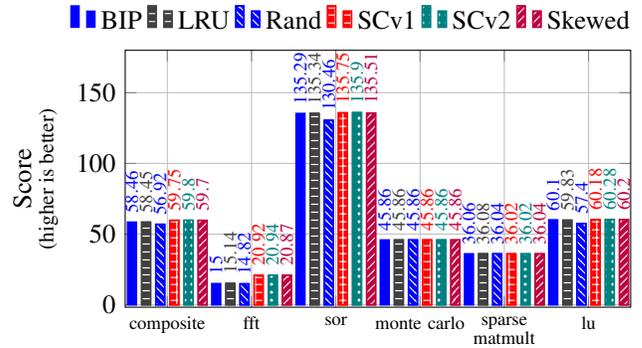

Figure 11: Scimark2 score simulated with gem5.

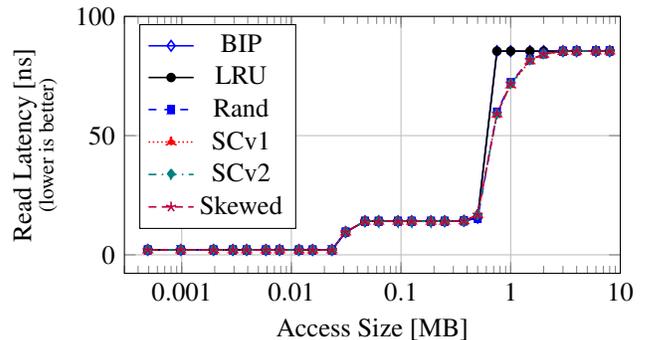

Figure 12: Memory read latency, simulated with gem5, with 32 byte stride (*i.e.*, one access per cache line).

set-associative caches only uses every 4<sup>th</sup> cache index, gives high cache hit rates and low read latencies for larger memory ranges due to less cache conflicts. This effect becomes visible in [Figure 13](#) as shift of the second step from 512 kB to 2 MB for the skewed cache variants.

Finally, as last benchmark, MiBench has been evaluated in small and large configuration. The individual results are visualized in [Figure 14](#) and [Figure 15](#) respectively. On average, the achieved performance results in MiBench are very similar to the results from the GAP benchmark suite. Again, caches with BIP and LRU replacement policy outperform the configurations with random replacement policy by a few percent. However, in some individual benchmarks (e.g., `qsort` in small, `jpeg` in large), skewed cache architectures like SCATTERCACHE outmatch the fixed set approaches.

In summary, our evaluations with gem5 in full system simulation mode show that the performance of SCATTERCACHE, in terms of hit rate, is basically identical to contemporary fixed set-associative caches with random replacement policy. Considering that we employ the same replacement strategy, this is an absolutely satisfying result by itself. Moreover, no tests indicated any notable performance degradation and in some tests SCATTERCACHE even outperformed BIP and LRU replacement policies.

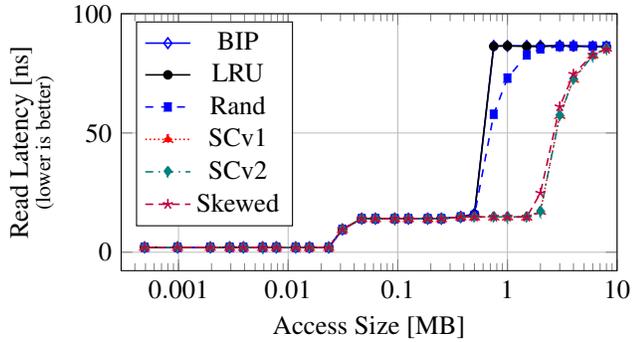

Figure 13: Memory read latency, simulated with gem5, with 128 byte stride (*i.e.*, one access in every fourth cache line).

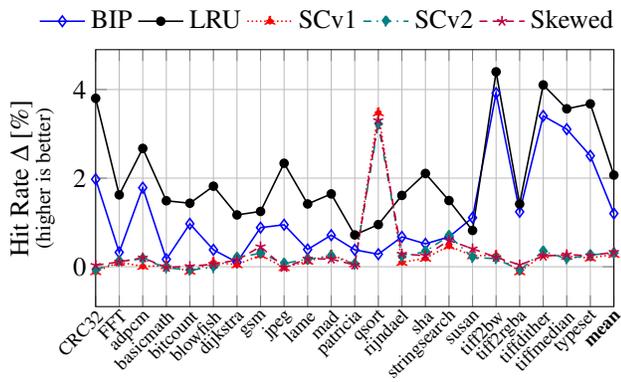

Figure 14: Cache hit rate, simulated with gem5, for MiBench in small configuration compared to random replacement.

## 5.4 Cache Simulation and SPEC Results

Lastly, we evaluated the performance of SCATTERCACHE using the SPEC CPU 2017 [66] benchmark with both the “SPECspeed 2017 Integer” and “SPECspeed 2017 Floating Point” suites. We performed all benchmarks in these suites with the exception of `gcc`, `wrf` and `cam4`, as these failed to compile on our system. Because these benchmarks are too large to be run in full system simulation, we created a software cache simulator, capable of simulating different cache models and replacement policies. Even so, the benchmarks proved to be too large to run in full, so we opted to run segments of 250 million instructions from each, following the methodology of Qureshi et al. [56]. We made an effort to select parts of the benchmarks that are representative of their respective core workloads. To be able to run the benchmarks with our simulator, we recorded a trace of all instruction addresses and memory accesses with the Intel PIN Tool [33]. We then replayed this access stream for different cache configurations. The simulator implements the set-associative replacement policies Pseudo-LRU (Tree-PLRU), LRU (ideal), BIP as described in [56], and random replacement, as well as the two

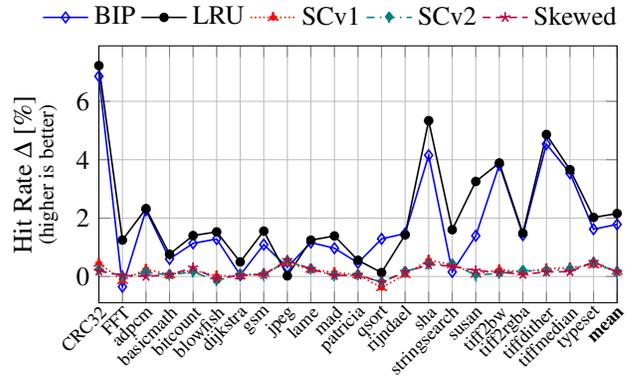

Figure 15: Cache hit rate, simulated with gem5, for MiBench in large configuration compared to random replacement.

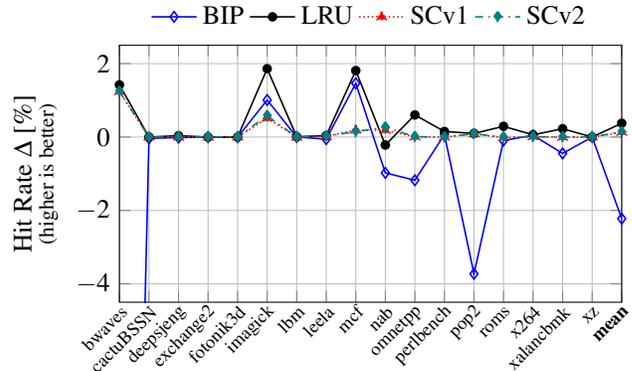

Figure 16: Average cache hit rate for SPEC CPU 2017 benchmarks compared to random replacement over 10 runs.

SCATTERCACHE variants. The number of ways per set, total cache size, number of slices, and cache line size are fully configurable. Additionally, the simulator supports multiple levels of inclusive caches, as well as a cache that is split for data and instructions. All simulations were run on an inclusive two level cache, where the L1 was separated into instruction and data caches, both of which use LRU replacement. Figure 16 shows results for the cache configuration, as described in Section 5.1, as the difference in percentage points for last-level hit rates when compared to random replacement. While we can see large differences in individual tests, the mean shows that both versions of SCATTERCACHE perform at least as well as random replacement and very similar to LRU. Using the same cache configuration but with 64 B cache lines, we actually observe a mean advantage of  $0.23 \pm 0.76$  pp of SCATTERCACHE over random replacement, where LRU sees a marginally worse result of  $-0.21 \pm 1.02$  pp. On a larger configuration with 64 B cache lines, 32 kB 8-way L1 and 2 MB 16-way LLC, the results show a slim improvement of  $0.035 \pm 0.10$  pp for SCATTERCACHE and  $0.37 \pm 1.14$  pp for LRU over random replacement.

## 6 Conclusion

In this paper, we presented SCATTERCACHE, a novel cache design to eliminate cache attacks that eliminates fixed cache-set congruences and, thus, makes eviction-based cache attacks unpractical. We showed how skewed associative caches when retrofitted with a keyed mapping function increase the attack complexity so far that it exceeds practical scenarios. Furthermore, high-frequency attacks become infeasible. Our evaluations show that the runtime performance of software is not curtailed and SCATTERCACHE can even outperform state-of-the-art caches for certain realistic workloads.

## Acknowledgments

We want to thank the anonymous reviewers and especially our shepherd, Yossi Oren, for their comments and suggestions that substantially helped in improving the paper. This project has received funding from the European Research Council (ERC) under Horizon 2020 grant agreement No 681402. Additional funding was provided by a generous gift from Intel. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the funding parties.

## Abstract

Remote Direct Memory Access (RDMA) is a technology that allows direct access from the network to a machine's main memory without involving its CPU. RDMA offers low-latency, high-bandwidth performance and low CPU utilization. While RDMA provides massive performance boosts and has thus been adopted by several major cloud providers, security concerns have so far been neglected.

The need for RDMA NICs to bypass CPU and directly access memory results in them storing various metadata like page table entries in their on-board SRAM. When the SRAM is full, RNICs swap metadata to main memory across the PCIe bus. We exploit the resulting timing difference to establish side channels and demonstrate that these side channels can leak access patterns of victim nodes to other nodes.

We design Pythia, a set of RDMA-based remote side-channel attacks that allow an attacker on one client machine to learn how victims on other client machines access data a server exports as an in-memory data service. We reverse engineer the memory architecture of the most widely used RDMA NIC and use this knowledge to improve the efficiency of Pythia. We further extend Pythia to build side-channel attacks on Crail, a real RDMA-based key-value store application. We evaluated Pythia on four different RDMA NICs both in a laboratory and in a public cloud setting. Pythia is fast ( $57 \mu\text{s}$ ), accurate (97% accuracy), and can hide all its traces from the victim or the server.

## 1 Introduction

Direct Memory Access (DMA) allows a machine's peripherals like storage and network devices to access its main memory directly without involving CPU, vastly increasing I/O performance and reducing CPU utilization. Inspired by DMA, Remote Direct Memory Access, or *RDMA*, is a technology that allows remote hosts to directly access (exported) memory of a node without having to go through its CPU. RDMA enables high throughput and low latency data transfers and

largely reduces CPU utilization in clusters.

In recent years, major cloud vendors like Microsoft Azure [73] and Alibaba Cloud [6] have adopted RDMA in their datacenters to speed up processing and to reduce cost of accessing large amounts of data. As the underlying protocols prosper [32], more and more servers leverage the RDMA protocol to speed up processing. The use of RDMA has revolutionized data sharing in cloud environments with implementations for efficient key-value stores [24, 25, 40, 56, 57], in-memory databases and transactional systems [19, 83, 88], and graph processing systems [68, 85].

There is a plethora of research work on RDMA, but the focus so far was all on performance, usability, and network protocols. Security has been largely overlooked in RDMA research and production<sup>1</sup>. With the rise of information leaks through memory-based side-channels [17, 26, 39, 41, 42, 86, 87], we have set out to evaluate the side-channel resistance of existing RDMA implementations.

In a scenario where multiple nodes connect to a server that provides remote access to its local memory through RDMA (e.g., for a key-value store), a malicious node may want to learn what data was accessed by benign nodes. We assume that the server is trusted and that the attacker tries to learn what data was accessed by the victim nodes through a *remote* side channel which leaks access patterns. Figure 1 illustrates this environment.

We discovered a new side channel that prevails across all RDMA hardware that we know of. NICs that support RDMA, or *RNICs*, cache metadata such as page table entries in their on-board SRAM so that they can perform all operations needed to access main memory on their own without involving CPU. However, the on-board SRAM size is limited and the RNIC can only cache hot metadata while leaving the rest in main memory. When an RDMA request's metadata is not cached, the RNIC takes extra time to fetch the metadata from main memory to its SRAM. We observe and characterize different side channels that can lead to this timing difference

<sup>1</sup>We made an initial exploration of security issues and opportunities in one-sided communication in a recent workshop [77].

on three generations of RNIC devices.

Based on our findings, we designed *Pythia*, a set of side-channel attacks that can be launched completely from the network through RDMA. The basic idea is to issue RDMA network requests to the server to fill its RNIC SRAM, eventually evicting the metadata of the target data. Then the attacker reloads the target data with an RDMA request and based on the time it takes, predict if the victim has accessed the data.

Although the basic idea is similar to the EVICT+RELOAD CPU cache side-channel attack [30], designing *Pythia* presents many new challenges. The first challenge is the difficulty in achieving good eviction performance. Existing CPU-cache based side-channel attacks leverage cache associativity to reduce the eviction set size, thereby improving eviction performance. However, RNICs are vendor owned and are complete black boxes to public knowledge. To confront this challenge, we reverse engineered the memory architecture of the Mellanox ConnectX-4 RNIC [48], the type of RNIC that is used in all major datacenter RDMA deployment. We successfully discovered the internal architectural organization of RNIC SRAM and leverage this knowledge to achieve low-latency eviction.

The second challenge is in the reload and prediction process. Because of our environment of being in a shared datacenter network, the latency of an RDMA request can vary with different network state. The traditional approach of using a static threshold to differentiate cache hit from cache miss is not a good fit for our environment. We take an adaptive approach to dynamically train a hit/miss classifier based on RDMA access latency at the time of attack and use the trained classifier to statistically predict victim accesses [22, 28].

We evaluated *Pythia* in our lab environment and in a public cloud [65] with four different types of RNICs. *Pythia* completes one EVICT+RELOAD cycle (across the network) in as low as  $57 \mu s$  with 97% accuracy<sup>2</sup> Moreover, *Pythia* effectively hides its traces from the server and victims because it performs all its attack using RDMA operations from a separate machine.

We further built three variations of *Pythia* to attack a real RDMA-based system, the Apache Crail key-value store system [7, 70]. On a real application like Crail, it is more challenging to establish a strong side-channel attack because of limited application interface and noise coming from application performance overhead. After improving *Pythia* to accommodate these difficulties, we successfully launched a side-channel attack solely from a separate client machine using the unmodified Crail client interface. This attack is efficient and can accurately learn a victim’s key-value pair access patterns.

The contributions of this paper are:

1. Discovery of new side channels in RDMA-based systems that leak client RDMA access patterns;

<sup>2</sup>The definition of accuracy throughout the paper is the percentage of successful guesses over total guesses.

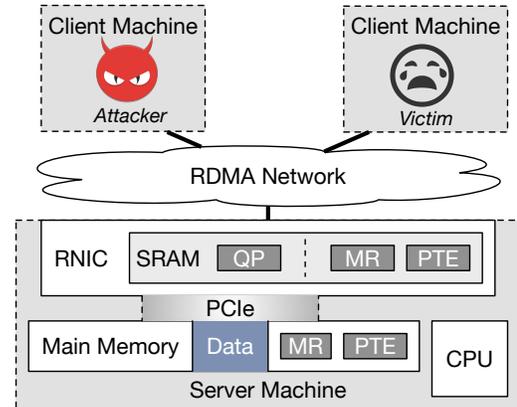

Figure 1: **Attack Environment and RNIC Architecture.** The attacker and the victim are both clients that can access data in the server machine’s memory through RDMA.

2. Reverse engineering of the most widely used RNIC hardware architecture, which can be leveraged in designing efficient side channels;
3. Design, implementation, and evaluation of a set of *Pythia* side-channel attacks, which are fast, accurate, and can be launched solely from a separate machine across the network;
4. A case study of *Pythia* in a real-world setting;
5. Discussion of possible mitigations, most of which are uniquely applicable to RDMA systems.

*Pythia* is the first work that explores side-channel vulnerabilities in RDMA and exploits the vulnerabilities to launch attacks on RDMA-based datacenter systems. With today’s datacenters all having robust defenses against direct sniffing or hijacking of network traffic, side channels are more feasible attack mechanisms and we believe that our work raises serious security concerns in a young but already widely-adopted network technology.

We have responsibly disclosed the weaknesses to Mellanox and Crail. Our implementation of *Pythia* is publicly available at <https://github.com/Wuklab/Pythia>.

## 2 Background on RDMA

### 2.1 RDMA Basics

Remote Direct Memory Access, or RDMA, is a network technology designed to offer remote low-latency, low-CPU-utilization access to exported memory regions. RDMA supports both *one-sided* and *two-sided* communication. One-sided RDMA operations directly access memory at a remote node without involving the remote node’s CPU, similar to DMA on a single machine. Two-sided RDMA operations involve both sender and receiver processing, similar to *send/recv* in traditional network messaging.

RDMA improves performance along several dimensions. First, one-sided RDMA requests bypass the CPU of the receiver. Second, applications issue RDMA requests directly from user space, bypassing kernel and avoiding kernel trap cost. Third, RDMA avoids memory copying (a technique called *zero-copy*). As a result, RDMA achieves low-latency, high-throughput performance.

There are three implementations of RDMA: InfiniBand (IB) [10, 11], RoCE [8, 9], and iWARP [63]. All implementations follow the standard RDMA protocol [64]. Among them, RoCE, or *RDMA over Converged Ethernet*, implements the RDMA protocol over standard Ethernet (RoCEv1) and UDP (RoCEv2), and is the preferred technology in existing datacenters [32].

One-sided RDMA is the key area where significant performance and CPU utilization improvements over other network technologies happen. Thus, we focus on one-sided RDMA. To perform a one-sided RDMA operation, an application process at a receiver node needs to first allocate a consecutive virtual memory space and then use the virtual memory address range to register a *memory region*, or *MR*, with the RNIC. An application can register multiple MRs over the same or different memory spaces. The RNIC will assign a pair of local and remote protection keys (called *lkey* and *rkey*) to each MR. This application then conveys the virtual address of the MR and its rkey to processes running on other nodes. After building connections between these other nodes (senders) and the node that the MR-registering application runs on (receiver), these processes can use 1) a virtual memory address that falls in the MR's virtual memory address range, 2) a size, and 3) the rkey of the MR to perform one-sided RDMA *read* and *write*. In RDMA's term, a connection is called a *Queue Pair*, or *QP*.

## 2.2 RDMA NICs

RDMA NICs, or *RNICs*, are where most RDMA functionalities are implemented. They usually contain complex hardware logic that implements the RDMA protocol and some SRAM to store metadata, and they are often connected to the host's PCIe bus (allowing the card access to main memory through DMA). Because of the need to bypass the kernel and receiver's CPU, most RDMA functionalities and data structures have to be offloaded to the RNIC hardware.

An RNIC's on-board SRAM stores three types of metadata. First, it stores metadata for each QP in its memory. Second, it stores lkeys, rkeys, and virtual memory addresses for all registered MRs. Third, it caches page table entries (PTEs) for MRs to obtain the DMA address of an RDMA request from its virtual memory address. RNICs have a limited amount of on-board SRAM which can only hold metadata for hot data. When the SRAM is full, an RNIC will evict its cached metadata to the main memory on the host machine, and on a future access, fetch the evicted metadata from the host main memory back through the PCIe bus. The timing difference between an RDMA access whose metadata is in RNIC SRAM

and one that is not is what we exploit in our side-channel attack. The SRAM architecture is vendor-specific and not disclosed or specified in the RDMA standard. We reverse engineer the SRAM architecture of the state-of-the-art RNIC in Section 4.4.

## 2.3 RDMA-Based Applications

RDMA was originally designed for high-performance computing environments, and it has been a popular choice of network system in these environments for the past two decades [34, 44, 54]. In recent years, major datacenters and public clouds adopted RDMA for its low CPU utilization and superior performance. For example, Microsoft Azure [73] and Alibaba [6] have deployed RDMA with RoCE at large, production scale.

Many datacenter systems and applications have been ported to or rebuilt with RDMA. These include in-memory key-value stores [7, 24, 25, 40, 56, 57, 70], in-memory databases and transactional systems [19, 83, 88], graph processing systems [68, 85], distributed machine learning systems [15], consensus implementations [60, 80], distributed non-volatile memory systems [45, 67, 93], and remote swap systems [5, 31]. Most of these applications use both one-sided and two-sided RDMA operations, with some being pure one-sided [14, 88]. Our work is applicable to all RDMA-based applications that use one-sided RDMA (but not necessary purely one-sided).

## 3 Threat Model

In our attack, there are three parties: the server which hosts data in its main memory for other client machines to access (*e.g.*, an in-memory database or an in-memory key-value store), the victim who accesses the server's in-memory data through RDMA, and the attacker who tries to infer the victim's accesses and access patterns. The attacker and the victim are both normal clients that can access the data store service the server provides, and they run on separate machines. Following the threat models of related work that introduces and evaluates side channels, we assume that the attacker does not have direct control over the victim. As victim and attacker execute on different machines and communication to the server happens through the network, we assume that the attacker *cannot* observe the victim's network packets (as otherwise, the attacker could directly infer the accessed addresses and values as RDMA is currently not encrypted). This assumption is reasonable as sniffing victim's packets would require an attacker to have `root` access on either the victim's machine or the server's machine [52, 72, 74] or to launch man-in-the-middle attack to the network, both of which are well defended in cloud datacenters. We also assume that the server *cannot directly* observe memory accesses of either the victim or the attacker as both victim and attacker interact with the server through one-sided RDMA operations, not involving the server's CPU.

## 4 Side-Channel Attacks on RDMA

RDMA exposes node-internal memory to external hosts. Due to best practices of optimizing accesses and caching, current RDMA hardware is vulnerable to a variety of timing side channels. We present an overview of RDMA-based side channels, two basic attacks, refined attacks with our reverse engineered knowledge of RNIC internals, and evaluation results of the attacks. Unless otherwise stated, all our experiments use three machines, each equipped with a Mellanox ConnectX-4 100 Gbps network adapter [48], two Intel Xeon E5-2620 2.40GHz CPUs, and 128 GB main memory. They are connected with a Mellanox SB7700 100 Gbps InfiniBand switch [50]. One machine is used as the server that serves in-memory data through RDMA. The other two machines are the victim client machine and the attacker client machine, both of which can perform RDMA operations to access data on the server. In all the experiments in this section, the victim has a 50% chance of accessing the targeted data that the attacker tries to infer accesses on.

### 4.1 Attack Overview

The basic idea of our side-channel attacks is to exploit two weaknesses in RNIC: 1) the RNIC caches metadata in its SRAM, RDMA accesses whose metadata is not in SRAM must wait until that data is fetched from main memory, and 2) all RDMA accesses from all applications share the RNIC SRAM. As explained in Section 2.2, RNICs store three types of metadata in their SRAM: QP information, MR information, and PTEs. An RDMA access involves all three types of metadata: upon receiving a network request, an RNIC needs to locate which QP the request belongs to, which MR it falls into, and which page it is accessing. If any of these metadata is not in the RNIC SRAM, the RNIC will fetch it from the host memory, stalling the request until the required data arrives. By exploiting this timing difference, we can launch side-channel attacks to know which QP, which MR, and which PTE the victim has accessed.

Traditional CPU-cache-based side-channel attacks take three major forms: *prime*-based (e.g., PRIME+PROBE [1–4, 42, 59, 75, 90]), *flush*-based (e.g., FLUSH+RELOAD [86]), and *evict*-based (e.g., EVICT+RELOAD [30]). Because RNICs do not provide any interface to flush their SRAM, all flush-based side-channel attacks such as FLUSH+RELOAD [86] and FLUSH+FLUSH [29] are incompatible with RDMA. All the operations that are needed in prime-based and evict-based attacks can be implemented through RDMA network requests that an attacker performs over the network. Attackers can hide their traces during the attacks, since one-sided RDMA reads are oblivious to the server or other clients. Hardware performance counters [35] may help servers track DMA traffic, but it is challenging to associate traffic with RDMA accesses or attacks. Even if the server suspects that an attack is happening, it is still hard, in practice, to attribute an attack based on traffic

counters.

For the rest of the paper, we focus on RDMA-based EVICT+RELOAD attacks. PRIME+PROBE attacks are also possible on RDMA and we briefly discuss them in Section 7.

### 4.2 Unique Advantages and Challenges

There are three unique advantages for attackers in RDMA systems. First, RDMA's one-sided communication pattern allows the attacker to hide her traces, since the receiving node is unaware of any one-sided accesses. Second, the RDMA network is much faster both in latency and in bandwidth than traditional datacenter networks. The latest generation of RDMA switches and RNICs can sustain 200 Gbps bandwidth and under  $0.6\mu s$  latency [53]. RDMA's superior performance enables fine-grained, high-throughput, timing-based side-channel attacks over the network. Finally, RDMA's one-sided communication bypasses the sender's OS and does not involve CPU at the receiver, both of which help reduce disturbance to timing-based attacks.

At the same time, attacking the RNIC presents several novel challenges that no CPU-cache-based side-channel attack experiences. First, it is hard to discover efficient side channels in RNIC hardware. Unlike CPU caches, there is no public knowledge of how RNICs organize or use their SRAM. RNICs store different types of information in SRAM compared to a linear layout of CPU caches. Second, we set a strict threat model where attacks are launched from a separate machine that is different from the victim's machine and the server machine. This goal means that attacks have to be performed using RDMA network requests only. Finally, since our side channels are established over the network, noise in the network could potentially increase difficulties for timing-based attacks.

### 4.3 Basic Attack

Before presenting our side-channel attacks, we first discuss the type of victim information we choose as our attack target and the type of metadata we use to perform the eviction phase. Notice that these two dimensions are orthogonal and both have three options: QP, MR, and PTE.

Among these three types of information, knowing which QP the victim accesses leaks little information about the victim and usually is not useful in real attacks. MRs and PTEs can both leak more information. Using PTE as the attack target unit will reveal memory page (in virtual memory) accesses. All OSes use 4 KB as the default page size. The MR size is decided by the application that creates and registers it. For performance reasons [55], most RDMA-based applications choose to use large MRs. Thus, we choose PTE as the target of our attack. However, most of our ideas and techniques can be used to perform attacks that target MRs.

After choosing the attack target, we must decide what metadata to use to evict RNIC SRAM. To answer this question, we tried to evict SRAM using the three types of metadata and

---

**Algorithm 1: MR-based eviction**

---

**Input** : a target victim virtual memory address  
**Output** :  
**if** *No access to sufficient amount of MRs* **then**  
| start process at server to create *MR\_set*;  
**else**  
| **foreach** *MR that the attacker has access to* **do**  
| | **if** *MR*  $\neq$  *victim's MR* **then**  
| | | insert *MR* into *MR\_set*;  
| | **end**  
| **end**  
**end**  
**foreach** *MR in MR\_set* **do**  
| perform 8-byte RDMA-read to *MR*;  
**end**

---

reload our targeted information (*i.e.*, PTE). We can successfully evict a PTE with PTEs, no matter whether or not the PTEs we use to evict belong to the same MR as the target PTE. We can also evict an MR with other MRs. We further find that when an MR is evicted, PTEs of all the pages belonging to this MR will also be evicted. But we can only use QPs to evict QP. This behavior implies that RNICs isolates the SRAM used for QPs and for MRs and PTEs. We present the evaluation results in Section 4.5. From this initial test, we discovered that we can evict a PTE by either evicting the MR it belongs to (using a large number of MRs) or by evicting the PTE directly using a large number of other PTEs.

### 4.3.1 Eviction by MRs

We now present our attack that evicts SRAM with MRs, *PythiaMR*. Algorithm 1 presents the pseudocode of *PythiaMR*.

Because the MR-based attack requires the attacker to use many MRs to evict the server's RNIC SRAM, the attacker requires access to a sufficient amount of MRs. If the number of MRs is restricted, the attacker may resort to a (hypothetical) MR gadget that allows her to register multiple MRs. One approach is to launch a process on the server that allows her to register multiple MRs (see Section 5.1 for details). Since RDMA provides the functionality of registering multiple MRs with the same memory space, the attacker process at the server only needs to allocate a small memory space (of arbitrary size) and register it multiple times. This process then needs to send the rkeys corresponding to these registered MRs to the attacker running on a client machine.

In the eviction phase, the attacker performs one-sided RDMA reads from a client machine to the MRs it has access to at the server (except for the MR that the victim PTE is in). Since the server's RNIC needs to fetch and store metadata for each MR when the MR is accessed, its SRAM will eventually be filled with MR metadata that the attacker accessed.

---

**Algorithm 2: Naive PTE-based eviction**

---

**Input** : a target victim virtual memory address  
**Output** :  
*VictimVPN*  $\leftarrow$  *victim\_address*  $\gg$  12;  
generate *eviction\_set* using *VictimVPN*;  
**foreach** *VPN in eviction\_set* **do**  
| perform 8-byte RDMA-read to address *VPN*  $\ll$  12;  
**end**

---

---

**Algorithm 3: Reload and predict**

---

**Input** : a target victim virtual memory address  
**Output** : prediction of if the victim has accessed the target address  
  
determine *Threshold* according to network status;  
  
start timer;  
RDMA-read *victim\_address*;  
end timer;  
*time*  $\leftarrow$  *elapsed\_time*;  
**if** *time*  $<$  *Threshold* **then**  
| output *accessed*;  
**else**  
| output *not\_accessed*;  
**end**

---

### 4.3.2 Eviction by PTEs

Alternatively, we can use PTEs to establish a side channel. Compared to MR-based attacks, PTE-based attacks can often be performed entirely from a client machine. Algorithm 2 presents the pseudocode of our PTE-based attack.

To perform PTE-based eviction, the attacker issues one-sided RDMA reads to a sufficiently big memory space (1 GB to 4 GB for the RNICs we study). Most RDMA-based applications are services that provide in-memory data storage and use a large amount of memory, thus meeting the requirements of PTE-based attacks.

Accessing different memory pages will cause the RNIC to fetch PTEs to its SRAM. Because all accesses to the same memory page will hit the same PTE, we only need to perform one RDMA read (with the smallest RDMA operation size of 8 bytes) in every 4 KB virtual memory address range. To avoid loading the PTE that the victim accesses, we skip the memory addresses that are close to the victim address.

### 4.3.3 Reload and Predict

After the eviction phase (either by MRs or by PTEs), the attacker reloads the targeted victim data. If the reload time is smaller than a threshold, the attacker determines that the data has been accessed by the victim. Algorithm 3 presents the pseudocode of the reload and prediction process.

The threshold used at the reload time directly affects the result of an attack. Different from traditional CPU-cache side-

channel attacks, our attacks are in a distributed environment where network status can vary with other workloads in the datacenter. Thus, instead of a fixed threshold, we adapt the threshold dynamically according to the network status. To adjust the threshold, the attacker periodically measures the latency of an RDMA operation which hits the RNIC SRAM and the latency of one that misses the SRAM. The threshold can be set as a value in the middle of these two latencies.

In addition to using an average threshold, other more advanced methods can also be used to determine the reload result. In fact, we design a statistical method to determine the reload result for our real-application attacks, as will be presented in Section 5.

#### 4.4 Finding PTE Eviction Sets

We call the attack that uses the eviction phase presented in Section 4.3.2 the basic PTE-based attack, or *PythiaPTE<sub>Basic</sub>*. In order to reduce the time to perform eviction and improve the efficiency of *PythiaPTE<sub>Basic</sub>*, we search for a smaller eviction set that achieves similar accuracy as *PythiaPTE<sub>Basic</sub>*. Specifically, we perform a set of experiments to systematically reverse engineer the internal organization of RNIC SRAM and use our learned knowledge to construct a minimal PTE eviction set.

Reverse engineering RNIC SRAM organization is significantly harder than reverse engineering traditional CPU caches because there is no public knowledge of the internal organization of any RNIC. All we know is that the RNIC caches three types of metadata (PTEs, MRs, and QPs) in its SRAM. Moreover, reverse engineering the RNIC involves network operations which add noise compared to a well-isolated CPU cache environment.

**First attempt in finding index bits.** We initially guess that RNICs organize their in-SRAM PTE caches as set-associative caches, similar to how CPUs organize their caches. To validate this guess, we assume that the PTE cache is organized as a fixed number of sets (e.g., 2, 4, 8) and different number of bits (e.g., 1, 2, 3) are used to calculate the index into these sets. Since PTEs are identified by virtual page number (VPN), we can ignore the lowest 12 bits (with page size being 4 KB). We then use the lowest  $K$  bits of VPNs to calculate the index into one of the  $2^K$  cache sets. These  $K$  bits correspond to the 12th to the  $(11 + K)$ th bits of the full virtual memory address (we call the lowest bit the 0th bit and count upwards to higher bits).

We call the VPN of a victim memory address *VictimVPN*. The eviction set of a *VictimVPN* is formed by setting the same  $K$  bits as the *VictimVPN* and varying other bits in VPNs. To put it another way, for every  $2^K$  pages, we pick one VPN to add to the eviction set. We keep adding distinct VPNs in this way until the number of VPNs in the set reaches an *eviction set size*. Algorithm 4 presents the pseudocode of how we form an eviction set. This is our straw-man approach and we call the PTE-based attack that uses this approach of forming

---

#### Algorithm 4: Forming Eviction Set - Strawman

---

**Input** : *VictimVPN*, eviction set size, num of index bits  
**Output** : an eviction set targeting *VictimVPN*

```

eviction_set ← {};
mask = VictimVPN & (1 << num_index_bits - 1);

for i = 0 to evict_set_size do
    VPN ← i << num_index_bits + mask;
    if VPN ≠ VictimVPN then
        insert VPN into eviction_set;
    end
end

eviction sets *PythiaPTE<sub>Straw</sub>*.

Figure 2 plots the attack accuracy when we vary  $K$  from 0 to 15. We use two groups of attacks on *VictimVPN* 0. In the first group (the solid line), each eviction set has  $2^7 = 128$  operations. The accuracy keeps improving until  $K$  is 13 and then flattens out. This result hints at the possibility of the RNIC using a set-associative cache with  $2^{13} = 8192$  sets. It is because when  $K$  is smaller than 13, part of the operations in the eviction set will fall into a different cache set as the *VictimVPN*'s set, making the eviction set too small to evict the whole victim's cache set.

To verify this guess, we perform a second group of attacks (the dashed line). In this group, we double the eviction set size every time when we decrease  $K$  by 1. For example, we set the eviction set size to 128 when  $K$  is 13 and to 256 when  $K$  is 12. If the RNIC uses 8192 cache sets, then when  $K$  is 13, all of the eviction set will fall into the *VictimVPN*'s set, and when  $K$  is 12, half of the eviction set will fall into the *VictimVPN*'s set. These two attacks will then have the same effect in evicting the *VictimVPN*. Our results confirm this assumption. When  $K$  is less than 13, the attack accuracy is similar to when  $K$  is 13. However, when  $K$  is larger than 14, the accuracy drops. This is because we only use 64 and 32 eviction set size when  $K$  is 14 and 15, and these eviction sets are not large enough to evict a whole cache set.

From this set of experiments, we suspect that virtual memory address bits 12 to 24 are used in calculating the PTE cache set index and that each PTE cache set has 128 entries (i.e., a 128-way cache).

**Discovering prefetching behavior.** Our guess above uses 13 bits as the index into the PTE cache and assumes that the PTE cache has 8192 sets. If this guess is correct, then an eviction set whose  $(VPN \% 8192)$  is different from  $(VictimVPN \% 8192)$  should fall completely into a different cache set from the victim's. To verify this assumption, we perform another set of attacks to the *VictimVPN* 0. In the  $n$ th attack, we construct its eviction set using VPNs where  $(VPN \% 8192 = n)$ , and we change  $n$  from 0 to 8191.

Figure 3 plots the accuracy of the first 64 attacks (the rest of

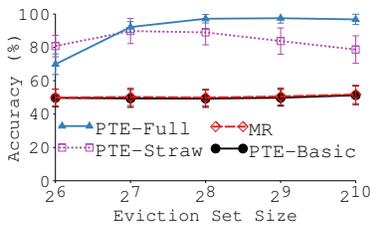

Figure 7: **Accuracy of Attacks.** Error bars show the standard deviation across 1000 VictimVPNs.

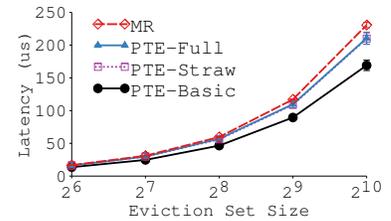

Figure 8: **Latency of Attacks.**

without any other network traffic.

**Timing differences.** Our side channels are based on timing differences between consecutive loads of the same memory address. To measure miss latency, we evict the RNIC SRAM using either MRs or PTEs and then issue an RDMA operation. To measure hit latency, we simply repeatedly issue the same RDMA operation. The measurements in Figure 6 show a clear timing difference between hit and miss latency. When we use MRs to evict SRAM, both the victim’s MR and all the PTEs under this MR will be evicted. An RDMA operation afterwards will need to fetch both the PTE and the metadata for the MR containing the page from host main memory through the PCIe bus. On the other hand, using PTEs to evict will only evict the victim’s PTE and reloading will only fetch the PTE. This explains why the miss latency of MR-based eviction is higher than that of PTE-based eviction.

**Attack accuracy and latency.** Figures 7 and 8 plot the accuracy and latency of four attack strategies: *PythiaMR*, *PythiaPTE<sub>Basic</sub>*, *PythiaPTE<sub>Straw</sub>*, and *PythiaPTE<sub>Full</sub>*, as we change the eviction set size. As expected, with the same eviction set size, the time to perform these four attacks is similar,

since they all use the same amount of RDMA operations. With bigger eviction sets, all attacks become slower.

*PythiaPTE<sub>Full</sub>*’s accuracy is the highest: it can achieve 97% accuracy with only 57  $\mu\text{s}$  per attack (when the eviction set size is 256). *PythiaMR* and *PythiaPTE<sub>Basic</sub>* have low accuracy, although we do observe *PythiaMR*’s accuracy improves significantly as the eviction set size increases (*PythiaMR*’s accuracy reaches 90% with  $2^{15}$  eviction set size). This result demonstrates the benefit of using our reverse engineering findings.

Another observation is that the accuracy of *PythiaPTE<sub>Full</sub>* peaks when the eviction set size is 256 and remains the same when increasing the size further. This implies that the PTE cache has 128 ways, since we construct two cache sets with 256 entries in total.

**Evaluation with different RNICs.** All our experiments so far are performed with the Mellanox ConnectX-4 RNIC (most RDMA deployments in real datacenters use ConnectX-4 [32, 47]). We further validate our attacks on Mellanox ConnectX-5 [49] and ConnectX-3 [46] RNICs. ConnectX-5 is the latest generation of RNICs from Mellanox and ConnectX-

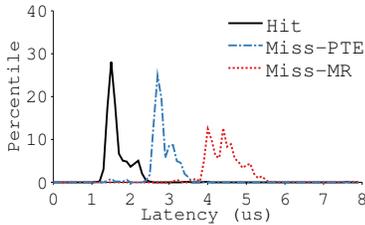

Figure 9: **Timing Differences in ConnectX-5.** Each line presents the timing differences of each case over 1000 trials.

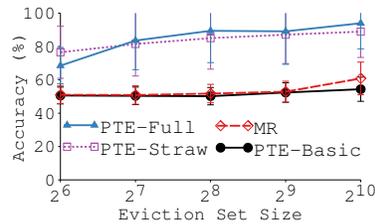

Figure 13: **Accuracy of Attacks in CloudLab.** Error bars show the standard deviation across 1000 VictimVPNs.

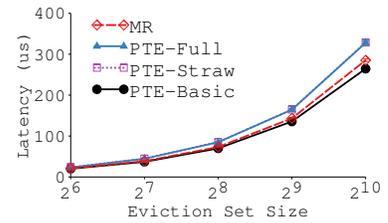

Figure 14: **Latency of Attacks in CloudLab.**

3 is the previous generation of ConnectX-4.

Figure 9 plots the timing results of SRAM hits and misses (due to eviction by MRs and by PTEs) on ConnectX-5. ConnectX-5’s performance is better than ConnectX-4 on all cases. A clear timing difference between misses and hits remains, and misses caused by MR-based eviction are slower than by PTE-based eviction. Figure 10 plots the accuracy of the four types of attacks. The accuracy results are similar to ConnectX-4. Attack latency is also similar to ConnectX-4 and we omit the latency figure. Thus, we can confirm that ConnectX-5 uses a similar SRAM architecture as ConnectX-4, and it has the same side channels as ConnectX-4. We can launch the same attacks on ConnectX-5 with high accuracy and low latency.

We then perform the same set of experiments on ConnectX-3, see Figure 11. The hit latency with ConnectX-3 is longer than ConnectX-4. As hardware evolves, its internal performance often improves, which can explain why hit latency improves over generations of Mellanox RNICs. Surprisingly, the miss latency due to MR-based eviction is shorter on ConnectX-3 than on ConnectX-4 and ConnectX-5. Misses in RNIC SRAM involve the RNIC fetching metadata from the host main memory. We suspect the reason why miss performance drops in newer generations is because RNICs add more metadata for each data entry in newer generations, requiring longer time to fetch more metadata. As a result, the timing difference between miss and hit for ConnectX-3 is small.

Comparing ConnectX-3, ConnectX-4, and ConnectX-5, the three generations of RNICs from Mellanox, we found that as hardware RNICs evolve, their performance improves quickly,

while the PCIe bus and host memory speed improve very slowly. As a result, the discrepancy between hit performance and miss performance becomes larger and we believe that this trend will continue in the future.

#### 4.5.2 Public Cloud Environment

CloudLab [65] is a public cloud that has close to 15,000 cores distributed across three sites in the United States. We evaluated our attacks on a cluster that is connected with RoCE switches. Each machine in this cluster equips two Mellanox ConnectX-4 25 Gbps adapters. These RNICs are of the same product generation as our lab’s ConnectX-4 RNICs, with the difference that our RNICs are 100 Gbps adapters. Both types of adapters can be configured for Ethernet (RoCE) and for InfiniBand. We configure ours for InfiniBand, and CloudLab’s are configured for RoCE. Apart from RNIC differences, CloudLab is used concurrently by many different users; it has a more complex, hierarchical network topology; and it uses a RoCE network instead of InfiniBand. At the time of our test, 129 out of 199 physical machines in the cluster were in use.

We repeat the same set of experiments as Section 4.5.1. Similar to our lab’s experiments, we use three machines, a server, a victim client, and an attacker client. Figure 12 plots the timing difference of RNIC SRAM hit and misses (due to MR-based eviction and PTE-based eviction). Similar to our isolated environment results, misses caused by MR-based eviction are slower than misses caused by PTE-based eviction, and both types of misses are slower than hits. In CloudLab’s shared network and shared machine environments, the latencies of all accesses are longer than in our lab environment,

but the timing differences are still clear.

Figures 13 and 14 plot the accuracy and latency of the four types of attacks in CloudLab. Similar to the results in Figures 7 and 8, With the same eviction set size (and thus similar latency), *PythiaPTE<sub>Full</sub>* and *PythiaPTE<sub>Straw</sub>* have higher accuracy than *PythiaMR* and *PythiaPTE<sub>Basic</sub>*. However, these attacks have larger variation in accuracy compared to attacks in our lab’s environment because of the more dynamic environment in CloudLab.

## 5 Attacking Real RDMA-Based Systems

To demonstrate the feasibility of launching side-channel attacks on real RDMA-based applications, we design and perform a set of attacks on *Crail* [7, 70], an open-source RDMA-based key-value store written in Java. A Crail system consists of several roles: a server which stores key-value pairs, a namenode which stores metadata and manages the control path, and clients which issue key-value pair *gets* and *sets* to the server via a Crail-provided API. We install each component on a separate machine and connect all of them with RDMA. This section presents our design and evaluation of attacks on Crail.

### 5.1 Attacks

Based on the attack primitives described in Section 4, we designed three attacks on Crail. All these attacks have the same goal: knowing whether or not the victim Crail client accesses a specific key-value pair.

**MR-based attack (*PythiaCrail<sub>MR</sub>*).** Our first attack uses MR-based eviction as described in Section 4.3.1. This attack requires three attacker processes. The first is a Crail client process ( $P_c$ ). The second and the third processes run our attack code, with the second one running on the Crail server machine ( $P_s$ ) and the third one running on any other machine ( $P_a$ ) (it can be the same machine as the one where  $P_c$  runs). In the preparation phase,  $P_s$  registers a large number of MRs. In the eviction phase,  $P_a$  issues one-sided RDMA reads to these MRs. Finally,  $P_c$  performs a Crail *get* operation to reload the victim key-value pair. *PythiaCrail<sub>MR</sub>* requires  $P_s$  and  $P_a$  because MR-based attacks need to access many MRs but by default Crail only registers a small set of MRs.

**PTE-based attack (*PythiaCrail<sub>PTE</sub>*).** The second attack uses PTE-based eviction. In this attack, we require three processes as in the MR-based attack:  $P_c$ ,  $P_s$ , and  $P_a$ . In the preparation phase, we first use  $P_s$  to allocate a big chunk of memory and register it with an MR. In the eviction phase,  $P_a$  performs one-sided RDMA reads to different VPNs in the allocated memory space. Afterwards,  $P_c$  issues a Crail *get* request to the victim key-value pair.

Our reverse engineering results in Section 4.4 can be leveraged to reduce the eviction set size in *PythiaCrail<sub>PTE</sub>*. However, to form the eviction set, we need to know the index of

the SRAM cache set(s), which is calculated by the virtual memory address. Without modifying the source code of Crail which is written in Java, it is difficult to directly know the virtual memory address of a target key-value pair. Instead, we use a “learning” phase before launching the actual attack to determine the eviction set to use for a target key-value pair. Specifically, we let  $P_c$  access the target key-value pair and let  $P_a$  try all 1024 different cache sets for eviction. After 1024 trials, we pick the cache set that yields the best accuracy as our attack eviction set.

**Client-only attack (*PythiaCrail<sub>Client</sub>*).** Our last attack on Crail is launched exclusively from a regular Crail client process and requires no other privileges or resources. The attacker (as a normal Crail client) issues Crail *get* requests to different key-value pairs during the eviction phase. After the eviction phase, it performs a Crail *get* operation to the victim key-value pair.

Our initial design of *PythiaCrail<sub>Client</sub>* randomly picks key-value pairs to access during the eviction phase. However, we soon discovered two issues with this naive approach. First, it needs a large number of key-value pairs to effectively evict the target key-value pair. Doing so not only makes the attack slow but also requires the Crail system under attack to already be storing many key-value pairs. Second, we found that the Crail system becomes slower and unstable as the server processes more client requests. We suspect this to be caused by Crail’s own (memory) management overhead. Unstable access latency makes our timing-based attack harder and prohibits an accurate prediction during the reload phase. We improve our initial design with the following optimization. We selectively choose a small set of key-value pairs as the eviction set. We make the assumption that key-value pairs are sequentially allocated in chunks of memory and pick the pairs that are likely to be in the same RNIC SRAM cache set as the victim key-value pair. After reducing the eviction set size, our attack runs very fast. Instead of continuously launching the attack in loops, we add some sleep time between eviction and reloading so that we do not issue too many Crail requests to make Crail unstable.

**Probabilistic prediction.** Under real workloads and noisy network environments, we found that a simple threshold as used in Section 4.3 cannot accurately determine if the victim has accessed the target data. Thus, we use a more dynamic and adaptive approach to predict the outcome of the attack. Similar to the approach used in TLBleed [28], we perform a learning phase to train a classifier of operation latency with KNN [22] before the attack. We use the trained model to predict the probability of a reload latency implying a victim access (*i.e.*, a hit).

### 5.2 Results

We evaluated *PythiaCrail<sub>MR</sub>*, *PythiaCrail<sub>PTE</sub>*, and *PythiaCrail<sub>Client</sub>* using both controlled tests and work-

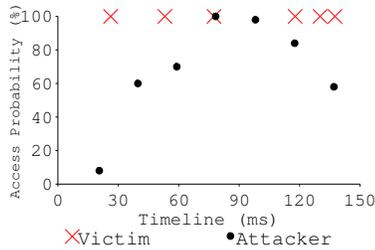

Figure 15: *PythiaCrail<sub>MR</sub>*

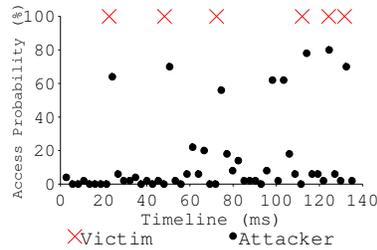

Figure 16: *PythiaCrail<sub>PTE</sub>*

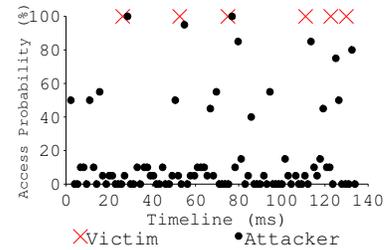

Figure 17: *PythiaCrail<sub>Client</sub>*

loads that model real datacenter key-value stores.

### 5.2.1 Controlled Test

We first compare the latency of a Crail client key-value pair *get* operation that hits RNIC SRAM, a client *get* that misses RNIC SRAM after the eviction phase in *PythiaCrail<sub>MR</sub>*, in *PythiaCrail<sub>PTE</sub>*, and in *PythiaCrail<sub>Client</sub>*. In these controlled tests, the victim client has a 50% chance of accessing the targeted key-value pair that the attacker tries to infer accesses on. Figure 18 plots these four types of latencies, each performing 1000 trials. All the three types of misses take longer than hits, with the timing difference of *PythiaCrail<sub>MR</sub>* the biggest and *PythiaCrail<sub>Client</sub>* the smallest. The timing difference implies that it is easiest to separate hits and misses with *PythiaCrail<sub>MR</sub>*.

We launch the *PythiaCrail<sub>MR</sub>*, and *PythiaCrail<sub>PTE</sub>*, and *PythiaCrail<sub>Client</sub>* attacks by first performing their respective eviction phases. Next, we let victim access or not access the target key-value pair. Finally, we measure the time to reload the key-value pair and compare it with a threshold we determined from the timing difference testing phase. As expected, *PythiaCrail<sub>MR</sub>* gives the best accuracy. The accuracies of *PythiaCrail<sub>MR</sub>*, *PythiaCrail<sub>PTE</sub>*, and *PythiaCrail<sub>Client</sub>* are 96%, 85%, and 79% respectively, and the time to perform these attacks are 19ms, 0.1ms, and 0.3ms.

### 5.2.2 Macro-benchmark Results

**Workloads.** To evaluate how our attacks perform with real datacenter key-value store workloads, we construct a macro-benchmark with the Yahoo! Cloud Serving Benchmark (YCSB) [21] and statistics reported by Facebook in their production key-value store [12]. YCSB provides key-value *get/set* access pattern but no inter-arrival time between requests. Facebook provides the inter-arrival time of requests received at a server in its cluster, which includes requests from all the clients to this server. We set each key-value pair size to be 1 KB, the average key-value pair size reported by Facebook.

**Attack environment setup.** In this experiment, the victim (on a Crail client machine) executes our macro-benchmark to access key-value pairs on a Crail server machine using the Crail APIs. Since Facebook only provides aggregated request inter-arrival time across clients and does not reveal

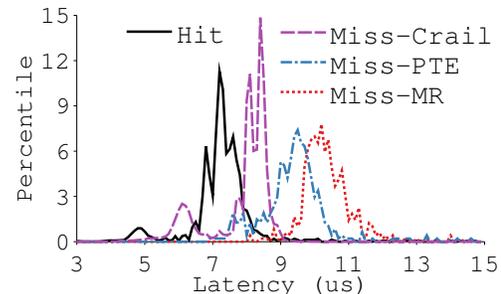

Figure 18: **Timing Difference in Crail.** Each line presents the timing differences of each case over 1000 trials.

how many clients there are, we use one client machine to model the aggregated effect of all clients with the provided inter-arrival time. We run an attacker process as a normal Crail client on another machine. A fourth machine serves as the Crail namenode. While the victim process executes the macro-benchmark, we repeatedly perform *PythiaCrail<sub>Client</sub>*, *PythiaCrail<sub>MR</sub>*, or *PythiaCrail<sub>PTE</sub>* to detect if the victim accesses a target key-value pair.

**Results.** Figures 15, 16, and 17 present the timeline of the victim accessing the target key-value pair (red crosses) and the attacker’s prediction (black dots with values as access probability). All three attacks can capture most if not all victim accesses. Among them, *PythiaCrail<sub>MR</sub>* is the worst in attack accuracy. This is because each attack in *PythiaCrail<sub>MR</sub>* takes 19ms, which is much longer than the Facebook inter-arrival time. As a result, *PythiaCrail<sub>MR</sub>* misses victim accesses that happen more frequent than its attack length. Both *PythiaCrail<sub>PTE</sub>* and *PythiaCrail<sub>Client</sub>* run very fast and capture all victim accesses. In fact, these two attacks run so fast that we add a sleep time of 1ms between evict and reload to avoid issuing too many Crail requests and making Crail’s performance unstable. Comparing *PythiaCrail<sub>PTE</sub>* and *PythiaCrail<sub>Client</sub>*, *PythiaCrail<sub>PTE</sub>*’s predictions are of low access probabilities and *PythiaCrail<sub>Client</sub>* has more predictions of around 50% access probabilities. The attacker can set a threshold accordingly to determine the final set of victim accesses (e.g., those with probabilities > 60% for *PythiaCrail<sub>Client</sub>*).

Overall, we believe *PythiaCrail<sub>Client</sub>* to be the most effective

tive attack, since it predicts victim accesses with high confidence and it requires the least amount of attacker resources: *PythiaCrail<sub>Client</sub>* can be launched exclusively from a separate client machine through the unmodified Crail client interface. If attackers can run modified Crail clients, they can launch more efficient side-channel attacks by forming the eviction set with known virtual addresses.

## 6 Mitigation Techniques

Defending against RDMA-based side-channel attacks is possible and feasible. We discuss both mitigations for current hardware as well as those for future hardware.

### **Huge virtual memory page or no virtual memory.**

PTE-based attacks are only possible when RNICs cache PTEs and when the attacker can form an effective eviction set. One way to prevent PTE-based attacks is to force all RDMA registrations and operations to directly use physical memory addresses. When physical memory addresses are used, RDMA does not need to access or cache PTEs, thereby preventing PTE-based attacks. Registering physical memory addresses is a privileged operation that RNICs allow the kernel [76] and privileged users to perform [51]. However, using physical memory addresses loses all the benefits of virtual memory and introduces new security concerns.

Another method to defend against PTE-based attacks is to use huge memory pages [24]. Using huge pages (e.g., 1 GB pages) introduces two types of difficulties for attackers. First, the attacker can only guess victim accesses at coarse granularity (e.g., 1 GB). Second, the attacker will need to have access to a huge memory space to form an eviction set with enough PTEs.

**Isolate server's resource.** Our experience with Crail demonstrates that attacking Crail is difficult when the attacker can only use Crail's interface without the access to a large number of PTEs or MRs and without knowing Crail's data layout in the virtual memory address space. Our experiments show that for *PythiaCrail<sub>MR</sub>* and *PythiaCrail<sub>PTE</sub>* to work, an attacker needs to run a process,  $P_s$ , on the server machine. Otherwise, the attacker would not be able to launch those attacks (although *PythiaCrail<sub>Client</sub>* still works). Thus, a server that hosts RDMA service can prohibit normal users from running any processes to help defend against side-channel attacks. Various address randomization techniques can also complicate attacks.

**Separate protection domains.** When we disclosed the attacks in this paper to Mellanox, the Mellanox engineers stated that separating *Protection Domains (PDs)* between different clients and connections can potentially mitigate the attacks. We evaluated this mitigation by moving the attacker to a different PD and found that doing so mitigates Pythia attacks. Unfortunately, all existing RDMA applications that we are

aware of [7, 24, 83] use only one PD for higher performance. Using multiple PDs results in low throughput and high latency overhead (15% throughput reduction and 21% latency overhead with 256 PDs in our experiments). We plan to further investigate both attack and defense mechanisms when separating PDs across clients.

**Introduce noise.** Our side channels are established on timing differences at the microsecond or sub-microsecond level. Attacking Crail running real workloads is more difficult than attacking raw RDMA accesses mainly because of Crail's non-deterministic performance overhead. Therefore, an effective countermeasure is to introduce random latency overhead at an RDMA-based application or in the datacenter RDMA network, which, however, could impact application performance.

**Detect and throttle attacker's network traffic.** Our attackers can hide their attacks because one-sided RDMA operations are completely hidden from the receiver CPU (the server in our case). To detect these attacks, the server can deploy traffic sniffing tools to sniff all incoming RDMA network requests. If the sniffer detects heavy network activity from a client, it can raise a flag that this client may be malicious. If it further detects an access pattern that matches eviction sets described in Section 4.4, this client is more likely to be an attacker. This defense comes with the same drawbacks of other heuristic-based defenses that an attacker may stay under the detection threshold.

A further countermeasure is to throttle the maximum bandwidth allowed at every client. If an attacker cannot issue enough operations to evict RNIC SRAM, its attack accuracy will drop significantly. However, throttling client bandwidth can hurt normal clients' performance.

**Better hardware design.** All existing RNICs share their SRAM across all users and across all connections. Because of this, an attacker can evict a victim's PTE and MR even when the attacker and the victim have different connections to the server. If RNICs can partition their SRAM to different isolated domains for different connections, then attackers can never evict victim's PTEs or MRs. However, isolation resources at hardware level will inevitably hurt performance and increase hardware complexity, which gives little incentive for RNIC vendors to change their hardware design.

## 7 Discussion

We now briefly discuss the implications, impact, and limitations of Pythia, and some other attacks on RDMA that can be designed based on Pythia.

### 7.1 RDMA Vulnerabilities

We discovered new vulnerabilities in RDMA systems that are fundamental to the design of RDMA and not specific to just one RDMA device. RNICs cache metadata as a result

of RDMA’s design philosophy of *one-sided* network communication. Because one-sided operations cannot involve host CPUs, RNICs have to handle and serve RDMA requests on their own, which involves accessing various types of metadata. With limited on-board SRAM, RNICs cannot store all the metadata and have to move metadata between their SRAM and the host machine’s main memory through the PCIe bus. As a result, there exists timing difference between RDMA operations that hit or miss SRAM, and this timing difference keeps increasing as RNICs evolve over generations.

We demonstrated the feasibility of exploiting the above vulnerability to launch side-channel attacks on RDMA-based systems. Pythia attacks are fast and accurate, and they can be performed completely from the network. Moreover, attackers can hide their traces because the attack uses one-sided network requests.

Both the RNIC side channels we discovered and our attacks’ unique advantages are fundamental to one-sided network communication. One-sided communication offers many performance and cost benefits that are attractive for datacenter systems. However, it also raises new security concerns [77], as we demonstrate in Pythia. Our work can inspire future security researchers in discovering and defending more vulnerabilities in RDMA.

## 7.2 Attacking Real Applications

We demonstrated that it is feasible to launch Pythia attacks on Crail, a real RDMA-based system developed by the Crail team. *PythiaCrailClient*, the attack that is launched by performing Crail-provided client APIs only, can successfully infer victim’s access patterns under real workloads.

We believe that Pythia can similarly attack other RDMA-based applications as well. Pythia only requires two features from an RDMA-based application: the application uses one-sided RDMA operations and allocates regular paged memory. Many applications meet these requirements, such as the NAM-DB RDMA-based in-memory database [88], the Pilaf RDMA-based key-value store [56], and the Wukong RDMA-based graph system [68]. Unfortunately, most of these systems are not available publicly.

## 7.3 Attack Limitations

Although our side-channel attacks are fast, accurate, and can be launched entirely from the network, they do have several limitations. First, the granularity of Pythia attacks (and therefore information leakage of accesses) is a memory page. Pythia currently cannot differentiate between two victim accesses that access the same target page. Second, Pythia can only predict if a data entity at the server has been accessed, but not which client machine(s) accessed it. Third, our MR-based attacks require access to a large number of MRs, and PTE-based attacks require access to large memory spaces. Finally, our attacks consume network bandwidth and can be detected by sniffing the network.

## 7.4 Other RDMA-Based Attacks

Pythia serves as a starting point for designing other types of RDMA-based attacks. For example, similar to Pythia EVICT+RELOAD attacks, it is possible to launch PRIME+PROBE attacks from the network by exploiting the MR or the PTE side channels.

The MR and the PTE side channels we established can also be used as covert channels. We implemented a naive covert-channel attack of using one EVICT+RELOAD cycle to transmit one bit and it could reach a sending rate of 20 Kbps with *PythiaPTEFull*.

## 8 Related Work

**Single-node side-channel attacks.** In recent years, a host of attacks that exploit various hardware features to establish side channels have been proposed. CPU-cache-based side-channel attacks such as PRIME+PROBE [1–4, 42, 59, 75, 78, 90], EVICT+RELOAD [30], FLUSH+RELOAD [86], and FLUSH+FLUSH [30, 78] can leak victim’s memory access patterns at fine granularity. CPU-cache-based side channels are also the key enabling factors in attacks like Meltdown [41], Spectre [39], and Foreshadow [17]. Other than CPU caches, TLB [28] or port contention [13] also expose hardware-based side channels. Side-channel attacks brought key concerns in cloud environments where one tenant can steal information of other tenants when they share the same physical resource [79, 89–91] or the same service [33]. But all these single-node side-channel attacks require the attacker to run on the same machine as the victim. Pythia is a remote side-channel attack that can be launched completely from a separate remote machine.

**Remote side-channel attacks.** Several remote side-channel attacks exploit TCP sequence numbers to hijack connections [18, 61, 62]. Another line of work relies on traffic analysis to exploit sensitive information [27, 37]. Brumley *et al.* perform a timing-based attack on OpenSSL’s ladder implementation to obtain the private key of a TLS server [16]. Cock *et al.* present an empirical study of remote timing channels on microkernel [20]. NetSpectre [66] presents an access-driven remote EVICT+RELOAD cache attack. Weinberg *et al.* combined CSS and JavaScript to remotely sniff victims’ browsing patterns [84]. Different from all previous remote side-channel attacks, Pythia targets the RDMA network. Moreover, Pythia exploits RNIC hardware features to establish timing-based side channels, while previous remote side channels exploit network protocols or software features. As far as we know, Throwhammer [71] is the only other attack related to RDMA. However, it simply uses RDMA network requests to launch a Rowhammer attack and does not explore or exploit vulnerabilities in the RDMA

technology itself.

**Mitigations to side-channel attacks.** Various defense mechanisms have been proposed to combat CPU cache side-channel attacks in both hardware [23, 36, 58, 81, 82] and software [38, 43, 69, 92, 94]. Unfortunately, none of the existing defense mechanisms can be directly applied to RDMA-based side-channel attacks. We propose a set of new mitigations that target RDMA-based side-channel attacks.

## 9 Conclusion

This paper presents Pythia, the first set of side-channel attacks on RDMA-based systems. We reverse engineer the internal data structures of current RDMA systems and leverage this information to improve our attack. Pythia can be launched completely from a normal client machine to steal access patterns of victims on other machines. We evaluate Pythia in laboratory settings to showcase the capabilities of the attack, on real software such as Crail, and on real data centers to show real-world impact. Pythia is fast, accurate, and can hide its trace from victims and the server.

## Acknowledgments

We would like to thank the anonymous reviewers for their tremendous feedback and comments, which have substantially improved the content and presentation of this paper. We are also thankful to Ahmad Atamlh, Noam Bloch, Brandon Hathaway, Yuval Itkin, Ariel Levanon, Alex Polak, Randy Splinter, and Patrick Stuedi for their feedback during our responsible disclosure to Mellanox and the Crail team.

This material is based upon work supported by the National Science Foundation under the following grant: NSF 1719215. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of NSF or other institutions.

## Abstract

Millions of users rely on mobile health (mHealth) apps to manage their wellness and medical conditions. Although the popularity of such apps continues to grow, several privacy and security challenges can hinder their potential. In particular, the simple fact that an mHealth app is installed on a user's phone can reveal sensitive information about the user's health. Due to Android's open design, any app, even without permissions, can easily check for the presence of a specific app or collect the entire list of installed apps on the phone. Our analysis shows that Android apps expose a significant amount of metadata, which facilitates fingerprinting them. Many third parties are interested in such information: Our survey of 2917 popular apps in the Google Play Store shows that around 57% of these apps explicitly query for the list of installed apps. Therefore, we designed and implemented `HideMyApp` (HMA), an effective and practical solution for hiding the presence of sensitive apps from other apps. HMA does not require any changes to the Android operating system or to apps yet still supports their key functionalities. By using a diverse dataset of both free and paid mHealth apps, our experimental evaluation shows that HMA supports the main functionalities in most apps and introduces acceptable overheads at runtime (*i.e.*, several milliseconds); these findings were validated by our user-study ( $N = 30$ ). In short, we show that the practice of collecting information about installed apps is widespread and that our solution, HMA, provides a robust protection against such a threat.

## 1 Introduction

Mobile health (mHealth), the use of technologies such as smartphones and wearable sensors for wellness and medical purposes, promises to improve the quality of and reduce the costs of medical care and research. An increasing number of people rely on mHealth apps to manage their wellness and to prevent and manage diseases.<sup>1</sup> For instance, more than a third of physicians in the US recommend mHealth apps to their

patients [23], and there are around 325,000 mHealth apps available in major mobile app stores.<sup>2</sup>

Given the sensitivity of medical data, the threats of privacy leakage are one of the main hindrances to the success of mHealth technologies [37]. In this area, a serious and often overlooked threat is that an adversary can infer sensitive information simply from the presence of an app on a user's phone. Previous studies have shown that private information, such as age, gender, race, and religion, can be inferred from the list of installed apps [22, 29, 47]. With the increasing popularity of mHealth apps, an adversary can now infer even more sensitive information. For example, learning that a user has a diabetes app reveals that the user probably suffers from this disease; such information could be misused to profile, discriminate, or blackmail the user. When inquired about this threat, 87% of the participants in our user-study expressed concern about it (Section 10.6).

Due to Android's open design, a zero-permission app can easily infer the presence of specific apps, or even collect the full list of installed apps on the phone [55]. Our analysis shows that Android exposes a considerable amount of static and runtime metadata about installed apps (Section 4); this information can be misused by a nosy app to accurately fingerprint these apps. In 2014, Twitter was criticized for collecting the list of installed apps in order to offer targeted ads.<sup>3</sup> But Twitter is not the only app interested in such information. Our static and dynamic analysis of 2917 popular apps in the US Google Play Store shows that approximately 57% of these apps include calls to API methods that explicitly collect the list of installed apps (Section 5). Our analysis, corroborating the findings of previous studies [29, 32], also shows that free apps are more likely to query for such information and that third-party libraries (libs) are the main requesters of the list of installed apps. As users have on average 80 apps installed on their phones,<sup>4</sup> most of them being free, there is a high chance of untrusted third-parties obtaining the list of installed apps.

Since 2015, Android has classified as potentially harmful apps (PHA)<sup>5</sup> the apps that collect information about other apps without user consent [1]. To avoid this classification,

developers simply need to provide a privacy policy that describes how the app collects, uses, and shares user data.<sup>6</sup> We find it interesting that only 7.7% of the evaluated apps clearly declared that they collect the list of installed apps in their privacy policies, and some even claim that such a list is non-personal information (Section 5.4). Also, few users read privacy policies [41], as our user study also confirmed (Section 10.6).

Android does not provide mechanisms to hide the use of sensitive apps on a phone; a few third-party tools, designed for other purposes, can provide only partial protection to some users (Section 6). Android announced that their security services will display warnings on apps that collect without consent users' personal information, including the list of installed apps.<sup>7</sup> This is a welcomed step, but the effectiveness of security warnings is known to be limited [30, 49] and it is unclear how queries by third-party libraries will be handled. It is also unclear if such an approach will be able to prevent more subtle attacks, where a nosy app checks for the existence of a specific app or a small set of sensitive apps by using more advanced fingerprinting techniques (Section 4).

We propose HideMyApp (HMA), the first system that enables organizations and developers to distribute sensitive apps to their users while considerably reducing the risk of such apps being detected by nosy apps on the same phone. Apps protected by HMA expose significantly less identifying metadata, therefore, it is more difficult for nosy apps to detect their presence, even when the nosy apps have all Android permissions and debugging privileges. With HMA, an organization such as a consortium of hospitals sets up an HMA app store where authorized developers collaborating with the hospitals can publish their mHealth and other sensitive apps. Users employ a client app called HMA Manager to anonymously (un)install, use, and to update the apps selected from the HMA app store; the HMA App Store does not learn about the set of apps that a user has installed from the store. HMA transparently works on stock Android devices, it does not require root access, and it preserves the app-isolation security model of the Android operating system (OS). Still, HMA preserves the key functionalities of mHealth apps, e.g., connecting to external devices via Bluetooth, sending information over the Internet, and storing information in databases.

With HMA, users launch a sensitive app inside the context of a container app, without requiring the sensitive app to be installed. A container app is a dynamically generated wrapper around the Android application package (APK) of the sensitive app, and it is designed in such a way that the sensitive app cannot be fingerprinted yet still can support inter-process communication between the sensitive app and other installed apps. To launch the APK from the container app, HMA relies on techniques described in existing work: the dynamic loading of compiled source code and app resources from the APKs and user-level app-virtualization techniques, e.g., [24, 25]. However, note that app virtualization alone is insufficient in provid-

ing robust protection against fingerprinting attacks, as many of the information leaks uncovered by our analysis are still possible when just app virtualization is used. Therefore, our main contribution is the design and evaluation of mechanisms built on top of app-virtualization in order to reduce the information leaks that could be exploited to fingerprint sensitive apps. HMA provides multiple tiers of protection: For baseline protection against current threats, HMA obfuscates static meta-data of sensitive apps (e.g., their package names and components). To provide more advanced protection (e.g., against side-channel attacks), HMA can add an additional layer of obfuscation for sensitive apps (e.g., randomizing memory access). In some cases, app developers might need to be involved to make changes to the apps. Moreover, we are the first to identify the security and functional limitations of using app virtualization for the purpose of hiding apps.

Our evaluation of HMA on a diverse set of both free and paid mHealth apps on the Google Play Store shows that HMA is practical, and that it introduces reasonable operational delays to the users. For example, in 90% of the cases, the delay introduced by HMA to the cold start of an mHealth app by a non-optimized proof-of-concept implementation of HMA is less than one second. At runtime, the delay introduced is of only several milliseconds. Moreover, our user-study ( $N = 30$ ) suggests that HMA is user-friendly and of interest to users.

Our main contributions in this work are as follows.

- *Systemized knowledge*: We are the first to investigate the techniques that an app can use to fingerprint another app.<sup>8</sup> Also, through our static and dynamic analysis on apps from the Google Play Store, we gain understanding about the prevalence of the problem of apps fingerprinting other installed apps.
- *Design and implementation of a solution for hiding sensitive apps*: We present HMA, a practical system that provides robust defense against fingerprinting attacks that target sensitive apps on Android. HMA works on stock Android, and no firmware modification or root privilege is required.
- *Thorough evaluation of HMA*: The evaluation of HMA's prototype on apps from the Google Play Store suggests that HMA is practical. Also, our user study suggests that HMA is perceived as usable. HMA's source code is available at <https://github.com/lcal/HideMyApp>.

## 2 Related Work

Researchers have actively investigated security and privacy problems in the Android platform. Existing works show that third-party libs often abuse their permissions to collect users' sensitive information [35, 48], and that apps have suspicious activities e.g., collecting call logs, phone numbers, and browser bookmarks [29, 42]. Zhou *et al.* [55] show that

Android's open design has made publicly available a number of seemingly innocuous phone resources, including the list of installed apps; these resources could be used to infer sensitive information about their users, *e.g.*, users' gender and religion [40, 46]. Similarly, Chen *et al.* [27] show how to fingerprint Android apps based on their power consumption profiles. A significant research effort has been devoted to fingerprinting Android apps based on their (encrypted) network traffic patterns [28, 51, 54]. Researchers have also shown that re-identification attacks are possible using a small subset of installed apps [22, 33]. Demetriou *et al.* [29], in the same line as our work, used static analysis to quantify the prevalence of the collections of the list of installed apps and their metadata by third-party libs. We go beyond their work, however, by systematically investigating all possible information leaks that nosy apps can exploit to fingerprint other apps and by performing a dynamic analysis and privacy-policy analysis.

Existing mechanisms for preventing apps from learning about the presence of another app are not sufficient (Section 6). As we will show in Section 8, user-level virtualization techniques that enable an app (called *target app*) to be encapsulated within the context of another app (called *container app*) can be used as a building block for HMA. These techniques are used to sandbox untrusted target apps (*e.g.*, [24, 25]) or to compartmentalize third-party libs from the host apps (*e.g.*, [34]). As they were designed for a different problem, however, they do not directly help hide the presence of a sensitive target app: They either require the target app to be first installed, thus exposing them to nosy apps through public APIs, or they run multiple target apps inside the same container app, thus violating the Android's app-isolation security model. They also do not provide any insight into the possible information leaks that can be exploited to fingerprint apps and how their techniques can be used for hiding the presence of apps.

### 3 Background on Android

**Android Security Model.** Android requires each app to have a unique package name defined by its developers and cannot be changed during its installation or execution. Upon installation, the Android OS automatically assigns a unique user ID (UID) to each app and creates a private directory where only this UID has read and write permissions. Additionally, each app is executed in its dedicated processes. Thus, apps are isolated, or sandboxed, both at the process and file levels.

Apps interact with the underlying system via methods defined by the Java API framework and the shell commands defined by the Linux-layer interface. Some API methods require users to grant apps certain permissions. Android defines three main protection levels for apps: normal, signature, and dangerous permissions.<sup>9</sup> Apps can have special permissions; users are required to grant these permissions to apps through the Settings app. Any app can execute shell commands; how-

ever, depending on its privilege, *i.e.*, default app privilege, debugging (adb)<sup>10</sup> or root, the outputs of the same shell commands are different.

**Android Apps and APK Files.** An Android app must contain a set of mandatory information: a unique package name, an icon, a label, a folder containing resources, and at least one of the following components: activity, service, broadcast receiver and content provider. An activity represents a screen, and a service performs long-running operations in the background. A broadcast receiver enables an app to subscribe and respond to specific system-wide events. A content provider manages the sharing of data between components in the same app or with other apps. Apps can optionally support other features such as implicit or explicit intents, permissions, and some customized app configurations. Apps are distributed in the form of APK files. An APK is a signed zip archive that contains the compiled code and resources of the app. Each APK also includes a manifest configuration file, called `AndroidManifest.xml`; this file contains a description of the app (*e.g.*, its package name and components).

### 4 Fingerprintability of Android Apps

Here, we demonstrate that an app, depending on its capabilities (its granted permissions and/or privileges), can retrieve information about other installed apps. This includes static information (*i.e.*, information available after apps are installed and that typically does not change during apps' lifetimes), and runtime information (*i.e.*, information generated or updated by apps at runtime). Our analysis was conducted on Android 8.0. Its findings are summarized in Table 1.

**Without Permissions.** An app can easily check if a specific app is installed on the phone. This can be done by invoking two methods `getInstalledApplications()` and `getInstalledPackages()` (hereafter abbreviated as `getIA()` and `getIP()`, respectively); they return the entire list of installed apps. An app can also register broadcast receivers (*e.g.*, `PACKAGE_INSTALLED`) to be notified when a new app is installed. It can also use various methods of the `PackageManager` class (*e.g.*, `getResourcesForApplication()`) as an oracle to check for the presence of a specific app. These methods take a package name as a parameter and return *null* if the package name does not exist on the phone.

If Android restricts access to package names of installed apps (*e.g.*, by requiring permissions), an app can still retrieve other static information about installed apps for fingerprinting attacks. This includes their mandatory information: the names of their components, their icons, labels, resources, developers' signatures and signing certificates. This also includes custom features used by installed apps: their permissions, apps configurations (themes, styles, and supported SDK). Such information can be obtained through a number of methods in

	Without Permissions	With Permissions	Default App Privilege	Debugging Privilege (adb)
<b>Static Information</b>	<u>Core attributes:</u> + Package name + Component's names + Resources + Icon, label + Developers' signatures <u>Customizations:</u> * Permissions * Themes * Phone configurations	(*) See note	+ Package names	+ Package names + APK path + APK file
<b>Runtime Information</b>	None	<u>Dangerous Permissions:</u> * Files in external storage ◇ Network traffic <u>Special Permissions:</u> ◇ Storage consumption + Running processes - Layouts and their content	◇ UI states <sup>†</sup> ◇ Power consumption <sup>†</sup> ◇ Memory footprints <sup>†</sup>	* Files in external storage * System log * System diagnostic outputs + Running processes ◇ Network consumption - Screenshots

Table 1: Identifying information about installed apps that an app can learn, w.r.t. its permissions and privileges, through the Java API framework and the Linux-layer kernel. Analysis was conducted on Android 8.0. Superscript <sup>†</sup> means that the information can be learnt only in older versions of Android (e.g., Android 8.0 requires the calling app to have adb privilege). (\*) *Note:* Granting permissions to a zero-permission app does not enable it to obtain more static information about other installed apps. The notations +, \* and ◇ indicate the resources that our system (HMA, see Section 8) can protect by default, by collaborating with app developers or by randomizing runtime information of the container apps, respectively. Resources marked with the – sign cannot be protected by HMA.

the `PackageManager` class, e.g., `getPackageInfo()`. Note that this can be done even when apps are installed with the forward-lock option enabled (option `-l` in the `adb install` command). We tested this in Android 6.0; Android 8.0 threw an exception for this `-l` option. A nosy app cannot retrieve the list of intent filters declared by other apps. However, it can learn the names of the components of installed apps that can handle specific intent requests, by using methods such as `resolveActivity()`.

**With Permissions.** An app granted with the `READ_EXTERNAL_STORAGE` permission, a frequently requested dangerous-permission, can inspect for unique folders and files in a phone's external storage (a.k.a. SD card). Apps with VPN capabilities (permission `BIND_VPN_SERVICE`) can intercept network traffic of other apps; existing work shows that network traffic, even encrypted, can be used to fingerprint apps with good accuracy [50, 51, 54].

With special permissions, an app can obtain certain identifying information about other apps at their runtime. For instance, the `PACKAGE_USAGE_STATS` permission permits an app to obtain the list of running processes (method `getRunningAppProcesses()`), and statistics about network and storage consumption of all installed apps, including their package names, during a time interval (method `queryUsageStats()`). In addition, accessibility services<sup>11</sup> (with the `BIND_ACCESSIBILITY_SERVICE` permission) can have access to the layouts and the layouts' contents of other apps.

**With Default App-Privilege.** An app can retrieve the list of all package names on the phone. This can be done by ob-

taining the set of UIDs in the `/proc/uid_stat` folder and using the `getNameForUid()` API call to map a UID to a package name. An app can also infer the UI states (e.g., knowing that another app is showing a login screen) [26], memory footprints (sequences of snapshots of the app's data resident size) [36] and power consumption [27] of other apps. Note that access to this information has been restricted in recent versions of Android (e.g., Android 8.0 requires the app to have adb privilege).

**With Debugging Privilege (adb).** An app can retrieve the list of package names (command `pm list packages`) and learn the path to the APK file of a specific app (command `pm path [package name]`). Moreover, the adb privilege enables an app to retrieve the APK files of other apps (command `pull [APK path]`); the app can then use API methods such as `getPackageArchiveInfo()` to extract identifying information from the APK files. Also an app can learn about runtime behaviors of other apps by inspecting the system logs and diagnostic outputs (commands `logcat` and `dumpsys`). Moreover, with the adb privilege, apps can directly retrieve the list of running processes (command `ps`), take screenshots [38] or gain access to statistics about network usage of other apps (folder `/proc/uid_stat/[uid]`).

Our analysis shows that Android's open design exposes a significant amount of information that facilitates app-fingerprinting attacks. App developers themselves cannot obfuscate most of the aforementioned information for the purpose of hiding sensitive apps. For example, by design, the package name of an app is a global identifier in the Google Play Store. As a result, the obfuscation of apps' package

names has to be done per user, *i.e.*, for each user, the same app needs to be uploaded to the Google Play Store with a different package name. Similarly, the names of the app's components also need to be obfuscated per user, hence this approach is not practical. To mitigate app-fingerprinting attacks, Android could follow an approach similar to iOS, *i.e.*, to remove or restrict API methods and OS resources that leak identifying information of apps. However, such an approach would be difficult to implement in Android, as most of these methods and resources have valid use cases and are widely used by apps. For instance, methods `getIA()` and `getIP()`, are used by many popular apps with millions of users, *e.g.*, launcher, security/antivirus, and storage/memory manager apps. Removing or restricting such methods would break many apps and anger both developers and users. Such an approach would also negatively affect the competitive advantages of Android, *i.e.*, its customizability and rich set of features, over iOS. In addition, restricting API methods would not solve the problem completely, as more subtle fingerprinting attacks would still be possible. For example, in iOS, the `canOpenURL()` method can be used to check if a particular app is on the phone. Since iOS 9.0, in order to have an arbitrarily high number of calls to this method, an app has to declare beforehand the set of apps that it wants to check. Otherwise, it can only call this method at most 50 times.<sup>12</sup> This restriction reduces the risks of fingerprinting attacks, but negatively affects both developers and users, *e.g.*, apps need to be updated frequently to update the list of apps. More importantly, even with 50 queries, a nosy app can still check if a specific app or small set of apps are installed on the phone.

A possibly better approach is for Android to include a new "sensitive" flag that enables users to hide sensitive apps from other apps in the same phone, *i.e.*, other apps will not be able to use Android API methods to infer the existence of apps flagged as sensitive. Moreover, Android can include a new permission that users can grant to certain apps in order to enable these apps to detect apps flagged as sensitive. This approach, however, requires significant modifications and testing of Android's APIs. Therefore, our goal is to design a solution that does not require changes to Android or sensitive apps and that can be available to users immediately.

## 5 Apps Inquiring about Other Apps

We analyze apps from the Google Play Store to estimate how common it is for apps to inquire about other installed apps. Our analysis focuses on API calls that directly retrieve the list of installed apps (hereafter called LIA): `getIA()` and `getIP()`, because these two methods clearly show the intent of developers to learn about other apps, whereas the other methods presented in Section 4 can be used in valid use cases. Therefore, the results presented in this section is a *lower-bound* on the number of apps that fingerprint other apps.

## 5.1 Data Collection

We gathered the following datasets for our analysis.

**APK Dataset.** We collected APK files of popular free apps in the Google Play Store (US site). For each app category in the store (55 total), we gathered the 60 most popular apps. After eliminating duplicate entries, default Android apps, and brand-specific apps, we were left with 2917 apps.

**Privacy-Policy Dataset.** We collected privacy policies that corresponded to the apps in our dataset. Out of 2917 apps, we gathered 2499 privacy policies by following the links included in the apps' Google Play Store pages.

## 5.2 Static Analysis

For our static analysis, by using Apktool,<sup>13</sup> we decompiled the APKs to obtain their smali code, a human-readable representation of the app's bytecode. We searched in the smali code for occurrences of two methods `getIA()` and `getIP()`.<sup>14</sup> API calls can be located in three parts of the decompiled code: in the code of Android/Google libs and SDKs, in the code of third-party libs and SDKs, or in the code of the app itself. To differentiate among these three origins, we applied the following heuristic. First, methods found in paths containing the "com/google", "com/Android" or "Android/support" substrings, are considered part of Android/Google libs and SDKs. Second, methods found in paths containing the name of the app are considered part of the code of the app. We believe this is a reasonable heuristics, because package names of Android apps follow the Java package-name conventions with the reversed internet domain of the companies, generally two words long. If the methods do not match the first two categories, then they are considered part of the code of a third-party lib or SDK. Note that this approach, also used in previous work [29], cannot precisely classify obfuscated code or code in paths with no meaningful names. Such cases, however, represent only a small fraction in our analysis (less than 5%).

Table 2 shows the proportions of apps that invoke `getIA()` and `getIP()` w.r.t. different call origins. Of the 2917 apps evaluated, 1663 apps (57.0%) include at least one invocation of these two methods in the code from third-party libs and the apps. These results show a significant increase in comparison with the results presented in 2016 by Demetriou *et al.* [29]. These results also show that most sensitive requests come from third-party libs or SDKs; app developers might not be aware of this activity, as has been the case for other sensitive data such as location.<sup>15</sup>

Static analysis has two main limitations. First, methods appearing in the code might never be executed by the app. Second, it is possible that the sensitive methods do not appear in the code included in the APK, rather in the code loaded dynamically at runtime. To address these issues, we also performed a dynamic analysis of the apps in our dataset.

Analysis method	Call origin	getIA () (%)	getIP () (%)	getIA () or getIP () (%)
Static	Third-party libs + Apps	36.4	43.6	57.0
Static	Apps only	8.1	8.4	13.9
Dynamic	Third-party libs + Apps	6.5	15.0	19.2

Table 2: Proportion of free apps that invoke `getIA ()` and `getIP ()`, to collect LIAs w.r.t. different call origins.

### 5.3 Dynamic Analysis

For our dynamic analysis, by using XPrivacy<sup>16</sup> on a phone with Android 6.0, we intercepted the API calls from apps. For the analysis to scale, for each app, we installed it and granted it all the permissions requested. Next, we launched all the runnable activities declared by the app for 10 minutes. Although this approach has limitations, as it only has a short period of time per app and it cannot emulate all the activities a user could do, it is sufficient to estimate a *lower-bound* on the number of apps that query for LIAs at runtime, as shown in our results.

Our results, shown in Table 2, show that 190 apps (6.54%) called `getIA ()`, 436 apps (15.0%) called `getIP ()`, and 19.2% of the apps called at least one of these two methods. Because XPrivacy does not provide information about the origin of the request, we performed some additional steps. For each app, we used the results of our static analysis and searched for occurrences of `getIA ()` and `getIP ()` in the code belonging to Google/Android libs. We found that most apps did not include calls to these sensitive methods in the code belonging to Google/Android libs: 181 out of 190 for `getIA ()` and 412 out of 436 for `getIP ()`. Hence, we conclude that these sensitive requests came mainly from third-party libs or from the code of the apps.

Interestingly, we found 49 apps that called at least one of the two sensitive methods in our dynamic analysis, but not in our static analysis. This could be because the decompiler tool produced incorrect smali code, or because these requests were dynamically loaded at runtime. Still, this represents only a small number of the apps found through our analysis.

Our static and dynamic analysis shows that a significant number of free apps actively queries for LIAs: between 19.2% (dynamic analysis) and 57% (static analysis) of the tested apps.<sup>17</sup> This shows that many third parties are interested in knowing about the installed apps on users' phones, and that, if Android blocked `getIA ()` and `getIP ()`, they would likely attempt to use other methods (see Section 4).

### 5.4 Analysis of Privacy Policies

Google's privacy-policy guidelines require apps that handle personal or sensitive user data to comprehensively disclose how they collect, use and share the collected data. An example of a common violation, shown in these guidelines, is "An app that doesn't treat a user's inventory of installed apps as personal or sensitive user data".<sup>18</sup> Next, we explain what developers understand about the guidelines.

As mentioned in Section 5.1, out of 2917 apps in our dataset, we found 2499 privacy policies. From the 1674 nosy apps found in the static and dynamic analysis, 1524 apps have privacy policies. We semi-automated the policy analysis as follows. We built a set of keywords consisting of nouns and verbs that might be used to construct a sentence to express the intention of collecting LIAs: retrieve, collect, fetch, acquire, gather, package, ID, installed, app, name, application, software, and list. For each privacy policy, we extracted the sentences that contain at least one of the keywords. From the extracted sentences, we manually searched for specific expressions such as "installed app", "app ID" and "installed software". Thereafter, we read the matched sentences and the corresponding privacy policy.

From the set of 2499 policies, we found 162 policies that explicitly mention the collection of LIAs. Among these, 129 belong to the set of 1674 nosy apps (7.7%). Some apps have exactly the same privacy policies, even though they are from different companies (e.g., [20] and [6]). 33 apps mentioned the collection of LIAs, but we did not find these apps in both static and dynamic analyses. For these apps, we performed a more thorough dynamic analysis: we used them as a normal user would, while intercepting API calls. We did not capture, however, any calls to the two sensitive methods. This might be because developers copy the privacy policies from other apps, or because the apps will make these calls in the future.

Besides the generic declared purposes of the collections of LIAs by apps, e.g., for improving the service (e.g., [14, 21]), some apps explicitly state that they collect LIAs for targeted ads (e.g., [3, 12]), and targeted ads by third-party ad networks (e.g., [15]). Unexpectedly, we found that of the 162 policies that mention the collections of LIAs, 76 categorize LIAs as *non-personal*, whereas Google defines this as personal information. This shows a misunderstanding between developers and Google's guidelines.

## 6 Existing Protection Mechanisms

To the best of our knowledge, there are no existing robust mechanisms for hiding sensitive apps. Below, we present some mechanisms that can offer partial protection.

### 6.1 Mechanisms by Google

Android does not provide users with a mechanism to hide the existence of apps from other apps. But users can repurpose existing Android mechanisms for partially hiding apps.

**Multiple Users.** Android supports multiple users on a single phone by separating user accounts and app data.<sup>19</sup> This feature could be used to prevent fingerprinting of sensitive apps by installing sensitive apps in one or more secondary accounts, thus isolating sensitive apps from nosy apps. However, a key disadvantage of using multiple users for this purpose is that it prevents inter-app communications (e.g., intent-based interactions) among apps in different user accounts. As a result, sensitive apps' functionalities can be significantly reduced because they cannot delegate tasks to other apps. For instance, a sensitive app will not have access to a user's calendar or contacts (unless the user replicates them on each account) or access to other apps for certain tasks, e.g., sending a message or picture via Whatsapp or Facebook, accessing files in Dropbox, sending an e-mail or SMS, and authenticating users with Google or Facebook accounts. In section 10.5, we show that popular mHealth apps use inter-app communications not only for delegating tasks but also for sharing their resources with other apps. Therefore, a solution that hides sensitive apps and that still supports inter-app communications is more desirable.

Multiple user accounts could also introduce new security and privacy issues [45]. Using multiple users will significantly affect the user experience, as users will have to switch back and forth among accounts to access different types of apps and data, introducing significant delays and confusion. While the primary account is in the foreground, apps on secondary accounts are put in the background and they cannot use Bluetooth services (important for mHealth apps). Another important problem is that some popular phone manufacturers (e.g., Samsung, LG, Huawei, Asus) disable multiple users in some of their devices,<sup>20</sup> thus affecting the availability of this solution to many users.

We have also found experimentally that the implementation of multiple users in the latest (Android 9) and earlier versions of Android does not effectively prevent nosy apps from learning what other apps are installed in different user accounts. To bypass this protection, a nosy app could do any of the following:

- On Android 7 or earlier, including an additional parameter flag (`MATCH_UNINSTALLED_PACKAGES`) in methods `getIA()` and `getIP()` will reveal the apps installed in secondary user accounts.
- On Android 9 or earlier, a nosy app can use multiple `PackageManager` methods, such as `getPackageUid()`, `getPackageGidS()`, `checkPermission()`, `checkSignatures()`, or `getApplicationEnabledSetting()`, as oracles to check if an app is installed on a secondary account or on a work profile. The nosy app only needs to include the package name of the targeted sensitive app as a parameter to these methods. Android's source code shows that these methods check the user ID of the app

calling the method to show only information of apps in the same user profile, but our experimental evaluation shows that currently deployed versions of Android do not enforce such checks. This approach was tested on Android 9.

- A nosy app can guess the UIDs of the apps installed on all the accounts and work profiles, by looking at the `/proc/uid` directory to learn the ranges of current UIDs in the system. It then guesses the UIDs of other apps and uses the `getNameForUid()` method to learn the package name. This method will return a package name given a UID as an input parameter; if the app does not exist, it returns null. As a result, it can be used as an oracle to retrieve the list of installed apps on the device. This was tested on Android 6, 8.1 and 9.
- A nosy app with adb privilege can easily verify if a sensitive app is running on the device, independently of the account or profile it was installed on, by using the shell command: `pidof <PackageName>`. This approach was tested on Android 9.
- A nosy app with adb privilege can obtain the list of installed apps, which includes apps on secondary accounts and work profiles, by using the shell command `dumppsys`. This approach was tested on Android 9.

**Android for Work.** Android supports an enterprise solution called Android for Work; this solution separates work apps from personal apps.<sup>21</sup> Our tests, using similar methods as with multiple users, also confirmed that, as with multiple users accounts, it is easy to identify which apps are in the work profile. In addition, Android for Work is only available to enterprise users.

Recently, Android introduced a new feature called *Instant Apps*;<sup>22</sup> this feature enables users to run apps instantly without installing them. Such an approach could be used to hide sensitive apps, however, it only supports a limited subset of permissions, and it does not support features that are crucial for mHealth apps such as storing users' data or connecting to Bluetooth-enabled devices.<sup>23</sup>

Google classifies the list of installed apps as *personal* information hence requires apps that collect this information to include in their privacy policies the purpose of their collection. Apps that do not follow this requirement are classified as Potentially Harmful Apps (PHAs) or Mobile Unwanted Softwares (MuWS) [1, 2]. Android security services, e.g., Google Play Protect [10], periodically scan users' phones and warn users if apps behave as PHAs or MuWS. Such mechanisms, however, do not seem to effectively protect against the unauthorized collection of the list of installed apps. Our analyses show that only 7.7% of the apps declare their collections of such information in their privacy policies, and some claim that a list of installed app is non-personal information (Section 5).

Furthermore, these mechanisms might fail to detect targeted attacks, *e.g.*, a nosy app might want to check if a small subset of sensitive apps exists on the phone.

## 6.2 Mechanisms by Third Parties

Samsung Knox<sup>24</sup> relies on secure hardware to offer isolation between personal and work-related apps, similar to Android for Work. Unfortunately, we were not able to evaluate the robustness of the protection offered by Knox w.r.t. hiding apps, because Samsung discontinued its support for work and personal spaces for private users; only enterprise users can use such a feature. Nevertheless, this solution is device specific and only hides apps from other apps in a different isolated environment, but not from apps in the same environment (apps in the same isolated environment can come from different, untrusted sources). That is, a solution that provides per-app isolation is preferable.

There are apps on the Google Play Store that help users to hide the icons of their sensitive apps from the Android app launcher (*e.g.*, [16]). Even though they help hide the presence of the sensitive apps from other human users (*e.g.*, nosy partners), these sensitive apps are still visible to other apps. Along the line of user-level virtualization techniques, on the Google Play Store, we found apps that use these techniques to enable users to run in parallel multiple instances of an app on their phones and to partially hide the app, (*e.g.*, [11, 17, 18]). However, these solutions require the hidden app to be installed first on the phone before protecting it, thus triggering installation and uninstallation broadcast events that can be detected by a nosy app. These apps provide only a single isolated space, *i.e.*, they do not protect apps from other apps in the same environment. Our preliminary evaluation of these apps also shows that their protection is limited, *e.g.*, the names of the hidden apps can be found in the list of running processes.

## 7 Our Solution: HideMyApp

We propose HideMyApp (HMA), a system for hiding the presence of sensitive apps w.r.t. to a nosy app on the same phone. In this section, we will present our system model, adversarial model, design goals and a high-level overview of the solution.

### 7.1 System Model

The scenario envisioned for HMA is as follows. A hospital or a hospital consortium (hereafter called hospitals) sets up an app store, called HMA App Store, where app developers working for the hospitals publish their mHealth apps. Hospitals want their patients to use their mHealth apps without disclosing their use to other apps on the same phone. Note that such organizations and their own app stores already exist, *e.g.*, the VA App Store set up by the U.S. Department of Veterans Affairs.

To enable the users to manage the apps provided by the HMA App Store, the HMA App Store provides the users with a client app called HMA Manager. This app can be distributed through any available app stores, *e.g.*, the Google Play Store. To allow the HMA Manager app to install apps downloaded from the HMA App Store, similarly to other Google Play Store alternatives *e.g.*, Amazon<sup>25</sup> and F-Droid [9], users need to enable the “allow apps from unknown sources” setting on their phones. Since Android 8.0, Google made this option more fine-grained by turning it into the “Install unknown apps” permission [19]. That is, users only need to grant this permission to the HMA Manager app to enable it to install apps from the HMA App Store.

### 7.2 Adversarial Model

We assume the Android OS on the user’s phone to be trusted and secure, including its Linux kernel and its Java API framework. We assume that the HMA App Store and the HMA Manager app are trusted and secure, and that they follow the prescribed protocols of the system. We discuss mechanisms to relax the trust assumptions on the HMA App Store and HMA Manager app in Section 9.2.

We assume there is a nosy app that wants to learn if a specific app is present on the phone. The nosy app has the default app-privilege, and it is granted all dangerous permissions by its user – these are the typical capabilities of apps that users often install on their phones. In Section 9, we discuss mechanisms for preventing more advanced fingerprinting attacks by malicious apps; a malicious app has more capabilities than a nosy app, *i.e.*, it can have special permissions (*e.g.*, `PACKAGE_USAGE_STATS` or `BIND_ACCESSIBILITY_SERVICE`) and the debugging privilege (adb), thus it can perform more advanced attacks, such as fingerprinting apps using their runtime information.

We assume that apps belonging to hospitals are nosy, *i.e.*, these apps are also curious about what other apps are installed on the user’s device.

### 7.3 Design Goals

The purpose of HMA is to effectively hide the presence of sensitive apps, yet preserve their usability and functionality.

- (G1) *Privacy protection.* It should be difficult for a nosy app to identify sensitive apps on the same phone.
- (G2) *No firmware modifications.* The solution should run on stock Android phones. That is, it should not require the phones to run customized versions of Android firmware, *e.g.*, extensions to Android’s middleware or the Linux kernel. This also means that the solution should not require the phones to be rooted.

- (G3) *Preserving the app-isolation security model of Android.* Each app should have its own private directory and run in its own dedicated process.
- (G4) *Few app modifications.* For baseline protection against nosy apps, the solution should not require app developers to change their apps. For protection against malicious apps, apps might need to be changed or some features might not be supported.
- (G5) *Usability.* The solution should preserve the usability and the key functionalities of sensitive apps.

## 7.4 HMA Overview

From a high-level point of view, HMA achieves its aforementioned design goals by enabling its users to install a container app for each sensitive app (as illustrated in Fig. 1). Each container app has a generic package name and obfuscated app components. As a result, nosy apps cannot fingerprint a sensitive app by using the information about its container app. At runtime, the container app will launch the APK file of the sensitive app within its context by relying on user-level virtualization techniques. That is, the sensitive app is not registered in the OS.

To do so, HMA requires the hospitals to bootstrap the system by setting up the HMA App Store and distributing the HMA Manager app to users (Section 8.1 and 8.2). Through the HMA Manager app, users can (un)install, open, and update sensitive apps without being discovered by the OS and other apps. We detail these operations in Section 8.3.

## 8 HMA System Description

Here, we detail the components and operations of HMA.

### 8.1 HMA Manager App

Recall, to hide their presence, sensitive apps are not registered in the OS; instead, their container apps are registered. Thus, if users open their default Android app launcher, they will only see container apps with generic icons and random names. To solve this usability issue, at installation time, the HMA Manager app keeps track of the one-to-one mappings between sensitive apps and their container apps. Using the mappings, the HMA Manager app can display the container apps to the users with the original icons and labels of their sensitive apps. To provide unlinkability between users and their sensitive apps w.r.t. the HMA App Store, the HMA Manager app *never* sends any identifying information of the users to the HMA App Store, and all the communications between the HMA App Store and the HMA Manager are anonymous. This is a reasonable assumption because the HMA Manager app can be open-sourced and audited by third parties. Also, in most

cases, users do not have fixed public IP addresses; they access the Internet via a NAT gateway offered by cellular providers. If needed, a VPN proxy or Tor could be used to hide network identifiers.

### 8.2 HMA App Store

The HMA App Store receives app-installation and app-update requests from HMA Manager apps and returns container apps to them. To reduce the delays introduced to the app-installation and app-update requests, the HMA App Store defines a set of  $P$  generic package names for container apps, e.g., app-1, ..., app-P. This set of generic names is shared by all sensitive apps, thus there is no one-to-one mapping between a sensitive app and a generic name or a subset of generic names.<sup>26</sup> For each sensitive app, the HMA App Store can generate beforehand  $P$  container apps corresponding to  $P$  predefined generic package names and store them in its database. Below, we explain the procedure followed by the HMA App Store to create a container app. Details about the app-installation and update requests from the HMA Manager apps are explained in Section 8.3.

**HMA Container-App Generation.** To generate a container app for a sensitive APK, the HMA App Store performs the following steps. Note that this operation cannot be performed by the HMA Manager app, because Android does not provide tools for apps to decompile and compile other apps.

- The HMA App Store creates an empty app with a generic app icon, a random package name and label, and it imports into the app the lib and the code for the user-level virtualization, *i.e.*, to launch the APK from the container app. Note that the lib and the code are independent from the APK.
- The HMA App Store extracts the permissions declared by the sensitive app and declares them in the manifest file of the container app.
- To enable the container app to launch the sensitive APK, app components (activities, services, broadcast receivers, and content providers) declared by the sensitive app need to be declared in the manifest file of the container app. This information, however, can be retrieved by nosy apps to fingerprint sensitive apps (Section 4). To mitigate this problem, the container app declares activities, services and broadcast receivers of the sensitive app with random names. At runtime, the container app will map these random names to the real names. The intent filters declared in the components of sensitive apps are also declared in the manifest file of their sensitive apps. In Section 9, we will discuss the case of content providers.
- The HMA App Store compiles the container app to obtain its APK and signs it.

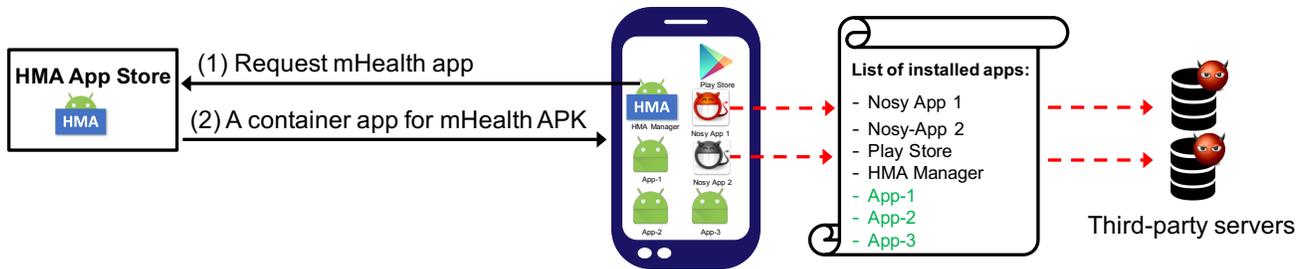

Figure 1: Overview of the HMA architecture. Nosy apps only learn the generic names of the container apps.

Note that for the sake of simplicity, here we only present a solution that protects mandatory features of Android apps. A malicious app might try to fingerprint sensitive apps based on, for instance, the runtime information produced by their container apps. We discuss this in Section 9.

**HMA User-Level Virtualization.** To launch the APK of a sensitive app without installing it, its container app generates a randomly named child-process in which the APK will run, *i.e.*, the APK is executed under the same UID as its container app. Thereafter, the container app loads the APK dynamically at runtime, and it intercepts and proxies the interactions between the sensitive app and the underlying system (the OS and the app framework). To do so, we rely on an open-source lib for app-virtualization called DroidPlugin [8].

### 8.3 HMA Operations

In this section, we detail the procedure followed by a user when she (un)installs, updates, or uses sensitive apps.

**App Installation.** To install a sensitive app, the user opens her HMA Manager app to retrieve the set of apps provided by the HMA App Store. Once she selects a sensitive app, the HMA Manager app sends to the HMA App Store an installation request consisting of the name of the sensitive app and her desired generic package name for the container app. The HMA App Store correspondingly finds in its database or creates a container app, and it sends the container app, together with the original label and icon of the sensitive app, to the HMA Manager. The HMA Manager prompts the user for her confirmation about the installation. Once the user accepts, the installation occurs as in standard app installation on Android. Also, the HMA Manager saves, in its private directory, a record of the package name of the container app and the package name, the original icon and the label of the sensitive app.

**App Launch.** To launch a sensitive app, the user opens her HMA Manager app to be shown with the set of container apps installed on her phone. Using the information stored in its database about the mappings between container apps and sensitive apps (Section 8.3), the HMA Manager displays to the user the container apps with the original labels and icons of the corresponding sensitive apps. Therefore, the user can easily identify and select her sensitive apps.

The *first time* a container app runs, it needs to obtain the sensitive APK from the HMA App Store; then it stores the APK in its private directory. This incurs some delays to the first launch of the sensitive app. However, it is needed to prevent the sensitive app from being fingerprinted: If the sensitive APK was included in the resources or assets folders of its container app so that the container app could copy and store the APK in its private directory at installation time, a nosy app would be able to obtain the sensitive APK. Recall, any app can obtain the resources and assets of other apps (Section 4). Also, Android does not permit apps to automatically start their background services upon installation.

At runtime, the container app dynamically loads the sensitive APK. Thereafter, it intercepts and proxies API calls and system calls between the sensitive app and the underlying system. If the version of the Android OS is at least 6.0, permissions requested by the sensitive app will be prompted by its container app at runtime. Thus, they will be shown with the generic package name of the container app. This, however, does not affect the comprehensibility of the permission requests, as shown by our user study (Section 10.6). Additionally, when an app sends an implicit intent with an action supported by the sensitive app, the operating system will show the sensitive app as an option for the user to choose to handle the requested action. This introduces a usability problem: the icon of the sensitive app presented to the user is a generic icon. This, however, can be solved by using the *direct share targets* feature in Android – a feature that enable apps to show finer-grained internal content in the *chooser dialog window*.<sup>27</sup>

**App Update.** When a sensitive app on the HMA App Store has an update, for each predefined generic container-app package name, the HMA App Store generates a corresponding container app for the updated sensitive app. This step is needed, because the configuration file of the container app needs to be updated w.r.t. the updates introduced by the sensitive app. The HMA App Store then sends a push notification to all HMA Manager clients to notify them about the update. If a user has the sensitive app on her phone, her HMA Manager sends the package name of its existing container app to the HMA App Store. In return, it receives the corresponding updated container app from the HMA App Store. It then prompts the user to confirm the installation. Once the user accepts, the updated container app is installed, similarly

to the standard app-update procedure on Android.

**App Uninstallation.** To uninstall a sensitive app, the user opens her HMA Manager app to be shown with the set of her container apps. Once she selects the container app, the HMA Manager prompts her to confirm the uninstallation. Thereafter, the uninstallation occurs similarly to the standard app-uninstallation procedure on Android.

## 9 Privacy and Security Analysis

Here, we present an analysis of HMA to show that it effectively achieves its privacy and security goals w.r.t. different capabilities of the nosy apps (*i.e.*, their granted permissions and privileges) as shown in Table 1.

### 9.1 Privacy

**Nosy Apps without Permissions.** HMA effectively protects, by default, the core attributes of sensitive apps. First, a nosy app cannot obtain the package name of a sensitive app, because the sensitive app is never registered on the system; instead, its container app with a generic package name is installed. Second, the resources, shared libraries, developers' signatures and developers' signing certificates of the sensitive app cannot be learnt by the nosy app, because they are not declared or included in the container-app's APK; instead they are dynamically loaded from the sensitive APK at runtime. Third, the nosy app cannot learn the components' names of the sensitive app, because these names are randomized. To prevent fingerprinting attacks based on the number of components declared in the container app, the HMA App Store adds dummy random components during the generation of the container app such that all the container apps declare the same number of components.

A nosy app might try to fingerprint sensitive apps by using the sets of permissions declared by their container apps. This can be mitigated if all container apps declare a union of permissions requested by sensitive apps in the HMA App Store. Note that for devices with Android 6 or later, the container app requests at runtime only the permissions needed by its sensitive app, and users can grant or decline these requests. This makes it difficult for nosy apps to fingerprint a sensitive app using the set of permissions granted to its container app.

HMA needs collaboration from app developers to prevent fingerprinting attacks based on the customized configurations of some sensitive apps, *e.g.*, themes and screen settings. The HMA App Store can define a guideline for app developers to follow such that all apps have the same configurations. This will affect the look and feel of the sensitive apps, but it is a trade-off between usability and privacy. Note that the same approach has been used in other deployed systems, *e.g.*, in the Tor browser where all the versions have the same default window size and user-agent strings.<sup>28</sup> To facilitate guideline

compliance, the HMA App Store can also provide developers with IDE plugins to help them write guideline-compliant code; such an approach has been proposed in existing work (*e.g.*, [43] and [31]).

App developers might want to use custom features, such as custom permissions, custom actions for the intent filters of their apps' components. These features, however, can be used to fingerprint their sensitive apps, hence should not be used by app developers. An app might want to support a content provider for sharing data between its components or for sharing data with other apps. HMA can support the former case; the container apps do not need to declare the content provider in its manifest file, but it handles the requests from the components of the sensitive apps internally. HMA, however, cannot support the case of sensitive apps using content providers to share data with other apps. This is because in order to do so, the container apps need to declare the URIs of their content providers in their manifest files, and these URIs can uniquely identify apps. These are limitations of HMA, however, from our analysis, only a small number of apps is affected by these limitations (Section 10.5).

**Nosy Apps with Permissions.** A nosy app can fingerprint sensitive apps based on their use of the external storage (SD card), *e.g.*, unique directories and files. To prevent this, container apps can intercept and translate calls from sensitive apps associated with the creation or access of files in external storage. However, note that apps are not recommended to store data there, especially mHealth apps. To prevent an app with VPN capabilities from fingerprinting sensitive apps based on the IP addresses in the header of the IP packages, the sensitive apps can relay their traffic through the HMA App Store servers; this protection is provided at the cost of additional communication delays for the apps and it requires collaboration with app developers.

A malicious app cannot fingerprint a sensitive app by using the list of running processes, because the sensitive app runs inside the child process of its container app with a random name. To prevent malicious apps from abusing its special permissions to fingerprint sensitive apps using their runtime statistics, *e.g.*, resources consumed by their container apps, the container apps can randomly generate dummy data to obfuscate the usage statistics of sensitive apps. Note that this does not require changes to the sensitive apps. In future work, we will evaluate techniques against these side-channel attacks such as [52] and [26]. HMA cannot prevent malicious apps, with permission to accessibility services, from fingerprinting sensitive apps. Accessibility services enable access to apps' unique layout information, and it is not practical to require all sensitive apps to use a generic layout. However, Google currently bans the use of accessibility services for purposes not related to helping users with disabilities.<sup>29</sup> Users should grant this permission only to apps they trust.

**Nosy Apps with Default App Privileges.** Recall, HMA, by default, hides the package name of the sensitive apps. To pre-

vent nosy apps from fingerprinting sensitive apps by using their UI states, the container apps can also obfuscate the UI states by overlaying transparent frames on the real screens of the sensitive apps. Similarly to the case of other runtime statistics discussed above, the container apps can also randomly generate dummy data to obfuscate the memory footprints and power consumptions of the sensitive apps.

**Malicious Apps with the Debugging Privilege (adb).** Recall, HMA protects the package name and the process names of the sensitive apps by default. Also recall, the container apps can randomize runtime statistics of the container apps. In addition, the paths to the APK files of the container apps do not reveal any information about the sensitive apps. Also, the malicious app cannot retrieve the APK files of the sensitive apps, because the APKs are stored inside the private directories of their container apps.

To prevent advanced attacks by malicious apps, *e.g.*, fingerprinting sensitive apps by reading the log of the phone, HMA requires collaboration from app developers. Developers should not write identifying information about their sensitive apps to the log. Apps with adb privilege can take screenshots of the phone and infer apps' names from the screenshots. HMA cannot prevent this attack. However, note that this attack requires the malicious app to do extra and error-prone operations (*e.g.*, image processing) to identify sensitive apps.

## 9.2 Security

By using user-level virtualization techniques to launch an APK, HMA does not require users to modify the OS of the phone. The Android's app-isolation security model is also preserved, because each APK runs inside the context of its container app. Thus, it is executed in a process under the same UID as its container app, and it uses the private data directory of its container app. Similarly to other third-party stores (*e.g.*, Amazon or F-Droid), HMA requires users to enable the "allow apps from unknown sources" setting on their phones. However, apps installed from these sources are still scanned and checked by Android security services for malware [10]. Also, recently, this setting was converted to a per-app permission [19]. As a result, granting the HMA Manager app the permission to install apps from unknown sources will not give other apps on the phone the same permission.

As on the Google Play Store, with HMA, app developers register their public keys on the HMA App Store, and sign their apps before they submit to the HMA App Store. Moreover, the HMA App Store signs the container apps that it generates to vouch for the integrity of the container apps and the sensitive apps. This mechanism, however, introduces a security issue for sensitive apps: Apps from different developers are signed by the same private key of the HMA App Store, hence a dishonest app developer might exploit this same-signature property to access signature-protected components of other apps.<sup>30</sup> Note that requesting or declaring signature-protection

permissions will facilitate fingerprinting of sensitive apps, hence HMA does not support this feature. As a result, this attack is not possible in HMA. Also note that few apps use signature-protected permissions (see Section 10.5). In future work, we will explore mechanisms for enabling container apps to verify the signatures of sensitive apps at runtime, in order to prevent unauthorized access to signature-protected components of their sensitive apps.

HMA container apps prompt users only for permissions requested by sensitive apps. To relax the trust assumptions on the HMA App Store and HMA Manager, the HMA App Store can provide an API so that anyone can implement her own HMA Manager app, or the HMA Manager app can be open-source, *i.e.*, anyone can audit the app and check if it follows the protocols as prescribed. Therefore, assuming that the metadata of the network and the lower communication layers cannot be used to identify users, *e.g.*, by using a proxy or Tor, the HMA App Store cannot link a set of sensitive apps to a user.

## 10 Evaluation

To evaluate HMA, we used a real dataset of free and paid mHealth apps on the Google Play Store. We looked into three evaluation criteria: (1) overhead experienced by mHealth apps, (2) HMA runtime robustness and its compatibility with mHealth apps, and (3) HMA usability.

### 10.1 Dataset

We selected 50 apps from the medical category on the Google Play Store, of which 42 apps are free and 8 apps are not. To have a significant and diverse dataset, we selected apps based on their popularity (more than 1000 downloads), their medical specialization, and their supported functionality. From the 50 apps, we filtered out apps that make calls to APIs that we did not support in our prototype implementations, including Google Mobile Services (GMS), Google Cloud Messaging (GCM) and Google Play Services APIs. Note that these services could be supported, similarly to other services, at the cost of additional engineering efforts. We also filtered out apps that use Facebook SDKs, because such SDKs often use custom layouts that are not yet supported by the user-level virtualization lib that HMA uses. Exploring the interaction mechanisms between custom layouts with the Android framework is an avenue for future work.

After filtering, we obtained a set of 30 apps (24 free apps and 6 paid apps, see Appendix B of our technical report at [44]) for 15 medical conditions. Also, these apps support features that are crucial for mHealth apps, *e.g.*, a Bluetooth connection with external medical devices (*e.g.*, Beurer HealthManager app [4]) and an internet connection (*e.g.*, Cancer.Net app [5]).

## 10.2 Implementation Details

Our prototype features the main components of HMA, including the HMA App Store and the HMA Manager app. To measure the operational delay introduced by HMA, we implemented a proof-of-concept HMA App Store on a computer (Intel Core i7, 3GHz, 16 GB RAM) with MacOS Sierra. Our HMA App Store dynamically generated container apps from APKs and relied on an open-source lib called DroidPlugin [8] for user-level virtualization. Our prototype container apps dynamically loaded the apps' classes and resources from the mHealth APKs and supported the interception and proxy of API calls commonly used by mHealth apps, e.g., APIs related to Bluetooth connections and SQLite databases.

## 10.3 Performance Overhead

In this section, we present the delays introduced by HMA to sensitive apps during app-installation and app-launch operations.<sup>31</sup> For the evaluation of delays added by the user-level virtualization to commonly used API methods and system calls at runtime, we refer the readers to existing work, e.g., Boxify [24] shows that such overhead is negligible (opening a camera introduces an overhead of 1.24 ms).

Results presented in this section were measured on a Google Nexus 5X phone running Android 7.0. In our experiments, the HMA App Store was connected to the phone through a micro-USB cable, hence network delays were not considered. Yet, compared to the standard use of apps, HMA incurs negligible network-delay overheads, because the only bandwidth overhead introduced by HMA is the container-app payload whose size is only several hundreds of kilobytes.

### 10.3.1 App Installation

When a user wants to install an mHealth app, the HMA App Store first creates a container app for it. Based on our experiments, assuming the HMA App Store decompiles the mHealth APKs beforehand, for 90% of the cases, generating a container app takes, on average, 5 s. Note that a large part of the delay comes from the compilation of the container app, and the measurement was performed on a laptop computer. Also note that the HMA App Store can always prepare in advance container apps for each mHealth app, as presented in Section 8.2. The size of the container app is only several hundreds of kilobytes, which takes less than a second for the HMA Manager app to download using a 3G or 4G Internet connection. As a result, the total delay overhead introduced by HMA would be less than 5 s in the *worst-case* scenario, and less than a second if container apps are generated beforehand, which is acceptable.

### 10.3.2 App Launch

On Android, apps can be launched from two different states: *cold starts* where apps are launched for the first time since the phone was booted or since the system killed the apps, and *warm starts* where the apps' activities might still reside in memory, and the system only needs to bring them to the foreground, hence faster than cold starts.

**Experiment Set-Up.** For cold-start delays, we rely on Android's official launch-performance profiling method [13]. For each app, we installed its container app, copied its APK file to its container app's private directory, and launched the container app through adb. We then extracted the time information from the `Displayed` entry of the `logcat` output. To simulate a first launch, before we launched an app, we used the command `adb shell pm clear [package-name]` to bring the app back to its initial state. To simulate a cold start, before we launched an app, we used the command `adb shell am force-stop [package-name]` to kill all the foreground activities and background processes of the app. For each app, we collected 50 measurements per launch setting. For a baseline, we measured the delays when the mHealth apps were executed without HMA.

To measure warm-start delays, due to the lack of Android supports for profiling warm starts, we have to instrument the source code of the sensitive apps to log the time that the app enters different stages in its lifecycle. Because apps in our dataset are closed source, we used an open-source app.<sup>32</sup> To simulate a warm start, we used the command `input keyevent 187` to bring the app to the background, and then we used the `monkey` command to bring the app back to the foreground. By subtracting the time when the `onResume()` method is successfully executed with the time before the monkey command is sent, we know the warm-start delay experienced by the app. We measured the warm-start delays experienced by the app in both settings (w/ and w/o HMA), 50 measurements per setting.

**Results.** Intuitively, in HMA, the first launch of an mHealth will experience longer delays than the subsequent cold starts, because the container app has to process the APK and store the information needed for user-level virtualization. Our experiments show that the median of this process takes  $6.5 \pm 0.16$  s (as compared to  $0.74 \pm 0.07$  s if the mHealth apps were launched w/o HMA). Note that this occurs only once, hence it is negligible w.r.t. the lifetime of the app.

Fig. 2 shows the bar plot of subsequent cold-start delays, with and without HMA, experienced by mHealth apps; the heights of the bars represent the mean values, and the error bars represent one standard deviation. It can be seen that the average delays are at most  $3.0 \pm 0.5$  s and  $1.3 \pm 0.05$  s if the apps are executed with and without HMA, respectively. For 90% of the cases, the average delay with HMA is less than  $2.0 \pm 0.3$  s. Note that our prototype is a proof-of-concept hence not optimized. Still, the observed delays are under the

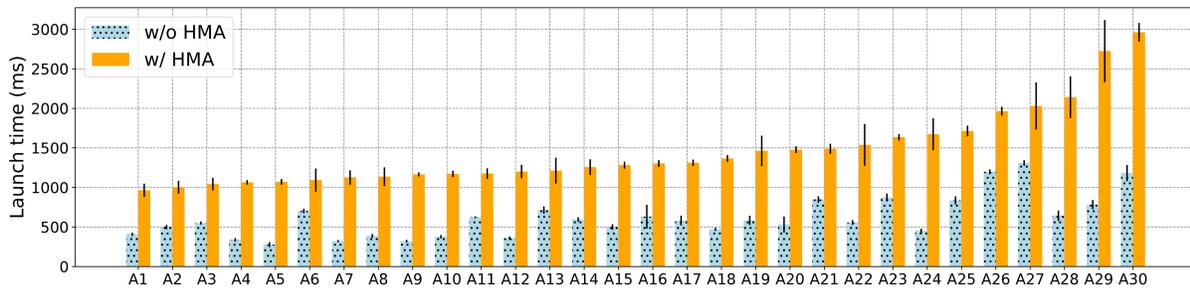

Figure 2: Cold-start delays experienced by mHealth apps when they are executed with and without HMA. Note that our HMA implementation is a proof-of-concept, hence not-optimized. The heights of the bars represent mean values and the error bars represent the standard deviation. For each setting, we collected 50 measurements per app. The full names of the apps can be found in Appendix B of our technical report at [44].

delay limit of 5 s suggested by Android [13]. Also, in our user study, 97% of participants agreed that a launch delay of 5 s is acceptable (Section 10.6).

Regarding warm-start delays, we found that the average delay experienced by our tested app, when it was launched with and without HMA, was  $\sim 0.55$  s. This is intuitive, because the app’s processes were still running and the activities still resided in the phone’s memory. In case the garbage collector evicts the activities from the phone’s memory, warm-start delays can be longer, due to the overheads of activity initializations. We cannot simulate this case, because Android does not provide methods to control the garbage collector. However, in this case, the delay will still be less than cold-start delays (*i.e.*, at most 3 s).

## 10.4 HMA Robustness and Compatibility

In this section, we present the evaluation of HMA in terms of its robustness and its compatibility with Android versions.

**Runtime Robustness.** Following the approach used in previous work, (*e.g.*, [35] and [53]), we manually tested each app in our dataset with HMA. For each mHealth app, we extracted its APK, created a container app using HMA App Store, and installed the container app on the phone. Thereafter, we used the HMA Manager to launch the app. We manually used most of the functionality of the mHealth app, and checked if it had crashed during its execution. We found that all of the apps in our dataset worked normally, except one app that threw an error when making an SQLite connection. To determine the cause of this error, we ran an example app<sup>33</sup> that uses the official Android API for database access (*i.e.*, `Android.database.sqlite`) to insert and retrieve records from an SQLite database, and the example app ran successfully. We suspect that the mHealth app threw an error because it specifies the full path to the database (*i.e.*, `/data/data/package-name/db-name`). Hence, when running the app inside of the HMA container app, the hard-coded path is no longer valid. To avoid this problem, developers should specify the relative path to the database (*i.e.*, `./db-name`) instead of its full path.

**Compatibility.** We ran HMA on a series of smartphones with Android OS from version 5.0 to 8.0, which accounts for 89% of the current Android version distribution [7]. We found that HMA can be successfully deployed on mainstream commercial Android devices. But, there are two apps (Mole Mapper and Alzheimer’s Speed of Processing Game) that initially failed to run on our Nexus 5X (Android 7.1.1) due to the incompatibility between 32-bit and 64-bit systems. We fixed the problem by enabling the option `-abi armeabi-v7a` when installing them. From the list of 20 apps that we filtered out, we found that 3 apps (Hearing Aid, What’s Up and Cardiac diagnosis) successfully ran on Android 5.0 and 6.0, but they failed to run in later versions of Android. We investigated the log of the three apps and found that API methods related to GMS services that we do not support were called in the later versions of Android. This problem could be solved if these services are hooked, as we discussed in Section 10.2. Note that, with the recent release of Android 9, Google has restricted the use of Java reflection<sup>34</sup> – the programming interface that all user-level virtualization techniques rely on. Therefore, for HMA to work seamlessly in Android 9, new user-level virtualization techniques need to be explored. Still, Android 9 has only less than 1% market share [7], which means HMA will be compatible with most Android devices in the coming years. Alternatively, HMA could work with rooted Android 9 devices by using dynamic customization frameworks, *e.g.*, Xposed.<sup>35</sup>

## 10.5 Inter-App Communication Support

Sharing resources with other apps via customized features (*e.g.*, custom permissions and custom intent-filters) and publicly exposing components (*e.g.*, activities, services and content providers) could facilitate fingerprinting attacks. HMA can partially support inter-app communications, but it is preferable to avoid such features to guarantee robust fingerprinting protection. Avoiding inter-app communication, however, can affect apps’ functionality and backward compatibility. To estimate the effect of using HMA and avoiding inter-app communication on existing apps, we analyzed a set of popular

sensitive apps from the Google Play Store. Our results show that a small number of apps use inter-app communication features that are not supported by HMA and, in many cases, such features are not directly related to apps' key functionalities.

**Dataset.** We collected a total of 1045 APK files from the most popular free apps in the Medical and Health&Fitness categories in the US Google Play Store. By checking the apps' descriptions, we found that approximately 60% directly match HMA's use case (*i.e.*, health- and fitness-related apps). The rest of the apps are less related to HMA's use case, *e.g.*, apps for medical doctors and nurses, apps for managing accounts with health providers, and apps for managing gym subscriptions. From the APK files, we extracted the manifest file using the `apktool` application.

**Custom Permissions.** Permissions defined by apps to control access to their components can be used to fingerprint them (*e.g.*, they typically include the app name), as any app can list the permissions of other apps. Hence, custom permissions should be avoided. We found that a total of 531 apps declared custom permissions. However, most of these permission declarations are related to deprecated services (Google Cloud Messaging and Android Maps API v2)<sup>36</sup> and can be replaced with newer alternatives that do not require custom permissions. Therefore, ignoring permissions associated with these deprecated services, we found that only 68 apps (6.5%) declared valid custom permissions.

**Signature-Level Permissions.** Signature permissions<sup>37</sup> are a subset of custom permissions, hence they can be used to fingerprint apps. Given that HMA container apps are all signed by the same key, a malicious app inside a container app could abuse signature permissions to access resources of sensitive apps in other container apps. Therefore, HMA currently does not declare signature permissions in the container apps. Our analysis shows that only 113 apps (10.8%) declared signature permissions and, as explained before, many of these permissions are associated with deprecated services (*e.g.*, Google Cloud Messaging and Android Maps API).

**Content Providers.** Any app can list the content providers of other installed apps and use this information to fingerprint them. Therefore, HMA obfuscates this information in the container app. This means that public content providers (used to share data with other apps) are not currently supported by HMA. Our analysis shows that only 84 apps (8%) declare public content providers. From these apps, 68% declare public content-providers associated with third-party frameworks (*e.g.*, Seattle Clouds) for services such as file sharing and authentication, and approximately 23% require permission to access the provider.

**Intent Filters.** Custom intent filters, *i.e.*, intent filters with app-specific actions, could be used to fingerprint apps. Apps cannot list the intent filters of other apps, but they can list all the activities of other apps that can be performed by a particular intent. Hence, developers should avoid using custom

intent filters in their apps' activities. Our analysis shows that this is not a problem, as only 38 apps (3.6%) have activities with custom intent filters.

**Activities and Explicit Intents.** Explicit intents are currently not supported by HMA because container apps obfuscate the activities' names of sensitive apps; thus, direct reference to sensitive apps' activities is not possible. However, it is recommended to use only explicit intents to launch internal activities; not activities of other apps (implicit intents should be used instead). Our analysis shows that 170 apps (16.2%) declare activities that can be launched by other apps via explicit intents only, *i.e.*, no intent filters. We noticed that many apps (67) declared this type of activities to support Google's Firebase authentication services. Yet, Firebase's official documentation does not seem to mention this approach to support its services. Hence, to be compatible with HMA, these apps could evaluate alternative (official) approaches to support Firebase services or rely on other services for user authentication.

**Services and Explicit Intents.** Explicit intents are recommended to access services offered by other apps. But, as stated before, it is not possible to use explicit intents with HMA. Our analysis show that 367 apps (35.1%) declare public services that require explicit intents. This is a significant number, yet we noticed that a large number of apps (252) use services with explicit intents to support Google Play services for authentication (Google Sign-In user revocation). Hence, these apps could use alternative user authentication services to be compatible with HMA. We also notice that only 44 apps declared services that belong to the app itself; this indicates that most of these services are associated with third-parties and probably are not part of apps' main functionalities.

**Broadcast Receivers.** Whereas any app can list the broadcast receivers of other apps, HMA container apps obfuscate the names of the receivers to defend against fingerprinting attacks. The container app can declare the same intent filters for receivers that the sensitive app declares (including custom intent filters) because other apps cannot list these intent filters. As broadcast receivers offer asynchronous communication, nosy apps cannot use API methods to check if an app is receiving a particular broadcast intent. In short, broadcast receivers are supported by HMA.

## 10.6 HMA Usability and Desirability

To evaluate the usability of HMA and the users' interest for it, we conducted a user study that was approved by our institutional ethical committee. It involved 30 student subjects (19 males, 11 females,  $22 \pm 4.5$  years old) from 18 areas of study. The participants were experienced Android users: 87% of them have used an Android phone for at least a year. Also, they were relatively concerned about their privacy; using the standard metric for measuring privacy perception (UIPC) [39], we found that, on a scale from 1 to 5, 97% of participants

graded at least 3.0 and an average of 4.1.

We began the study with an entry survey about demographic information, privacy postures, users' awareness and concerns about the problem of LIA collections. Then, we provided each participant with a fresh phone and asked them to install and use two apps: a popular public-transportation app for our city and an mHealth app called `Cancer.Net`. To precisely measure the users' perceptions of the delay introduced by HMA, the participants were asked to use the two aforementioned apps with and without HMA; detailed instructions were provided to them. 67% of the participants had used the transportation app before, whereas only 7% of them had used the `Cancer.Net` app or an mHealth app. We finished the user study with an exit survey containing questions related to the usability of HMA and the users' levels of interest in HMA. The user-study session took  $\sim 45$  minutes, and we paid each participant  $\sim \$25$  (*i.e.*, 25 CHF). The transcript of survey questions and the instructions can be found at <sup>38</sup>.

Our study shows that the participants are concerned about the privacy of health-related data: 90% of the participants would be at least concerned if their health-related information were collected by apps installed on their phones and shared with third parties, and 87% of participants would be at least concerned if third parties learned that they had used health-related apps. Indeed, our study confirms the findings from previous works (*e.g.*, [41]) that the majority of people never read privacy policies. Therefore, the current solution of using privacy policies by Google for LIA collections is not satisfactory. These findings make clear the case for HMA.

Regarding the usability of HMA, only 30% of the participants noticed a difference when the two apps ran with and without HMA. Note that the delays that users experienced in the user study were the first-launch delays, which are  $4.2 \pm 0.06$  s and  $5.1 \pm 0.07$  s for the transportation app and the `Cancer.Net` app, respectively. From the open-ended question in our exit survey, we found that the observed differences are mainly about the launching delay of the apps and the change in the app names in permission prompts. From the close-ended questions, which were coded using a five-point Likert scale, we observe the following. Almost all participants agree that these changes and delays are acceptable (97% and 93% of the participants, respectively). 93% of the participants also agree that the use of an HMA Manager to install and launch apps is at least somewhat acceptable. Also, 90% of the participants agreed that HMA does not affect the user experience of the apps that it protects, and that they are at least somewhat interested in using HMA. These results suggest that HMA is usable and desirable.

## 11 Conclusion

In this work, we have shown that apps can collect a significant amount of static and runtime information about other apps, to fingerprint them. Our analysis has shown that many third

parties are interested in learning about the apps installed on people's phones. Moreover, we have shown that there are no existing mechanisms for hiding the presence of an app from other apps. We have proposed HMA, the first solution that addresses this problem. HMA does not require any modifications to the Android OS and preserves the key functionalities of apps. The results of our evaluation and user study suggest that HMA is usable and of interest to users.

## Acknowledgements

We thank our anonymous reviewers and our shepherd Sven Bugiel for their insightful comments on this work. We are grateful to oncologist Olivier Michielin who helped us identify the problem addressed in this work. This project was supported by the grant #2017-201 of the Strategic Focal Area "Personalized Health and Related Technologies (PHRT)" of the ETH Domain. The work was carried out while Anh Pham was a PhD student at EPFL.

# TESSERACT: Eliminating Experimental Bias in Malware Classification across Space and Time

## Abstract

Is Android malware classification a solved problem? Published  $F_1$  scores of up to 0.99 appear to leave very little room for improvement. In this paper, we argue that results are commonly inflated due to two pervasive sources of experimental bias: *spatial bias* caused by distributions of training and testing data that are not representative of a real-world deployment; and *temporal bias* caused by incorrect time splits of training and testing sets, leading to impossible configurations. We propose a set of space and time constraints for experiment design that eliminates both sources of bias. We introduce a new metric that summarizes the expected robustness of a classifier in a real-world setting, and we present an algorithm to tune its performance. Finally, we demonstrate how this allows us to evaluate mitigation strategies for time decay such as active learning. We have implemented our solutions in TESSERACT, an open source evaluation framework for comparing malware classifiers in a realistic setting. We used TESSERACT to evaluate three Android malware classifiers from the literature on a dataset of 129K applications spanning over three years. Our evaluation confirms that earlier published results are biased, while also revealing counter-intuitive performance and showing that appropriate tuning can lead to significant improvements.

## 1 Introduction

Machine learning has become a standard tool for malware research in the academic security community: it has been used in a wide range of domains including Windows malware [12, 34, 51], PDF malware [27, 32], malicious URLs [28, 48], malicious JavaScript [11, 43], and Android malware [4, 22, 33]. With tantalizingly high performance figures, it seems malware should be a problem of the past.

Malware classifiers operate in dynamic contexts. As malware evolves and new variants and families appear over time, prediction quality decays [26]. Therefore, temporal consistency matters for evaluating the effectiveness of a classifier.

When the experimental setup allows a classifier to train on what is effectively future knowledge, the reported results become biased [2, 36].

This issue is widespread in the security community and affects multiple security domains. In this paper, we focus on Android malware and claim that there is an endemic issue in that Android malware classifiers [4, 13, 18, 22, 33, 49, 56, 57] (including our own work) are not evaluated in settings representative of real-world deployments. We choose Android because of the availability of (a) a public, large-scale, and timestamped dataset (AndroZoo [3]) and (b) algorithms that are feasible to reproduce (where all [33] or part [4] of the code has been released).

We identify experimental bias in two dimensions, *space* and *time*. *Spatial bias* refers to unrealistic assumptions about the ratio of goodware to malware in the data. The ratio of goodware to malware is domain-specific, but it must be enforced consistently during the testing phase to mimic a realistic scenario. For example, measurement studies on Android suggest that most apps in the wild are goodware [21, 30], whereas for (desktop) software download events most URLs are malicious [31, 41]. *Temporal bias* refers to temporally inconsistent evaluations which integrate future knowledge about the testing objects into the training phase [2, 36] or create unrealistic settings. This problem is exacerbated by families of closely related malware, where including even one variant in the training set may allow the algorithm to identify many variants in the testing.

We believe that the pervasiveness of these issues is due to two main reasons: first, possible sources of evaluation bias are not common knowledge; second, accounting for time complicates the evaluation and does not allow a comparison to other approaches using headline evaluation metrics such as the  $F_1$ -Score or AUROC. We address these issues in this paper by systematizing evaluation bias for Android malware classification and providing new constraints for sound experiment design along with new metrics and tool support.

Prior work has investigated challenges and experimental bias in security evaluations [2, 5, 36, 44, 47, 54]. The *base-rate*

<sup>\*</sup>Equal contribution.

*fallacy* [5] describes how evaluation metrics such as *TPR* and *FPR* are misleading in intrusion detection, due to significant class imbalance (most traffic is benign); in contrast, we identify and address experimental settings that give misleading results *regardless* of the adopted metrics—even when correct metrics are reported. Sommer and Paxson [47], Rossow et al. [44], and van der Kouwe et al. [54] discuss possible guidelines for sound security evaluations; but none of these works identify temporal and spatial bias, nor do they *quantify* the impact of errors on classifier performance. Allix et al. [2] and Miller et al. [36] identify an initial temporal constraint in Android malware classification, but we show that even results of recent work following their guidelines (e.g., [33]) suffer from other temporal and spatial bias (§4.4). To the best of our knowledge, we are the first to identify and address these sources of bias with novel, actionable constraints, metrics, and tool support (§4).

This paper makes the following contributions:

- We identify *temporal* bias associated with incorrect train-test splits (§3.2) and *spatial* bias related to unrealistic assumptions in dataset distribution (§3.3). We experimentally verify on a dataset of 129K apps (with 10% malware) that, due to bias, performance can decrease up to 50% in practice (§3.1) in two well-known Android malware classifiers, DREBIN [4] and MAMADROID [33], which we refer to as ALG1 and ALG2, respectively.
- We propose novel building blocks for more robust evaluations of malware classifiers: a set of spatio-temporal constraints to be enforced in experimental settings (§4.1); a new metric, AUT, that captures a classifier’s robustness to time decay in a single number and allows for the fair comparison of different algorithms (§4.2); and a novel tuning algorithm that empirically optimizes the classification performance, when malware represents the minority class (§4.3). We compare the performance of ALG1 [4], ALG2 [33] and DL [22] (a deep learning-based approach), and show how removing bias can provide counter-intuitive results on real performance (§4.4).
- We implement and publicly release the code of our methodology (§4), TESSERACT, and we further demonstrate how our findings can be used to evaluate performance-cost trade-offs of solutions to mitigate time decay such as active learning (§5).

TESSERACT can assist the research community in producing comparable results, revealing counter-intuitive performance, and assessing a classifier’s prediction qualities in an industrial deployment (§6).

We believe that our methodology also creates an opportunity to evaluate the extent to which spatio-temporal experimental bias affects security domains other than Android malware, and we encourage the security community to embrace its underpinning philosophy.

**Use of the term “bias”:** We use (*experimental*) *bias* to refer to the details of an experimental setting that depart from

the conditions in a real-world deployment and can have a misleading impact (*bias*) on evaluations. We do not intend it to relate to the classifier bias/variance trade-off [8] from traditional machine learning terminology.

## 2 Android Malware Classification

We focus on Android malware classification. In §2.1 we introduce the reference approaches evaluated, in §2.2 we discuss the domain-specific prevalence of malware, and in §2.3 we introduce the dataset used throughout the paper.

### 2.1 Reference Algorithms

To assess experimental bias (§3), we consider two high-profile machine learning-driven techniques for Android malware classification, both published recently in top-tier security conferences. The first approach is ALG1 [4], a linear support vector machine (SVM) on high-dimensional binary feature vectors engineered with a lightweight static analysis. The second approach is ALG2 [33], a Random Forest (RF) applied to features engineered by modeling caller-callee relationships over Android API methods as Markov chains. We choose ALG1 and ALG2 as they build on different types of static analysis to generate feature spaces capturing Android application characteristics at different levels of abstraction; furthermore, they use different machine learning algorithms to learn decision boundaries between benign and malicious Android apps in the given feature space. Thus, they represent a broad design space and support the generality of our methodology for characterizing experimental bias. For a sound experimental baseline, we reimplemented ALG1 following the detailed description in the paper; for ALG2, we relied on the implementation provided by its authors. We replicated the baseline results for both approaches. After identifying and quantifying the impact of experimental bias (§3), we propose specific constraints and metrics to allow fair and unbiased comparisons (§4). Since ALG1 and ALG2 adopt traditional ML algorithms, in §4 we also consider DL [22], a deep learning-based approach that takes as input the same features as ALG1 [4]. We include DL because the latent feature space of deep learning approaches can capture different representations of the input data [19], which may affect their robustness to time decay. We replicate the baseline results for DL reported in [22] by re-implementing its neural network architecture and by using the same input features as for ALG1.

It speaks to the scientific standards of these papers that we were able to replicate the experiments; indeed, we would like to emphasize that we do not criticize them specifically. We use these approaches for our evaluation because they are available and offer stable baselines.

We report details on the hyperparameters of the reimplemented algorithms in §A.1.

### 2.2 Estimating in-the-wild Malware Ratio

The proportion of malware in the dataset can greatly affect the performance of the classifier (§3). Hence, unbiased experi-

ments require a dataset with a realistic percentage of malware over goodware; on an already existing dataset, one may enforce such a ratio by, for instance, downsampling the majority class (§3.3). Each malware domain has its own, often unique, ratio of malware to goodware typically encountered in the wild. First, it is important to know if malware is a minority, majority, or an equal-size class as goodware. For example, malware is the minority class in network traffic [5] and Android [30], but it is the majority class in binary download events [41]. On the one hand, the estimation of the percentage of malware in the wild for a given domain is a non-trivial task. On the other hand, measurement papers, industry telemetry, and publicly-available reports may all be leveraged to obtain realistic estimates.

In the Android landscape, malware represents 6%–18.8% of all the apps, according to different sources: a key industrial player<sup>1</sup> reported the ratio as approximately 6%, whereas the AndRadar measurement study [30] reports around 8% of Android malware in the wild. The 2017 Google’s Android security report [21] suggests 6–10% malware, whereas an analysis of the metadata of the AndroZoo dataset [3] totaling almost 8M Android apps updated regularly, reveals an incidence of 18.8% of malicious apps. The data suggests that, in the Android domain, malware is the minority class. In this work, we decide to stabilize its percentage to 10% (a de-facto average across the various estimates), with per-month values between 8% and 12%. Settling on an average overall ratio of 10% Android malware also allows us to collect a dataset with a statistically sound number of per-month malware. An aggressive undersampling would have decreased the statistical significance of the dataset, whereas oversampling goodware would have been too resource intensive (§2.3).

### 2.3 Dataset

We consider samples from the public AndroZoo [3] dataset, consisting of more than 8.5 million Android apps between 2010 and early 2019: each app is associated with a timestamp, and most apps include VirusTotal metadata results. The dataset is constantly updated by crawling from different markets (e.g., more than 4 million apps from Google Play Store, and the remaining from markets such as Anzhi and AppChina). We choose to refer to this dataset due to its size and timespan, which allow us to perform realistic space- and time-aware experiments.

**Goodware and malware.** AndroZoo’s metadata reports the number  $p$  of positive anti-virus reports on VirusTotal [20] for applications in the AndroZoo dataset. We chose  $p = 0$  for goodware and  $p \geq 4$  for malware, following Miller et al.’s [36] advice for a reliable ground-truth. About 13% of AndroZoo apps can be called grayware as they have  $0 < p < 4$ . We exclude grayware from the sampling as including it as either goodware or malware could disadvantage classifiers whose features were designed with a different labeling threshold.

<sup>1</sup>Information obtained through confidential emails with the authors.

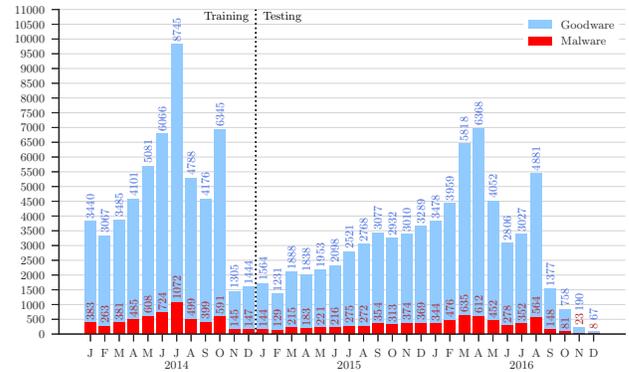

Figure 1: *Details of the dataset considered throughout this paper.* The figure reports a stack histogram with the monthly distribution of apps we collect from AndroZoo: 129,728 Android applications (with average 10% malware), spanning from Jan 2014 to Dec 2016. The vertical dotted line denotes the split we use in all time-aware experiments in this paper (see §4 and §5): training on 2014, testing on 2015 and 2016.

**Choosing apps.** The number of objects we consider in our study is affected by the feature extraction cost, and partly by storage space requirements (as the full AndroZoo dataset, at the time of writing, is more than 50TB of apps to which one must add the space required for extracting features). Extracting features for the whole AndroZoo dataset may take up to three years on our research infrastructure (three high-spec Dell PowerEdge R730 nodes, each with 2 x 14 cores in hyperthreading—in total, 168 vCPU threads, 1.2TB of RAM, and a 100TB NAS), thus we decided to extract features from 129K apps (§2.2). We believe this represents a large dataset with enough statistical significance. To evaluate time decay, we decide on a granularity of one month, and we uniformly sample 129K AndroZoo apps in the period from Jan 2014 to Dec 2016, but also enforce an overall average of 10% malware (see §2.2)—with an allowed percentage of malware per month between 8% and 12%, to ensure some variability. Spanning over three years ensures 1,000+ apps per month (except for the last three months, where AndroZoo had crawled less applications). We consider apps up to Dec 2016 because the VirusTotal results for 2017 and 2018 apps were mostly unavailable from AndroZoo at the time of writing; moreover, Miller et al. [36] empirically evaluated that antivirus detections become stable after approximately one year—choosing Dec 2016 as the finishing time ensures good ground-truth confidence in objects labeled as malware.

**Dataset summary.** The final dataset consists of 129,728 Android applications (116,993 goodware and 12,735 malware). Figure 1 reports a stack histogram showing the per-month distribution of goodware/malware in the dataset. For the sake of clarity, the figure also reports the number of malware and goodware in each bin. The training and testing splits

used in §3 are reported in Table 1; all the time-aware experiments in the remainder of this paper are performed by training on 2014 and testing on 2015 and 2016 (see the vertical dotted line in Figure 1).

### 3 Sources of Experimental Bias

In this section, we motivate our discussion of bias through experimentation with ALG1 [4] and ALG2 [33] (§3.1). We then detail the sources of temporal (§3.2) and spatial bias (§3.3) that affect ML-based Android malware classification.

#### 3.1 Motivational Example

We consider a motivational example in which we vary the sources of experimental bias to better illustrate the problem. Table 1 reports the  $F_1$ -score for ALG1 and ALG2 under various experimental configurations; rows correspond to different sources of temporal experimental bias, and columns correspond to different sources of spatial experimental bias. On the left-part of Table 1, we use squares (■/▒) to show from which time frame training and testing objects are taken; each square represents six months (in the window from Jan 2014 to Dec 2016). Black squares (■) denote that samples are taken from that six-month time frame, whereas periods with gray squares (▒) are not used. The columns on the right part of the table correspond to different percentages of malware in the training set  $Tr$  and the testing set  $Ts$ .

Table 1 shows that both ALG1 and ALG2 perform far worse in realistic settings (bold values with green background in the last row, for columns corresponding to 10% malware in testing) than in settings similar to those presented in [4, 33] (bold values with red background). This is due to inadvertent experimental bias as outlined in the following.

**Note.** We clarify to which similar settings of [4, 33] we refer to in the cells with red background in Table 1. The paper of ALG2 [33] reports in the abstract performance “up to 99%  $F_1$ ”, which (out of the many settings they evaluate) corresponds to a scenario with 86% malware in both training and testing, evaluated with 10-fold CV; here, we rounded off to 90% malware for a cleaner presentation (we have experimentally verified that results with 86% and 90% malware-to-benign class ratio are similar). ALG1’s original paper [4] relies on hold-out by performing 10 random splits (66% training and 33% testing). Since hold-out is almost equivalent to k-fold CV and suffers from the same spatio-temporal biases, for the sake of simplicity in this section we refer to a k-fold CV setting for both ALG1 and ALG2.

#### 3.2 Temporal Experimental Bias

*Concept drift* is a problem that occurs in machine learning when a model becomes obsolete as the distribution of incoming data at test-time differs from that of training data, i.e., when the assumption does not hold that data is independent and identically distributed (i.i.d.) [26]. In the ML community, this problem is also known as *dataset shift* [50]. *Time decay*

is the decrease in model performance over time caused by concept drift.

Concept drift in malware combined with similarities among malware within the same family causes *k-fold cross validation* (CV) to be *positively biased*, artificially inflating the performance of malware classifiers [2, 36, 37]. K-fold CV is likely to include in the training set at least one sample of each malware family in the dataset, whereas new families will be unknown at training time in a real-world deployment. The all-black squares in Table 1 for 10-fold CV refer to each training/testing fold of the 10 iterations containing at least one sample from each time frame. The use of k-fold CV is widespread in malware classification research [11, 12, 27, 31, 34, 37, 41, 49, 51, 57]; while a useful mechanism to prevent overfitting [8] or estimate the performance of a classifier in the *absence* of concept drift when the i.i.d. assumption holds (see considerations in §4.4), it has been unclear how it affects the real-world performance of machine learning techniques with non-stationary data that are affected by time decay. Here, in the first row of Table 1, we quantify the performance impact in the Android domain.

The second row of Table 1 reports an experiment in which a classifier’s ability to detect past objects is evaluated [2, 33]. Although this characteristic is important, high performance should be expected from a classifier in such a scenario: if the classifier contains at least one variant of a past malware family, it will likely identify similar variants. We thus believe that experiments on the performance achieved on the detection of past malware can be misleading; the community should focus on building malware classifiers that are robust against time decay.

In the third row, we identify a novel temporal bias that occurs when goodware and malware correspond to different time periods, often due to having originated from different data sources (e.g., in [33]). The black and gray squares in Table 1 show that, although malware testing objects are posterior to malware training objects, the goodware/malware time windows do not overlap; in this case, the classifier may learn to distinguish applications from different time periods, rather than goodware from malware—again leading to artificially high performance. For instance, spurious features such as new API methods may be able to strongly distinguish objects simply because malicious applications predate that API.

The last row of Table 1 shows that the realistic setting, where training is temporally precedent to testing, causes the worst classifier performance in the majority of cases. We present decay plots and a more detailed discussion in §4.

#### 3.3 Spatial Experimental Bias

We identify two main types of spatial experimental bias based on assumptions on percentages of malware in testing and training sets. All experiments in this section assume temporal consistency. The model is trained on 2014 and tested on 2015 and 2016 (last row of Table 1) to allow the analysis of spatial

Experimental setting		Sample dates		% mw in testing set Ts							
				10% (realistic)				90% (unrealistic)			
				% mw in training set Tr							
Training	Testing	10%	90%	10%	90%	10%	90%	10%	90%		
		ALG1 [4]	ALG2 [33]	ALG1 [4]	ALG2 [33]	ALG1 [4]	ALG2 [33]	ALG1 [4]	ALG2 [33]		
10-fold CV	gw: ■■■■■■ mw: ■■■■■■	gw: ■■■■■■ mw: ■■■■■■	0.91	0.56	0.83	0.32	0.94	0.98	0.85	0.97	
Temporally inconsistent	gw: ■■■■■■ mw: ■■■■■■	gw: ■■■■■■ mw: ■■■■■■	0.76	0.42	0.49	0.21	0.86	0.93	0.54	0.95	
Temporally inconsistent gw/mw windows	gw: ■■■■■■ mw: ■■■■■■	gw: ■■■■■■ mw: ■■■■■■	0.77	0.70	0.65	0.56	0.79	0.94	0.65	0.93	
Temporally consistent (realistic)	gw: ■■■■■■ mw: ■■■■■■	gw: ■■■■■■ mw: ■■■■■■	0.58	0.45	0.32	0.30	0.62	0.94	0.33	0.96	

Table 1:  $F_1$ -Score results that show impact of spatial (in columns) and temporal (in rows) experimental bias. Values with red backgrounds are experimental results of (unrealistic) settings similar to those considered in papers of ALG1 [4] and ALG2 [33]; values with green background (last row) are results in the realistic settings we identify. The dataset consists of three years (§2.3), and each square on the left part of the table represents a six month time-frame: if training (resp. testing) objects are sampled from that time frame, we use a black square (■); if not, we use a gray square (■).

bias without the interference of temporal bias.

**Spatial experimental bias in testing.** The percentage of malware in the testing distribution needs to be estimated (§2.2) and *cannot* be changed, if one wants results to be representative of in-the-wild deployment of the malware classifier. To understand why this leads to biased results, we artificially vary the testing distribution to illustrate our point. Figure 2 reports performance ( $F_1$ -Score, Precision, Recall) for increasing the percentage of malware during testing on the  $X$ -axis. We change the percentage of malware in the testing set by randomly downsampling goodwill, so the number of malware remains fixed throughout the experiments.<sup>2</sup> For completeness, we report the two training settings from Table 1 with 10% and 90% malware, respectively.

Let us first focus on the malware performance (dashed lines). All plots in Figure 2 exhibit constant Recall, and increasing Precision for increasing percentage of malware in the testing. Precision for the malware (mw) class—the positive class—is defined as  $P_{mw} = TP/(TP+FP)$  and Recall as  $R_{mw} = TP/(TP+FN)$ . In this scenario, we can observe that TPs (i.e., malware objects correctly classified as malware) and FNs (i.e., malware objects incorrectly classified as goodwill) do not change, because the number of malware does not increase; hence, Recall remains stable. The increase in number of FPs (i.e., goodwill objects misclassified as malware) decreases as we reduce the number of goodwill in the dataset; hence, Precision improves. Since the  $F_1$ -Score is the harmonic mean of Precision and Recall, it goes up with Precision. We also observe that, inversely, the Precision for the goodwill (gw) class—the negative class— $P_{gw} = TN/(TN+FN)$  decreases (see yellow solid lines in Figure 2), because we are reducing the TNs while the FNs do not change. This example shows how considering an unrealistic testing distribution with more malware than goodwill in this context (§2.2) positively inflates Precision and hence the  $F_1$ -Score of the malware classifier.

<sup>2</sup>We choose to downsample goodwill to achieve up to 90% of malware

**Spatial experimental bias in training.** To understand the impact of altering malware-to-goodware ratios in training, we now consider a motivating example with a linear SVM in a 2D feature space, with features  $x_1$  and  $x_2$ . Figure 3 reports three scenarios, all with the same 10% malware in testing, but with 10%, 50%, and 90% malware in training.

We can observe that with an increasing percentage of malware in training, the hyperplane moves towards goodwill. More formally, it improves Recall of malware while reducing its Precision. The opposite is true for goodwill. To minimize the overall error rate  $Err = (FP+FN)/(TP+TN+FP+FN)$  (i.e., maximize Accuracy), one should train the dataset with the same distribution that is expected in the testing. However, in this scenario one may have more interest in finding objects of the minority class (e.g., “more malware”) by improving Recall subject to a constraint on maximum FPR.

Figure 4 shows the performance for ALG1 and ALG2, for increasing percentages of malware in training on the  $X$ -axis; just for completeness (since one cannot artificially change the test distribution to achieve realistic evaluations), we report results both for 10% mw in testing and for 90% malware in testing, but we remark that in the Android setting we have estimated 10% mw in the wild (§2.2). These plots confirm the trend in our motivating example (Figure 3), that is,  $R_{mw}$  increases but  $P_{mw}$  decreases. For the plots with 10% mw in

(mw) for testing because of the computational and storage resources required to achieve such a ratio by oversampling. This does not alter the conclusions of our analysis. Let us assume a scenario in which we keep the same number of goodwill (gw), and increase the percentage of mw in the dataset by oversampling mw. The precision ( $P_{mw} = TP/(TP+FP)$ ) would increase because TPs would increase for any mw detection, and FPs would not change—because the number of gw remains the same; if training (resp. testing) observations are sampled from a distribution similar to the mw in the original dataset (e.g., new training mw is from 2014 and new testing mw comes from 2015 and 2016), then Recall ( $R_{mw} = TP/(TP+FN)$ ) would be stable—it would have the same proportions of TPs and FNs because the classifier will have a similar predictive capability for finding mw. Hence, if the number of mw in the dataset increases, the  $F_1$ -Score would increase as well, because Precision increases while Recall remains stable.

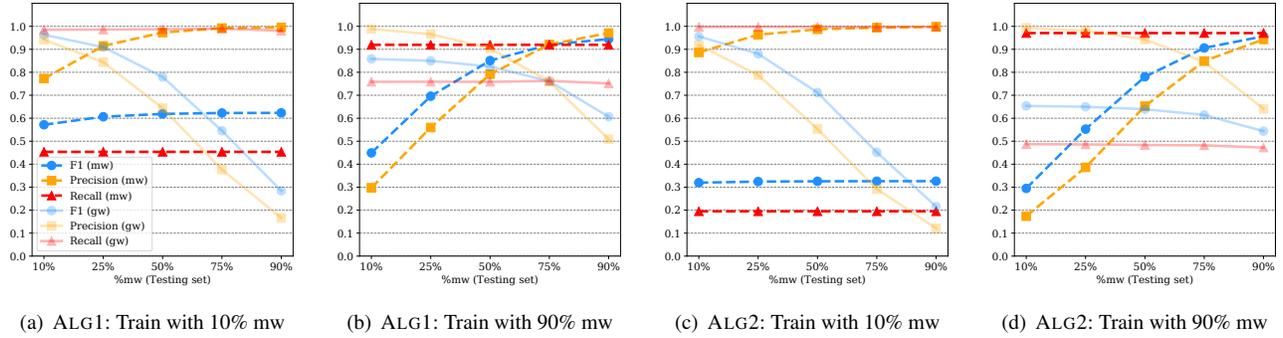

Figure 2: *Spatial experimental bias in testing.* Training on 2014 and testing on 2015 and 2016. For increasing % of malware in the testing (unrealistic setting), Precision for malware increases and Recall remains the same; overall,  $F_1$ -Score increases for increasing percentage of malware in the testing. However, having more malware than goodware in testing does not reflect the in-the-wild distribution of 10% malware (§2.2), so the setting with more malware is unrealistic and reports biased results.

testing, we observe there is a point in which  $F_1\text{-Score}_{mw}$  is maximum while the error for the gw class is within 5%.

In §4.3, we propose a novel algorithm to improve the performance of the malware class according to the objective of the user (high Precision, Recall or  $F_1$ -Score), subject to a maximum tolerated error. Moreover, in §4 we introduce constraints and metrics to guarantee bias-free evaluations, while revealing counter-intuitive results.

## 4 Space-Time Aware Evaluation

We now formalize how to perform an evaluation of an Android malware classifier free from spatio-temporal bias. We define a novel set of constraints that must be followed for realistic evaluations (§4.1); we introduce a novel time-aware metric, AUT, that captures in one number the impact of time decay on a classifier (§4.2); we propose a novel tuning algorithm that empirically optimizes a classifier performance, subject to a maximum tolerated error (§4.3); finally, we introduce TESSERACT and provide counter-intuitive results through unbiased evaluations (§4.4). To improve readability, we report in Appendix A.2 a table with all the major symbols used in the remainder of this paper.

### 4.1 Evaluation Constraints

Let us consider  $D$  as a labeled dataset with two classes: malware (positive class) and goodware (negative class). Let us define  $s_i \in D$  as an *object* (e.g., Android app) with timestamp  $time(s_i)$ . To evaluate the classifier, the dataset  $D$  must be split into a training dataset  $Tr$  with a time window of size  $W$ , and a testing dataset  $Ts$  with a time window of size  $S$ . Here, we consider  $S > W$  in order to estimate long-term performance and robustness to decay of the classifier. A user may consider different time splits depending on his objectives, provided each split has a significant number of samples. We emphasize that, although we have the labels of objects in  $Ts \subseteq D$ , all the evaluations and tuning algorithms *must* assume that labels  $y_i$  of objects  $s_i \in Ts$  are unknown.

To evaluate performance over time, the test set  $Ts$  must be split into time-slots of size  $\Delta$ . For example, for a testing set time window of size  $S = 2$  years, we may have  $\Delta = 1$  month. This parameter is chosen by the user, but it is important that the chosen granularity allows for a statistically significant number of objects in each test window  $[t_i, t_i + \Delta)$ .

We now formalize three constraints that must be enforced when dividing  $D$  into  $Tr$  and  $Ts$  for a realistic setting that avoids spatio-temporal experimental bias (§3). While C1 was proposed in past work [2, 36], we are the first to propose C2 and C3—which we show to be fundamental in §4.4.

**C1) Temporal training consistency.** All the objects in the training must be *strictly* temporally precedent to the testing ones:

$$time(s_i) < time(s_j), \forall s_i \in Tr, \forall s_j \in Ts \quad (1)$$

where  $s_i$  (resp.  $s_j$ ) is an object in the training set  $Tr$  (resp. testing set  $Ts$ ). Eq. 1 must hold; its violation inflates the results by including future knowledge in the classifier (§3.2).

**C2) Temporal gw/mw windows consistency.** In every testing slot of size  $\Delta$ , all test objects must be from the same time window:

$$t_i^{min} \leq time(s_k) \leq t_i^{max}, \quad \forall s_k \text{ in time slot } [t_i, t_i + \Delta) \quad (2)$$

where  $t_i^{min} = \min_k time(s_k)$  and  $t_i^{max} = \max_k time(s_k)$ . The same should hold for the training: although violating Eq. 2 in the training data does not bias the evaluation, it may affect the sensitivity of the classifier to unrelated artifacts. Eq. 2 has been violated in the past when goodware and malware have been collected from different time windows (e.g., ALG2 [33], re-evaluated in §4.4)—if violated, the results are biased because the classifier may learn and test on artificial behaviors that, for example, distinguish goodware from malware just by their different API versions.

**C3) Realistic malware-to-goodware ratio in testing.** Let us define  $\phi$  as the average percentage of malware in training

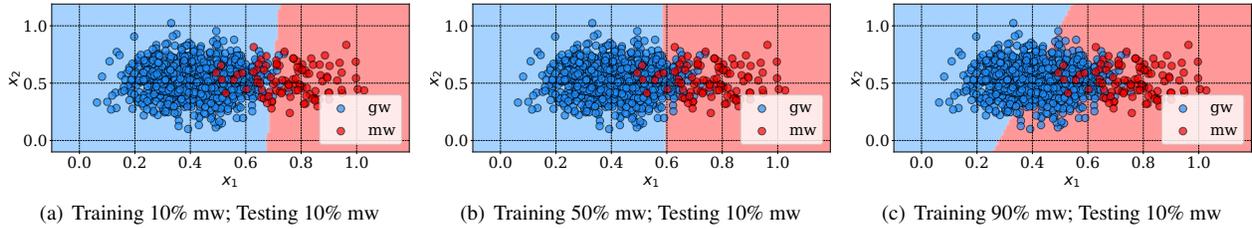

Figure 3: Motivating example for the intuition of *spatial experimental bias in training* with Linear-SVM and two features,  $x_1$  and  $x_2$ . The training changes, but the testing points are fixed: 90% gw and 10% mw. When the % of malware in the training increases, the decision boundary moves towards the goodware class, improving Recall for malware but decreasing Precision.

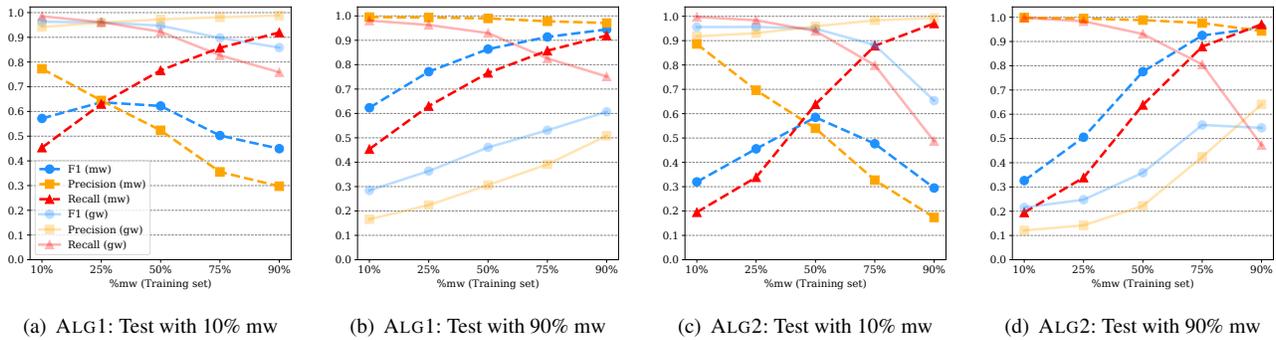

Figure 4: *Spatial experimental bias in training*. Training on 2014 and testing on 2015 and 2016. For increasing % of malware in the training, Precision decreases and Recall increases, for the motivations illustrated in the example of Figure 3. In §4.3, we devise an algorithm to find the best training configuration for optimizing Precision, Recall, or  $F_1$  (depending on user needs).

data, and  $\delta$  as the average percentage of malware in the testing data. Let  $\hat{\sigma}$  be the estimated percentage of malware in the wild. To have a realistic evaluation, the average percentage of malware in the testing ( $\delta$ ) must be as close as possible to the percentage of malware in the wild ( $\hat{\sigma}$ ), so that:

$$\delta \simeq \hat{\sigma} \quad (3)$$

For example, we have estimated that in the Android scenario goodware is predominant over malware, with  $\hat{\sigma} \approx 0.10$  (§2.2). If C3 is violated by overestimating the percentage of malware, the results are positively inflated (§3.3). We highlight that, although the testing distribution  $\delta$  cannot be changed (in order to get realistic results), the percentage of malware in the training  $\phi$  may be tuned (§4.3).

#### 4.2 Time-aware Performance Metrics

We introduce a time-aware performance metric that allows for the comparison of different classifiers while considering time decay. Let  $\Theta$  be a classifier trained on  $Tr$ ; we capture the performance of  $\Theta$  for each time frame  $[t_i, t_i + \Delta]$  of the testing set  $Ts$  (e.g., each month). We identify two options to represent per-month performance:

- **Point estimates (pnt)**: The value plotted on the  $Y$ -axis for  $x_k = k\Delta$  (where  $k$  is the test slot number) computes the performance metric (e.g.,  $F_1$ -Score) only based on predictions  $\hat{y}_i$  of  $\Theta$  and true labels  $y_i$  in the interval  $[W + (k - 1)\Delta, W + k\Delta]$ .

- **Cumulative estimates (cml)**: The value plotted on the  $Y$ -axis for  $x_k = k\Delta$  (where  $k$  is the test slot number) computes the performance metric (e.g.,  $F_1$ -Score) only based on predictions  $\hat{y}_i$  of  $\Theta$  and true labels  $y_i$  in the cumulative interval  $[W, W + k\Delta]$ .

Point estimates are always to be preferred to represent the real performance of an algorithm. The cumulative estimates can be used to highlight a smoothed trend and to show overall performance up to a certain point, but can be misleading if reported on their own if objects are too sparsely distributed in some test slots  $\Delta$ . Hence, we report only point estimates in the remainder of the paper (e.g., in §4.4), while an example of cumulative estimate plots is reported in Appendix A.3.

To facilitate the comparison of different time decay plots, we define a new metric, *Area Under Time* (**AUT**), the area under the performance curve over time. Formally, based on the trapezoidal rule (as in AUROC [8]), AUT is defined as follows:

$$AUT(f, N) = \frac{1}{N-1} \sum_{k=1}^{N-1} \frac{[f(x_{k+1}) + f(x_k)] \cdot (1/N)}{2} \quad (4)$$

where:  $f(x_k)$  is the value of the point estimate of the performance metric  $f$  (e.g.,  $F_1$ ) evaluated at point  $x_k := (W + k\Delta)$ ;  $N$  is the number of test slots, and  $1/(N - 1)$  is a normalization factor so that  $AUT \in [0, 1]$ . The perfect classifier with robustness to time decay in the time window  $S$  has  $AUT = 1$ . By

default, AUT is computed as the area under point estimates, as they capture the trend of the classifier over time more closely; if the AUT is computed on cumulative estimates, it should be explicitly marked as  $AUT_{cml}$ . As an example,  $AUT(F_1, 12m)$  is the point estimate of  $F_1$ -Score considering time decay for a period of 12 months, with a 1-month interval. We highlight that the simplicity of computing the AUT should be seen as a benefit rather than a drawback; it is a simple yet effective metric that captures the performance of a classifier with respect to time decay, de-facto promoting a fair comparison across different approaches.

$AUT(f, N)$  is a metric that allows us to evaluate performance  $f$  of a malware classifier against time decay over  $N$  time units in realistic experimental settings—obtained by enforcing C1, C2, and C3 (§4.1). The next sections leverage AUT for tuning classifiers and comparing different solutions (§4.4).

### 4.3 Tuning Training Ratio

We propose a novel algorithm that allows for the adjustment of the training ratio  $\phi$  when the dataset is imbalanced, in order to optimize a user-specified performance metric ( $F_1$ , Precision, or Recall) on the minority class, subject to a maximum tolerated error, while aiming to reduce time decay. The high-level intuition of the impact of changing  $\phi$  is described in §3.3. We also observe that ML literature has shown ROC curves to be misleading on highly imbalanced datasets [14, 25]. Choosing different thresholds on ROC curves *shifts* the decision boundary, but (as seen in the motivating example of Figure 3) re-training with different ratios  $\phi$  (as in our algorithm) also changes the *shape* of the decision boundary, better representing the minority class.

Our tuning algorithm is inspired by one proposed by Weiss and Provost [55]; they propose a progressive sampling of training objects to collect a dataset that improves AUROC performance of the minority class in an imbalanced dataset. However, they did not take temporal constraints into account (§3.2), and heuristically optimize only AUROC. Conversely, we enforce C1, C2, C3 (§4.1), and rely on AUT to achieve three possible targets for the malware class: higher  $F_1$ -Score, higher Precision, or higher Recall. Also, we assume that the user already has a training dataset  $Tr$  and wants to use as many objects from it as possible, while still achieving a good performance trade-off; for this purpose, we perform a *progressive subsampling* of the goodware class.

Algorithm 1 formally presents our methodology for tuning the parameter  $\phi$  to find the value  $\phi_{\mathbb{P}}^*$  that optimizes  $\mathbb{P}$  subject to a maximum error rate  $E_{max}$ . The algorithm aims to solve the following optimization problem:

$$\text{maximize}_{\phi} \{\mathbb{P}\} \quad \text{subject to: } E \leq E_{max} \quad (5)$$

where  $\mathbb{P}$  is the target performance: the  $F_1$ -Score ( $F_1$ ), Precision ( $Pr$ ) or Recall ( $Rec$ ) of the malware class;  $E_{max}$  is the

maximum tolerated error; depending on the target  $\mathbb{P}$ , the error rate  $E$  has a different formulation:

- if  $\mathbb{P} = F_1 \rightarrow E = 1 - \text{Acc} = (FP + FN) / (TP + TN + FP + FN)$
- if  $\mathbb{P} = Rec \rightarrow E = FPR = FP / (TN + FP)$
- if  $\mathbb{P} = Pr \rightarrow E = FNR = FN / (TP + FN)$

Each of these definitions of  $E$  is targeted to limit the error induced by the specific performance—if we want to maximize  $F_1$  for the malware class, we need to limit both FPs and FNs; if  $\mathbb{P} = Pr$ , we increase FNs, so we constrain FNR.

Algorithm 1 consists of two phases: *initialization* (lines 1–5) and *grid search* of  $\phi_{\mathbb{P}}^*$  (lines 6–14). In the initialization phase, the training set  $Tr$  is split into a proper training set  $ProperTr$  and a validation set  $Val$ ; this is split according to the space-time evaluation constraints in §4.1, so that all the objects in  $ProperTr$  are temporally anterior to  $Val$ , and the malware percentage  $\delta$  in  $Val$  is equal to  $\hat{\sigma}$ , the in-the-wild malware percentage. The maximum performance observed  $P^*$  and the optimal training ratio  $\phi_{\mathbb{P}}^*$  are initialized by assuming the estimated in-the-wild malware ratio  $\hat{\sigma}$  for training; in Android,  $\hat{\sigma} \approx 10\%$  (see §2.2).

The grid-search phase iterates over different values of  $\phi$ , with a learning rate  $\mu$  (e.g.,  $\mu = 0.05$ ), and keeps as  $\phi_{\mathbb{P}}^*$  the value leading to the best performance, subject to the error constraint. To reduce the chance of discarding high-quality points while downsampling goodware, we prioritize the most uncertain points (e.g., points close to the decision boundary in an SVM) [46]. The constraint on line 6 ( $\hat{\sigma} \leq \phi \leq 0.5$ ) is to ensure that one does not under-represent the minority class (if  $\phi < \hat{\sigma}$ ) and that one does not let it become the majority class (if  $\phi > 0.5$ ); also, from §3.3 it is clear that if  $\phi > 0.5$ , then the error rate becomes too high for the goodware class. Finally, the grid-search explores multiple values of  $\phi$  and stores the best ones. To capture time-aware performance, we rely on AUT (§4.2), and the error rate is computed according to the target  $\mathbb{P}$  (see above). Tuning examples are in §4.4.

### 4.4 TESSERACT: Revealing Hidden Performance

Here, we show how our methodology can reveal hidden performance of ALG1 [4], ALG2 [33], and DL [22] (§2.1), and their robustness to time decay.

We develop TESSERACT as an open-source Python framework that enforces constraints C1, C2, and C3 (§4.1), computes AUT (§4.2), and can train a classifier with our tuning algorithm (§4.3). TESSERACT operates as a traditional Python ML library but, in addition to features matrix  $X$  and labels  $y$ , it also takes as input the timestamp array  $t$  containing dates for each object. Details about TESSERACT’s implementation and generality are in §A.5.

Figure 5 reports several performance metrics of the three algorithms as point estimates over time. The  $X$ -axis reports the testing slots in months, whereas the  $Y$ -axis reports different scores between 0 and 1. The areas highlighted in blue correspond to the  $AUT(F_1, 24m)$ . The black dash-dotted horizontal lines represent the best  $F_1$  from the original papers [4, 22, 33],

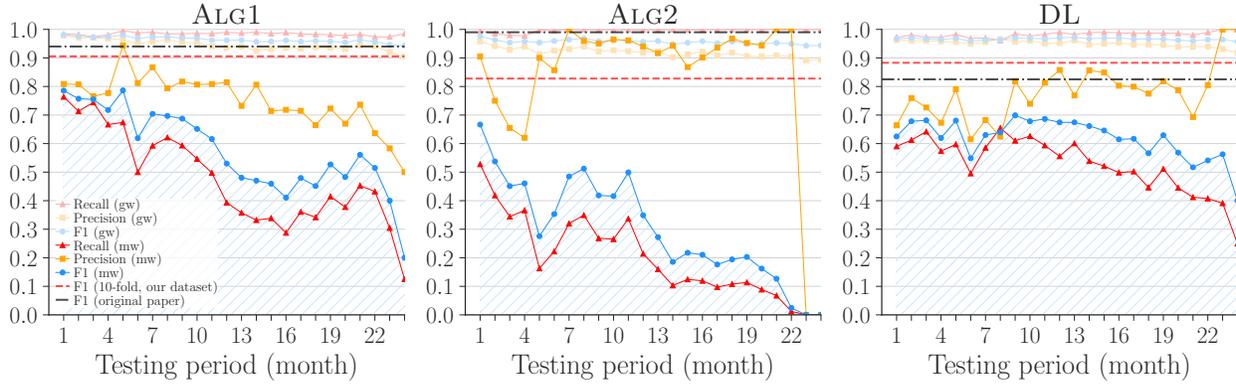

Figure 5: Time decay of ALG1 [4], ALG2 [33] and DL [22]—with  $AUT(F_1, 24m)$  of 0.58, 0.32 and 0.64, respectively. Training and test distribution both have 10% malware. The drop in the last 3 months is also related to lower samples in the dataset.

### Algorithm 1: Tuning $\varphi$ .

**Input:** Training dataset  $Tr$

**Parameters:** Learning rate  $\mu$ , target performance  $\mathbb{P} \in \{F_1, Pr, Rec\}$ , max error rate  $E_{max}$

**Output:**  $\varphi_p^*$ , optimal percentage of mw to use in training to achieve the best target performance  $\mathbb{P}$  subject to  $E < E_{max}$ .

- 1 Split the training set  $Tr$  into two subsets: actual training ( $ProperTr$ ) and validation set ( $Val$ ), while enforcing C1, C2, C3 (§4.1), also implying  $\delta = \hat{\sigma}$
- 2 Divide  $Val$  into  $N$  non-overlapped subsets, each corresponding to a time-slot  $\Delta$ , so that  $Val_{array} = [V_0, V_1, \dots, V_N]$
- 3 Train a classifier  $\Theta$  on  $ProperTr$
- 4  $P^* \leftarrow AUT(\mathbb{P}, N)$  on  $Val_{array}$  with  $\Theta$
- 5  $\varphi_p^* = \hat{\sigma}$
- 6 **for** ( $\varphi = \hat{\sigma}$ ;  $\varphi \leq 0.5$ ;  $\varphi = \varphi + \mu$ ) **do**
- 7     Downsample gw in  $ProperTr$  so that percentage of mw is  $\varphi$
- 8     Train the classifier  $\Theta_\varphi$  on  $ProperTr$  with  $\varphi$  mw
- 9     performance  $P_\varphi \leftarrow AUT(\mathbb{P}, N)$  on  $Val_{array}$  with  $\Theta_\varphi$
- 10    error  $E_\varphi \leftarrow$  Error rate on  $Val_{array}$  with  $\Theta_\varphi$
- 11    **if** ( $P_\varphi > P^*$ ) **and** ( $E_\varphi \leq E_{max}$ ) **then**
- 12      $P^* \leftarrow P_\varphi$
- 13      $\varphi_p^* \leftarrow \varphi$
- 14 **return**  $\varphi_p^*$ ;

corresponding to results obtained with 10 hold-out random splits for ALG1, 10-fold CV for ALG2, and random split for DL; all these settings are analogous to k-fold from a temporal bias perspective, and violate both C1 and C2. The red dashed horizontal lines correspond to 10-fold  $F_1$  obtained on our dataset, which satisfies C3.

**Differences in 10-fold  $F_1$ .** We discuss and motivate the differences between the horizontal lines representing original papers' best  $F_1$  and replicated 10-fold  $F_1$ . The 10-fold  $F_1$  of ALG1 is close to the original paper [4]; the difference is likely related to the use of a different, more recent dataset. The 10-fold  $F_1$  of ALG2 is much lower than the one in the paper. We verified that this is mostly caused by **violating C3**: the best  $F_1$  reported in [33] is on a setting with 86% malware—hence, spatial bias increases even 10-fold  $F_1$  of ALG2. Also **violating C2** tends to inflate the 10-fold performance as the

classifier may learn artifacts. The 10-fold  $F_1$  in DL is instead slightly higher than in the original paper [22]; this is likely related to a hyperparameter tuning in the original paper that optimized Accuracy (instead of  $F_1$ ), which is known to be misleading in imbalanced datasets. Details on hyperparameters chosen are in §A.1. From these results, we can observe that even if an analyst wants to estimate what the performance of the classifier would be in the *absence* of concept drift (i.e., where objects coming from the same distribution of the training dataset are received by the classifier), she still needs to enforce C2 and C3 while computing 10-fold CV to obtain valid results.

**Violating C1 and C2.** Removing the temporal bias reveals the real performance of each algorithm in the presence of concept drift. The  $AUT(F_1, 24m)$  quantifies such performance: 0.58 for ALG1, 0.32 for ALG2 and 0.64 for DL. In all three scenarios, the  $AUT(F_1, 24m)$  is lower than 10-fold  $F_1$  as the latter violates constraint C1 and may violate C2 if the dataset classes are not evenly distributed across the timeline (§4).

**Best performing algorithm.** TESSERACT shows a counter-intuitive result: the algorithm that is most robust to time decay and has the highest performance over the 2 years testing is the DL algorithm (after removing space-time bias), although for the first few months ALG1 outperforms DL. Given this outcome, one may prefer to use ALG1 for the first few months and then DL, if retraining is not possible (§5). We observe that this strongly contradicts the performance obtained in the presence of temporal and spatial bias. In particular, if we only looked at the best  $F_1$  reported in the original papers, ALG2 would have been the best algorithm (because spatial bias was present). After enforcing C3, the k-fold on our dataset would have suggested that DL and ALG1 have similar performance (because of temporal bias). After enforcing C1, C2 and C3, the AUT reveals that DL is actually the algorithm most robust to time decay.

**Different robustness to time decay.** Given a training dataset, the robustness of different ML models against perfor-

mance decay over time depends on several factors. Although more in-depth evaluations would be required to understand the theoretical motivations behind the different robustness to time decay of the three algorithms in our setting, we hereby provide insights on possible reasons. The performance of ALG2 is the fastest to decay likely because its feature engineering [33] may be capturing relations in the training data that quickly become obsolete at test time to separate goodware from malware. Although ALG1 and DL take as input the same feature space, the higher robustness to time decay of DL is likely related to feature representation in the *latent feature space* automatically identified by deep learning [19], which appears to be more robust to time decay in this specific setting. Recent results have also shown that linear SVM tends to overemphasize a few important features [35]—which are the few most effective on the training data, but may become obsolete over time. We remark that we are *not* claiming that deep learning is always more robust to time decay than traditional ML algorithms. Instead, we demonstrate how, in this specific setting, TESSERACT allowed us to highlight higher robustness of DL [22] against time decay; however, the prices to pay to use DL are lower explainability [23, 42] and higher training time [19].

**Tuning algorithm.** We now evaluate whether our tuning (Algorithm 1 in §4.3) improves robustness to time decay of a malware classifier for a given target performance. We first aim to maximize  $\mathbb{P} = F_1$ -Score of malware class, subject to  $E_{max} = 10\%$ . After running Algorithm 1 on ALG1 [4], ALG2 [33] and DL, we find that  $\varphi_{F_1}^* = 0.25$  for ALG1 and DL, and  $\varphi_{F_1}^* = 0.5$  for ALG2. Figure 6 reports the improvement on the test performance of applying  $\varphi_{F_1}^*$  to the full training set  $Tr$  of 1 year. We remark that the choice of  $\varphi_{F_1}^*$  uses only training information (see Algorithm 1) and no test information is used—the optimal value is chosen from a 4-month validation set extracted from the 1 year of training data; this is to simulate a realistic deployment setting in which we have no a priori information about testing. Figure 6 shows that our approach for finding the best  $\varphi_{F_1}^*$  improves the  $F_1$ -Score on malware at test time, at the cost of slightly reduced goodware performance. Table 2 shows details of how total FPs, total FNs, and AUT changed by training ALG1, ALG2, and DL with  $\varphi_{F_1}^*$ ,  $\varphi_{Prec}^*$ , and  $\varphi_{Rec}^*$  instead of  $\hat{\sigma}$ . These training ratios have been computed subject to  $E_{max} = 5\%$  for  $\varphi_{Rec}^*$ ,  $E_{max} = 10\%$  for  $\varphi_{F_1}^*$ , and  $E_{max} = 15\%$  for  $\varphi_{Prec}^*$ ; the difference in the maximum tolerated errors is motivated by the class imbalance in the dataset—which causes lower FPR and higher FNR values (see definitions in §4.3), as there are many more goodware than malware. As expected (§3.3), Table 2 shows that when training with  $\varphi_{F_1}^*$  Precision decreases (FPs increase) but Recall increases (because FNs decrease), and the overall AUT increases slightly as a trade-off. A similar reasoning follows for the other performance targets. We observe that the AUT for Precision may slightly differ even with a similar number of total FPs—this is because  $AUT(Pr, 24m)$  is sensitive to the

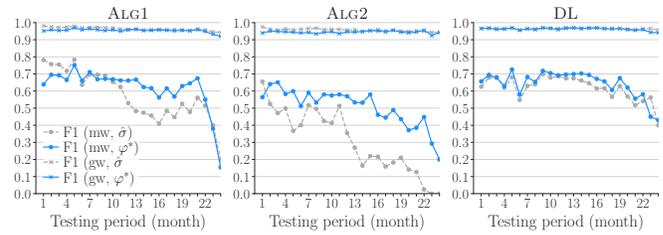

Figure 6: Tuning improvement obtained by applying  $\varphi_{F_1}^* = 25\%$  to ALG1 and DL, and  $\varphi_{F_1}^* = 50\%$  to ALG2. The values of  $\varphi_{F_1}^*$  are obtained with Algorithm 1 and one year of training data (trained on 8 months and validated on 4 months).

Algorithm	$\varphi$	FP	FN	AUT( $\mathbb{P}, 24m$ )		
				$F_1$	$Pr$	$Rec$
ALG1 [4]	10% ( $\hat{\sigma}$ )	965	3,851	0.58	0.75	0.48
	25% ( $\varphi_{F_1}^*$ )	2,156	2,815	0.62	0.65	0.61
	10% ( $\varphi_{Pr}^*$ )	965	3,851	0.58	0.75	0.48
	50% ( $\varphi_{Rec}^*$ )	3,728	1,793	0.64	0.58	0.74
ALG2 [33]	10% ( $\hat{\sigma}$ )	274	5,689	0.32	0.77	0.20
	50% ( $\varphi_{F_1}^*$ )	4,160	2,689	0.53	0.50	0.60
	10% ( $\varphi_{Pr}^*$ )	274	5,689	0.32	0.77	0.20
	50% ( $\varphi_{Rec}^*$ )	4,160	2,689	0.53	0.50	0.60
DL [22]	10% ( $\hat{\sigma}$ )	968	3,291	0.64	0.78	0.53
	25% ( $\varphi_{F_1}^*$ )	2,284	2,346	0.65	0.66	0.65
	10% ( $\varphi_{Pr}^*$ )	968	3,291	0.64	0.78	0.53
	25% ( $\varphi_{Rec}^*$ )	2,284	2,346	0.65	0.66	0.65

Table 2: Testing AUTs performance over 24 months when training with  $\hat{\sigma}$ ,  $\varphi_{F_1}^*$ ,  $\varphi_{Pr}^*$  and  $\varphi_{Rec}^*$ .

time at which FPs occur; the same observation is valid for total FNs and AUT Recall. After tuning, the  $F_1$  performance of ALG1 and DL become similar, although DL remains higher in terms of AUT. The tuning improves the  $AUT(F_1, 24m)$  of DL only marginally, as DL is already robust to time decay even before tuning (Figure 5).

The next section focuses on the two classifiers less robust to time decay, ALG1 and ALG2, to evaluate with TESSERACT the performance-cost trade-offs of budget-constrained strategies for delaying time decay.

## 5 Delaying Time Decay

We have shown how enforcing constraints and computing AUT with TESSERACT can reveal the real performance of Android malware classifiers (§4.4). This *baseline AUT performance* (without retraining) allows users to evaluate the general robustness of an algorithm to time decay. A classifier may be retrained to update its model. However, *manual labeling* is costly (especially in the Android malware setting), and the ML community [6, 46] has worked extensively on mitigation strategies—e.g., to identify a limited number of *best* objects to label (active learning). While effective at postponing time decay, strategies like these can further complicate the fair evaluation and comparison of classifiers.

In this section, we show how TESSERACT can be used

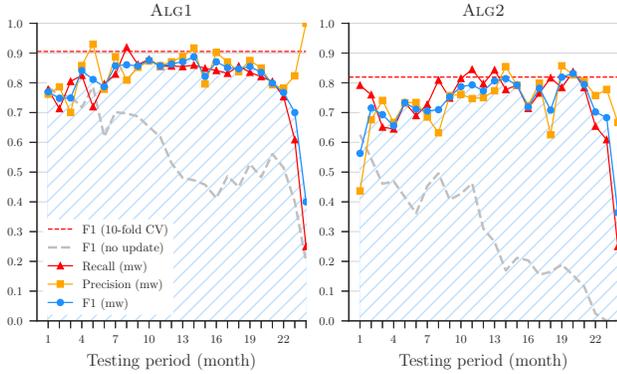

Figure 7: Delaying time decay: incremental retraining.

to compare and evaluate the trade-offs of different budget-constrained strategies to delay time decay. Since DL has shown to be more robust to time decay (§4.4) than ALG1 and ALG2, in this section we focus our attention these to show performance-cost trade-offs of different mitigations.

### 5.1 Delay Strategies

We do not propose novel delay strategies, but instead focus on how TESSERACT allows for the comparison of some popular approaches to mitigating time decay. This shows researchers how to adopt TESSERACT for the fair comparison of different approaches when proposing novel solutions to delaying time decay under budget constraints. We now summarize the delay strategies we consider and show results on our dataset. For interested readers, we include additional background knowledge on these strategies in §A.4.

**Incremental retraining.** We first consider an approach that represents an ideal upper bound on performance, where *all* points are included in retraining every month. This is likely unrealistic as it requires continuously labeling all the objects. Even assuming a reliance on VirusTotal, there is still an API usage cost associated with higher query rates and the approach may be ill-suited in other security domains. Figure 7 shows the performance of ALG1 and ALG2 with monthly incremental retraining.

**Active learning.** Active Learning (AL) strategies investigate how to select a subset of test objects (with unknown labels) that, if manually labeled and included in the training set, should be the most valuable for updating the classification model [46]. Here, we consider the most popular AL query strategy, *uncertainty sampling*, in which the points with the most uncertain predictions are selected for retraining, under the intuition that they are the most relevant to adjust decision boundaries. Figure 8 reports the active learning results obtained with uncertainty sampling, for different percentages of objects labeled per month. We observe that even with 1% AL, the performance already improves significantly.

Delay method	Costs				Performance			
	$L$		$Q$		$P: \text{AUT}(F_1, 24m)$			
	ALG1	ALG2	ALG1	ALG2	$\phi = \hat{\sigma}$		$\phi = \phi_{F_1}^*$	
No update	0	0	0	0	0.577	0.317	0.622	0.527
Rejection ( $\hat{\sigma}$ )	0	0	10,283	3,595	0.717	0.280	—	—
Rejection ( $\phi_{F_1}^*$ )	0	0	10,576	24,390	—	—	0.704	0.683
AL: 1%	709	709	0	0	0.708	0.456	0.703	0.589
AL: 2.5%	1,788	1,788	0	0	0.738	0.509	0.758	0.667
AL: 5%	3,589	3,589	0	0	0.782	0.615	0.784	0.680
AL: 7.5%	5,387	5,387	0	0	0.793	0.641	0.801	0.714
AL: 10%	7,189	7,189	0	0	0.796	0.656	0.802	0.732
AL: 25%	17,989	17,989	0	0	0.821	0.674	0.823	0.732
AL: 50%	35,988	35,988	0	0	0.817	0.679	0.828	0.741
Inc. retrain	71,988	71,988	0	0	0.818	0.679	0.830	0.736

Table 3: Performance-cost comparison of delay methods.

**Classification with rejection.** Another mitigation strategy involves rejecting a classifier’s decision as “low confidence” and delaying the decision to a future date [6]. This isolates the rejected objects to a *quarantine* area which will later require manual inspection. Figure 9 reports the performance of ALG1 and ALG2 after applying a reject option based on [26]. In particular, we use the third quartile of probabilities of incorrect predictions as the rejection threshold [26]. The gray histograms in the background report the number of rejected objects per month. The second year of testing has more rejected objects for both ALG1 and ALG2, although ALG2 overall rejects more objects.

### 5.2 Analysis of Delay Methods

To quantify performance-cost trade-offs of methods to delay time decay without changing the algorithm, we characterize the following three elements: **Performance** ( $P$ ), the performance measured in terms of AUT to capture robustness against time decay (§4.2); **Labeling Cost** ( $L$ ), the number of testing objects (if any) that must be labeled—the labeling must occur periodically (e.g., every month), and is particularly costly in the malware domain as manual inspection requires many resources (infrastructure, time, expertise, etc)—for example, Miller et al. [36] estimated that an average company could manually label 80 objects per day; **Quarantine Cost** ( $Q$ ), the number of objects (if any) rejected by the classifier—these must be manually verified, so there is a cost for leaving them in quarantine.

Table 3, utilizing  $\text{AUT}(F_1, 24m)$  while enforcing our constraints, reports a summary of labeling cost  $L$ , quarantine cost  $Q$ , and two performance columns  $P$ , corresponding to training with  $\hat{\sigma}$  and  $\phi_{F_1}^*$  (§4.3), respectively. In each row, we highlight in purple cells (resp. orange) the column with the highest AUT for ALG2 (resp. ALG1). Table 3 allows us to: (i) examine the effectiveness of the training ratios  $\phi_{F_1}^*$  and  $\hat{\sigma}$ ; (ii) analyze the AUT performance improvement and the corresponding costs for delaying time decay; (iii) compare the performance of ALG1 and ALG2 in different settings.

First, let us compare  $\phi_{F_1}^*$  with  $\hat{\sigma}$ . The first row of Table 3 represents the scenario in which the model is trained only once at the beginning—the scenario for which we originally

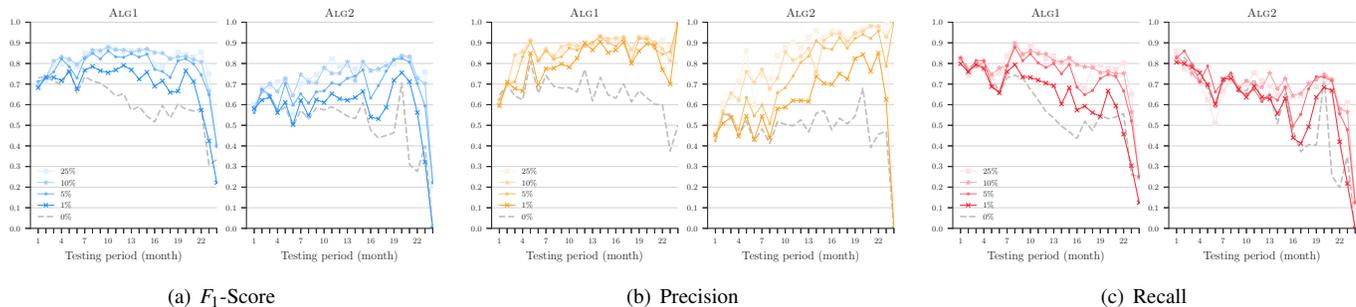

Figure 8: Delay time decay: performance with active learning based on uncertainty sampling.

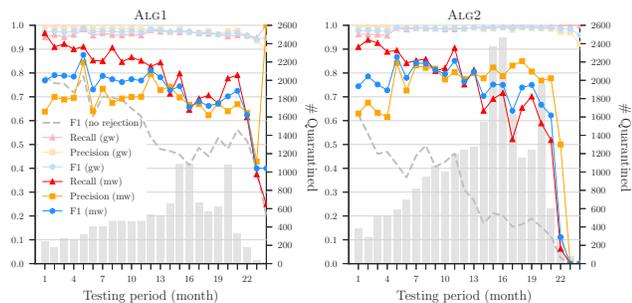

Figure 9: Delay time decay: classification with rejection.

designed Algorithm 1 (§4.3 and Figure 6). Without methods to delay time decay,  $\varphi_{F_1}^*$  achieves better performance than  $\hat{\sigma}$  for both ALG1 and ALG2 at no cost. In all other configurations, we observe that training  $\varphi = \varphi_{F_1}^*$  always improves performance for ALG2, whereas for ALG1 it is slightly advantageous in most cases except for rejection and AL 1%—in general, the performance of ALG1 trained with  $\varphi_{F_1}^*$  and  $\hat{\sigma}$  is consistently close. The intuition for this outcome is that  $\varphi_{F_1}^*$  and  $\hat{\sigma}$  are also close for ALG1: when applying the AL strategy, we re-apply Algorithm 1 at each step and find that the average  $\varphi_{F_1}^* \approx 15\%$  for ALG1, which is close to 10% (i.e.,  $\hat{\sigma}$ ). On the other hand, for ALG2 the average  $\varphi_{F_1}^* \approx 50\%$ , which is far from  $\hat{\sigma}$  and improves all results significantly. We can conclude that our tuning algorithm is most effective when it finds a  $\varphi_{F_1}^*$  that differs from the estimated  $\hat{\sigma}$ .

Then, we analyze the performance improvement and related cost of using delay methods. The improvement in  $F_1$ -Score granted by our algorithm comes at no labeling or quarantine cost. We can observe that one can improve the in-the-wild performance of the algorithms at some cost  $L$  or  $Q$ . It is important to observe that objects discarded or to be labeled are not necessarily malware; they are just the objects most uncertain according to the algorithm, which the classifier may have likely misclassified. The labeling costs  $L$  for ALG1 and ALG2 are identical (same dataset); in AL, the percentage of retrained objects is user-specified and fixed.

Finally, Table 3 shows that ALG1 consistently outperforms ALG2 on  $F_1$  for all performance-cost trade-offs. This confirms

the trend seen in the realistic settings of Table 1.

This section shows that TESSERACT is helpful to both researchers and industrial practitioners. Practitioners need to estimate the performance of a classifier in the wild, compare different algorithms, and determine resources required for  $L$  and  $Q$ . For researchers, it is useful to understand how to reduce costs  $L$  and  $Q$  while improving classifiers performance  $P$  through comparable, unbiased evaluations. The problem is challenging, but we hope that releasing TESSERACT’s code fosters further research and widespread adoption.

## 6 Discussion

We now discuss guidelines, our assumptions, and how we address limitations of our work.

**Actionable points on TESSERACT.** It is relevant to discuss how both researchers and practitioners can benefit from TESSERACT and our findings. A *baseline AUT performance* (without classifier retraining) allows users to evaluate the general robustness of an algorithm to performance decay (§4.2). We demonstrate how TESSERACT can reveal true performance and provide counter-intuitive results (§4.4). Robustness over extended time periods is practically relevant for deployment scenarios without the financial or computational resources to label and retrain often. Even with retraining strategies (§5), classifiers may not perform consistently over time. Manual labeling is costly, and the ML community has worked on mitigation strategies to identify a limited number of *best* objects to label (e.g., active learning [46]). TESSERACT takes care of removing spatio-temporal bias from evaluations, so that researchers can focus on the proposal of more robust algorithms (§5). In this context, TESSERACT allows for the creation of comparable baselines for algorithms in a time-aware setting. Moreover, TESSERACT can be used with different time granularity, provided each period has a significant number of samples. For example, if researchers are interested in increasing robustness to decay for the upcoming 3 months, they can use TESSERACT to produce bias-free comparisons of their approach with prior research, while considering time decay.

**Generalization to other security domains.** Although we used TESSERACT in the Android domain, our methodology

generalizes and can be immediately applied to any machine learning-driven security domain to achieve an evaluation without spatio-temporal bias. Our methodology, although general, requires some domain-specific parameters that reflect realistic conditions (e.g., time granularity  $\Delta$  and test time length). This is not a weakness of our work, but rather an expected requirement. In general, it is reasonable to expect that spatio-temporal bias may afflict other security domains when affected by concept drift and i.i.d. does not hold—however, further experiments in other domains (e.g., Windows malware, code vulnerabilities) are required to make any scientific conclusion. TESSERACT can be used to understand the extent to which spatio-temporal bias affects such security domains; however, the ability to generalize requires access to large timestamped datasets, knowledge of realistic class ratios, and code or sufficient details to reproduce baselines.

**Domain-specific in-the-wild malware percentage  $\hat{\sigma}$ .** In the Android landscape, we assume that  $\hat{\sigma}$  is around 10% (§2.2). Correctly estimating the malware percentage in the testing dataset is a challenging task and we encourage further representative measurement studies [30, 53] and data sharing to obtain realistic experimental settings.

**Correct observation labels.** We assume goodwill and malware labels in the dataset are correct (§2.3). Miller et al. [36] found that AVs sometimes change their outcome over time: some goodwill may eventually be tagged as malware. However, they also found that VirusTotal detections stabilize after one year; since we are using observations up to Dec 2016, we consider VirusTotal’s labels as reliable. In the future, we may integrate approaches for *noisy oracles* [15], which assume some observations are mislabeled.

**Timestamps in the dataset.** It is important to consider that some timestamps in a public dataset could be incorrect or invalid. In this paper, we rely on the public AndroZoo dataset maintained at the University of Luxembourg, and we rely on the `dex_date` attribute as the approximation of an observation timestamp, as recommended by the dataset creators [3]. We further verified the reliability of the `dex_date` attribute by re-downloading VirusTotal [20] reports for 25K apps<sup>3</sup> and verifying that the `first_seen` attribute always matched the `dex_date` within our time span. In general, we recommend performing some sanitization of a timestamped dataset before performing any analysis on it: if multiple timestamps are available for each object, consider the most reliable timestamp you have access to (e.g., the timestamp recommended by the dataset creators, or the VirusTotal’s `first_seen` attribute) and discard objects with “impossible” timestamps (e.g., with dates which are either too old or in the future), which may be caused by incorrect parsing or invalid values of some timestamps. To improve trustworthiness of the timestamps, one could verify whether a given object contains time inconsistencies or features not yet available when the app

<sup>3</sup>We downloaded only 25K VT reports (corresponding to about 20% of our dataset) due to restrictions on our VirusTotal API usage quota.

was released [29]. We encourage the community to promptly notify dataset maintainers of any date inconsistencies. In the TESSERACT’s project website (§8), we will maintain an updated list of timestamped datasets publicly available for the security community.

**Choosing time granularity ( $\Delta$ ).** Choosing the length of the time slots (i.e., time granularity) largely depends on the sparseness of the available dataset: in general, the granularity should be chosen to be as small as possible, while containing a statistically significant number of samples—as a rule of thumb, we keep the buckets large enough to have at least 1000 objects, which in our case leads to a monthly granularity. If there are restrictions on the number of time slots that can be considered (perhaps due to limited processing power), a coarser granularity can be used; however if the granularity becomes too large then the true trend might not be captured.

**Resilience of malware classifiers.** In our study, we analyze three recent high-profile classifiers. One could argue that other classifiers may show consistently high performance even with space-time bias eliminated. And this should indeed be the goal of research on malware classification. TESSERACT provides a mechanism for an unbiased evaluation that we hope will support this kind of work.

**Adversarial ML.** Adversarial ML focuses on perturbing training or testing observations to compel a classifier to make incorrect predictions [7]. Both relate to concepts of *robustness* and one can characterize adversarial ML as an artificially induced worst-case concept drift scenario. While the adversarial setting remains an open problem, the experimental bias we describe in this work—endemic in Android malware classification—must be addressed prior to realistic evaluations of adversarial mitigations.

## 7 Related Work

A common experimental bias in security is the *base rate fallacy* [5], which states that in highly-imbalanced datasets (e.g., network intrusion detection, where most traffic is benign), TPR and FPR are misleading performance metrics, because even  $FPR = 1\%$  may correspond to *millions* of FPs and only *thousands* of TPs. In contrast, our work identifies experimental settings that are misleading *regardless* of the adopted metrics, and that remain incorrect even if the right metrics are used (§4.4). Sommer and Paxson [47] discuss challenges and guidelines in ML-based intrusion detection; Rossow et al. [44] discuss best practices for conducting malware experiments; van der Kouwe et al. [54] identify 22 common errors in system security evaluations. While helpful, these works [44, 47, 54] do not identify temporal and spatial bias, do not focus on Android, and do not *quantify* the impact of errors on classifiers performance, and their guidelines would not prevent all sources of temporal and spatial bias we identify. To be precise, Rossow et al. [44] evaluate the percentage of objects—in previously adopted datasets—that are “incorrect” (e.g., goodwill labeled as malware, malfunctioning malware),

but without evaluating impact on classifier performance. Zhou et al. [58] have recently shown that Hardware Performance Counters (HPCs) are not really effective for malware classification; while interesting and in line with the spirit of our work, their focus is very narrow, and they rely on 10-fold CV in the evaluation.

Allix et al. [2] broke new ground by evaluating malware classifiers in relation to time and showing how future knowledge can inflate performance, but do not propose any solution for comparable evaluations and only identify C1. As a separate issue, Allix et al. [1] investigated the difference between in-the-lab and in-the-wild scenarios and found that the greater presence of goodwill leads to lower performance. We systematically analyze and explain these issues and help address them by formalizing a set of constraints (jointly considering the impact of temporal and spatial bias), introducing AUT as a unified performance metric for fair time-aware comparisons of different solutions, and offering a tuning algorithm to leverage the effects of training data distribution. Miller et al. [36] identified *temporal sample consistency* (equivalent to our constraint C1), but not C2 or C3—which are fundamental (§4.4); moreover, they considered the test period to be a uniform time slot, whereas we take time decay into account. Roy et al. [45] questioned the use of recent or older malware as training objects and the performance degradation in testing real-world object ratios; however, most experiments were designed without considering time, reducing the reliability of their conclusions. While past work highlighted some sources of experimental bias [1, 2, 36, 45], it also gave little consideration to classifiers’ aims: different scenarios may have different goals (not necessarily maximizing  $F_1$ ), hence in our work we show the effects of different training settings on performance goals and propose an algorithm to properly tune a classifier accordingly (§4.3).

Other works from the ML literature investigate imbalanced datasets and highlighted how training and testing ratios can influence the results of an algorithm [9, 25, 55]. However, not coming from the security domain, these studies [9, 25, 55] focus only on some aspects of spatial bias and do *not* consider temporal bias. Indeed, concept drift is less problematic in some applications (e.g., image and text classification) than in Android malware [26]. Fawcett [16] focuses on challenges in spam detection, one of which resembles spatial bias; no solution is provided, whereas we introduce C3 to this end and demonstrate how its violation inflates performance (§4.4). Torralba and Efros [52] discuss the problem of *dataset bias* in computer vision, distinct from our security setting where there are fewer benchmarks; moreover in images the negative class (e.g., “not cat”) can grow arbitrarily, which is less likely in the malware context. Moreno-Torres et al. [38] systematize different *drifts*, and mention *sample-selection bias*; while this resembles spatial bias, they do not propose any solution/experiments for its impact on ML performance. Other related work underlines the importance of choosing appropri-

ate performance metrics to avoid an incorrect interpretation of the results (e.g., ROC curves are misleading in an imbalanced dataset [14, 24]). In this paper, we take imbalance into account, and we propose actionable constraints and metrics with tool support to evaluate performance decay of classifiers over time.

**Summary.** Several studies of bias exist and have motivated our research. However, none of them address the entire problem in the context of evolving data (where the i.i.d. assumption does not hold anymore). Constraint C1, introduced by Miller et al. [36], is by itself insufficient to eliminate bias. This is evident from the original evaluation in MAMADROID [33], which enforces only C1. The evaluation in §4.4 clarifies why our novel constraints C2 and C3 are fundamental, and shows how our AUT metric can effectively reveal the true performance of algorithms, providing counter-intuitive results.

## 8 Availability

We make TESSERACT’s code and data available to the research community to promote the adoption of a sound and unbiased evaluation of classifiers. The TESSERACT project website with instructions to request access is at <https://s2lab.kcl.ac.uk/projects/tesseract/>. We will also maintain an updated list of publicly available security-related datasets with timestamped objects.

## 9 Conclusions

We have identified novel temporal and spatial bias in the Android domain and proposed novel constraints, metrics and tuning to address such issues. We have built and released TESSERACT as an open-source tool that integrates our methods. We have shown how TESSERACT can reveal the real performance of malware classifiers that remain hidden in wrong experimental settings in a non-stationary context. TESSERACT is fundamental for the correct evaluation and comparison of different solutions, in particular when considering mitigation strategies for time decay. We are currently working on integrating a time-varying percentage of malware in our framework to model still more realistic scenarios, and on how to use the slope of the performance decay curve to better differentiate algorithms with similar AUT.

We envision that future work on Android malware classification will use TESSERACT to produce realistic, comparable and unbiased results. Moreover, we also encourage the security community to adopt TESSERACT to evaluate the impact of temporal and spatial bias in other security domains where concept drift still needs to be quantified.

## Acknowledgements

We thank the anonymous reviewers and our shepherd, Roya Ensafi, for their constructive feedback, which has improved the overall quality of this work. This research has been partially sponsored by the UK EP/L022710/1 and EP/P009301/1 EPSRC research grants.

## A Appendix

### A.1 Algorithm Hyperparameters

We hereby report the details of the hyperparameters used to replicate ALG1, ALG2 and DL.

We replicate the settings and experiments of ALG1 [4] (linear SVM with  $C=1$ ) and ALG2 [33] (package mode and RF with 101 trees and max depth of 64) as described in the respective papers [4, 33], successfully reproducing the published results. Since on our dataset the ALG1 performance is slightly lower (around 0.91 10-fold  $F_1$ ), we also reproduce the experiment on their same dataset [4], achieving their original performance of about 0.94 10-fold  $F_1$ . We have used SCIKIT-LEARN, with `sklearn.svm.LinearSVC` for ALG1 and `sklearn.ensemble.RandomForestClassifier` for ALG2.

We then follow the guidelines in [22] to re-implement DL with KERAS. The features given as initial input to the neural network are the same as ALG1. We replicated the best-performing neural network architecture of [22], by training with 10 epochs and batch size equal to 1,000. To perform the training optimization, we used the stochastic gradient descent class `keras.optimizers.SGD` with the following parameters: `lr=0.1`, `momentum=0.0`, `decay=0.0`, `nesterov=False`. Some low-level details of the hyperparameter optimization were missing from the original paper [22]; we managed to obtain slightly higher  $F_1$  performance in 10-fold setting (§4.4) likely because they have performed hyperparameter optimization on the Accuracy metric [8]—which is misleading in imbalanced datasets [5] where one class is prevalent (goodware, in Android).

## A.2 Symbol table

Table 4 is a legend of the main symbols used throughout this paper to improve readability.

Symbol	Description
gw	Short version of goodwill.
mw	Short version of malware.
ML	Short version of Machine Learning.
$D$	Labeled dataset with malware (mw) and goodwill (gw).
$Tr$	Training dataset.
$W$	Size of the time window of the training set (e.g., 1 year).
$T_s$	Testing dataset.
$S$	Size of the time window of the testing set (e.g., 2 years).
$\Delta$	Size of the test time-slots for time-aware evaluations (e.g., months).
$AUT(f, N)$	Area Under Time, a new metric we define to measure performance over time decay and compare different solutions (§4.2). It is always computed with respect to a performance function $f$ (e.g., $F_1$ -Score) and $N$ is the number of time units considered (e.g., 24 months)
$\hat{\sigma}$	Estimated percentage of malware (mw) in the wild.
$\phi$	Percentage of malware (mw) in the training set.
$\delta$	Percentage of malware (mw) in the testing set.
$\mathbb{P}$	Performance target of the tuning algorithm in §4.3; it can be $F_1$ -Score, Precision ( $Pr$ ) or Recall ( $Rec$ ).
$\phi_{\mathbb{P}}^*$	Percentage of malware (mw) in the training set, to improve performance $\mathbb{P}$ on the malware (mw) class (§4.3).
$E$	Error rate (§4.3).
$E_{max}$	Maximum error rate when searching $\phi_{\mathbb{P}}^*$ (§4.3).
$\Theta$	Model learned after training a classifier.
$L$	Labeling cost.
$Q$	Quarantine cost.
$P$	Performance; depending on the context, it will refer to AUT with $F_1$ or $Pr$ or $Rec$ .

Table 4: Symbol table.

## A.3 Cumulative Plots for Time Decay

Figure 10 shows the cumulative performance plot defined in §4.2. This is the cumulative version of Figure 5.

## A.4 Delay Strategies

We discuss more background details on the mitigation strategies adopted in Section 5.

**Incremental retraining.** Incremental retraining is an approach that tends towards an “ideal” performance  $P^*$ : all test objects are periodically labeled manually, and the new knowledge introduced to the classifier via retraining. More formally, the performance of month  $m_i$  is determined from the predictions of a model  $\Theta$  trained on:  $Tr \cup \{m_0, m_1, \dots, m_{i-1}\}$ , where  $\{m_0, m_1, \dots, m_{i-1}\}$  are testing objects, which are manually labeled. The dashed gray line represents the  $F_1$ -Score *without* incremental retraining (i.e., stationary training). Although incremental retraining generally achieves optimal performance throughout the whole test period, it also incurs the highest labeling cost  $L$ .

**Active learning.** Active learning is a field of machine learning that studies *query strategies* to select a small number of

testing points close to the decision boundaries, that, if included in the training set, are the most relevant for updating the classifier. For example, in a linear SVM the slope of the decision boundary greatly depends on the points that are closest to it, the *support vectors* [8]; all the points further from the SVM decision boundary are classified with higher confidence, hence have limited effect on the slope of the hyperplane.

We evaluate the impact of one of the most popular active learning strategies: *uncertainty sampling* [36, 46]. This query strategy selects the most points the classifier is least certain about, and uses them for retraining; we apply it in a time-aware scenario, and choose a percentage of objects to retrain per month. The intuition is that the most uncertain elements are the ones that may be indicative of concept drift, and new, correct knowledge about them may better inform the decision boundaries. The number of objects to label depends on the user’s available resources for labeling.

More formally, in binary classification uncertainty sampling gives a score  $x_{LC}^*$  (where LC stands for *Least Confident*) to each sample [46]; this score is defined as follows<sup>4</sup>:

$$x_{LC}^* := \operatorname{argmax}_x \{1 - P_{\Theta}(\hat{y}|x)\} \quad (6)$$

where  $\hat{y} := \operatorname{argmax}_y P_{\Theta}(y|x)$  is the class label with the highest posterior probability according to classifier  $\Theta$ . In a binary classification task, the maximum uncertainty for an object is achieved when its prediction probability equal to 0.5 for both classes (i.e., equal probability of being goodwill or malware). The test objects are sorted by descending order of uncertainty  $x_{LC}^*$ , and the top-n most uncertain are selected to be labeled for retraining the classifier.

Depending on the percentage of manually labeled points, each scenario corresponds to a different labeling cost  $L$ . The labeling cost  $L$  is known a priori since it is user specified.

**Classification with rejection.** Malware evolves rapidly over time, so if the classifier is not up to date, the decision region may no longer be representative of new objects. Another approach, orthogonal to active learning, is to include a *reject option* as a possible classifier outcome [17, 26]. This discards the most uncertain predictions to a *quarantine* area for manual inspection at a future date. At the cost of rejecting some objects, the overall performance of the classifier (on the remaining objects) increases. The intuition is that in this way only high confidence decisions are taken into account. Again, although performance  $P$  improves, there is a quarantine cost  $Q$  associated with it; in this case, unlike active learning, the cost is not known a priori because, in traditional classification with rejection, a threshold on the classifier confidence is applied [17, 26].

<sup>4</sup>In multi-class classification, there is a query strategy based on the entropy of the prediction scores array; in binary classification, the entropy-based query strategy is proven to be equivalent to the “least confident” [46].

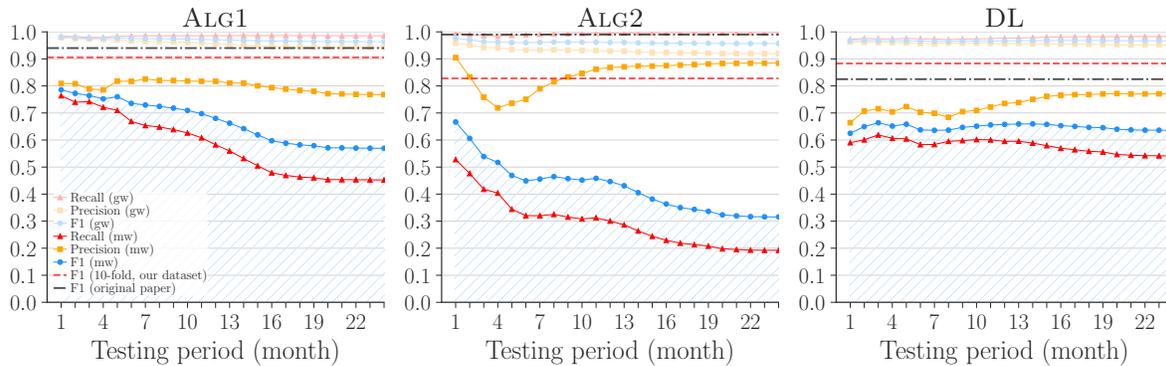

Figure 10: Performance time decay with cumulative estimate for ALG1, ALG2 and DL. Testing distribution has  $\delta = 10\%$  malware, and training distribution has  $\phi = 10\%$  malware.

## A.5 TESSERACT Implementation

We have implemented our constraints, metrics, and algorithms as a Python library named TESSERACT, designed to integrate easily with common workflows. In particular, the API design of TESSERACT is heavily inspired by and fully compatible with SCIKIT-LEARN [39] and KERAS [10]; as a result, many of the conventions and workflows in TESSERACT will be familiar to users of these libraries. Here we present an overview of the library’s core modules while further details of the design can be found in [40].

**temporal.py** While machine learning libraries commonly involve working with a set of predictors  $X$  and a set of output variables  $y$ , TESSERACT extends this concept to include an array of `datetime` objects  $t$ . This allows for operations such as the time-aware partitioning of datasets (e.g., `time_aware_partition()` and `time_aware_train_test_split()`) while respecting temporal constraints C1 and C2.

**spatial.py** This module allows the user to alter the proportion of the positive class in a given dataset. `downsample_set()` can be used to simulate the natural class distribution  $\hat{\delta}$  expected during deployment or to tune the performance of the model by over-representing a class during training. To this end we provide an implementation of Algorithm 1 for finding the optimal training proportion  $\phi^*$  (`search_optimal_train_ratio()`). This module can also assert that constraint C3 (§4.1) has not been violated.

**metrics.py** As TESSERACT aims to encourage comparable and reproducible evaluations, we include functions for visualizing classifier assessments and deriving metrics such as the accuracy or total errors from slices of a time-aware evaluation. Importantly we also include `aut()` for computing the AUT for a given metric ( $F_1$ , Precision, AUC, etc.) over a given time period.

**evaluation.py** Here we include the `predict()` and `fit_predict_update()` functions that accept a classifier,

dataset and set of parameters (as defined in §4.1) and return the results of a time-aware evaluation performed across the chosen periods.

**selection.py and rejection.py** For extending the evaluation to testing model update strategies, these modules provide hooks for novel query and reject strategies to be easily plugged into the evaluation cycle. We already implement many of the methods discussed in §5 and include them with our release. We hope this modular approach lowers the bar for follow-up research in these areas.

## A.6 Summary of Datasets Evaluated by Prior Work

As a reference, Table 5 reports the composition of the dataset used in our paper (1st row) and of the datasets used for experimentally biased evaluations in prior work ALG1 [4], ALG2 [33], and DL [22] (2nd and 3rd row). In this paper, we always evaluate ALG1, ALG2 and DL with the dataset in the first row (more details in §2.3 and Figure 1), because we have built it to allow experiments without spatio-temporal bias by enforcing constraints C1, C2 and C3. Details on experimental settings that caused spatio-temporal bias in prior work are described in §3 and §4. *We never use the datasets of prior work [4, 22, 33] in our experiments.*

## Abstract

Finding logic flaws today relies on the program analysis that leverages the functionality information reported in the program's documentation. Our research, however, shows that the documentation alone may already contain information for *predicting* the presence of some logic flaws, even before the code is analyzed. Our first step on this direction focuses on emerging syndication services that facilitate integration of multiple payment services (e.g., Alipay, Wechat Pay, PayPal, etc.) into merchant systems. We look at whether a syndication service will cause some security requirements (e.g., checking payment against price) to become unenforceable due to losing visibility of some key parameters (e.g., payment, price) to the parties involved in the syndication, or bring in implementation errors when required security checks fail to be communicated to the developer. For this purpose, we developed a suite of Natural Language Processing techniques that enables automatic inspection of the syndication developer's guide, based upon the payment models and security requirements from the payment service. Our approach is found to be effective in identifying these potential problems from the guide, and leads to the discovery of 5 new security-critical flaws in popular Chinese merchant systems that can cause circumvention of payment once exploited.

## 1 Introduction

Logic vulnerabilities are a category of security defects caused by faulty program logic, which have long been known to be hard to analyze, due to their close ties to specific functionalities of a system. Finding these defects relies on evaluating the target system's behaviors, at the code level, against a set of invariants describing its function-related security properties (e.g., expected authentication and authorization operations).

\*Work was done when the first author was at Indiana University Bloomington.

<sup>†</sup>Key Laboratory of Network Assessment Technology, CAS.

<sup>‡</sup>Beijing Key Laboratory of Network Security and Protection Technology

<sup>§</sup>State Key Laboratory of Information Security, IIE, CAS

A great source for such invariants is the system's documentation, which states its security goals and has been leveraged by prior research for the purposes such as model checking on the system's code [27]. In the meantime, the documentation also provides detailed accounts of how the system is designed to achieve the goals and how it should be used to remain secure. Such information can be valuable for *predicting* whether security-critical logic flaws are present in the system or applications that use the system: for example, prior research shows that logic vulnerabilities could be related to low-quality documentations, such as those missing explanations about implicit assumptions for secure integration of authentication SDKs [49]; also a conflict between the system's operations, as described in its documentation, and its security goals may indicate the existence of a design flaw. However, never before has any effort been made to dig into the details contained in a myriad of software documentations to understand their security implications, not to mention any attempt to exploit their full value for logic flaw detection.

**Logic vulnerabilities in payment syndication.** In this paper, we present preliminary evidence that system documentations indeed carry abundant vulnerability-related indicators, which can help identify logic flaws *even before the code of the system has been analyzed*. Further we show that this documentation-based approach can be automated, enabling more effective vulnerability detection through providing guidance to program analysis such as fuzzing. This first step has been made possible by a study on *syndication services* that facilitate integration of various payment services (e.g., Alipay [2], WeChat Pay [17], PayPal [25]) in mobile apps. These payment services have different APIs and SDKs, and an app often needs to use all of them to offer its customers different payment options. To simplify integration of these options, a syndication service encapsulates each payment service with a *wrapper* that exposes to the developer a uniform interface. This, however, injects the syndicator as a proxy into the already complicated payment interactions among the payer (the app user), the payee (the merchant) and the payment service provider (e.g., Paypal). Logic flaws can therefore be induced

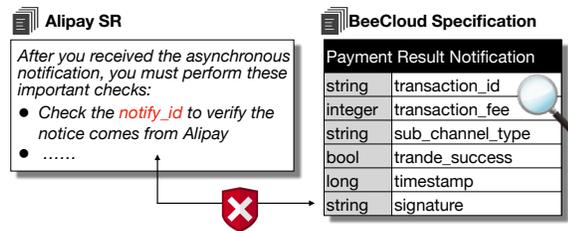

Figure 1: Inconsistency example.

at the design level, when the wrapper causes some security checks hard to proceed (e.g., verification of payment against price), or at the implementation level, when the developer fails to perform security checks correctly, due to incomplete instructions given by the syndicator.

These payment syndication services today become increasingly popular: according to the reports [35, 36], their total transactions in year 2018 have reached 21.1 trillion yuan (3.15 trillion dollars). Any vulnerability inside these services, once exploited, will have significant impacts, affecting 251 million syndication users world-wide. We believe that their documentations, developer’s guide in particular, contain information that can help predict or even detect the logic flaws in their customers’ systems. As an example, Figure 1 demonstrates the inconsistency discovered when comparing an Alipay’s security requirement, which asks for inspecting `notify_id`, with the payment notification issued by BeeCloud [6] (a popular service syndicating Alipay and other payment services), which does *not* include this information, as discovered from its developer’s guide; therefore, the merchant server receiving the notification will *not* be able to perform the required check. This logic problem has been *confirmed* in our research. A question here is how to systematically identify such logic vulnerabilities from documentation. Also, developer’s guides are typically long and complicated, including a lot of irrelevant information (e.g., instructions for using the syndicator’s tools like dashboard). For example, Ping++ has 1093 KB text documents online with at least 278 KB related technical content [12]. Inspecting all the content manually is both time-consuming and error-prone. Automated techniques therefore need to be developed to help vulnerability discovery.

**Document analysis for flaw detection.** In our research, we developed *Dilution* (Documentation Inspector for Logic Vulnerability Prediction), a new technique that automatically analyzes the developer’s guide of a payment syndication to infer potential security flaws in the merchant systems integrating the service. *Dilution* is designed to predict missing security checks in the integration, which is caused by either improper encapsulation of a payment service that renders its security checks impossible to perform through the wrapper, or failure in communicating the necessary checks to the developer through the guide. For this purpose, we utilize natural language processing (NLP) to automatically recover semantic information from the wrapper’s integration instructions docu-

mented by the developer’s guide and compared it against the finite state machine (FSM) of the payment service encapsulated. Note that this payment FSM was manually extracted but considered as one-time efforts (Section 3.1). Our analysis automatically infers the relation between the syndication payment process and the payment FSM, maps important payment states to the related instructions in the guide and further recovers the parameters for required security checks (e.g., Alipay key for signature verification, price) at the state from the text. By analyzing the merchant or syndicator’s visibility of the parameters, we can determine whether these checks can still be performed by the merchant or the syndicator. Also from related descriptions in the guide, our approach can automatically find out whether the developer is informed about these security requirements when integrating the wrapper. Missing such instructions indicates the possible absence of security checks in the merchant’s code.

We implemented *Dilution* using a suite of NLP techniques, including dependency parsing and word embedding, and evaluated it on labeled content extracted from the developer’s guides of real-world syndication services. Our study shows that *Dilution* accurately caught logic flaws and went through 182 KB text document content within 3.18 seconds, averagely.

**Finding.** Further, we ran *Dilution* on the documentations of eight popular syndication services, including Ping++ [12], Paymax [11], BeeCloud [6], etc., which have tens of thousands of merchants each and power the apps with millions of users. From 1,456 KB documentations, our approach automatically predicted totally 41 potential issues, including 11 highly likely to be logic flaws from five syndication services: Fuqianla [8], BeeCloud, TrPay [15], UMF Pay [16] and 66zhifu [1]. All the issues reported were found to be accurate by our manual inspection of the documentations. Despite the challenges in finding the apps integrating these services, due to the obfuscations these services suggest [20, 23, 26], we collected 17 popular Chinese apps using two of these syndication services. Through a black-box testing on these apps and their merchant systems, we concluded that all 5 logic flaws related to these syndication services predicted by *Dilution* are indeed present in either the syndicators’ systems or their customers’ code. All such confirmed flaws are security-critical, and once exploited, will have serious consequences, allowing the adversary to shop at a lower price or even for free. We reported our findings to the providers of the syndications and the merchants who are affected, and they all acknowledged the importance of the problems we discovered. Now we are in the process of helping them fix these vulnerabilities. Video demos of our attacks are posted online [4].

**Contributions.** The contributions of the paper are outlined as follows:

- *New direction.* We explore the potential to predict the presence of logic vulnerabilities in a software system from its documentation. Our preliminary study on payment syndica-

tion services shows that this is indeed feasible. Research along this line could bring in a new perspective to software security analysis, enabling more effective and intelligent vulnerability detection and helping enhance software security quality.

- *New techniques.* We developed Dilution, the first semantics-based documentation analyzer, to automatically inspect the developer’s guide and infer possible security fallacies in the merchant’s integration of the syndication service. Our approach includes a suite of NLP techniques tuned towards software documentation, which are found to be effective and efficient, as demonstrated by our evaluation.

- *New findings.* We analyzed the developer’s guides of 8 most popular syndication services using Dilution and discovered potential security issues. Among these we can validate, we confirmed that all 5 logic flaws predicted by our approach are indeed present in syndicator or merchant systems. These vulnerabilities, once exploited, allows the adversary to shop at an arbitrarily low price he set or completely for free, affecting millions of users. We are working with affected syndicators and merchants to fix these problems.

## 2 Background

**Payment and syndication service.** A third-party payment service (aka. a *payment processor*) like PayPal [25] is an Internet service to help handle transactions between the buyer (the payer) and the seller (the payee) [43]. Such a service simplifies transaction managements on both the payer and the payee sides and therefore plays an important role in e-commerce. Figure 2(a) shows how the service works using Alipay [2], the largest online payment processor with over 1 billion users around the world [47], as an example. The buyer first places an order through the app (①) and receives a payment-related `credential` from the merchant (②), including order ID, price, seller account and others, and then forwards it to Alipay (③). After the order is paid by the buyer, Alipay issues a notification to inform the merchant the completion of the transaction (④). The interfaces exposed by these payment services tend to be complicated. Figure 3(a) further details the process the app developer (working for the merchant) is supposed to do for using Alipay : the merchant server generates an Alipay specific argument `orderInfo` (part of `credential`) with 36 entries once the buyer places an order; then the buyer-side app of the merchant invokes Alipay’s payment service.

To simplify this integration process, syndication services emerge to wrap different payment processors into a uniform interface for the developer to conveniently incorporate them into her app. Figure 2(b) and 3(b) shows a common syndication payment process for Alipay. Instead of asking merchant developer to implement anything specific to Alipay, the syndicator receives an order from the buyer on behalf of the merchant (①), construct the `credential` (②) and then invokes Alipay payment service from the buyer’s app (③). Note that,

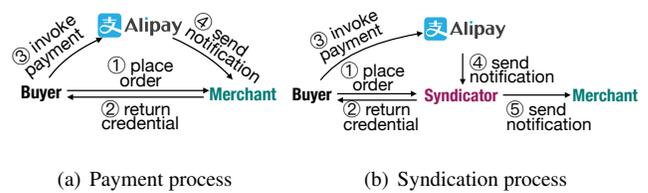

Figure 2: Examples of payment and syndication process.

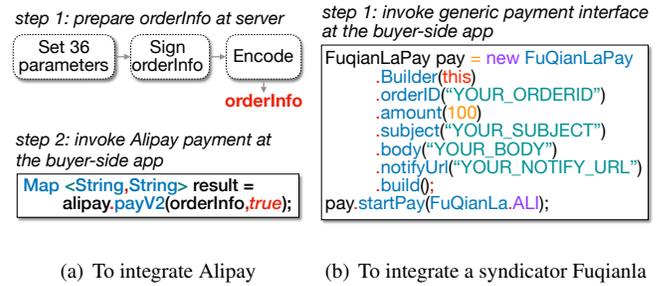

Figure 3: The implementation examples.

③ only requires the app to invoke a generic payment interface provided by the syndicator’s SDK in the app, and the target payment processor, i.e., Alipay in this case, will be invoked by the syndicator’s SDK. Once the payment is done, the syndicator receives the notification from the the payment processor (④) and restructures the message to a uniform format before forwarding it to the merchant server (⑤). In this way, a simple integration of a single syndication service on both the app end and the merchant server end will allow the merchant to work with multiple payment processors supported by the syndicator. The developer is only supposed to follow a single set of instructions from the syndicator to ensure the secure payment process.

**Security requirements.** Online payment is a security-critical process, so it is safeguarded by various security checks performed both by the payment processor and by the merchant, as required by the payment processor on its developer’s guide. We call these checks *security requirements* (SRs)<sup>1</sup> throughout the paper. For instance, most third-party payments ask their merchants to verify the payment amount on the notification against the price of the purchase, the seller account information to ensure that the merchants are intended payees, etc. In Section 4.2, we present more examples for common security requirements. In the case that the payment syndication is used, we expect that either the developer or the syndicator is still at the position to perform these required checks, and also in the former case, the developer should be properly informed through the guide provided by the syndicator.

**Natural language processing.** In our research, we utilized two NLP techniques to automatically analyze the documentation of the payment syndication service: *dependency parsing* and *word embedding*, as explained below.

<sup>1</sup>All the abbreviation’s explanation are summarized in Table 5 at Appendix for convenience.

Table 1: Examples of the relations between linguistic units

Example sentence: *She gave me a very happy smile and a hug.*

Abbreviation	Description	Relation example
SBV	Subject-verb	She <- gave
VOB	Verb-object	gave ->smile, gave ->hug
IOB	Indirect object	gave ->her
ATT	Attribute	happy <- smile
ADV	Adverbial	very <- happy
COO	Coordinate	smile ->hug

Dependency parsing is an NLP technique to reveal the syntactic structure of a sentence by analyzing the grammatical relations between linguistic units such as words. Examples of such relations include subject-verb(SBV), verb-object(VOB), indirect object(IOB), attribute(ATT), adverbial(ADV), coordinate(COO) and others (see detailed explanation and examples of these relations in Table 1). The result of the dependency parsing is represented as a rooted parsing tree. At the center of the tree is the verb of a clause structure, which is linked, directly or indirectly, by other linguistic units. The state-of-the-art dependency parser (e.g., Stanford parser [31]) can achieve a 92.2% accuracy in grammatical relation discovery from a sentence. In our study, we leveraged the parsing tree generated from sentences in a developer’s guide to locate the parties involved in a payment process and the content transmitted between them.

Word Embedding is a set of language modeling and feature learning techniques that map text (words or phrases) from a vocabulary to high-dimensional vectors of real numbers. Such a mapping can be implemented in different ways. The state-of-the-art word embedding tool, *Word2vec* [37], initializes word representations by random values and uses as its input a joint probability distribution of words’ context by applying a continuous Bag-of-Words or a skip-gram model. This distribution is then utilized during the training of a neural network, in which word vectors are continuously updated to maximize the joint probability. The outcome of the training ensures that related words are given approximate vectors for their similar contexts while irrelevant words are mapped into different vectors. In our study, we leveraged *Word2vec* to generate a semantic vector for each word and measured their semantic difference by cosine distance between vectors.

**Threat model.** In our research, we consider a malicious buyer who intends to get a product for free or at a lower price by exploiting the vulnerabilities in the payment process, particularly the logic flaws caused by incorrect or inadequate security checks on the merchant or the syndicator side. This adversary has the capability to modify or forge the messages delivered to both the merchant server and the syndicator.

### 3 Dilution: Design

#### 3.1 Overview

We believe that a critical security goal of a payment syndication is to ensure that all the security requirements made by the payment processor it wraps are met through proper

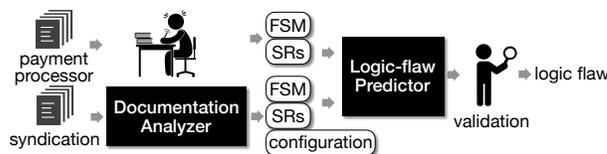

Figure 4: Architecture of our approach.

security checks, either by the merchant integrating the service or by the syndicator itself. The purpose of Dilution, therefore, is to identify from the developer’s guide of the syndication *indicators* that some SRs may fall through the cracks.

To this end, our approach is designed to compare the information observed by the syndicator and the merchant (including its app) with the SRs expected at individual states of the original payment process (e.g., that of Alipay), to determine whether either of the syndicator or the merchant has enough information to fulfill these requirements at the states. Also analyzed is whether these SRs have been explicitly stated in the developer’s guide provided by the syndicator, when related checks need to be done on the merchant’s side. More specifically, we first extract an FSM from the payment process, with some of its states associated with SRs and the parameters they are predicated on. This FSM is then extended to include the operations performed by the wrapper, based upon the information automatically recovered from the guide. Further using the text content related to each state of the extended FSM, we evaluate whether all parameters of each SR at the state are still visible to the merchant or the syndicator. Finally, our approach automatically analyzes the content of the guide to determine whether the SRs are explained to the developer.

**Architecture.** Figure 4 illustrates the architecture of Dilution, including a preprocessing component, *Documentation Analyzer* (DoA), *Logic-flaw Predictor* (LFP) and a validation component. The preprocessing step is done manually in our current system, which involves extraction of the FSM and label of SRs for a payment processor. Since our focus is the syndication service, so we consider this step as a one-time effort: for each third-party payment, the information identified can be used to automatically analyze tens of syndication services, each with a development guide containing hundreds of thousands of words. Such documentations are inspected by DoA, which utilizes NLP techniques to extend the payment FSM with the states representing the wrapper’s actions, and further recover the description for each SR from the guide. The extended FSM and the parameters are then analyzed by the LFP to identify the SRs that cannot be fulfilled by the merchant and the syndicator, and those that have not been properly explained to the developer. Also, the logic flaws predicted by LFP are validated on the merchant’s integration of the syndicator (the merchant’s app and its server-side component) to confirm the presence of these vulnerabilities.

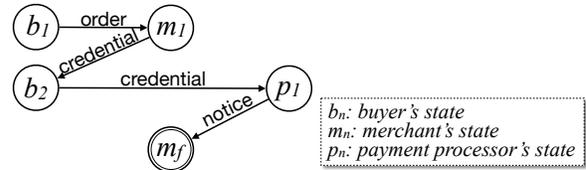

**Example.** Here, we use an example to describe how our approach works. Figure 5(a) shows Alipay’s FSM, with one of

its SRs at state  $m_f$  being verification of the payment amount against the price of an item. Analyzing the developer’s guide from Fuqianla (a popular syndicator), DoA discovers that the order has been sent to the syndicator, instead of the merchant (“The merchant client sends a payment query to the Fuqianla server”), and the notification from Alipay is delivered to the syndicator (“The Fuqianla server will receive a payment notification from the payment service”), before it is forwarded to the merchant. The semantics recovered from the text is then used to replace state  $m_1$  in Figure 5(a) with state  $w_1$  and add state  $w_2$  to the FSM, converting it to the syndication FSM as shown in Figure 5(b). This extended FSM and all the parameters it carries is then further inspected by LfP. Here let us look at the aforementioned SR at  $m_f$ . At this state, LfP concludes that the syndicator cannot check the payment amount, as it gets the price information from the buyer not the merchant, which cannot be trusted. On the other hand, though the merchant is at the position to make the security check, LfP cannot find a sentence, right after the description of the last communication (from  $w_2$  to  $m_f$ ), informing the developer about the SR, through a dependency analysis on all the sentences involving terms related to the subject (the merchant), the object (price and payment amount) and the expected action of the security check. This leads to the conclusion that the SR may not be communicated to the developer, and so may not be fulfilled on the merchant side.

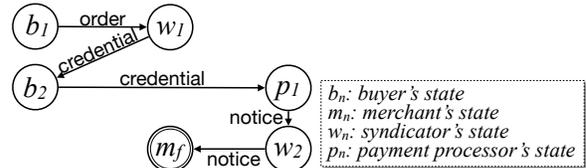

### 3.2 Preprocessing

As mentioned earlier, our approach involves a one-time preprocessing step in which the FSMs of major payment processors (Alipay, Wechat, PayPal, etc.) are constructed and the SRs for different states are identified. Such information can typically be found from these payment services’ integration guides. For example, Figure 11 at Appendix shows the excerpts from Alipay’s documents. Its payment process is clearly described through a diagram, which can be easily converted into an FSM. From the figure, we can also see the content for SRs, their parameters and the relations with the payment process. Following we present the FSM that models the payment process and the SRs. From such content, we extract the payment process model and security checks, as formally described below.

**Payment model.** The FSM for a payment process is described as a 5-tuple:  $(S, D, E, b_1, m_f)$ . Here  $S$  is a set of payment states, in each of which an actor (buyer  $b$ , merchant  $m$  or syndicator  $w$ ) can send out a message  $d \in D$ ;  $E : S \times D \rightarrow S$  is a function that drives the transition from one payment state to the next, given a specific message  $d \in D$  sent out from the former;  $b_1$  is the initial state in which the buyer places an order to start the whole payment transaction, and  $m_f$  is the final state that the merchant receives the last message and the transaction is complete. For example, Figure 5(a) illustrates such an FSM for Alipay.

(a) The FSM of the payment processor using Alipay

(b) The FSM of the syndication using Fuqianla

Figure 5: FSM examples of the payment processor and syndication.

**Security requirement.** A security requirement SR describes a security check that needs to be performed at a certain state: for example, at  $m_f$  of Alipay’s FSM (Figure 5(a)), the merchant is supposed to verify  $payment = price$ . As we can see from the example, central to the SR are the state ( $m_f$ ), subject (*merchant*), object (*payment*), a verification function (the *equal function* in the example) and additional parameters for the verification (*price*). However, in the context of the payment FSM, each state is bound to an actor who is actually the subject performing a security check. Further since all we care is the feasibility of fulfilling the SR at a given state, we just need to know whether all the inputs of the verification function (object and other parameters) are visible to the subject at the state, not the function itself. Therefore, we can simply model an SR as a 3-tuple:  $(SR_{state}, SR_{obj}, SR_{para})$ , to represent its state, object and other parameters for the expected security check. Note that the object and parameters here are *types of information*, i.e., the *key* part of a key-value pair. This is because all we want to know is whether the merchant at a state can see these keys (*payment* and *price*) so as to perform the required check; the outcome of the check, which depends on their specific values, is not important for our purpose.

### 3.3 Syndication FSM Discovery

With the FSM and SRs collected from a payment processor, we can run DoA to automatically analyze the developer’s guides of different syndication services that wrap the processor. Most important here is to discover the syndicated payment process through extending the payment FSM, which further allows us to find out whether the parameters of required security checks are still visible to the new states supposed to perform the checks, and how these security requirements are explained to the developer (Section 3.4).

**FSM extension structures.** Fundamentally, a syndication service is meant to support a merchant’s interactions with the payment service, in terms of generating the input for the

service and converting its output to a unified form easy for the merchant to interpret. This observation allows us to come up with a set of possible *extension structures*, which are then confirmed by the evidence extracted from the syndication’s document (its developer’s guide).

Specifically, given a payment processor’s FSM, we consider two types of states<sup>2</sup> that the syndicator can help:  $m$  where the merchant generates an input for the payment service, and  $m_f$  when the merchant receives the final notification from the payment service. More specifically, the operations at the state  $m$  can be assisted by a syndication state for input construction; payment notification the merchant finally receives at  $m_f$  can be converted by a syndication state first. Following this line of thinking, we can identify all possible extensions of  $m$  and  $m_f$ , which are present in Figure 6. As we can see here, for  $m$ , the extensions include the situations when either the merchant or the syndicator produces the full output of  $m$ , that is, the input for the payment service (see a.1 and a.4), and those when they jointly create the output (see a.2, a.3, a.5 and a.6). The latter can be further broken down into the cases when the same party receives and issues the messages related to  $m$  (see a.2 and a.5), or when different parties do (see a.3 and a.6). For  $m_f$ , since the payment process must end at this merchant state, only three situations exist: no extension (see b.1), the merchant getting the input (see b.2) and the syndicator receiving the original input (see b.3). DoA automatically inspects every merchant state and evaluates the consistency between each possible extension structure and the evidence discovered from the developer’s guide through NLP, to find out how the syndication indeed happens.

Taking the syndicator Fuqianla as an example (see Figure 5(b)), through inspecting its documentation, DoA determines that Fuqianla uses the extension structures a.4 and b.3 to wrap the payment processor. Specifically, its state  $w_1$  replaces the original state  $m_1$  to generate credential, which is an input for invoking the payment processor; the syndicator at state  $w_2$  receives the payment notification from the merchant and converts it to a unified form (across different payment services it supports) before forwarding it to the merchant at state  $m_f$ .

**Extension discovery from document.** The evidence collected from the syndication developer’s guide is the sentence that describes the message transferred from a sender to a receiver in the FSM (the buyer, the merchant, the payment provider and the syndicator). For example, from the sentence “the merchant client sends a payment query to the Fuqianla server”, we know that the payment query from the buyer has been sent to the syndication server, not the merchant, which confirms the existence of a transition from  $b$  to  $w$  in the extension structure a.5 and a.6 (Figure 6). Our idea is to find all

<sup>2</sup>Note that we are only interested in these states because per payment services’ guides [2, 17, 25], the inputs they accept are supposed to be generated by the merchant server and the outcome of a transaction will be delivered to the server.

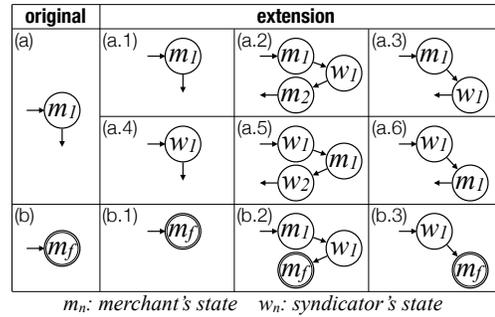

Figure 6: FSM possible extension structures.

such descriptions and extract their transition-related *semantic information*, in the form of (*Sender, Receiver, Content*), to identify all transitions introduced by the syndication and further determine the way merchant states have been extended.

For this purpose, we utilized a suite of NLP techniques to first find out all sentences related to transmission activities (e.g., including predicates like “send”, “receive”, etc.), then performs a syntactic analysis on each sentence and further converts detected syntactic elements to a *semantic triplet* describing the parties involved in a transition as well as the message sent (*Sender, Receiver, Content*). The challenges here come from the ambiguity of the descriptions and diversity of sentence structures in the developer’s guide. Particularly, we found that a variety of terms are used to describe message delivery and reception: not only common synonyms like “transmit”, “dispatch”, etc., but also those specific to the integration domains such as “call” (a remote function) and “invoke” (a remote client).

To identify those synonymous terms, we leverage the observation that such expressions, no matter how diverse they are, all share the similar context. For example, from the sentences “call the merchant API to place an order” and “send the order to the merchant”, we know that “call” and “send” are semantically close given their relations with ‘merchant’ and ‘order’. So in our research, we trained a *word embedding* model [18] over the documentations of two syndicators, Ping++ [12] and Fuqianla [8], and two payment service providers, Alipay [2] and Wechat Pay [17]. The model maps each word to a vector that represents its context. So the cosine distance between the vectors quantifies their semantic similarity. In our research we first manually collected a small set of “seeds”, words semantically related to “send” and “receive”, such as “call” and “invoke”, and then built a synonym list for these words with the embedding model we trained over the aforementioned documentations, using LTP [19] to segment Chinese words. These lists are utilized to identify sentences in a developer’s guide involving these transmission-related terms.

On each sentence discovered, DoA needs to extract its semantics – the triplet. For this purpose, we come up with a unique technique that utilizes dependency parsing (LTP [19]) to first identify a sentence’s syntactic elements (subject, object, etc.) and then determine their semantics (*Sender, Receiver,*

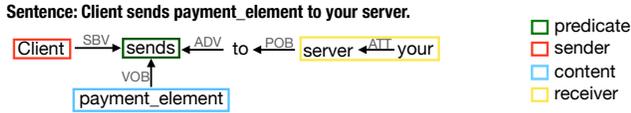

Figure 7: Entities in data-transmission related sentence.

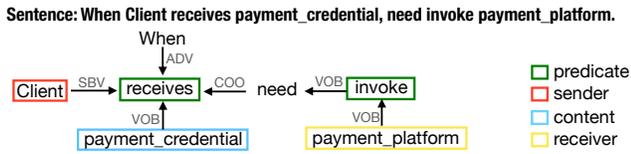

Figure 8: Entities in complex sentence.

*Content*). This is quite intuitive for a simple sentence. For example, Figure 7<sup>3</sup> shows the dependency relations between the predicate “send” and other words or phrases. As we can see here, the subject of the predicate (“client”) is *Sender*, direct object (“payment\_element”) is *Content* (the message delivered), and indirect object (“your server”) is the receiver. These elements can then be mapped to a transition on the FSM, based upon their semantic similarity with payment parties, as measured by the distances between their vectors. However, the semantics of the syntactic elements become more difficult to determine in the presence of more complicated sentence structures. For example, Figure 8 shows a complex sentence with multiple clauses, including both “When Client receives payment\_credential” and “(Client) needs to invoke payment\_platform”. In this case, the subject of “receives” (“Client”) becomes *Sender*, the object of “invoke” (“payment\_platform”) is *Receiver* and the *Content* in the sentence is found to be the object of “receives” (“payment\_credential”). To address this challenge, we trained an SVM classifier on a labeled dataset with transmission related sentences discovered from payment documentations and syndication documentations. The model uses the predicates and their relations (e.g., order) as features to predict their subject, object and indirect object’s semantic class labels (*Sender*, *Receiver* or *Content*).

Using the triplets recovered from the sentences, DoA continues to inspect each merchant state to determine whether and how it is extended by a syndicator. Specifically, for each transition in the extension structures described in Figure 6, denoted by  $s' = E(s, d)$ , we try to align *Sender* to the name of the actor at  $s$  (e.g., “merchant”), *Receiver* to the actor of  $s'$  (e.g., “syndicator”) and *Content* to  $d$  (representing message name here, such as “order”). Note that in the case any of these entities is described by a phrase, instead of a word (e.g., “payment element”), we calculate its *phase vector* as the average of its individual word vectors (e.g., those of “payment” and “element”). We consider that an alignment succeeds when all these elements are found to be similar to their counterparts on the transition. When this happens, we believe that

<sup>3</sup>Figure 7, Figure 8 and Figure 10 show Chinese grammatical relations between words. The words shown in the figure were translated from Chinese.

this transition exists in the extended FSM. To discover more transitions, our approach also leverages partial information collected, when only two elements of the triplet has been recovered. If one of these elements is *Content*, DoA still compares them against the transitions and confirms the presence of a transition if an alignment is found.

Based upon all the transitions discovered, our approach further determines the extension structure used by a syndication: the one contains all these transitions is selected. When there are more than one such structures, we consider that all such extensions are possible and predict the presence of potential logic flaws if one of them is found to be problematic.

### 3.4 SR Information Discovery

The syndication FSM discovered tells us how a payment transaction proceeds among the buyer, the merchant and the payment service provider, in the presence of the syndicator. To find out whether all security checks required by the payment service can be performed on this new FSM, we need to take a further look at the information visible to the states that need to fulfill these security requirements. Also to be understood is how the SRs are presented to the developers who are supposed to integrate these checks in merchant-side code. All such information has been automatically recovered from the syndication developer’s guide, as elaborated below.

**API parameter discovery.** At a syndication or merchant state a security check is expected to happen ( $SR_{state}$ ), the information required for the check ( $SR_{obj}$ ,  $SR_{para}$ ) either *comes from the message it receives* (e.g., *payment\_result*) or *is already in the possession of the syndicator or the merchant*. In the former case, the communication with the syndicator always goes through its APIs, as integrated in the merchant’s client or server side code. These APIs are documented in the developer’s guide and their attributes describe the information passed by a message. A question is how to determine which API is used in a transition. Such an API is explicitly mentioned in some sentences, such as “call the Creating Charge to invoke a payment processor”. In our research, we utilized a SVM model for labeling syntactic elements to detect the API names, which serve as the object of “call”.

However this approach turns out to be inadequate, since more often than not, a transition-related sentence in the developer’s guide does not include any API name: for example, “initiate payment”. In this case, we found that the semantics of the message name ( $d$  in the transition and its corresponding *Content*) is always highly related to the name of the API to be used. In the above example, an API “initiate payment” is responsible for sending the message of payment requirement. This is understandable since the guide is supposed to inform the developer how to establish communication with the syndicator. If this has not been done explicitly, using semantically related API names is an implicit way to do so. Our DoA automatically identifies such APIs using our

Figure 9: An excerpt of configuration HTML.

word-embedding model to compare the phrase similarity between each API name and  $d$  and  $Content$ . Again, here we utilized LTP [19] for Chinese word segmentation and word extraction from API names. Whenever an API is found to be semantically similar to either  $d$  or its related  $Content$ , our approach collects all its attributes and consider that their values have been exposed to the actor at the state receiving  $d$ .

**Configuration information extraction.** As mentioned earlier, the information for a security check can also be provided to the actor in a certain state before a transaction happens. For example, the merchant has her private key for signing a payment credential and she can also delegate this task to the syndicator by configuring her account on the syndication website. Such preconfigured information is documented by the developer’s guide. However, the details are often included in images, together with those irrelevant ones for explaining the payment or syndication service. Content extraction from these images using OCR [39] did not work well in our study. So our DoA is designed to discover the configuration data directly from the syndication website, the one from which we collect the developer documentation.

Specifically, our approach first searches for the entry link labeled with “Alipay configuration”, “Wechat Pay management”, “PayPal setup”, etc., the standard names for the configuration page on a syndication site, using named entity recognition and keywords (e.g., Alipay) together with synonyms for “configuration”, etc. On such a page, we inspect its HTML tags, looking for the input type – the entry item for the merchant to enter her data, and its inline header, which is the *key* for the data. Figure 9 shows part of the configuration page of Ping++ [12]. From the text entry identified, we can recover its header “Alipay public key” under the tag *h4*. Also as we can see from the example, other keys that can be found from the configuration page includes APP ID, seller account, etc. The information is gathered for comparing with SR parameters for a given payment service such as Alipay.

**SR description recovery.** Also important to logic vulnerability discovery is to find out whether required security checks have been properly explained to the developer. For this purpose, DoA has also been made to search for the description of the SRs for a given payment service. Such an SR is typically presented in a sentence: e.g., “The merchant should verify whether the payment amount equals to the order price.” From the sentence, we know that the merchant is the party responsible for this SR, so the check is supposed to happen on a merchant state ( $SR_{state}$ ), payment amount is the object

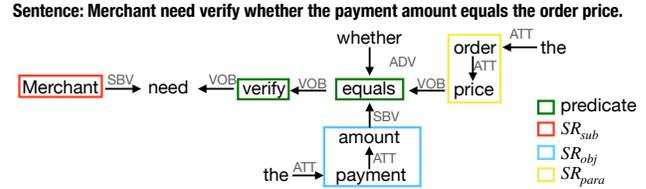

Figure 10: Entities in sentences describing SR.

( $SR_{obj}$ ) and the order price is the additional parameter for the security check ( $SR_{para}$ ). Our idea is to automatically discover all SR-related sentences based upon the actions to be taken, as we did in the FSM extension discovery (see Section 3.3), and then perform a syntactic analysis to discover  $SR_{obj}$  and  $SR_{para}$ , before finally determining the state of the potential check ( $SR_{state}$ ).

Specifically, to find all SR-related sentences, our approach first utilizes a small set of *seed action terms* including “check”, “match”, “verify”, etc., and runs our word-embedding model on the training documents (guides for syndication and payment services) to extend these seeds with their synonyms. Then DoA inspects a given document to collect all the sentences containing the term(s) on the list. Each of them is analyzed using dependency parsing to label the subject, object and indirect object of the action term (“verify”, “check”, etc.), as demonstrated by the example in Figure 10. Given the fact that the developer’s guide is meant to explain implementation details to the developer working for the merchant, we expect that an SR-related subject should be “merchant”, “developer”, “you”, and their synonyms (e.g, “seller”, “verdor”, etc.). Also we consider the merchant to be the subject of all imperative sentences, e.g., “please make sure that the payment amount equals to the order price”. From these sentences, we further identify the object and indirect object (if exists) of the predicate, and label them as potential  $SR_{obj}$  and  $SR_{para}$ .

Before we can report possible SR-related description, we also need to determine the state for the potential security check ( $SR_{state}$ ). Our approach is to look at where the sentence is found: intuitively a reminder of a security check should appear under the context of state transition. For example, the sentence “The merchant needs to verify whether the payment amount matches the order price.” comes right after “The syndicator will send a Webhook request to the merchant server.” in Beecloud [6]. So for each potential SR-related sentence, DoA tries to locate a transition-related sentence in the same paragraph, before the SR sentence. Once the transition is found, we further check whether its destination is a *merchant* state, so the merchant is supposed to perform the security inspection mentioned in the sentence. In this case, we set  $SR_{state}$  to that merchant state.

The only other place where security check description can be found is the specification of the API used for the state transition. For example, under the API “Transaction-result-notification” (iAppPay [9]), there is a note that reminds the developer to inspect payment: “Please verify the transaction

payment is the same as the product price”. So when the SR-related sentence is discovered in such a specification, we look at the state the API leads to, and make it  $SR_{state}$  if it is a merchant state.

### 3.5 Logic-flaw Prediction and Validation

From the FSM and the SR information discovered from the syndication documentation, LfP infers the possible presence of logic flaws: the SRs expected by the payment processor (e.g., Alipay) that cannot be fulfilled in the syndication FSM, and those that have not been explained to the developer. Following we explicate how to determine the states expected to perform the required security checks, how to evaluate whether the checks can take place, and how to capture the SRs that have not been properly communicated to the developer.

**Security goals.** Consider a syndicator  $W$  that wraps a payment service  $P$ . We believe that  $W$  needs to achieve the following two security goals:

- *Secure Design (SD)*: for any security requirement  $SR$  to be enforced at a state  $s$  of  $P$ , there exists an *enforceable*  $SR'$  at the state  $s'$  of  $W$  such that  $SR$  and  $SR'$  are equivalent except their states, and  $s'$  is a state in the extension structures for  $s$  (Figure 6). Intuitively, this means that every payment SR should still be fulfilled after syndication.
- *Secure Implementation (SI)*: every  $SR$  of  $W$  is correctly implemented by either the merchant or the syndicator.

To achieve SD, for every  $SR$  of the state  $s$  in the payment FSM, LfP first identifies all extended states of  $s$  and then inspects each of them  $s'$  to determine whether the state has the *visibility* of the object ( $SR_{obj}$ ) and other parameters ( $SR_{para}$ ) of  $SR$ . As mentioned earlier,  $s'$  is identified by the extension structures (Figure 6). Any state among these replacing  $s$  is considered to be a possible location for enforcing  $SR$ . As an example, consider  $b.3$ , which is an extension of  $b$ , and  $SR = (m_f, payment, price)$ , which checks  $payment = price$ . This inspection can happen at either  $m_f$  or  $w$ , when at least one of them can observe both  $payment$  from the payment service (e.g., Alipay) and  $price$  from the merchant.

For SI, without looking at the code of the extended FSM, LfP goes through the developer’s guide for the indicators that could lead to implementation flaws. The most important one used in our current design is the absence of the explanations about SRs, a clear signal that the related security checks might not be implemented by the uninformed developer. Also we are concerned about the SRs that can only be enforced by the syndication state, since they are out of the merchant’s control. So in both cases, LfP will predict potential logic flaws and suggests a code-level validation.

**Design flaws identification.** When none of the states in the extension structure of a payment state can observe  $SR_{obj}$  and  $SR_{para}$  for a security requirement  $SR$ , we can conclude that the syndication service contains a design flaw. To detect such a flaw, LfP needs to analyze visibility of data at each exten-

sion state. As mentioned earlier, such data either comes from the message a given state receives, whose content is described by all the attributes of the API used for transmitting the message (Section 3.4), or preconfigured by the merchant in her syndication account, with all data attributes (APP ID, public key, seller account, etc.) discovered by DoA. Our approach directly compares these attributes with the SR information. Note that *only the data delivered through a secure channel and from a trusted source can be used in a security check*: for example, the payment amount should be signed by the payment provider and the price should come from the merchant (through preconfiguration, signed message or local storage).

Specifically, at a given extension state, let  $TA$  be a set of *trusted* message attributes (e.g., signed by the payment provider) as collected from related API specifications, and when the state is controlled by the syndicator,  $TC$  be a set of collected attributes for preconfigured merchant information. Also, we abuse notations a little bit, using  $SR_{obj}$  and  $SR_{para}$  to represent the *sets* for the object and for the additional parameters, respectively, of a given security requirement  $SR$  at that state. The objective of LfP is to find out whether there exists an extension state such that for a given  $SR$  on the corresponding payment state,  $SR_{obj} \cup SR_{para} \subseteq TA \cup TC$  for the  $TA$  and  $TC$  of the extension state ( $TC$  includes all the local data for a merchant state). If none of such an extension state can be found, LfP reports that the SR can no longer be enforced and therefore a design flaw is detected.

For a data attribute (e.g., “price”, “public\_key”, etc.)  $a \in SR_{obj} \cup SR_{para}$ , it is *nontrivial* to determine whether it is also in  $TA \cup TC$ , simply because the attribute names of the SR collected from a payment service (e.g., Alipay) may not match those included in the message API and the configuration web page. Our solution here, again, is using our word-embedding model to product a semantic vector for  $a$  and then find whether there is an attribute in  $TA \cup TC$  whose vector is sufficiently close to that of  $a$ . When every attribute of the SR can find its counterpart in  $TA$  or  $TC$ , we consider that the SR is enforceable at the current extension state.

**Implementation flaws prediction.** As mentioned earlier, implementation flaws can also be predicted when a required security check has not been properly communicated to the developer. LfP is designed to inspect the SR descriptions recovered by DoA to identify such missing security guidance.

Specifically, for each  $SR$  enforced at the state  $s$  in the payment FSM, LfP searches across all security requirements discovered from the guide by DoA for those associated with the extension states of  $s$ . Let  $SR'$  be such a requirement. Our approach tries to determine whether  $SR_{obj} = SR'_{obj}$  and  $SR_{para} = SR'_{para}$ . Again, here we need to deal with the inconsistency in attribute names during the comparisons, which has been addressed in our implementation using our word-embedding model and distance measurement between semantic vectors. If  $SR'$  here indeed matches  $SR$ , we have reason to believe that the developer knows the security check required

by the payment provider. If such  $SR'$  cannot be found, then we know that such information has not been conveyed to the developer. When the  $SR$  can only be enforced by the merchant, LfP will raise the alarm since we doubt that an uninformed developer can make the protection right.

Even when all the  $SR$ s are found to be enforceable on the syndication FSM and all merchant-side  $SR$ s are properly mentioned in the developer's guide, we are still concerned about the security checks that can only be performed by the syndicator, who does not mention that this has actually been implemented. Given the fact that the merchant essentially loses the control of these security checks that they could do without the syndication, we believe that these  $SR$ s should be evaluated to ensure that they have been put in place. So our current implementation of LfP also reports all such  $SR$ s, which are evaluated during the validation step.

**Validation.** Fully automated verification of our predicted flaws is possible but nontrivial, due to the requirements of entering user credentials (password, fingerprint) to trigger a payment process and handling diverse user interfaces in different mobile apps for entering purchase information (product, quantity, address, etc.). Although existing GUI testing tools could be enhanced to serve this purpose and likely industry-grade fuzzers can already support these operations, building such techniques are outside the scope of our research. So we manually validated all the flaws predicted by Dilution. Specifically, based upon the specific security requirement that we consider hard to enforce, we acted as a malicious buyer to adjust the payment parameters to find out whether the predicted flaw can indeed be exploited. As an example, consider the payment process in Figure 5(b). Dilution predicts an implementation flaw that the merchant does not check the payment amount. In our research, we set a lower price in the *orderInfo* given to an app. This transaction got through (Section 5.2), which confirmed the presence of the flaw we predicted.

## 4 Implementation and Evaluation

### 4.1 Implementation

Dilution is implemented in a prototype. In the DoA, we employ Language Technology Platform (LTP) [19], for word segmenting, POS tagging and dependency parsing to analyze the sentences. To adopt the open domain toolkit to payment document analysis, we craft external dictionaries containing 48 domain-specific terms (e.g., payment element and payment credential) in the payment process to improve the performance of word segmenting and embedding. Taking the results of dependency parsing as features we further implement the classifier for entity recognition with LIBSVM [30] in version 3.23. To map words into vectors we utilize the word2vec model in Gensim library [18] in 3.7.1 version. Moreover, we ran the crawler *Scrapy* [44] in version 1.6 to crawl all the web pages of syndications' official websites, and then utilize the *BeautifulSoup* [42] in version 4.4.0 to parse webpages

and extract the developer's guides and configuration. For the LfP, we implement with 404 lines of Python code for interring the supposed  $SR$ s and inspecting each of them to predict flaws. We are going to release the source code of Dilution online [14].

### 4.2 Experiment Settings

**Dataset.** In our research, we utilized four datasets for model training and evaluation:

- *Groundtruth set.* The groundtruth set was used for logic flaw detection, entity recognition and phrase alignment.

For logic flaw detection, the groundtruth set includes two syndication documents (Ping++ [12] and Fuqianla [8]) and their corresponding 17 potential logic flaws. In particular, we manually analyzed the documents and identified 11 implementation flaws in the documentations of syndication Ping++, 1 design flaw and 5 implementation flaws in the documentation of syndication Fuqianla, as elaborated in Section 5.

The groundtruth set for entity recognition in the payment process consists of 574 entities (148 *Sender*, 175 *Receiver* and 251 *Content*) from 242 sentences describing data transmission. These sentences were collected from a training corpus including documents of two payment services Alipay and Wechat and two syndicators Ping++ and Fuqianla. We implemented a 2-fold cross validation with half of the data as the training set each time.

We manually labelled the groundtruth set for phrase alignment upon the syndication documents of Ping++ and Fuqianla, which contain 14 data-transmission sentences, 103 APIs and 1,986 parameters in total. The groundtruth set includes 63 and 203 positive pairs, and 45 and 40,866 negative pairs in transition mapping for extension discovery and API parameter discovery, respectively.

- *Unknown syndication documents.* To evaluate *Dilution*, we ran our prototype on the developer's guides of six syndications, including Paymax [11], BeeCloud [6], iAppPay [9], Trpay [15], UMF Payment [16] and 66zhifu [1]. These documents consist of 3,613 sentences and 46,098 words in total. They are all publicly available, well-written documentations including the description of data transmission in payment processes, API parameter explanations,  $SR$ s and configuration information. Note that those services are popular, serving tens of thousands apps and millions users.

- *Third-party payment documents.* The third-party payment documents we manually analyzed to extract FSMs and  $SR$ s come from Alipay, WeChat Pay and PayPal, which are the three most popular mobile payment services in the world [45]. We read all the related documentations about the payment process and searched keywords related to  $SR$ s including "security", "requirement", "check", "inspect", "compare" to collect all the  $SR$ s. Three experts spent 2 days to finish the extraction and the  $SR$ s are validated across all three experts. The detailed  $SR$ s are summarized in Table 2.

Table 2: Security requirements of payment service

$notify_{id}$ : The id of a notification,  $seller_{id}$ : The id of a seller,  $txn_{id}$ : The id of a transaction,  
 $receiver_{email}$ : The account of the merchant,  $mc_{gross}$ : The amount of a payment,  $mc_{currency}$ : The currency of a payment.

Payment Service	No.	SR description	SR
Alipay	SR1	Check the signature in the notification.	$(m2, notification, key)$
	SR2	Check the $notify_{id}$ to verify the message comes from Alipay.	$(m2, notify_{id}, 0)$
	SR3	Check the price in the notification is the same with the amount in the order.	$(m2, payment, price)$
	SR4	Check the $seller_{id}$ represents the supposed merchant.	$(m2, seller_{id}, merchant)$
WeChat Pay	SR5	Verify the signature in the payment notification message.	$(m2, notification, key)$
	SR6	Check the price in the notification equals the price in the order.	$(m2, payment, price)$
PayPal	SR7	Verify the message came from PayPal.	$(m2, message, 0)$
	SR8	Check the $txn_{id}$ against the previous PayPal transaction that you processed to ensure the IPN message it not duplicate.	$(m2, txn_{id}, previous\ txn_{id})$
	SR9	Check that the $receiver_{email}$ is the email address registered in your account.	$(m2, receiver_{email}, registered\ email)$
	SR10	Check that the price carried in $mc_{gross}$ are correct for the item.	$(m2, payment, price)$
	SR11	Check that the currency carried in $mc_{currency}$ are correct for the item.	$(m2, receipt\ currency, supposed\ currency)$

• *Payment corpora for word embedding model training.* For training the word embedding model, we built a corpus for payment service by combining two payment documentations (Alipay, Wechat) and two syndication documentations (Ping++, Fuqianla), which were crawled from the corresponding websites. After word segmenting, the training corpus contains 1715.2 KB text with 23,576 sentences and 306,680 words.

**Parameters.** The parameters for our implementation are set as follows:

- *Entity classifier.* We implemented the classifier for entity recognition with LIBSVM [30]. The classifier was trained with the following settings:  $c=8.0$ ,  $g=0.5$  and default settings.
- *Word2vec.* We utilized skip-gram with negative sampling as the framework of the word2vec model, which was trained with the following parameters:  $sg=1$ ,  $size=100$ ,  $sample=0.0001$ ,  $window=10$ ,  $iter=5$ ,  $min\_count=1$ ,  $negative=20$  and other default settings.
- *Threshold.* We utilized phrase similarity to find out whether two phrases are semantically close. For payment-related expressions (e.g., `payment_element`, `payment_credential`), the threshold used in transition mapping, API name matching and parameter matching were set to 0.91, 0.91, and 0.97 respectively. As for other phrases, the threshold in three tasks were set to 0.87, 0.87, and 0.96, respectively.

**Platform.** All the experiments in our study were conducted on the macOS with 2.3GHz CPU, 16GB memory and 512GB hard drivers using a single process.

### 4.3 Effectiveness

We first evaluated the overall effectiveness of our prototype in predicting potential logic flaws from documentations. Running on both the groundtruth set (Ping++ and Fuqianla) and the unknown dataset containing six syndicators, Dilution achieved 100% accurate predictions. More specifically, on the six unknown documentations, our system predicted 1 design flaw and 16 potential implementation flaws. We manually verified each of them and found that all reports were correct (based upon the descriptions in the documentations).

Further, we evaluated the two internal modules of DoA: en-

tity recognition and API parameter discovery. The evaluation for entity recognition was run on the groundtruth set for entity recognition (242 data-transmission related sentences with 574 entities including 148 *Sender*, 175 *Receiver* and 251 *Content*). Under the two-fold cross validation, our model achieved a precision of 89.38%, 93.28%, 94.57% and a recall of 96.88%, 97.72%, 96.81% when taking *Sender*, *Receiver*, *Content* as the positive class, respectively. The effectiveness of our model is acceptable since our algorithm for discovering the state extension is capable of addressing the false positives and false negatives induced by entity recognition through alignment with the transitions in the extension structures (Section 3.3). As for the API parameter discovery, the experiment results on the guides of all eight syndications show that all phrase pairs aligned by DoA are accurate.

### 4.4 Performance

We ran Dilution on the developer’s guide of 8 syndications (1,456KB) to predict the presence of logic flaws. Averagely, our system spent merely 3,177.8 ms to go through the whole process on one syndication. The time of the analysis ranges from 2,743.2ms to 3,873.8 ms, with the medium being 3,099.1 ms. More specifically, DoA spent 2,738.8 ms to 3,840.0 ms with an average of 3,166.2 ms. LfP took 2.9 ms to 33.8 ms with an average of 11.6 ms. This result offers strong evidence that Dilution can easily scale to the level expected for processing a large amount of documentation.

## 5 Discoveries in the Wild

In this section, we report the logic flaws predicted by Dilution from the developer’s guides of real-world syndication services and the end-to-end exploits to validate the predictions through popular merchant apps. We show that our document-only predictions are indeed accurate, leading to the discovery of security-critical vulnerabilities.

### 5.1 Finding from Documentations

There are more than 30 syndication services, with the number continuing to grow. However, most of them provide developer’s guides to paid users only. Actually we found that just

Table 3: Summary of predictions by Dilution

(DF: design flow, IF: implementation flow, CI: cases of interest)

(a) design & implementation

(b) cases of interest

Syndication	Type	SR No.	Syndication	Type	SR No.
Fuqianla	DF	1	Ping++	CI	1 - 11
	IF	3, 6	Fuqianla	CI	2, 4, 5
BeeCloud	DF	1	Paymax	CI	1 - 6
	IF	11	BeeCloud	CI	2, 4, 5, 7, 8, 9
TrPay	IF	3, 6	iAppPay	CI	2
UMF Pay	IF	3, 6	TrPay	CI	2
66zhifu	IF	3, 6	UMF Pay	CI	2
Total	DF	2	66zhifu	CI	2
	IF	9	Total	CI	30

8 of them have well-documented guides publicly available. These syndicators are all popular, with hundreds of millions of users. In our research, we ran Dilution on all of their guides (over 1.4 MB), which reported its findings in a few seconds.

**Landscape.** Table 3 shows all the syndications we analyzed and the logic flaws predicted. Specifically, Dilution reported 41 potential issues from all the syndications. Among them, 11 are highly likely to be logic flaws, including 2 design flaws (in BeeCloud and Fuqianla), in which required security checks cannot be done, and 9 likely implementation flaws, with critical security checks missed in the guides. In addition, the remaining 30 are “cases of interest”, since their SRs can only be or should be fulfilled by syndicators if merchants cannot achieve them or do not be told. Therefore they are considered to be risky and need to be validated.

**Design flaws.** Among all the syndication services, BeeCloud and Fuqianla are found to contain a design flaw each (SR1 in Table 2). Specifically, Dilution reported that these syndicators receive payment notifications from Alipay on behalf of their merchants, helping them finish the final security checks before informing them of the completion of the transactions. The problem is that the merchants of these services cannot configure their Alipay’s verification keys<sup>4</sup> to the syndicators. As a result, the syndicators cannot check the authenticity of the messages, nor can their merchants, since they do not get the signed notifications. We further found that the practice of processing payment messages for the merchants without forwarding them the original messages is very common across all syndications we studied. This is because the syndication aims to unify the merchant-side interfaces with different payment services to reduce the complexity in integrating them, which, however, makes the syndicator-side operations complicated and error-prone. Although only two design flaws were revealed by Dilution, due to the small number of syndicators we evaluated, we believe that the practice likely brings in design lapses to other syndication services.

**Implementation flaws.** Dilution predicted 9 potential implementation flaws by the merchant developers in 5 syndication services. Specifically, our approach found that the syndicators Fuqianla, TrPay, UMP Pay and 66zhifu cannot verify the

<sup>4</sup>Each merchant has a unique key-pair for verifying the messages from Alipay.

payment amount since they do not have access to the price of a purchase. In the meantime, they fail to remind their merchant developers of enforcing the security requirements (SR3 and SR6) through verifying the amount. Similarly, BeeCloud encapsulates PayPal but does not tell its merchant that the currency type for a purchased item needs to be checked. As a result, we believe that very likely the required security checks will fall through the cracks.

## 5.2 Attacks on Real-World Systems

**Challenges in validating predicted flaws.** To find out whether the predicted logic flaws are indeed present in syndicators or the merchant-side code, we need to validate them through merchant apps. This attempt, however, faces two challenges. First, finding the apps integrating a given syndication is difficult. Even though these services are popular (e.g., at least 25K apps using Ping++), with tens of millions of users according to their websites, rarely do they provide a list of the merchants that use their services. Actually, most syndicators ask their merchant developers to obfuscate their code, possibly for the purpose of IP protection [29]. Second, even given an app integrating a syndication, exploiting its logic flaws may need additional resources we do not have and some of the flaws may not even be exploitable in the absence of other flaws. Particularly, in 7 out of the 30 cases of interest reported by Dilution, we need to produce Alipay’s signature on the payment notification to confirm whether the syndicator (e.g., Paymax) indeed fails to perform a security check (e.g., on the payment amount), since the syndicator may still verify Alipay’s signature. The exploit can only be executed with the help of a merchant under our control: we can make a purchase from our own merchant and use the notification to determine whether the syndicator indeed verifies its attributes (e.g., payment amount). We manually analyzed our findings and believe that if the predicted flaws are there, we can exploit them in this way. However, merchant registration (with Alipay) is complicated, which we did not do in our research.

Despite the challenges, still we were able to find 17 apps to confirm 5 logic flaws across 2 syndication services and their merchants. These 17 apps were found from over 50K apps we analyzed. Most importantly, *for every merchant app that could be analyzed, every single logic flaw or case of interest predicted by Dilution has been confirmed.* Specifically, we randomly crawled over 50K apps from the Baidu Market, a top Chinese app market [5], and ran Apktool [3] to reverse-engineer them. The 17 were found because the names of their syndication SDKs or the domains of syndication servers have not been obfuscated. Among them, 16 use BeeCloud [6] and 1 uses TrPay [15]. Both the syndication services and the apps are very popular. As shown in Table 4 in Appendix, BeeCloud claims to have tens of thousands merchants, and these apps have hundreds of millions of users. In our experiment, we ran a proxy called Burp Suite [7] and a network API testing tool called Postman [13] to modify or forge the messages

delivered from the apps or our site to the merchant or the syndicator server.

**Attacks on design flaws.** As mentioned earlier (Section 5.1), Dilution reported two design flaws, one for BeeCloud and the other for Fuqianla, in which the syndicator cannot verify Alipay’s signature on a payment notification due to its lack of the verification key. In our research, we could not find the app using Fuqianla possibly due to the obfuscation it suggests to its users [23]. The 16 apps using BeeCloud, however, were predicted to all have the *same* logic flaw. Therefore, we just randomly picked one of them, a Chinese education app called Chuangyebang [21], for the validation. Specifically, we placed an order for an online class provided by the app without payment, then used Postman to forge an unsigned Alipay’s notification and delivered to the BeeCloud server. As predicted, the syndicator accepted the fake message and we successfully got the digital product for free<sup>5</sup>. This demonstrates that the design flaw is real and exploitable, which has a serious consequence given the fact that BeeCloud is serving tens of thousands of merchants [28]. Actually, the 16 apps we collected have 82.8 million downloads in total, selling products ranging from 0.1 dollars to 2,000 dollars. Even Changyebang is reported 490,000 installs.

**Attacks on implementation flaws.** Also we were able to find a Chinese tool app called OffPhone [24] (with 830,000 downloads) that integrates TrPay, another popular syndication service [15] wrapping WeChat and Alipay payment services. This enabled us to validate 2 potential implementation flaws that Dilution predicted. Both problems happen at the final state  $m_f$  (one for WeChat and the other for Alipay), where the merchant is supposed to check the payment amount, which the developer’s guide of TrPay fails to mention. Since in both cases, the syndicator generates the credential (including the price of the order) for payment at WeChat or Alipay, based upon the order issued through the app, the adversary can control the app to provide wrong price information to mislead TrPay into producing a credential with a lower price. If the payment amount reported by WeChat Pay or Alipay has not been verified by the merchant (OffPhone) at  $m_f$ , the adversary can get the item with the price she set. In our experiment, we modified the order placed through the OffPhone app to reduce the price of a VIP membership from 5 dollars to just 1 cent, causing TrPay to send a credential to the payment services. In the end, both transactions went through, which indicates that indeed the payment amount has *not* been checked by the merchant, as Dilution predicted.

Furthermore, Dilution also reported 2 “cases of interest” in BeeCloud, where the syndicator is supposed to perform some security checks on behalf of the merchant. Specifically, we found that on receiving the payment notification from Alipay, BeeCloud only passes some of the notification content to the merchant. An attribute not being forwarded is

*notify\_id*, the merchant’s identity issued by Alipay for finding out whether the merchant is the right recipient of the notification. Also, although another attribute, *seller\_id*, serving the same purpose is indeed sent to the merchant, BeeCloud fails to mention in its developer’s guide that the attribute should be verified. Both attributes are *required* to be inspected by Alipay [2]. Here, we tried to find out whether the checks have been done by BeeCloud on the merchant’s behalf. For this purpose, we randomly selected another app from the 16 apps, called Clean [22], a memory cleaner with 850,000 downloads, to find out whether the SR2 and SR4 in Table 2 have been enforced. In the experiment, we ran Postman to fake a payment notification including a random *notify\_id* and *seller\_id*, which did not prevent our payment transaction from getting through. In the end, we got a paid version of the app (without Ads) for free. The same attack also succeeded on Chuangyebang. Evidently, not only does BeeCloud fail to verify *notify\_id* and *seller\_id*, but Clean (the merchant) does not check *seller\_id* either, in line with the predictions made by Dilution. These flaws open the door for an attack in which one pays for her own merchant while getting product from a different store [49]. Also note that since the merchant is not given *notify\_id*, remaining 15 apps and others using BeeCloud are certain to have the same flaw.

**Responsible experiment design.** We carefully designed our end-to-end attack in a responsible manner. The entire study was conducted under the guidance of a lawyer at our University. We strictly followed the principles below when attacking the real-world apps and services: (1) we performed no intrusion of either merchant servers and syndicator servers; (2) we ensured that no financial damage caused by returning items, paying the shipping costs, not getting refunded, not using electronic products, paying for items hard to return; (3) we reported all security flaws to affected apps and syndications and did what we could to help them improve their systems. All the flaws discovered have been acknowledged by the syndicators and merchants, who are very grateful for our help.

## 6 Discussion

**Limitations.** Our research demonstrates that logic flaws can be predicted from the developer’s documentation, even before the system code is inspected. This finding can lead to new techniques that make full use of information available for enhancing software security. Our current design and implementation, however, are still preliminary. We only focus on the payment syndication service with limited targets on missing security checks. More complicated flaws, such as policy enforcement weaknesses (possibly caused by inaccurate guidance), and more complicated service procedures (e.g., refund, bonus, etc.), are all missing from the picture, not to mention documentation-based analysis on other security-critical systems. Further, the NLP techniques underlying Dilution can only deal with well-written documents, not those containing

<sup>5</sup>All the exploit video demos are post online [4].

typos, grammatical errors, ambiguous sentence structures, etc. as observed in real-world developer's guides. Also, our current approach still needs human involvements: particularly, we extracted SRs and FSMs of payment processors manually, which has two reasons. First, the number of payment processors is small. Second, we want the extracted SRs and FSMs to be precise, based on which we built syndicators' FSMs and predicted logic flaws. However, we envision it's possible to automate this process using open-source NER tools. All these issues need to be addressed in the future research.

**Future research.** Down the road, we expect more explorations on this new direction, toward the end of an intelligent, semantics-based methodology that combine documentation-level and code-level analysis together for more effective flaw discovery. In addition to the direct improvement of our approach mentioned above, we envision that document-based flaw prediction will be applied to secure other syndication services, those for single sign-on services in particular, such as MobSDK [10]. More importantly, we believe that with the help of machine learning and automatic inference, other subtle, semantics-dependent weaknesses only detectable by experienced analysts today will become increasingly manageable by automatic techniques, leading to a significant improvement in software security quality.

## 7 Related Work

Numerous studies have looked into logic flaw detection in various applications. For example, [49] discovered logic flaws of the payment service. [48, 50] investigated logic flaws on authorization. Traditional logic flaws discovery heavily relies on domain experts [33]. Recent year witnesses the trend of automatic logic flaw detection, mainly based on model checking. The typical approach based on model check first standardizes a logic process, and then detects whether the application violates the predefined logic. For instance, both [41] and [32] automatically extracted a model from a number of correct behavioral patterns. Then, they checked the source code statically, using model checking over symbolic input to identify violated program paths. [34] manually summarized the correct usage of OpenSSL APIs and then statically analyzed whether an application violates the correct usage. Different from previous researches, our approach does not touch program code and automatically utilizes only documentation to predict logic flaws.

The closest to our study are the works of payment logic flaw assessment [49] [51]. [49] is the first work, which relies on human effort, to discover serious payment logic vulnerabilities and reveal their security implications. A set of follow-up studies identified different types of payment logic flaws in various applications. For instance, [51] extended the work of [49] to investigate the logic flaws in mobile payment and detected seven security rule violations to the payment in Android apps. [46] detected violations of the invariant in secure

checkout processes, which revealed 11 new logic vulnerabilities in web payment modules. Given these studies, a bunch of policies and guidelines for secure online shopping were investigated [38, 40]. In contrast to previous works, which assessed logic flaws by manual efforts, we report the first work towards automatic payment logic flaw discovery. Also, we investigate a novel payment service, payment syndication, which has never been studied before.

## 8 Conclusion

In this paper, we report the first step towards automatic documentation-based logic flaw discovery. Our study on the emerging payment syndication services shows that their developer's guide contains abundant information that can be leveraged to predict the presence of logic flaws in their customers' systems. Using a suite of NLP techniques, our approach effectively analyzed over 1.4 MB of technical documentations from real-world syndicators within seconds, and accurately predicted 5 new security-critical flaws in the Chinese merchant systems with millions of users. The research demonstrates that software documentations can be more effectively used to help find the security risks hard to automatically detect today.

## Abstract

A new type of malicious crowdsourcing (a.k.a., crowdturfing) clients, mobile apps with hidden crowdturfing user interface (UI), is increasingly being utilized by miscreants to coordinate crowdturfing workers and publish mobile-based crowdturfing tasks (e.g., app ranking manipulation) even on the strictly controlled Apple App Store. These apps hide their crowdturfing content behind innocent-looking UIs to bypass app vetting and infiltrate the app store. To the best of our knowledge, little has been done so far to understand this new abusive service, in terms of its scope, impact and techniques, not to mention any effort to identify such stealthy crowdturfing apps on a large scale, particularly on the Apple platform. In this paper, we report the first measurement study on iOS apps with hidden crowdturfing UIs. Our findings bring to light the mobile-based crowdturfing ecosystem (e.g., app promotion for worker recruitment, campaign identification) and the underground developer's tricks (e.g., scheme, logic bomb) for evading app vetting.

## 1 Introduction

*Crowdturfing* is a term coined for underground crowdsourcing [44], in which an illicit actor (typically a cybercriminal) hires a large number of small-time workers to perform questionable and often malicious tasks online. Supporting such an operation is a crowdturfing platform, the underground counterpart of Amazon Mechanical Turk [1] that acts as an intermediary for the cybercriminal to recruit small-time workers for the hit jobs like creating fake accounts on an online store, posting fake Yelp reviews, spreading rumors through Twitter, etc. These attacks damage the quality of online social media, manipulate political opinions, etc., thereby threatening the public confidence in the cyberspace, which is the very foundation of the open web ecosystem.

**Mobile crowdturfing.** With the fast growth of mobile markets today, crowdturfing is extending its reach to mobile computing, serving illegal missions like inflation of an app's rating or mass collection of coupons or other bonus during a sales promotion. For this purpose, a mobile client (app) needs to be deployed to a large number of underground workers. Such an app, however, is prohibited by both Apple and Android

\*The two lead authors contributed equally to this work.

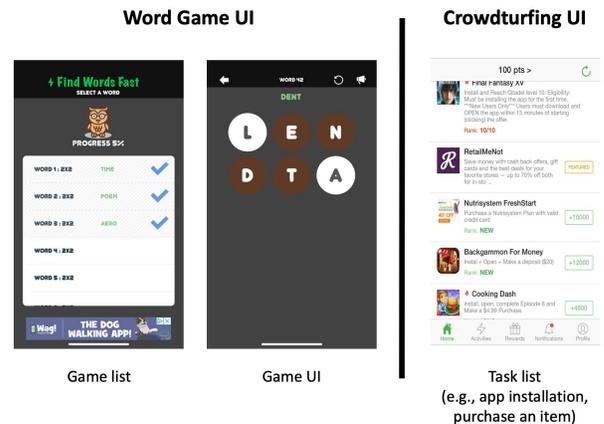

Figure 1: A Word Game with hidden crowdturfing UIs.

app stores according to their guidelines [21, 28], and will be taken down once detected. Although dissemination of the crowdturfing apps is still possible in the fragmented Android world, through less regulated third-party stores, on the Apple platform, cybercriminals find it hard to reach out to the iPhone users, due to the centralized app vetting and installation enforced by the Apple App Store. To circumvent this security check, it has been reported [52] that crowdturfing Trojans have been increasingly used to infiltrate the iOS App Store, through embedding stealthy crowdturfing user interfaces (UI) in innocent-looking iOS apps. An example is shown in Figure 1. Compared with *web-based crowdturfing* [37, 45, 46, 49], these apps are used to deliver mobile based crowdturfing tasks, such as fake app review and app ranking manipulation. Also, they are characterized by utilizing hidden UI techniques to bypass app vetting and deliver tasks for their small-time workers, which raise the challenges for finding them. So far, little has been done to systematically discover and analyze such hidden crowdturfing apps, not to mention any effort to understand the underground ecosystem behind them.

**Finding crowdturfing apps.** In this paper, we report the first measurement study on iOS crowdturfing apps. The study relies on the discovery of such malicious apps from the Apple App Store, which is challenging, due to the difficulty in identifying their elusive hidden UIs. These UIs are under the cover of benign ones and can only be invoked under some specific conditions (e.g., time, commands from C2 servers).

Even when they indeed show up, likely they operate similarly as the legitimate UIs: no malware downloading, no illicit use of private APIs, etc. To capture their illegitimacy, one needs to read their content and understand their semantics. This, however, requires human involvement and therefore does not scale during app vetting. The attempt to detect such UIs becomes even more complicated for the third party, who does not have the source code of the related apps and therefore needs to work on binary executables. Indeed, our research has brought to light almost 100 such apps already published on Apple App Store, completely bypassing its vetting protection.

To address these challenges, we come up with a new triage methodology, *Cruiser*, that identifies the iOS apps likely to contain hidden crowdturfing UIs for further manual inspection. A key observation here is that such apps are characterized by their conditionally triggered UIs (e.g., triggered not by user actions but by network events), as demonstrated through UI transitions. Also, the content of such hidden UIs is related to crowdturfing semantically (e.g., app ranking manipulation), which is inconsistent with their hosting app's public description. These unique features make it possible to detect these iOS apps through a combination of binary, UI layout and content analyses. From 28,625 iOS apps covering 25 app categories, our system reports 102 most likely involving hidden crowdturfing UIs; considering the large scale of Apple App Store (2 million apps [3]) and the relatively high false detection rate (8.8%) of our tool, we manually examined all the 102 flagged apps, and found that 93 apps indeed contain hidden crowdturfing UIs.

**Measurement and discoveries.** Looking into the apps with hidden crowdturfing UIs reported by *Cruiser*, we are surprised to find that this new threat is indeed trending, with a big impact on today's mobile ecosystem. More specifically, from the 93 apps detected, we discover 67 different mobile crowdturfing platforms, which handle a variety of crowdturfing tasks, such as app ranking manipulation, fraud account registration, fake reviews, online blog reposting, and order scalping, etc. Also importantly, these apps are found to bypass app vetting several times and have a long lifetime. Such apps are popular, having been installed by a large number of users (32.4 million in total). Some of them even appear on the Apple leaderboards, with 25 of them ranked among the top 100 in their corresponding categories.

Also interesting is the ecosystem of mobile crowdturfing, as discovered in our study, which includes app promotion for worker recruitment, campaign identification, etc. In particular, crowdturfing platform owners are found to advertise their apps through multiple channels, including crowdturfing app gateway sites, in-app promotion and a pyramid (or referral) scheme that rewards the individuals for recommending crowdturfing apps to other users. In the crowdturfing app gateway sites, we observe that around 50% of hidden crowdturfing apps have been downloaded more than 18K times; there are 32.4 million downloads in total. Also, we find that the app

with hidden UIs is in high demand from the underground market: e.g., cybercriminals are willing to pay hundreds of dollars for developing such an app to circumvent Apple's vetting.

Furthermore, we analyze the evasion techniques employed by the crowdturfing apps, and bring to light new techniques that utilize complicated conditions to trigger their malicious behaviors: such apps not only know whether they have passed Apple's review so they can change their behaviors accordingly, but also protect their hidden UIs with the conditions involving user interactions or communication with a malicious website. Up to our knowledge, such techniques have not been reported to the Apple platform before, and therefore bring new challenges to its vetting process. Further discovered in our research is the way underground developers reuse their product and work with each other: we see that different developers inject different crowdturfing UIs to similar apps, and the same developer hides the same UIs into her different products. Also interestingly, almost identical apps, with both over and cover UIs, are found to be submitted to the store under different developer IDs. We disclosed our findings to Apple, which acknowledged us and has removed all reported apps from the App Store, though new attack apps of this type continue to pop up due to Apple's lack of effective means to detect them; also upon Apple's request, we provided a list of fingerprints for eliminating the apps similar to the malicious ones.

**Contributions.** The contributions of the paper are outlined as follows:

- *New methodology.* We developed a novel approach that utilizes a binary-code analysis on UI hierarchy and Natural Language Processing (NLP) analysis on UI semantics to detect the iOS apps with hidden crowdturfing UI.
- *New findings.* *Cruiser* helps us gain new insights into the mobile crowdturfing ecosystem and exposes the underground developer's new tricks for evading Apple's app vetting. Also importantly, our study sheds light on a new attack vector that has long been ignored: use of hidden UIs to evade even most restrictive app vetting to distribute illicit content.

**Roadmap.** The rest of the paper is organized as follows: Section 2 provides background information for our study; Section 3 elaborates on the design of *Cruiser*; Section 4 presents our measurement study and new findings; Section 5 discusses the limitations of our current design and potential future research; Section 6 reviews related prior research and Section 7 concludes the paper

## 2 Background

**Crowdturfing platform.** As mentioned earlier, crowdturfing, also called malicious crowdsourcing, is an illicit business model, in which cybercriminals (i.e., *intermediaries*) recruit *small-time workers* to carry out malicious tasks (e.g., app ranking manipulation) for *dishonest third parties* (e.g., app

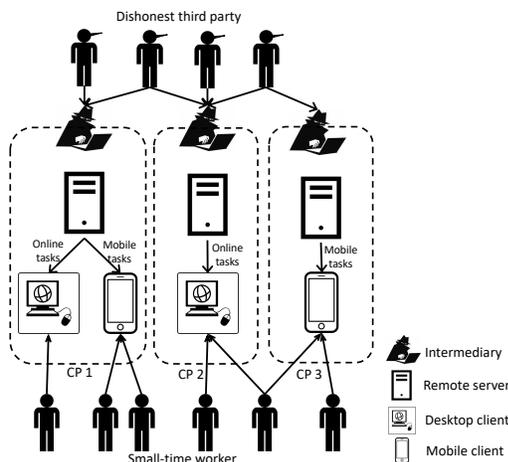

Figure 2: Overview of modern crowdurfing platforms, where “CP” represents a crowdurfing platform.

owner). Moving from the desktop browser-based clients (e.g., Zhubajie [5] and Sandaha [4]) to mobile devices, crowdurfing today increasingly happens through the apps deployed to workers’ smartphones. As an example, consider a dishonest app owner who intends to inflate the app’s installation volume and therefore seeks help from a crowdurfing platform; through the platform, the owner can pay workers to download and install his app so as to fake its popularity. Other hit jobs performed by the platform include the spread of fake reviews, defamatory rumors, etc.

Figure 2 illustrates modern crowdurfing platforms supporting both desktop browser-based clients and mobile clients. Such a platform, generally created and maintained by intermediaries, is designed to coordinate crowdurfing tasks and organize small-time criminals (workers) to do the tasks. As shown in the figure, a crowdurfing platform consists of servers to distribute crowdurfing tasks, and desktop browser-based clients or mobile clients to interact with the workers (e.g., publishing the tasks and checking the quality of the work). Unlike the platforms with browser-based clients, those with mobile clients mainly aimed at mobile-related crowdurfing (e.g., app ranking manipulation).

However, mobile crowdurfing clients, in the form of apps, are widely considered to be illicit by app stores, including Apple App Store [21] and reputable Android App stores like Google Play [28]. Especially for iOS crowdurfing clients, it is extremely hard for such apps to get through Apple’s restrictive vetting process. Actually, from the underground forum, we find that some intermediaries seek experienced developers to build apps capable of infiltrating the Apple store, by hiding their crowdurfing UIs (Section 4.4). Also interestingly, due to the difficulty in publishing crowdurfing apps, we find from the Apple store that multiple servers even share one client (Section 4).

**iOS UI design.** The UIs of an iOS app include view, view controller (VC) and data: *view* defines the UI elements to be displayed (e.g., button, image, and shape); *data* is the information delivered through the defined UI elements; and a VC controls both views and their data to present a UI. All the VCs of an app and their relations, which describe the transitions between different UIs, form a *VC hierarchy*, with its root (called *anchor*) being the initial VC of the app or the VC launched by the iOS object *AppDelegate*. Implementing a VC hierarchy can be done using either VC transition APIs (e.g., *pushViewController:animated*), or storyboard [19], a visual tool in the Xcode interface builder. In the storyboard, a sequence of scenes are used to represent VCs, and they are connected by *segue objects*, which describe transitions between VCs. iOS employs *layout files* (a.k.a., nib files) to implement UIs, which can be generated using storyboard.

Over a VC hierarchy, developers commonly define two kinds of transitions between a pair of VCs: *Modal* and *Push*. A *modal VC* does not contain any navigation bar or tab bar, and is used when developers create outgoing connections between two UIs. To present a modal VC, the developer can directly use APIs (e.g., *presentViewController:animated:completion:*), or define a modal segue object [20] in a storyboard. An API needs to be called in order to dismiss such a modal VC. On the other hand, *Push* uses a navigation interface for VC transitions. Selecting an item in the VC pushes a new VC onscreen, thereby hiding the previous VC. Tapping the back button in the navigation bar removes the top VC and reveals the background VC. More specifically, developers can display the view of a VC by pushing it to the navigation stack using the *pushViewController:animated:* API, or define a push segue in a storyboard. In the meantime, tapping the back button will pop up the top VC from the navigation stack and makes the new top displayed.

In our research, we observe that hidden crowdurfing UIs exhibits conditionally triggered navigation patterns in an app’s VC hierarchy, including multiple root VCs as entry UIs, entry VC not triggered by the users nor dismissed by itself, etc. (Section 3.2).

**Natural language processing.** The semantic information our system relies on is automatically extracted from UIs using Natural Language Processing (NLP). Below we briefly introduce the key NLP techniques used in our research.

- **Word embedding.** Word Embedding is an NLP technique that maps text (words or phrases) to high-dimensional vectors. Such a mapping can be done in different ways, e.g., using the continual bag-of-words model or the skip-gram technique to analyze the context in which the words show up. Such a vector representation ensures that synonyms are given similar vectors and antonyms are mapped to different vectors. Tools such as *Word2vec* [50] could be used to generate such vectors. *Word2vec* takes a corpus of text (e.g., Wikipedia dataset) as inputs, and assigns a vector to each unique word in the

corpus by training a neural network. In our study, we leverage Word2vec to quantify the semantic similarity between the words based on the cosine distance of their vectors.

- **Topic model for keyword extraction.** Topic model is a statistical model for finding the abstract "topics" of a document, and topic modeling is a common text-mining tool for discovering keywords from corpora. Among various topic modeling approaches, Latent Dirichlet Allocation (LDA) [13] is one of the most popular methods. The basic idea is that documents are represented as random mixtures over latent topics, where a topic is characterized by a distribution over words, and the statistically significant words are selected to represent the topic. In our study, we leverage the LDA implementation of *Stanford Topic Modeling Toolbox* [48] for keyword extraction.

**Threat Model.** In our research, we consider an adversary who tries to publish iOS apps carrying hidden crowdturfing content on Apple App Store. Examples of such crowdturfing activities include fake review posting, app ranking manipulation and order scalping [15], etc. For this purpose, the adversary creates iOS apps with hidden crowdturfing UIs. These UIs are meant for displaying the tasks assigned by a crowdturfing platform and providing guidance on how to accomplish the tasks, so typically they do not ask for additional capabilities (guarded on iOS by entitlements). To publish such apps, the adversary is supposed to be knowledgeable about Apple’s vetting process. Use of private APIs or side-loading are the focus of Apple’s vetting and therefore not considered in our research. Also, in our research, we only cover native iOS apps. The cross-platform framework (e.g., react native) based apps, which are built using different languages (e.g., javascript), are out of the scope of this work.

### 3 Methodology

Here we elaborate on the design and implementation of a new technique for identifying apps with hidden crowdturfing UIs. We begin with an overview of the idea behind *Cruiser*, and then present the design details of each component.

#### 3.1 Overview

**Architecture.** Figure 3 illustrates the architecture of *Cruiser*, which includes a *Structure Miner* and a *Semantic Analyzer*. After fetching and decrypting iOS apps from App Store, *Structure Miner* takes as its input a set of decrypted iOS apps, and disassemble them. The disassembled apps are then utilized by the Structure Miner to construct a VC hierarchy for identifying the VCs with conditionally triggered UIs (e.g., two entry UIs). Here we define *checkpoint VCs* as all VCs associated with conditionally triggered UIs and their corresponding children VCs (see detail in Section 3.2). We also consider children VC, since VCs with conditionally triggered patterns

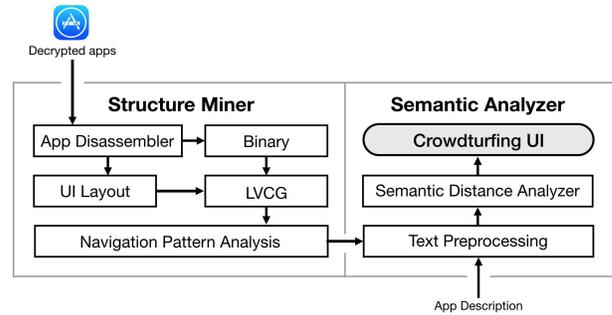

Figure 3: Architecture of *Cruiser*.

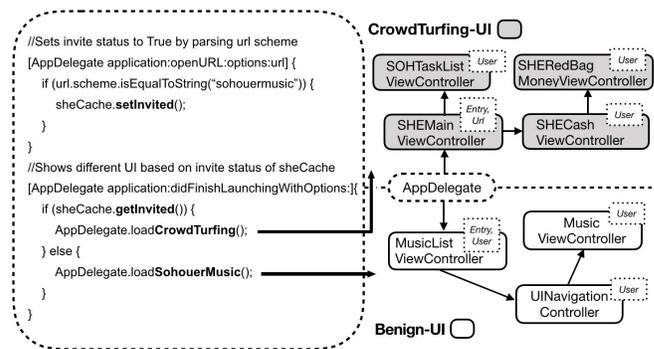

Figure 4: Pseudocode and simplified LVCG with conditionally triggered UIs.

sometimes may not contain sufficient texts for semantic analysis. On each checkpoint VC, the Semantic Analyzer further extracts texts from it, and evaluates its content through a set of NLP techniques to determine whether it is used for crowdturfing.

**Example.** To explain how *Cruiser* works, here we walk through its workflow (Figure 3) using a Music Player app with a hidden app ranking manipulation UI, *com.sohouer.music*. *Cruiser* first automatically decrypts the app and disassembles it into binary, UI layout files and resource files. Meanwhile, we also crawl the app’s metadata (i.e., description for the Music Player app) from the App Store as the input for the Semantic Analyzer.

The Structure Miner processes the binary and UI layouts of the *com.sohouer.music* app and creates a VC hierarchy in the form of a labeled view controller graph (LVCG) (as shown in Figure 4). From the LVCG, our approach extracts VCs with conditionally triggered UIs and marks them as the checkpoint VCs. More specifically, the Structure Miner identifies VCs and VC transitions from the app binary and UI layout files to construct the LVCG (Figure 4). From the LVCG, the Structure Miner discovers the conditionally triggered UIs: two root VCs of *MusicListViewController* and *SHEMainViewController*, which indicate that there are two entry UIs for the app. Depending on whether the app has received a particular scheme invocation before, different main UIs will be

displayed when the app is launched. Therefore, these two VCs are labeled as checkpoint VCs for the follow-up semantic analysis.

Once the checkpoint VCs are found, the Semantic Analyzer then processes their text data to identify semantic features: the *MusicListViewController* VC contains a series of *Music Player* related words, such as  $\{album, singer, shuffle, song, music, radio\}$ , which are consistent with the app's description. On the other hand, the topic words under *SHEMainViewController* are  $\{task, cash, earn, withdrawal, join, pay, reward\}$ . Given the semantic inconsistency discovered, the Semantic Analyzer flags the app as a crowdturfing client.

**Data collection.** In our research, we collected 28,625 iOS apps for discovering new hidden crowdturfing apps, which we call *unknown set*. Specifically, we scanned the entire iOS app list from iTunes Preview website [34] using an app crawler running on an iPhone, and then selected the apps updated after Jan. 1, 2016 to download and decrypt. This is because apps with hidden crowdturfing UI is an emerging threat, and recently updated apps tend to have more active users. In this way, we collected 28,625 iOS apps, which cover 25 app categories.

## 3.2 Structure Miner

The Structure Miner is designed to identify the VCs with conditionally triggered UIs from an app's disassembled code and UI layout files. Examples of such patterns include two different main UIs, as discovered from *com.sohouer.music*, and the UI that can only be invoked by a specific network or other events, not directly by the user, indicating the potential presence of evasive behaviors. To discover such patterns, we first construct a VC hierarchy in the form of an LVCG through analyzing the app's binary and retrieving UIs from the UI layout files to identify their corresponding VCs and establish their transition relations among them. Then, from the LVCG, we search for predefined conditionally triggered UIs and mark those having these UIs as checkpoint VCs for further analysis.

**LVCG.** LVCG is a directed graph as shown in Figure 4, in which each node is a VC and each directed edge describes a transition from one VC (corresponding to a UI) to another.

**Definition 1.** An LVCG is a directed graph  $G = (V, E, \alpha)$  over a node label space  $\Omega$ , where:

1.  $V$  is a node set, with each node being a VC;
2. Edge set  $E \subseteq V \times V$  is a set of transitions between VCs;
3. Node labeling function  $\alpha : V \rightarrow \Omega$  marks each node with its UI properties and text data. Each node is given four property labels: *entry, user, url, others*. Table 1 shows the definition of each property and the corresponding method names.

**LVCG construction.** The construction of an LVCG requires both an app's binary and its UI layout files. This is because the VC of a UI is in the code and even the UI itself can be

programmed through APIs (e.g., *initWithFrame*: API in *UIViewControllerAnimated*) so becoming part of the VC, and in the meantime, all the UIs built through storyboard can only be found in the layout files, including the transitions between them. To address this complexity, *Cruiser* builds two LVCGs, one from the binary and the other from the layout files, before combining them together.

Specifically, on the binary code, we look for system VC class names (e.g., *UIViewController*) and method names (e.g., *setNavigationBarHidden*), which help identify individual VCs and their properties (see Table 1). Then we track the data flows from a VC to another to recover the transitions between the detected VCs. For this purpose, our approach first maps the addresses in the binary code to symbols (e.g., class name, method name) using a binary analysis tool Capstone [7], and then uses a set of targeted system VC class names (e.g., *UIViewController*) and method names (e.g., *setNavigationBarHidden*) to recognize VCs and their properties (e.g., *entry*) from the symbols. After that, the Structure Miner performs a data-flow analysis using an implementation similar to the prior techniques [18, 23], to connect the transition APIs (*performSegueWithIdentifier:sender:*) discovered in a VC to another one, the transition target.

To construct a LVCG on the layout files under the storyboard folder generated by Apple's interface builder, we need to extract VCs and VC transitions from the files. The former can be found from the storyboard plist file that includes the mappings from VC names to the obfuscated names of nib files. The latter is recorded by the nib files, each of which carries a subset of a VC's properties, e.g., the types of some elements (such as button, textbox, etc.) and the transitions between VCs.

Our approach directly recovers VCs from the plist file and further detects each VC's nib files from the mappings it records. More challenging here, however, is to identify the transitions between the VCs, since objects included in a nib file are undocumented. To enable the Structure Miner to interpret the file, we reverse-engineered part of its format relevant to the transition and content extraction. Specifically, we started from the interface builder, through which one can define one or multiple scenes to represent a UI and a *Segue* to describe a transition. Through a differential analysis, we compared the compiled nib files with and without a specific transition to pinpoint the nib objects corresponding to different *Segue* types (e.g., push, modal, unwind), such as *ClassSwapper*. From such objects, the Structure Miner is then able to collect the transitioning data, in the form of *src, dst, type, etc.*. This allows us to restore the recorded transition information and build up the LVCG of an app.

Given the LVCGs generated from the binary and the layout files, our approach automatically combines them together, based on the relations between the VCs on these graphs: particularly, when a transition is found from a VC in the layout to the one defined in the code, two LVCGs can then

Table 1: LVCG node properties and their corresponding method names.

Property	Definition	Method/Class names
entry	root VC	setRootViewController:
user	VC triggered by a user interaction	addTarget:action:forControlEvents:
url	VC rendering web content	openURL:, UIWebViewController
others	other properties (e.g., self-dismiss)	dismissViewControllerAnimated:completion:

be linked together through this VC pair. On the combined LVCG, further we remove the dead VCs introduced by the part of libraries and other shared code not used by an app. To this end, our approach performs a test to find out all the VCs that cannot be reached from the app’s entry points (such as *AppDelegate*, the initial VC of the main storyboard) and drops them. In this way, we remove 1,053,161 dead VCs (55.4%) from the 28,625 iOS apps we collect (see Section 3.1).

**Conditionally triggered UI extraction.** Given 17 apps with hidden crowdturfing UI collected from *9I.ssz* [8] (see detail in Section 3.4), without loss of generality, in our study, we consider two types of conditionally triggered UIs on the LVCG, as elaborated below:

- *More than one root VCs.* We consider an LVCG to be suspicious if it has more than one root VCs, i.e., app has two entry points, that is, two different root UIs. The root VC is the first one launched (by *AppDelegate*) when an app starts running. One evasion trick the adversary often plays is to run two root VCs, one legitimate and the other illicit, depending on some trigger conditions (e.g., the app’s execution environment). For example, in the app *com.sohouer.music* (see Section 3.1), besides the benign UI (i.e., *MusicListViewController*), the hidden crowdturfing UI (i.e., *SHEMainViewController*) can also be invoked by *AppDelegate*. Such a pattern can be described as  $|\alpha(v) == 'root'| \geq 2$ . In this case, we label the two VCs and their corresponding children VCs as checkpoint VCs for further semantic analysis.

- *VC not triggered by users.* If an entry VC or intermediate VC is not triggered by the user, but by other external events (e.g., network), i.e.,  $\alpha(v)['entry'] = True \wedge \alpha(v)['user'] = False$  or  $\alpha(v)['user'] = False \wedge \alpha(v)['url'] = True$ , we consider it as suspicious, since such UI is difficult to be triggered during app vetting. In such a case, we mark such a VC  $v$  and its children VCs as checkpoint VCs.

Looking into all 28,625 apps, we discover 34,679 checkpoint VCs using conditionally triggered UIs. These VCs are further evaluated by the Semantic Analyzer. Our evaluation (see Section 3.4) shows that the Structure Miner maintains a good coverage on hidden crowdturfing UIs while filtering out most legitimate apps.

### 3.3 Semantic Analyzer

The Semantic Analyzer determines whether checkpoint VCs are crowdturfing UIs. Serving this purpose is a set of NLP

based semantic analysis techniques: we first extract UI texts from the VCs, and then find out whether they are related to crowdturfing by calculating the semantic distance between the texts and crowdturfing keywords.

**Text discovery.** As mentioned earlier, the format of the UI layout files (the nib files) is undocumented. However, they can be converted into the XML form using *ibtool* [42]. From their XML content, we can find plain-text strings under *NSString* objects, a property of UI element objects like button, table, textbox, font, color, etc. Some of these strings are part of the content a UI displays, while the others are not, depending on the type of the UI element objects. For example, *UIFont* and *UIColor* carry strings such as “.HelveticaNeueInterface-Regular” and “blackColor” for defining fonts and UI color, respectively. To extract UI content from the nib files, we come up with a blacklist of UI element objects that do not include UI texts, and use that list to filter out irrelevant text strings. More specifically, we randomly sampled 70 iOS apps from our unknown set, which gives us 1,307 nib files including 28,469 *NSString* objects. We clustered them based on the types of their UI element objects, and manually went over all 103 types discovered. In this way, we constructed a blacklist with 21 patterns that cover 64 object types that do not contain any meaningful UI texts. Table 8 in Appendix shows the blacklist. When analyzing a given app, the Semantic Analyzer locates all *NSString* objects from its checkpoint VCs and further recovers their host UI element objects from the app’s UI object tree (i.e., a tree built on layout files). If the element is on the blacklist, we ignore its *NSString* object.

In addition to the text strings in the *NSString* objects, other UI content can be embedded in images and therefore cannot be easily extracted. To collect more semantic information for crowdturfing UI detection, we utilize an app’s meaningful variable names (e.g., *\_album\_id*), class names (e.g., *TicketDetailViewController*) and method names (e.g., *setSongIdsArrayM*), which are preserved in the binary’s symbol table by the Object-C compiler. These human-readable symbols are recovered by our approach from the variables, class names, etc. output by Capstone [7] for each checkpoint VC. Also for the VCs with Web UIs (e.g., *UIWebViewController*), we include the text content collected from the URL embedded in the VC. An example of the data gathered from both UI layouts and a binary is presented in Table 2.

**Crowdturfing UI identification.** Given the UI content recovered from each checkpoint VC, we analyze whether such data is semantically associated with crowdturfing: to this end,

Table 2: Sample text data.

Object Type	Text Data
<i>UILabel</i>	“Proceed to checkout”
<i>NSLocalizedString</i>	“start making money”
<i>Class Name</i>	“TaxiViewController”, “GameView” “TicketDetailViewController”
<i>Method Name</i>	“setSongIdsArrayM:”, “setBuyAllProductId:”
<i>Instance Variables</i>	“_album_id”, “_uploadMedia ”, “_btnPaid”
<i>CFString</i>	“Select photo from photo library” “more clear free voice calls”
<i>URL</i>	<i>booking.com</i> “hotel” “city”, “trip”, “taxi”

we first preprocess the texts to address the issues like multi-language, noisy words, and then identify the keywords representing their semantics. In the meantime, we crawl a set of popular crowdurfing websites (e.g., Zhubajie [5] and Sandaha [4]) to build a crowdurfing word list. Words on the list are compared with the UI keywords using Word2vec [50] to find out their semantic distances. When such a distance becomes sufficiently small, the checkpoint VC is then flagged as a hidden crowdurfing UI. In the following, we elaborate on each step of this analysis.

At the preprocessing step, our approach runs Google Translate [2] to convert content in other languages into English. For the text in the languages without delimiters, Chinese in particular, we first use open source tools [27, 30] to segment texts into words before the translation; for the class/method names extracted from the binary, we tokenize them using regular expressions that cover common naming conventions (e.g., *CamelCase* style). Further, we drop all common stop words (e.g., NLTK stop words), and the frequent words from iOS frameworks and programming languages (e.g., “UIViewController”, “ignoreTouch:forEvent:” and “raiseException”), as well as program language and debugging related texts (e.g., “socket”, “connection”, “memory”, “allocation”). These words come from 74 framework-libraries of iOS 8.2.1, and are gathered in our research from sections such as *\_\_cf-string* and *\_\_objc\_methname*. Selected from these documents are 1,806 frequent words whose inverse document frequency (IDF) values are larger than a threshold (we use  $\log(5)$  in our implementation). Also 1,031 program language and debugging related words are hand-picked for *Objective-C*, *Swift*, and *Javascript*.

After removing these words from a checkpoint VC, the remaining words are then analyzed using affinity propagation [26], which clusters them based upon their semantics (represented by the vectors computed using an embedding technique) and reports the most significant cluster. The words in such a cluster are then used by our approach to represent the semantics of their hosting VC.

To collect crowdurfing keywords, we crawl 280 web pages from the popular crowdurfing websites (i.e., Zhubajie [5] and Sandaha [4]). From these pages, we identify their topic keywords using the Latent Dirichlet Allocation (LDA) method. In this way, we build a crowdurfing list of 214 words. A problem for directly using these words is the observation that some of the crowdurfing words may also appear in legitimate apps: for example, “coupon” is certainly a meaningful word for a shopping app, not necessarily referring to the illicit task of bounty hunting. To address this problem, we compare these words with the keywords extracted from an app’s description, dropping those related to the app’s publicly stated functionality before the comparison below.

Given keywords discovered from the checkpoint VCs and the list of crowdurfing words, we run *Word2vec* [50] on each of these words, which maps the word to a vector that describes its semantics. Using these vectors, our approach measures the semantic relations between the UI keywords and the crowdurfing keywords by calculating their vectors’ cosine similarities. For each UI keyword, its average similarity with all the crowdurfing keywords is used to determine its relevance with crowdurfing. We find that when the average relevance score of all the keywords of a checkpoint VC reaches 0.525 or above, the VC is nearly certain to be a crowdurfing UI.

### 3.4 Challenges in Identification

Here we evaluate *Cruiser* and elaborate on the challenges in crowdurfing app identification.

**Evaluation with ground-truth set and unknown set.** We evaluated *Cruiser* over the following *ground-truth datasets*: for the bad set, we collected the apps with hidden crowdurfing UIs from *9Issz* [8]. *9Issz* is a website that hosts the apps with the features (e.g., spam forums, earn money) violating Apple’s guidelines. We manually examined 290 apps and confirmed 17 with hidden crowdurfing UIs (the other 273 apps do not have hidden UIs and are *only* accessible through third-party black markets). The good set were gathered from the top paid app list found from Apple App Store charts, which are considered to be mostly clean. We randomly sampled 17 of them (the same size of the bad set) to build the good set. Note that we manually examined those apps and verified that they are indeed benign. Running on these sets, *Cruiser* shows a precision of 88.9% and a recall of 94.1%.

Next we further report the results when running our approach on the unknown set, including all the apps collected from the Apple App Store (Section 3.1), at each stage of our analysis pipeline. We statically analyzed disassembled code and UI layout files over the 28,625 iOS apps, and discovered 34,679 checkpoint VCs, which are related to 3,999 (14.0%) apps using conditionally triggered UIs. Then, we executed the Semantic Analyzer, which flagged 102 apps. We manually examined all of them and found that 93 apps indeed contain hidden crowdurfing UIs. This gives us a precision

of 91.2%. The 9 falsely detected apps, though not including crowdturfing UIs, also turned out to be less legitimate. Below we elaborate on the missed apps and the falsely detected apps.

**Missed apps.** On the ground-truth set, only one crowdturfing app was missed by *Cruiser*. The app fell through the cracks due to inadequate semantic content extracted from their UIs. It is found to construct the URL for the content to be displayed during its runtime and dynamically loads crowdturfing pages through the URL. While *Cruiser* can find the suspicious view controller, it cannot statically gather semantic content from the crowdturfing pages and therefore fail to provide enough semantic information for the Semantic Analyzer to make a decision.

Determining the number of missed crowdturfing apps in the unknown set (with 28K iOS apps) is challenging. Given the low density of such malicious apps in the dataset, we could not randomly sample from the set hoping to capture ones missed by our methodology. So what we did in our study is to lower down the threshold used by the Semantic Analyzer for detection, which improved the recall, at the expense of precision. With the threshold decreasing from 0.525 to 0.513, our approach flagged 313 more apps. We manually analyzed all these apps and found only 3 new crowdturfing apps (false negatives), while the remaining 310 were all false positives. Looking into these 3 missed apps, interestingly we found that they were all web-based apps that dynamically download crowdturfing content from the web during their runtime, as we observed on the ground-truth set.

**Falsely detected apps.** All false detections reported come from the apps indeed carrying conditionally triggered UIs. These apps are not only structurally but also semantically related to a true crowdturfing app. More specifically, their hidden UIs all contain monetary content, which is one of the semantic features for crowdturfing apps. For example, among the 9 false detections, 7 are about “Health & Fitness” but actually include hidden lottery UIs. The remaining two are “Education” apps, which declare to be free but later display a remotely controllable UI asking for payment. Note that all these UIs are potentially unwanted, since they are undocumented (in the apps’ description) and forbidden by Apple’s guideline [21]. We consider these apps (with illicit UIs) as false detections, just because they are not directly related to crowdturfing.

**Legitimate use of conditionally triggered UI.** In Section 3, we report the observation of 14% apps including conditionally triggered UIs. Through a manual analysis, we found that these apps use two entry UIs to display notifications, a tour or a guide for the app, special events (e.g., New Year) and etc. All their hidden UIs cannot be reached through user interactions. This demonstrates the importance of the Semantic Analyzer, which utilizes NLP to determine the irrelevance of these apps to crowdturfing, thereby controlling the FDR of our approach.

### 3.5 Comparison to Other Approaches

***NaiveCruiser: Semantic analysis on all VCs.*** *Cruiser* is characterized by a two-step analysis (by the Structure Miner and then the Semantic Analyzer), first filtering out the VCs with normal navigation pattern and then analyzing the semantics of suspicious VCs. This strategy is designed to minimize the overheads incurred by the Semantic Analyzer, which is crucial for making our system scalable for analyzing the 28K apps in the wild. In the meantime, there is a concern whether the performance benefit comes with an impact on the technique’s effectiveness, making it less accurate. To understand the problem, we compared our implementation of *Cruiser* with an alternative solution, called *NaiveCruiser*, which conducts a semantic analysis on all VCs in the app. This approach is fully tuned toward effectiveness, completely ignoring the performance impact.

In particular, we also evaluated the *NaiveCruiser* over the same *ground-truth datasets* we used to evaluate *Cruiser*. Running on these sets, *NaiveCruiser* shows a precision of 90.9% and a recall of 93.2%, which is in line with *Cruiser* (precision of 88.9% and recall of 94.1%). This indicates that our two-step design does not affect the effectiveness of detection. We also show the large performance degrade of *NaiveCruiser*, compared to *Cruiser*, in Appendix.

**Crowdturfing keyword search.** Simply searching for crowdturfing keywords is not effective. This is because the words used in crowdturfing UI (e.g., money, withdrawal, cash) are common, which often appear on other legitimate UIs (e.g., stock apps, accounting apps). Therefore, a simple keyword-based approach would bring in a high FDR (see below). Our approach utilizes a suite of techniques (e.g., looking for structural features of conditionally triggered UIs and corresponding VCs, removing words related to app descriptions) to avoid false reporting of legitimate UIs.

To understand how effective these techniques are, we evaluated the baseline – the naive keyword search on the 28K iOS apps. Specifically, we automatically extracted keywords from crowdturfing content collected from our ground-truth set, and then manually crafted a list of 32 most representative keywords for crowdturfing tasks (e.g., reward, task and installation). In the experiment, we studied the effectiveness of these keywords by first searching for the apps containing individual words and then analyzing their combinations (those including 2, 3, ..., 32 words). The more keywords an app includes, the more likely it is problematic but the fewer such apps would be found. In the end, we did not see any app involving more than 8 keywords. Among those carrying no more than 8 words, the highest precision achieved was 15.38% (an FDR of 84.62%), for those with 8 words. In this case, only 5 apps were reported. By comparison, our approach achieved a precision of 91.2%, reporting 93 malicious apps on the unknown set. This result demonstrates that the naive keyword search is indeed inadequate.

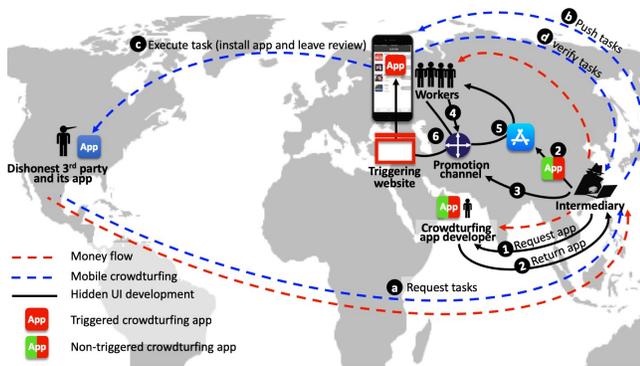

Figure 5: Overview of modern crowdurfing value chain, which consists of hidden crowdurfing app development (1-6) and mobile crowdurfing operations (a-d).

## 4 Understanding iOS-based Crowdurfing

Based on the detected crowdurfing apps, we further performed a measurement study to understand the iOS-based crowdurfing ecosystem. In this section, we first present as an example a real value chain of modern crowdurfing (Section 4.1), and then describe the scope and magnitude of this malicious activity as discovered in our research (Section 4.2), before elaborating the two key components of the value chain: *crowdurfing app development and promotion* (Section 4.3) and *mobile crowdurfing operations* (Section 4.4).

### 4.1 Mobile-Crowdurfing Value Chain

Before coming to the details of our measurement findings, first let us summarize the mobile-crowdurfing value chain discovered in our research.

A cybercriminal (i.e., intermediary), who owns a modern crowdurfing platform *chinazmob*, intends to publish a mobile client, which is downloadable from the App Store, to publish crowdurfing tasks and coordinate with small-time workers. Hence, the intermediary seeks underground app developers to build an app with hidden crowdurfing UIs (1, see Section 4.3). The hidden crowdurfing UI will only be triggered when app users visit the website *ioswall.chinazmob.com*. Once done, the app *Pleasant Music* (id115\*\*\*\*781), which disguises as a music player, passes the vetting of the App Store and is published (2). Then, the intermediary promotes this app on social networks (3) with links to the App Store and the triggering website *ioswall.chinazmob.com*. Small-time workers, who observe the promotion (4) and download the *Pleasant Music* app (5), will access the mobile crowdurfing client after triggering the hidden UI (6) to execute crowdurfing tasks. Meanwhile, in the underground business of mobile crowdurfing, a dishonest mobile app owner of *Anjuka* who plans to inflate the app’s installation volume reported by the App Store, pays for a crowdurfing platform *chinazmob* to

manage crowdsourced app downloading tasks (a). Then, the intermediary will publish a task on its mobile client and recruit small-time workers (b) to do the task. These workers will install *Anjuka* and write fake reviews for the app (c). Once done and verified by the crowdurfing platform (d), the workers will get commissions from the platform.

In the rest of the section, we discuss the security implication introduced by these hidden UI apps, considering both crowdurfing app development and promotion and mobile crowdurfing operations in the value chain. As evidence for their impacts, those apps successfully infiltrated the App Store, even reached a high rank and bypassed the app vetting multiple times. In addition, we discovered various hidden UI techniques and the underground services that support the development of such apps. In particular, we revealed a set of techniques (e.g., logic bomb, scheme) deployed by the cybercriminals, as well as the underground services that are willing to pay \$450 for developing such iOS apps. For app promotion, we identified 40 crowdurfing app gateway sites used by cybercriminals to promote 67.7% of such apps, which also enabled us to estimate the volume of the users. Furthermore, we report the findings related to *mobile-based* crowdurfing and discuss their insights, which have never been done before. For example, in contrast to the web-based crowdurfing dominated by a small number of platforms, on the mobile side we observed a fragmented crowdurfing market and a stealthy iOS crowdurfing ecosystem: we detected 93 hidden crowdurfing apps related to 9 campaigns, after clustering them based on similar app information, code structure and network behavior. Finally, we report a case study on an app with a hidden app ranking manipulation UI.

### 4.2 Landscape

**Scope and magnitude.** Our study reveals that apps with hidden crowdurfing UI are indeed trending in the Apple App store. Altogether, *Cruiser* detected 93 apps with hidden crowdurfing UIs, which are related to 67 crowdurfing platforms. To the best of our knowledge, this is the largest finding on mobile crowdurfing ever reported.

Apps with hidden crowdurfing UI, as discovered in our experiment, are found in 15 categories of the Apple App Store. As shown in Table 3, over 77.4% of the apps are in the categories of *Music*, *Utilities*, *LifeStyle*, and *Entertainment*. These apps are often built upon existing open source projects (see Section 4.4). Surprisingly, we found that some crowdurfing apps are of high ranks: six apps, including the wifi helper app (*cn.qimai2014.polarbearwifi*), the recorder utility app (*com.amzhushou.app*), the Temple Run style app (*com.funinteract.ballgame*) and several word guessing game apps reached top 20 of the leaderboard across different countries (e.g., *China*, *Laos*), based on the ranking data available from App Annie [6]; also, we observed that at least 14 apps were once ranked within the top 50, and 25 apps were in the

Table 3: Top 5 app store categories of apps with hidden crowdturfing UI.

Category	# apps	Benign UI examples
Music	32 (34.4%)	Ringtones, Piano Pieces
Utilities	15 (16.1%)	Recorder, File Manager
LifeStyle	15 (16.1%)	Story Teller
Entertainment	10 (10.8%)	Web Browsers, <i>Jeopardy</i> -style Quiz
Games	5 (5.4%)	Word Guess, Fruit Cutting

top 100 of their corresponding categories.

**Impact of hidden crowdturfing apps.** Furthermore, our study shows that the apps with hidden crowdturfing UIs have indeed successfully infiltrated App Store. Figure 6 illustrates the *Version* distribution of the crowdturfing apps. Most of them (73%) have only few updates, with a version number in the range from 0 to 1.5. However, still a non-negligible portion of apps (27% apps have *Version*  $\geq$  2.0) seem to be capable of carrying their suspicious payloads even to their higher versions. This is interesting since apps need to go through Apple’s inspection for every new version submitted to the App Store.

Then, we analyzed the trend of the infiltration performed by the crowdturfing apps. Figure 7 shows the distribution of the number of such apps on the Apple App store over their release date. The trend-line based on the linear forecast regression indicates that those apps are still on the rise and require further attention. We observed that the newly-released apps with hidden crowdturfing UI have increased by 150% from Jan. 2015 to Jun. 2017.

### 4.3 App Development and Promotion

**App development.** Apparently, the development of crowdturfing apps is in strong demand on the underground market. Our research shows that one could get an illicit app, with desired hidden UIs, on the App Store for \$450 [25]. Specifically, a quick search on Google yields dozens of recruitment posts for such app development; e.g., *freelancer* [24,25], *Code Mart* [17], *witmart* [51], *dongcoder* [22], *Code4App* [16]. As shown in the task description [25], the illicit app to be developed should be capable of displaying a benign UI during app vetting, and switching to an illicit UI once it is published on the App Store.

Also illicit app developers tend to minimize the effort to develop the benign UIs for covering the crowdturfing ones. One common approach they take is to hide the crowdturfing UIs to the app built upon an open source project ([31,35,43]). In particular, we extracted strings from the benign VCs of the detected crowdturfing apps, and then searched them in leading code repositories (e.g., Github). Interestingly, we found that the benign UIs of six crowdturfing apps come from two open source projects: *ESTMusicPlayer* and *LittleFrog-MusicPlayer*. Note that according to Apple’s guidelines [21] (4.3 and 4.2.6),

such template apps should have been rejected. However, we observe that Apple seems to loosen its policy, which makes developing such illicit apps easier. To verify the observation, we designed a hidden crowdturfing app by utilizing one of the open source projects, *ESTMusicPlayer* [35], as the benign template. The app successfully got into the App Store in two days (we removed the app immediately before any user downloaded it).

**UI hiding techniques: Triggers.** We found that such illicit apps utilize a spectrum of UI hiding techniques to evade app vetting, which are described as follows:

- *Logic bomb.* Apparently, the adversary tends to trigger hidden crowdturfing UI when certain conditions are met (e.g., after app vetting). Some detected hidden crowdturfing apps contain logic bombs; e.g., the app sets off the hidden crowdturfing UI when a specified time (e.g., after “2017-01-18 00:00:00”), location (e.g., “isCN”), or device information (e.g., connected to cellular) conditions are met. For instance, the crowdturfing UI in *cn.music.s3b* is only activated when the device is connected to network and has its area/language code set to “zh”.

- *C2 server.* Like bots, apps with hidden crowdturfing UI are also found to leverage command and control servers (C2 servers) to trigger their hidden UIs. For instance, *com.catTestPlay.app* retrieves a “status” code from its web server *http://[domain]/itunes\_app/sound\_dog* to decide whether to switch to its hidden UI.

- *Scheme.* Another interesting observation is that the app developers utilize extremely sophisticated triggering conditions, which even require the user to take certain actions. An interesting example is that a hidden crowdturfing UI can only be invoked by a specific scheme. Those apps promoted themselves on the social networks or websites; when users download those hidden crowdturfing apps from the App Store, the promoted sites provide the users an activation link to trigger the hidden crowdturfing UIs. More specifically, when the activation link is clicked, a scheme (e.g., *babyforring://[params]*), that releases the illicit UI, is sent to the app.

- *Others.* Several other techniques are also used to differentiate normal users’ devices and vetting environment. As an example, we observe that a UI is hidden by the combination of scheme and logic bomb: the app *com.qianying.music* will first determine whether a user has logged into her WeChat app on the device, and then release its illicit UI only when receiving a scheme from a specific website.

**App Clones.** We observed that illicit app owners resubmitting clones of removed or existing illicit apps by only changing their bundle IDs through different Apple developer IDs; e.g., after *com.cloud.NHCORE* was removed from App Store, it was quickly resubmitted as *com.good.jingling*. Developers also submitted multiple repackaged apps containing the same hidden crowdturfing UI; e.g., two apps, music

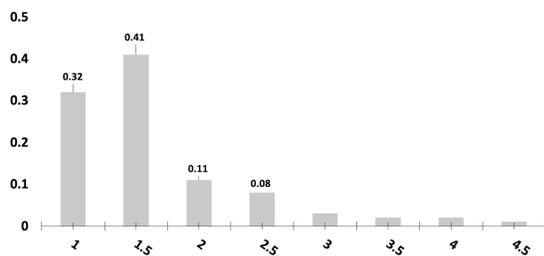

Figure 6: Version distribution of apps with hidden crowdturfing UIs.

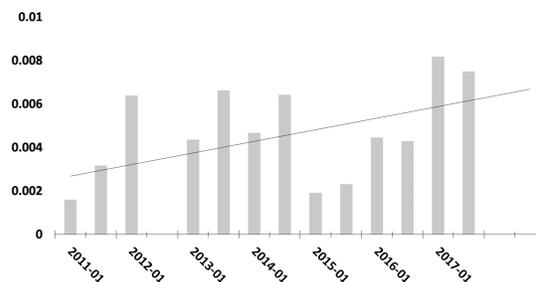

Figure 7: Release date distribution of apps with hidden crowdturfing UIs.

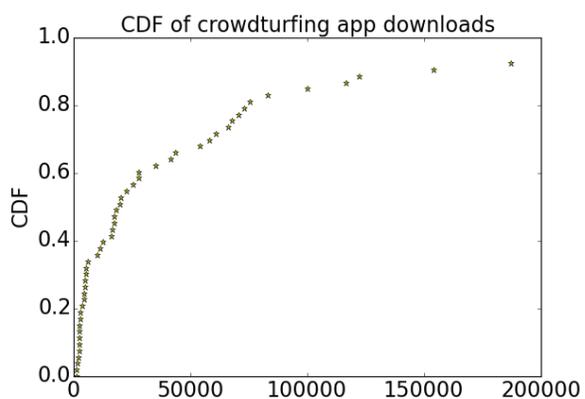

Figure 8: Cumulative distribution of crowdturfing app downloads.

player *com.yueyuemusic* and eBook reader *com.Qingyu* app, were found to integrate the identical crowdturfing platform (i.e., *rehulu.com*). To mitigate the threat of such persistent infiltration attempts, we provided a list of words that could help to fingerprint such apps upon Apple’s request, and meanwhile are actively collecting resubmitted/repackaged hidden crowdturfing apps.

**App Promotion and worker recruitment.** To understand how crowdturfing platform owners disseminate such apps and recruit workers, we searched for the apps’ names on the search engine and manually analyzed top-10 results to identify their promotion websites. In this way, we gathered 50 websites advertising 78 (83.9%) hidden crowdturfing apps. We found that the owners of these hidden crowdturfing apps promote their apps through multiple channels: advertising on the online communities (e.g., *BBS*, *tieba*), social networks (e.g., youtube, weibo), and crowdturfing app gateway sites (e.g., *app522.com*, *i8i3.com*).

Of particular interest is the crowdturfing app gateway sites, which refer the visitors to multiple hidden crowdturfing apps. We identified 40 such gateway sites that promoted 63 (67.7%) hidden crowdturfing apps. For example, the

*com.cq.diaoaqianyaner.pro.bookstore* app was found to be promoted on eight crowdturfing sites: *qisw123.com*, *yzzapp.com*, *eshiwan.com*, etc. Most intriguing is the discovery that all the apps actively promoted on those gateway websites have been detected by *Cruiser* from the unknown set. Since those websites record apps’ download volume, we were able to estimate the number of these apps’ users. Figure 8 illustrates the cumulative distribution of the number of downloads per crowdturfing app. As shown in the figures, around 50% of the crowdturfing apps were downloaded more than 18K times, with 32.4 million downloads in total.

Another interesting promotion channel is the referral bonus policy, which is provided through the app: the app’s owner pays workers (users) if they invite other workers to use this app for crowdturfing. We found that 23% of the crowdturfing apps are using such a channel to recruit workers.

#### 4.4 Mobile Crowdturfing Operations

**Crowdturfing tasks.** Table 4 illustrates the top-6 most common illicit crowdturfing tasks found in the apps with hidden crowdturfing UIs. As we can see here, most of them are mobile based crowdturfing tasks. According to our findings, app ranking manipulation is supported by a significant portion (88.2%) of crowdturfing apps, followed by fraud account registration, and fake review. Figure 9 illustrates the cumulative distribution of the task categories per app. We observe that about 62.5% apps only provide one kind of crowdturfing tasks, among which 86.7% are designed for iOS app ranking manipulation. Surprisingly, when analyzing apps seeking crowdturfing for iOS app ranking manipulation, we observe several popular and reputable apps. Examples include a calendar app, which ranked Top 10 in the App Store category of Utilities across 15 countries, and a restaurant review app, which ranked Top 10 in Lifestyle category across 49 countries.

To measure the task volume of an app (i.e., number of tasks × number of required workers per task), we crawled five apps’ task information and the number of required workers through their crowdturfing UIs. Table 5 presents the average daily task volume for each app. For instance, the app ranking manip-

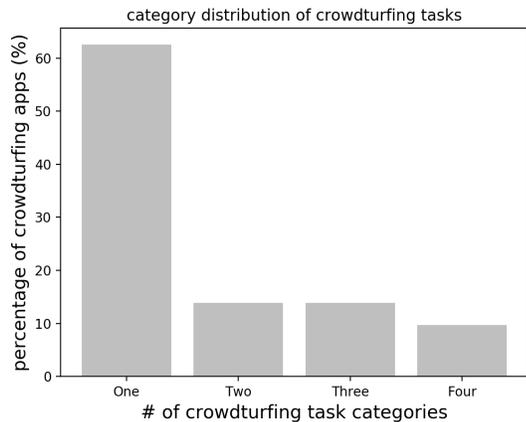

Figure 9: Distribution of the categories of crowdturfing tasks per app.

Table 4: Top-6 most common illicit crowdturfing tasks in apps with hidden crowdturfing UIs.

Crowdturfing tasks	# apps	# download (K)	Highest ranking
App ranking manipulation	82	32,268	5
Fraud account registration	28	15,618	64
Fake review	13	1,218	79
Bonus scalping	11	13,990	18
Online blog reposting	9	14,602	19
Order scalping	9	601	122

ulation app *com.zhang.samusic* has a daily task volume of 42,064 for manipulating 24 apps. Given an average task price of \$0.14, the revenue for all those tasks is around \$5.88K.

Furthermore, we analyze network traffic of such apps to study their servers, which distribute the tasks to the apps (see Figure 2). Interestingly, due to the difficulty in publishing crowdturfing apps, we find that multiple servers even share one client. In particular, besides their own servers, six apps are found to receive crowdturfing tasks from seven other servers (e.g., *qumi.com* and *domob.cn*) and all these tasks are related to app ranking manipulation.

**Campaign discovery.** In contrast to the web-based crowdturfing platforms [49], which are dominated by a few popular websites, we observed that the iOS-based crowdturfing platforms are more diverse. To study the relations among these crowdturfing apps, we built a graph for campaign discovery and further manually analyzed large campaigns identified. In the graph, each app is regarded as a node, and an edge connecting two apps represents that they are all from the same developer, with similar code or similar network behaviors. In particular, we crawled apps’ developer information from the

Table 5: Task volume and price of five apps with hidden crowdturfing UIs

App	# tasks	task volume	Per task price
<i>com.zhang.samusic</i>	24	42,064	0.14
<i>com.roidmi.mifm</i>	29	29,000	0.12
<i>com.miaolaierge.iosapp</i>	12	7,500	0.13
<i>com.applyape.yycuimian</i>	15	16,715	0.11
<i>com.jialiang.weka</i>	8	10,000	0.14

Table 6: Top-3 campaigns with most apps with hidden crowdturfing UI.

Campaign	# apps	Remote server
<i>uxiaowei</i>	9	<i>uxiaowei.com</i>
<i>apptyk</i>	6	<i>apptyk.com</i> <i>laizhuan.com</i> <i>diaoqianyaner.com.cn</i>
<i>rehulu</i>	6	<i>rehulu.com</i>

iTunes Preview website [34]. Then, we checked the common strings referenced by different apps’ hidden crowdturfing UIs. If the strings from two different apps have more than 90% in common, we link them together. To capture the network behavior, we triggered all these apps by signing onto their platforms. If two apps’ hidden crowdturfing UIs connect to the same server, we consider them to belong to the same campaign.

Table 6 shows top-3 campaigns with most crowdturfing apps. The largest one includes nine apps with hidden app ranking manipulation UIs, and all of them connect to the server *uxiaowei.com*. Interestingly, we observe that seven crowdturfing app owners (e.g., *id109\*\*\*\*906*, *id110\*\*\*\*416*, *id110\*\*\*\*262*, *id114\*\*\*\*820*) are related to this campaign. This campaign enjoyed a long lifetime, from May 2016 to March 2018.

## 4.5 Case Study

Here we introduce a typical app with hidden crowdturfing UI *sohouermusic*, which disguises as a music player, but also receives app ranking manipulation tasks (download, install, make up fake reviews, etc.). We observed that triggering the illicit service is surprisingly difficult, and such triggering process is designed to evade app vetting. Specifically, the *sohouermusic* app is promoted on popular social networks (e.g., WeChat), which redirect users to a website (*play.sohouer.com*). Only when a user visits the website on his iPhone and requires an invitation scheme *sohouermusic://invite=[serial number]* to be sent, will the app load its hidden UI. However, before the UI is actually rendered, the *sohouer* app checks whether it has passed the vetting process via its server, and the hidden crowdturfing UI shows up only when the remote server re-

sponds with “*isreview: 0*” and a *scripturl*. Besides acting as a client of a crowdturfing platform, such an app also stealthily collects user’s data ; e.g., device type, version, jailbreak status, location. Another interesting observation is that the *sohouermusic* developers are persistent: after the *sohouermusic* app was removed (after we reported to Apple), the hidden crowdturfing UI was quickly repackaged into a *sohouercamera* app and was submitted through a different developer account.

## 5 Discussion

**Evasion.** The current implementation of *Cruiser* is based on identifying two types of conditionally triggered UIs for further semantic analysis (see Section 3.2). Hence, to evade *Cruiser*, the adversary may use the hidden crowdturfing UI, which is triggered by users and also avoids the root UI. Such evasion techniques, however, will cause the possible crowdturfing UIs to be triggered during app vetting. This is because all clickable elements may be triggered by Apple employee’s manual or automatic analysis during app vetting [47]. This defeats the purpose of hidden UI.

The adversary may play other evasion tricks, by hiding semantic texts on the hidden crowdturfing UI to downgrade the accuracy of the Semantic Analyzer. In particular, the adversary can show crowdturfing related texts in the images, or obfuscate class names and method names, even dynamically fetch the crowdturfing related content. One possible solution is to run an Optical Character Recognition (OCR) tool [36] to extract the texts from images in the resource files, which enables to identify enough UI semantic even when the code is obfuscated. Considering the dynamically fetched hidden crowdturfing content, the adversary may deliver it on runtime using dynamic code loading (e.g., JSPatch [12]). However, Apple regulates and carefully monitors those dynamic code enabling techniques (e.g., hot patching frameworks) to minimize the attack vector; recently, Apple even bans or rejects any apps that use hot patch [39] from their App Store.

**Limitations.** Although *Cruiser* can already achieve a precision around 90%, still human involvement is needed to ensure that the apps reported are indeed problematic. Therefore, in the current form, it can only serve as a triage tool, instead of a full-fledged detection system. Also, as mentioned earlier, our current design is focused on iOS based apps, since cybercriminals have more intentions to utilize hidden UI to infiltrate the iOS app store than that of Android: centralized app vetting and installation make it hard for the crowdturfing app to reach out to the iPhone users. In the meantime, based on our observations, such hidden crowdturfing apps exist, though less pervasive, in the Android world. In particular, we conducted a small-scale study to find whether our detected apps have Android versions by searching for app names on Google Play, third-party stores and app download portals, and further manually examining them. We did not find any hidden

crowdturfing apps, but did observe blatant crowdturfing apps (without hidden UIs) in less regulated third-party Android app stores.

Moreover, besides crowdturfing, we do think that cybercriminals can use hidden UI techniques for other abusive services, such as delivering unauthorized content, or even malware. When looking into such apps (those found in our research to carry hidden UIs but not perform crowdturfing), we found instances such as covering a phishing UI behind a travel app. A natural follow-up step is to investigate all abusive services exploring hidden UI to infiltrate the iOS app store and characterize the underground markets behind them. We will leave this as our future work.

**Ethical issue.** Our research only involved analysis of pre-existing code and app content and did not collect new data during the study. Therefore, it is just a secondary analysis of already published materials, which does not constitute human-subject research. Another ethical concern comes from the potential that *Cruiser* could be used to identify possible benign hidden UIs; e.g., for censorship circumvention. Here we clarify that *Cruiser* is just a methodology for discovery and understanding of a new type of cybercrime, and during our study, we did not observe any such censorship evasion attempts. We acknowledge that any evasion detection techniques, including ours, could also be used for censorship. In the meantime, our methodology has been tailored towards crowdturfing detection: e.g., the features used by the structure miner are based upon the structures of real-world crowdturfing apps, the Word2vec model and other NLP components are all built on crowdturfing data. We are not sure how effective our approach would be when applying it to detect other types of hidden content, and how much additional effort is needed to make it a full-fledged censorship tool.

**Responsible disclosure.** Since the discovery of apps with hidden crowdturfing UI, we have been in active communication with Apple. So far, we have reported all the apps detected in our research to Apple, who has removed all of them from the App Store; also upon Apple’s request, we provided a list of fingerprints for eliminating the similar apps.

## 6 Related Work

**Study on crowdturfing.** The ecosystem of *web-based* crowdturfing has been studied for long. Motoyama et al. [37] identified the labor market Freelance involved in service abuse (e.g., fraud account creation) and characterized how pricing and demand evolved in supporting this activity. Wang et al. [49] studied two Chinese online crowdturfing platforms and also revealed the impact of the crowdturfing followers task on those platforms to microblogging sites. Stringhini et al. [45] investigated five Twitter follower markets to study the size of these markets and the price distribution of their service. Su et al. [46] studied the spamming activity of “Add To Fa-

avorites” by collecting the several “Add To Favorites” tasks information from one crowdurfing platform. In our research, to the best of our knowledge we for the first time investigate the crowdurfing platforms on the mobile devices, and reveal several unique characteristics; e.g., fragmented crowdurfing markets, mobile targeted crowdurfing tasks, stealthy worker recruitment channel, hidden crowdurfing UI techniques.

**Illicit iOS app detection.** Compared with Android, the Apple platforms are much less studied in terms of their security protection. Egele et al [23] proposed PiOS, which uses control flow analysis to detect privacy leaks in iOS apps. Deng et al [18] presented an approach to detect private API abuse by binary instrumentation and static analysis. Chen et al. [14] determines potentially harmful iOS libraries by looking for their counterparts on Android. Bai et al. [11] and Xing et al. [53] uncovered several zero configuration and cross-app resource sharing vulnerabilities, and proposed the corresponding detection methods. Understanding the security implications of hidden crowdurfing UI in iOS apps has never been done before. Also, none of the prior research provides a UI based detection mechanism to identify illicit iOS apps with hidden UI.

**Text analysis for mobile security.** Numerous studies have looked into *apps’ UI texts* to detect mobile threats such as task jacking, mobile phishing attack, ransomware, or to protect user privacy. AsDroid [33] checks the coherence between the semantics of the UI text (e.g., text of button) and program behavior associated with the UI (e.g., button) to detect malicious behavior (e.g., sensitive API) in Android apps such as sending short messages and making phone calls. Heldroid [10] uses a supervised classifier to detect threatening *sentences* from Android apps to detect ransomware. SUPOR [32], UIPicker [38] and UiRef [9] identify sensitive user inputs within user interfaces to protect user privacy. In particular, SUPOR [32] extracts layouts by modifying the static rendering engine of the Android Developer Tool (ADT). UIPicker [38] operates directly on the XML specification of layouts. UiRef [9] resolves the semantics of user-input widgets by analyzing the GUIs of Android applications. It improves the accuracy of SUPOR by addressing ambiguity of descriptive text through word embedding. In addition to UI texts, researchers intensively leverage Natural Language Processing (NLP) to process *app descriptions* for mobile security research. Examples include WHYPER [40] and AutoCog [41], which check whether an Android app properly indicates its permission usage in its app description, CHABADA [29] applied topic modeling technique on an app’s text description to help infer user’s expectation of security and privacy relevant actions. Different from previous works, our work compared the semantics of conditionally triggered UI texts of iOS apps, crowdurfing keywords and app descriptions to identify hidden crowdurfing apps. Also, sensitive or private APIs are not used for detection in our work as the illicit behavior of the app we detect are

based on UI not API. Also, different from SUPOR, UIPicker and UiRef, we extract UI texts from UI hierarchies (LVCG) we generated from iOS apps.

## 7 Conclusion

In this paper, we report our study on illicit iOS apps with hidden crowdurfing UIs, which introduce conditionally triggered UIs and a large semantic gap between hidden crowdurfing UI and other UIs in the app. Exploiting these features, our crowdurfing UI scanner for iOS, *Cruiser*, utilizes iOS UI hierarchy analysis technique and NLP techniques to automatically generate a UI hierarchy from binary and UI layout files and investigate conditionally triggered UI and the semantic gap to identify such illicit apps. Our study shows that *Cruiser* introduces a reasonable false detection rate (about 11.1%) with over 94.1% coverage. Running on 28K iOS apps, *Cruiser* automatically detects 93 apps with hidden crowdurfing UIs, which brings to light the significant impact of such illicit apps: they indeed successfully infiltrate App Store, even bypassing app vetting several times. What is worse, we observed an increasing trend of the number of such apps in App Store. Our research further uncovers a set of unique characteristics of iOS crowdurfing, which has never been revealed before: for example, we observe several remote crowdurfing servers share one iOS crowdurfing app as a client, which may be due to the difficulty of infiltration; also, such illicit apps were promoted by crowdurfing gateway sites to recruit workers, etc. Moving forward, we further investigate the hidden UI techniques providing by illicit app developers, including logic bomb, command and control infrastructure, and scheme technique etc.

## 9 Appendix

### 9.1 Performance evaluation of *Cruiser* and *NaiveCruiser*

To understand the performance of *Cruiser*, we measured the time it takes to process all the apps in the unknown set, on our Red Hat server using 14 processes. The breakdowns of the delays observed at each stage (Structure Miner and Semantic Analyzer) are reported in Table 7. As we can see here, on average, 27.4 seconds were spent on each app. The results demonstrate that *Cruiser* scales well and can easily process a large number of iOS apps. Furthermore, we evaluated the performance of *NaiveCruiser* (Table 7). As we can see, in the absence of the conditionally triggered UI detection step to first filter out legitimate VCs, the performance overhead of the Semantic Analyzer became overwhelming: introducing a delay at least 14 times as large as our original approach, which makes it difficult to scale. In addition, we evaluated the

performance of app collection. On average, downloading an app took 15 seconds and decrypting it took 10 seconds; however, the time varied greatly depending on the network speed, program sizes and etc. In total collecting and decrypting apps took 3 months.

Table 7: Running time at different stages, where SM means Structure Miner and SA means Semantic Analyzer.

<i>Cruiser</i>	Average time (s/app)	<i>NaiveCruiser</i>	Average time (s/app)
SM	18.88	LVCG construction	16.2
SA	8.56	SA	122.95
Total	27.43	Total	139.15

### 9.2 UI element objects without semantic UI texts

Table 8: UI element objects without semantic UI texts

Pattern type	UI element object	Parent UI element object <sup>1</sup>
A <sup>3</sup>	NSKey	* <sup>2</sup>
A	UIColor	*
A	UIFont	*
A	UINibKeyValuePair	*
A	NS.rectval	*
A	UIViewContentHuggingPriority	*
A	UIViewContentCompressionResistancePriority	*
A	UIOriginalClassName	*
A	UINibName	*
A	UIDestinationViewControllerIdentifier	*
A	UIActionName	*
A	UISource	*
A	UIDestination	*
A	UIStoryboardIdentifier	*
A	NSLayoutIdentifier	*
B <sup>4</sup>	UIProxiedObjectIdentifier	UIProxyObject
B	UIAction	UIStoryboardUnwindSegueTemplate
B	UIKeyPath	_UIAttributeTraitStorage
B	_UILayoutGuideIdentifier	_UILayoutGuide
B	UIKeyPath	_UIRelationshipTraitStorage
B	runtimeCollectionClassName	UIRuntimeOutletCollectionConnection

<sup>1</sup> Parent UI element object: The parent UI object of UI element object.

<sup>2</sup> \*(asterisk): Any Object.

<sup>3</sup> Type A: The string of a UI element object will be removed regardless its parent.

<sup>4</sup> Type B: The string of a UI element object will be removed only if its parent UI element object also matches.
